Abstract

In this paper, we empirically investigate adversarial attack on NMT from two aspects: languages (the source vs. the target language) and positions (front vs. back). For autoregressive NMT models that generate target words from left to right, we observe that adversarial attack on the source language is more effective than on the target language, and that attacking front positions of target sentences or positions of source sentences aligned to the front positions of corresponding target sentences is more effective than attacking other positions. We further exploit the attention distribution of the victim model to attack source sentences at positions that have a strong association with front target words. Experiment results demonstrate that our attention-based adversarial attack is more effective than adversarial attacks by sampling positions randomly or according to gradients.

1 Introduction

Despite remarkable progress in recent years, neural machine translation (NMT) models are vulnerable to small perturbations (Cheng et al., 2018; Zhao et al., 2018). Adversarial training, which allows NMT models to learn from adversarial samples with perturbations, as a general approach, is widely used to improve the robustness of NMT (Ebrahimi et al., 2018; Vaibhav et al., 2019; Cheng et al., 2019, 2020a,a; Zou et al., 2019). Generally, NMT models yield target translations in an autoregressive way[1], which makes previous incorrectly predicted target tokens have a negative impact on future tokens to be generated. However, most approaches to generating NMT adversarial examples inject perturbations only into source sentences. Hence, are NMT models more vulnerable to adversarial attack on the source side? What roles do injecting perturbations into source sentences or into target translations play in improving the robustness of NMT?

The key interest of this paper is to attempt to answer these questions by an empirical and comparative study on different adversarial attacks on NMT models. First, we investigate adversarial attacks on the source side versus those on the target side. This study is to know which attack is more effective for NMT by measuring performance drop of the attacked models. Second, we empirically study the impact of attacking different positions on either source sentences or target translations to find whether NMT robustness is sensitive to positions. Third, based on the findings of the study, we propose a new adversarial attack generation method based on attention distribution.

Our contributions can be summarized as follows:

- By the study, we have empirically found that adversarial attack on the source side is more effective than that on the target side in terms of the performance degradation of NMT models under attack.
- We have further empirically found that adversarial attacks on front positions are more effective than those on back positions on the target side due to the autoregressive translation nature. We have also found that adversarial attacks on positions of the source side which are aligned to front positions of the target side are more effective than attacks on other positions on the source side.
- We propose a new adversarial attack generation approach that samples positions for injecting perturbations according to the attention distribution. Experiment results demonstrate that attention-based position sampling is more effective than random sampling and gradient-

based sampling.

2 Related Work

Robustness is a well-known problem for neural networks (Szegedy et al., 2014; Goodfellow et al., 2015). Recent years have witnessed that many adversarial training approaches have been proposed to improve the robustness of NMT models. Cheng et al. (2018) generate adversarial samples at the lexical and feature level, and apply the adversarial learning to make adversarial samples natural. Zhao et al. (2018) utilize generative adversarial networks to generate adversarial examples that lie on the data manifold by searching in the semantic space of dense and continuous data representations. Ebrahimi et al. (2018) propose an attack framework for character-level NMT, which uses gradient to rank adversarial manipulations and to search for adversarial examples via either greedy search or beam search methods. Belinkov and Bisk (2018) attack character-level NMT by randomizing the order of letters or randomly replacing letters with their adjacent letters on the keyboard. Vaibhav et al. (2019) use back translation to generate adversarial samples that emulate natural noises. Cheng et al. (2020a) exploit the projected gradient method combined with gradient regularization to generate adversarial samples. Zou et al. (2019) employ reinforcement learning to decide which positions to attack. Tan et al. (2020) present a method to change inflectional morphology of words to craft plausible and semantically similar adversarial examples. Emelin et al. (2020) propose to generate adversarial examples by eliciting disambiguation errors.

All these approaches attack the source side of NMT in different ways. However distortions exist in not only the source language, but also the target language. This inspires us to compare the effectiveness of adversarial attack on the source and target side to NMT models. We have found that the NMT models are vulnerable to both the source and target attack. However, to our best knowledge, only Cheng et al. (2019) and Cheng et al. (2020b) take noises in target sentences into account. They generate adversarial samples for both source and target sentences. Their target-side adversarial examples are generated according to the attacked positions in corresponding source sentences, while their source-side adversarial samples are generated by randomly sampling positions to attack. We improve their method by attacking the source side according to the attention distribution. Experiments validate the effectiveness of our method.

3 Data and Setup

We conducted experiments on two translation tasks: English-Chinese and English-Japanese. Data for English-Chinese translation are from the United Nations English-Chinese corpus (Ziemski et al., 2016). We built the training/validate/test set for this task by randomly sampling 3M/2K/2K sentence pairs from the whole corpus. For the English-Japanese translation task, we aggregated the training set of KFTT (Neubig, 2011), JESC (Pryzant et al., 2018) and TED talks (Cettolo et al., 2012) as our training set, which consists of 3.9M sentence pairs. We evaluated our models on the validation set and test set of KFTT (Neubig, 2011). We split words into sub-word units with subword regularization (Kudo, 2018) and built a shared vocabulary of 32K subwords for both English-Chinese and English-Japanese.

We used the base Transformer model (Vaswani et al., 2017) with 512 hidden units as the victim model. The hyper-parameters of the base Transformer follows the default setting in Vaswani et al. (2017). We implemented the adversarial attack and training methods of Cheng et al. (2019) and followed their hyper-parameter setting in our experiments. The details of our implementation is shown in Section 4.

We injected perturbations into either source sentences or target sentences to generate adversarial examples which were used to evaluate NMT models. Since we could not inject perturbations into the target inputs of NMT models at the test time, we evaluated NMT models with target-side adversarial samples at training time on the validation dataset. Except where otherwise specified, the performance of the victim model was measured by word accuracy on the validation data. If we evaluated the victim model on the test set, detokenized BLEU (Papineni et al., 2002) and BERTScore (Zhang et al., 2020) were reported. Although the target-side inputs of NMT models could not be attacked at test time, there still exists noise or errors in them due to error propagation in the autoregressive decoding. Evaluating NMT with perturbated target sentences at training time enables us to analyze the vulnerability of NMT to the noise in target-side inputs, and inspires us to improve the robustness of NMT models to such noise.

4 Implementation Details

The adversarial attack and training framework used in this paper is based on Cheng et al. (2019). They inject perturbations into the source/target sentences by replacing a word in a sentence with the words that are semantically similar to the words being replaced. Words to be replaced in a source sentence are sampled according to the uniform distribution, while those in a target sentence are sampled according to the attention distribution. We tried three different ways to sample words to inject perturbations into source sentence in Section 8. Given a word to be replaced, Cheng et al. (2019) use a bi-directional language model to choose candidate words from vocabulary which share similar semantics to it, and then use gradients to search a word from candidate words to replace it. Cheng et al. (2019) combine a left-to-right and right-to-left language model to rank candidate words, while we combine the two uni-directional language models by multiplying their likelihood for simplicity. Cheng et al. (2019) train their NMT models with both clean data and adversarial samples from scratch. To save training time, we pretrain our NMT models with clean data before adversarial training.

5 Adversarial Attack on Source vs. Target

In this section, we compare the effect of the source and target attack according to the performance of the victim model. We adversarially inject perturbations into source sentences and keep target translations unchanged (clean) for the source attack while the target attack works the other way around. Our adversarial examples for both the source and target attack are generated by the method of Cheng et al. (2019). To make the comparison between the source and target attack fair, we randomly sample positions to attack for both of them.

Results are shown in Table 1. The NMT model with noisy source and clean target performs worse

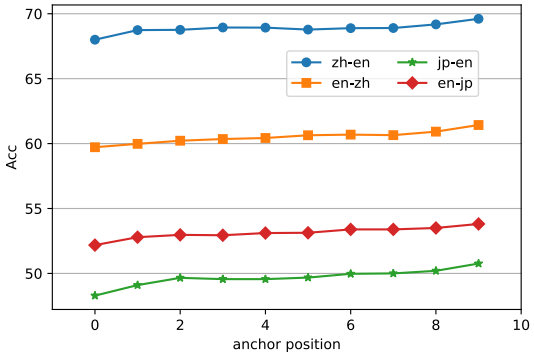

Figure 1: The word translation accuracy of an NMT model under attack at different anchor positions on the target side.

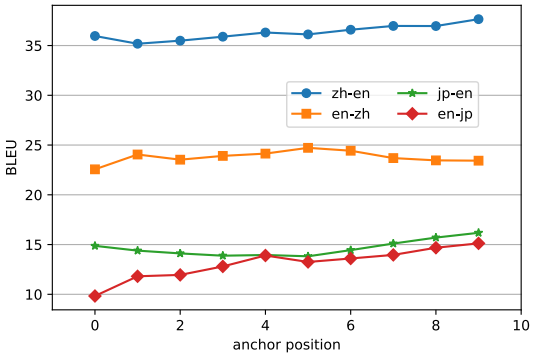

Figure 2: The BLEU score of an NMT model under attack at different anchor positions on the source side.

than that with clean source and noisy target on all translation tasks, in terms of word translation accuracy, which indicates that the source attack is more effective than the target attack. We also oberve that the adversarial attack on the source together with target side is much better than that on a single side, therefore we suggest that adversarial attacks on both the source and target side should be conducted to deploy a robust NMT system.

6 Adversarial Attack at Different Positions

In this section, we investigate the impact of attacked positions in the source and target sentences on NMT. We start with adversarial attack on the target side. Adversarial attacks at the front of a target sentence are supposed to be more effective than those at the end of the target sentence, since noises in the front of the target sentence will negatively affect future target tokens, while noises at the end of the target sentence could not affect already

generated tokens for a left-to-right decoder.

Given a sentence of length L, we uniformly select 10 anchor positions from the sentence:

$$\hat{x_j} = [\frac{L \times j}{10}] \quad (1)$$

where $\hat{x_j}$ is the jth anchor position ($0 <= j < 10$), $[\cdot]$ is a rounding operation. For each anchor position $\hat{x_j}$, we sample several positions close to it according to the discrete Gaussian distribution, which is formulated as:

$$p(x) = \frac{e^{-(x-\hat{x})^2}}{\sum_{i=0}^{L-1} e^{-(i-\hat{x})^2}} \quad (2)$$

where $p(x)$ is the probability that position x is attacked, $\hat{x}$ is the anchor position that we want the sampled positions to surround. The denominator normalizes the sum of the probabilities to 1.

Results of adversarial attack on different anchor positions on the target side are shown in Figure 1. On all translation tasks, the word translation accuracy of the victim model goes up as attacked positions move from the starting position to the end of target sentences, which confirms that attacking at the front of a target sentence is more effective than attacking at the end.

We also perform adversarial attack on source sentences at different anchor positions. Results are displayed in Figure 2. We measure the performance of the victim model for the source attack at different positions on the test set with the metric of BLEU. On both English-Chinese and English-Japanese tasks, BLEU scores go up as the attacked positions move from the start to the end of source sentences, which indicates that attacking the front of a source sentence is also more effective than attacking the end for both English-Chinese and English-Japanese translation. We suppose that the reason for this is that words at front positions of source sentences usually align to words at front positions of target sentences for the two language pairs. Experiment results in Section 7 empirically validate this hypothesis.

7 Attention Weights at Different Positions

In section 6, we suppose that words at front positions of source sentences usually align to words at front positions of target sentences for both English-Chinese and English-Japanese. We empirically validate this by comparing the attention weights from source tokens at different positions to the first target token. Following the sampling technique in section 6, we uniformly select 10 anchor positions from a source sentence and then sample positions surrounding these anchor positions according to the distribution formulated in Eq (2). For every anchor position, we report the sum of attention weights from the sampled source tokens around the anchor position to the first target token. The results are shown in Figure 3. As expected, the attention weights from the sampled source tokens to the first target token go down as the their corresponding positions move from the start to the end of the source sentence in both English-Chinese and English-Japanese translation, which confirms that words at front positions of source sentences have a stronger association with words at front positions of target sentences than other positions for the two language pairs.

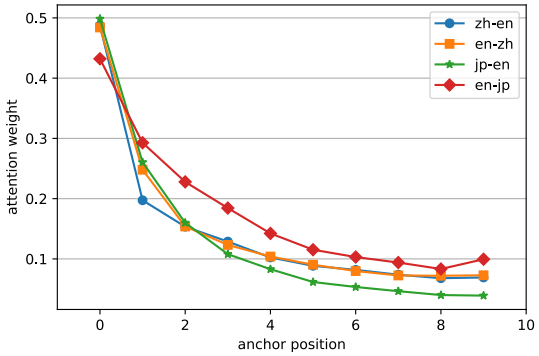

Figure 3: Attention weights from different anchor positions of source sentences to the first token of target sentences.

8 Adversarial Attack based on Attention Distribution

In Section 6, we have found that generating perturbations at front positions on the target side is more effective than attacking other positions. As attention weights in NMT models can be seen as the strength of association between the source and target tokens (Bahdanau et al., 2015). Hence we sample positions of a source sentence to inject perturbations according to the attention distribution. Particularly, the query used to produce the attention distribution is the representation of the first target token and the key is the set of representations of source tokens. There are multiple cross-attention heads in Transformer, each of which produces an

attack / model	rand		grad		attn	
	BELU	BERTScore	BELU	BERTScore	BELU	BERTScore
victim	19.2	83.8	22.2	84.7	**17.4**	**83.4**
train-rand	25.0	86.1	28.9	87.1	**22.2**	**85.6**
train-grad	23.6	85.7	28.6	87.1	**21.3**	**85.2**
train-attn	24.0	85.7	27.7	86.8	**23.3**	85.8

Table 2: BLEU and BERTScore of the victim model and three adversarially trained models. "rand", "grad" and "attn" indicates that adversarial examples are generated at attacked positions sampled randomly, according to gradients and attention distribution, respectively. "train-X" denotes that NMT models are adversarially trained with adversarial examples generated by the "X" method. The models were evaluated on the test set of the English-Chinese corpus.

attention matrix. The average of attention distributions of all heads is hence used for attacking.

We compare our proposed attention-based attack with attacks that either randomly sample source positions or sample positions according to gradients. For gradient-based sampling, we follow Liang et al. (2018) to estimate the L_∞ norm of the gradient of a word embedding as the importance score of the corresponding word, and then sample positions to attack from the normalized importance score. We have implemented the three adversarial attack methods based on the framework proposed in Cheng et al. (2019).[2] The only difference of these methods is that they use different ways to sample positions to attack. We also use the adversarial training method proposed in Cheng et al. (2019) to fine-tune NMT model with adversarial samples generated with the three attacking methods.

BLEU scores and BERTScores of the three adversarially trained models on the test set are shown in Table 2. It can be seen that BLEU scores and BERTScores of almost all models under our proposed attack ("attn") are lower than those under the other two attacking methods, which indicates the superiority of the proposed attention-based attack over the other two attack methods. It is surprising that the attack that samples positions according to the gradient ("grad") is not better than the attack that samples from a uniform distribution ("rand"), which may suggest that the L_∞ norm of the gradient cannot measure the importance of a word in a sentence. We can further extend our method to the black-box attack with the alignment from SMT models (Och and Ney, 2003), which is left to our future work. Our attention-based attack is proposed for autoregressive NMT models that generate target translations from left to right. It will not work for non-autoregressive NMT models (Gu et al., 2017) or autoregressive NMT models that generates translations in an arbitrary order (Stern et al., 2019).

[2]Cheng et al. (2019) randomly sample positions to attack source sentences in their paper.

9 Conclusion

In this paper, we have empirically investigated adversarial attack on NMT models. We compare adversarial attack on the source vs. target side, and find that the former is more effective than the latter. We also study adversarial attack at different positions in either source or target sentences, and observe that attacking front positions in either source or target sentences for English-Chinese and English-Japanese translation is more effective than attacking back positions. We further exploit attention distribution to attack words of a source sentence at positions that have a high association with words at front positions of the corresponding target sentence. Experiments validate the effectiveness of our proposed attention-based attack.

Abstract

SOTA coreference resolution produces increasingly impressive scores on the OntoNotes benchmark. However lack of comparable data following the same scheme for more genres makes it difficult to evaluate generalizability to open domain data. This paper provides a dataset and comprehensive evaluation showing that the latest neural LM based end-to-end systems degrade very substantially out of domain. We make an OntoNotes-like coreference dataset called OntoGUM publicly available, converted from GUM, an English corpus covering 12 genres, using deterministic rules, which we evaluate. Thanks to the rich syntactic and discourse annotations in GUM, we are able to create the largest human-annotated coreference corpus following the OntoNotes guidelines, and the first to be evaluated for consistency with the OntoNotes scheme. Out-of-domain evaluation across 12 genres shows nearly 15-20% degradation for both deterministic and deep learning systems, indicating a lack of generalizability or covert overfitting in existing coreference resolution models.

1 Introduction

Coreference resolution is the task of grouping referring expressions that point to the same entity, such as noun phrases and the pronouns that refer to them. The task entails detecting correct mention or 'markable' boundaries and creating a link with previous mentions, or antecedents. A coreference chain is a series of decisions which groups the markables into clusters. As a key component in Natural Language Understanding (NLU), the task can benefit a series of downstream applications such as Entity Linking, Dialogue Systems, Machine Translation, Summarization, and more (Poesio et al., 2016).

In recent years, deep learning models have achieved high scores in coreference resolution. The end-to-end approach (Lee et al., 2017, 2018) jointly scoring mention detection and resolution currently not only beats earlier rule-based and statistical methods but also outperforms other deep learning approaches (Wiseman et al., 2016; Clark and Manning, 2016a,b). Additionally, language models trained on billions of words significantly improve performance by providing rich word and context-level information for classifiers (Lee et al., 2018; Joshi et al., 2019a,b).

However, scores on the identity coreference layer of benchmark OntoNotes dataset (Pradhan et al., 2013) do not reflect the generalizability of these systems. Moosavi and Strube (2017) pointed out that lexicalized coreference resolution models, including neural models using word embeddings, face a covert overfitting problem because of a large overlap between the vocabulary of coreferring mentions in the OntoNotes training and evaluation sets. This suggests that higher scores on OntoNotes-test may not indicate a better solution to the coreference resolution task.

To investigate the generalization problem of neural models, several projects have tested other datasets consistent with the OntoNotes scheme. Moosavi and Strube (2018) conducted out-of-domain evaluation on WikiCoref (Ghaddar and Langlais, 2016), a small dataset employing the same coreference definitions. Results showed that neural models (with fixed embeddings) do not achieve comparable performance (16.8% degradation in score) as on OntoNotes. More recently, the e2e model using BERT (Joshi et al., 2019b) showed gains on the GAP corpus (Webster et al., 2018) using contextualized embeddings; however GAP only contains name-pronoun coreference, a very specific subset of coreference, and is limited in domain to the same single source – Wikipedia.

Though previous work has already identified the overfitting problem, it also has three main shortcomings. First, the scale of out-of-domain evalua-

Table 1: Genre-breakdown Statistics of OntoGUM.

tion has been small and homogeneous: WikiCoref only contains 30 documents with ∼60K tokens, much smaller than the OntoNotes test set, and the single genre Wiki domain in both WikiCoref and GAP is arguably not very far from some OntoNotes materials. Second, pretrained LMs, e.g. BERT (Devlin et al., 2019), popularized after the WikiCoref paper, can learn better representations of markables and surrounding sentences. Other than GAP, which targets a highly specific subtask, no study has investigated if contextualized embeddings encounter the same overfitting problem identified by Moosavi and Strube. Third, previous work may underestimate the performance degradation on WikiCoref in particular due to bias: In Moosavi and Strube (2018), embeddings were also trained on Wikipedia themselves, potentially making the model easier to learn coreference relations in Wikipedia text, despite limitations in other genres.

In this paper, we explore the generalizability of existing coreference models on a new benchmark dataset, which we make freely available. Compared with work using WikiCoref and GAP, our contributions can be summarized as follows:

- We propose OntoGUM, the largest open, gold dataset consistent with OntoNotes, with 168 documents (∼150K tokens, 19,378 mentions, 4,471 coref chains) in 12 genres,[1] including conversational genres, which complement OntoNotes for training and evaluation.
- We show that the SOTA neural model with contextualized embeddings encounter nearly 15% performance degradation on OntoGUM, showing that the overfitting problem is not overcome by contextualized language models.
- We give a genre-by-genre analysis for two popular systems, revealing relative strengths and weaknesses of current approaches and the range of easier/more difficult targets for coreference resolution.

2 Related Work

OntoNotes and similar corpora OntoNotes is a human-annotated corpus with documents annotated with multiple layers of linguistic information including syntax, propositions, named entities, word sense, and within document coreference (Weischedel et al., 2011; Pradhan et al., 2013). It covers three languages—English, Chinese and Arabic. The English subcorpus has 3,493 documents and ∼1.6 million words. WikiCoref, which is annotated for anaphoric relations, has 30 documents from English Wikipedia (Ghaddar and Langlais, 2016), containing 7,955 mentions in 1,785 chains, following OntoNotes guidelines.

GUM The Georgetown University Multilayer (GUM) corpus (Zeldes, 2017) is an open-source corpus of richly annotated texts from 12 types, including 168 documents and over 150K tokens. Though it originally contains more coreference phenomena than OntoNotes using more exhaustive guidelines, it also contains rich syntactic, semantic and discourse annotations which allow us to create the OntoGUM dataset described below. We also note that due to its smaller size (currently about 10% the size of the OntoNotes coreference dataset), it is not possible to train SOTA neural approaches directly on this dataset while maintaining strong performance.

Other corpora As mentioned above, GAP is a gender-balanced labeled corpus of ambiguous

pronoun-name pairs, used for out-of-domain evaluation but limited in coreferent types and genre. Several other comprehensive coreference datasets exist as well, such as ARRAU (Poesio et al., 2018) and PreCo (Chen et al., 2018), but these corpora cannot be used for out-of-domain evaluation because they do not follow the OntoNotes scheme. Their conversion has not been attempted to date.

Coreference resolution systems Prior to the introduction of deep learning systems, the coreference task was approached using deterministic linguistic rules (Lee et al., 2013; Recasens et al., 2013) and statistical approaches (Durrett and Klein, 2013, 2014). More recently, three neural models achieved SOTA performance on this task: 1) ranking the candidate mention pairs (Wiseman et al., 2015; Clark and Manning, 2016a), 2) modeling global features of entity clusters (Clark and Manning, 2015, 2016b; Wiseman et al., 2016), and 3) end-to-end (e2e) approaches with joint loss for mention detection and coreferent pair scoring (Lee et al., 2017, 2018; Fei et al., 2019). The e2e method has become the dominant one, gaining the best scores on OntoNotes. To investigate differences between deterministic and deep learning models on unseen data, we evaluate the two approaches on OntoGUM.

3 Dataset Conversion

GUM's annotation scheme subsumes all markables and coreference chains annotated in OntoNotes, meaning we do not need human annotation to recognize additional mentions in the conversion process, though mention boundaries differ subtly (e.g. for appositions and verbal mentions). Since GUM has gold syntax trees, we were able to process the entire conversion automatically. Additionally, most coreference evaluations use gold speaker information in OntoNotes, which is available in GUM (for *fiction*, *reddit* and spoken data) and could be assembled automatically as well.

The conversion is divided into two parts: removing coreference relations not included in the OntoNotes scheme, and removing or adjusting markables. For coreference relation deletion, we cut chains by removing expletive cataphora, and identifying the definiteness of nominal markables, since indefinites cannot be anaphors in OntoNotes. In addition to modifying existing mention clusters, we also remove particular coreference relations and mention spans, such as Noun-Noun compounding (only included in OntoNotes for proper-name modifiers), bridging anaphora, copula predicates, nested entities ('i-within-i'= single mentions containing coreferring pronouns), and singletons (all not included in OntoNotes). We note that singletons are removed as the final step, in order to catch singletons generated during the conversion process. We also contract verbal markable spans to their head verb, and merge appositive constructions into single mentions, following the OntoNotes guidelines. [2]

To evaluate conversion accuracy, three annotators, including an original OntoNotes project member, conducted an agreement study on 3 documents, containing 2,500 tokens and 371 output mentions. Re-annotating from scratch based on OntoNotes guidelines, the conversion achieves a span detection score of ∼96 and CoNLL coreference score of ∼92, approximately the same as human agreement scores on OntoNotes. After adjudication, the conversion was found to make only 8/371 errors, in addition to 2 errors due to mistakes in the original GUM data, meaning that degradation due to conversion errors is marginal, and consistency should be close to the variability in OntoNotes itself.

4 Experiments

We evaluate two systems on the 12 OntoGUM genres, using the official CoNLL-2012 scorer (Pradhan et al., 2012, 2014). The primary score is the average F1 of three metrics – MUC, B^3, and $CEAF_{\phi 4}$.

Deterministic coreference model We first run the deterministic system (dcoref, part of Stanford CoreNLP, Manning et al. 2014) on the OntoGUM benchmark, as it remains a popular option for off-the-shelf coreference resolution. As a rule-based system, it does not require training data, so we directly test it on OntoGUM's test set. However, POS tags, lemmas, and named-entity (NER) information are predicted by CoreNLP, which does have a domain bias favoring newswire. The system's multi-sieve structure and token-level features such as gender and number remain unchanged. We expect that the linguistic rules will function similarly across datasets and genres, notwithstanding biases of the tools providing input features to those rules.

SOTA neural model Combining the e2e approach with a contextualized LM and span masking is the current SOTA on OntoNotes. The system

Table 2: Results on the OntoGUM's test dataset with the deterministic coref model (top) and the SOTA coreference model (bottom). The blue text is the lowest score across 12 genres and red text is the highest.

utilizes the pretrained SpanBERT-large model, fine-tuned on the OntoNotes training set. Hyperparameters are identical to the evaluation of OntoNotes test to ensure comparable results between the benchmarks. We note that while we choose the SOTA system as a 'best case scenario', most off-the-shelf neural NLP toolkits (e.g. spaCy) actually use somewhat simpler e2e models than SpanBERT-large, due to memory/performance constraints.

5 Results

OntoGUM vs. OntoNotes The last rows in each half of Table 2 give overall results for the systems on each benchmark. e2e+SpanBERT encounters a substantial degradation of 15 points (19%) on OntoGUM, likely due to lower test set lexical and stylistic overlap, including novel mention pairs. We note that its average score of 64.6 is somewhat optimistic, especially given that the system receives access to gold speaker information wherever available (including in *fc*, *cn* and *it*, some of the better scoring genres), which is usually unrealistic. dcoref, assumed to be more stable across genres, also sees losses on OntoGUM of over 18 points (30%). We believe at least part of the degradation may be due to mention detection, which is trained on different domains for both systems (see the last three columns in the table). These results suggest that input data from CoreNLP degrades substantially on OntoGUM, or that some types of coreferent expressions in OntoGUM are linguistically distinct from those in OntoNotes, or both, making OntoGUM a challenging benchmark for systems developed using OntoNotes.

Comparing genres Both systems degrade more on specific genres. For example, while *vl* (with gold speaker information) fares well for both systems, neither does well on *tx*, and even the SOTA system falls well below (or around) 60s for the *nw*, *wh* and *tx* genres. This might be surprising for *vl*, which contains transcripts of spontaneous unedited speech from YouTube Creative Commons vlogs quite unlike OntoNotes data; conversely the result is less expected for carefully edited texts which are somewhat similar to data in OntoNotes: OntoNotes

contains roughly 30% newswire text, and it is not immediately clear that GUM's *nw* section, which comes from recent Wikinews articles, differs much in genre. Examples (1)–(2) illustrate incorrectly predicted coreference chains from both sources and the type of language they contain.

(1) *I've been here just crushing ultrasounds ... I've been like crushing these all day today ... I got sick when I was on Croatia for vacation. I have no idea what it says, but I think they 're cough drops.* (example from a radiologist's vlog, incorrect: ultrasounds ≠ cough drops)

(2) *The report has prompted calls for all edible salt to be iodised ... Tasmania was excluded from the study - where a voluntary iodine fortification program using iodised salt in bread, is ongoing* (newswire example, incorrect span and coref: [the study - where a voluntary...])

These examples show that errors occur readily even in quite characteristic news writing, while genre disparity by itself does not guarantee low performance, as in the case of the vlogs whose lanugage is markedly different. In sum, these observations suggest that accurate coreference for downstream applications cannot be expected in some common well edited genres, despite the prevalence of news data in OntoNotes (albeit specifically from the Wall Street Journal, around 1990). This motivates the use of OntoGUM as a test set for future benchmarking, in order to give the NLP community a realistic idea of the range of performance we may see on contemporary data 'in the wild'.

We also suspect that prevalence of pronouns and gold speaker information produce better scores in the results. Table 3 ranks genres by their e2e CoNLL score, and gives the proportions of pronouns, as well as score rankings for span detection. Because pronouns are usually easier to detect and pair than nouns (Durrett and Klein, 2013), more pronouns usually means higher scores. On genres with more than 50% pronouns and gold speakers (*vl*, *it*, *cn*, *sp*, *fc*) e2e gets much higher results, while genres with few pronouns (<30%) have lower scores (*ac*, *vy*, *nw*). This diversity over 12 genres supports the usefulness of OntoGUM, which can evaluate the genrealizability of coreference systems.

	PRON (R)	Other (R)	Total	CoNLL	Span

6 Conclusion

This paper presented OntoGUM, the largest open, gold coreference dataset following the OntoNotes scheme, adding several new genres (including more spoken data) to the OntoNotes family. The corpus is automatically converted from GUM by modifying the existing markable spans and coreference relations using multi-layer annotations, such as dependency trees. Results showed a lack of generalizability of existing systems, especially in genres low in pronouns and lacking speaker information. We suspect that at least part of the success of SOTA approaches is due to correct mention detection and high matching scores in genres rich in pronouns, and more so with gold speaker information. Success for other types of mentions in OntoNotes data appears to be much more sensitive to lexical features, performing well on the benchmark test set with high lexical overlap to the training data, but degrading very substantially outside of it, even on newswire texts from our OntoGUM data. This supports use of this challenging dataset for future work, which we hope will benefit evaluations of systems targeting the OntoNotes standard.

Abstract

Visual Question Answering (VQA) methods aim at leveraging visual input to answer questions that may require complex reasoning over entities. Current models are trained on labelled data that may be insufficient to learn complex knowledge representations. In this paper, we propose a new method to enhance the reasoning capabilities of a multi-modal pretrained model (Vision+Language BERT) by integrating facts extracted from an external knowledge base. Evaluation on the KVQA dataset benchmark demonstrates that our method outperforms competitive baselines by 19%, achieving new state-of-the-art results. We also perform an extensive analysis highlighting the limitations of our best performing model through an ablation study.

1 Introduction

Visual Question Answering (VQA) is a popular multi-modal task of answering a question about an image. It tracks both inter-modal interactions and reasoning capabilities of models (Wang et al., 2017; Marino et al., 2019). Recent studies have tested compositional reasoning (Johnson et al., 2016; Hudson and Manning, 2019) and the integration of external knowledge (Wang et al., 2017, 2016; Shah et al., 2019; Marino et al., 2019) for VQA. In this paper, we address Knowledge-aware VQA (KVQA) (Shah et al., 2019)[1] , defined as a VQA task where it is not reasonable to expect a model without access to a knowledge base to be able to answer the questions in the test set.

In a uni-modal textual context, both synthetic dataset (Kassner et al., 2020) and task-driven (Ding et al., 2020) studies of neural models have shown significant competence at symbolic reasoning. This is encouraging, as neural pretrained Language Models such as BERT (Devlin et al., 2019) achieve state-of-the-art results in a wide range of natural language inference tasks and benchmarks such as Natural Language Inference (Bowman et al., 2015). (Rajani et al., 2019) uses pretraining on a domain-specific dataset to improve CommonsenseQA by 10% absolute accuracy. Tamborrino et al. (2020) develop an improved training objective to improve COPA by 10% absolute accuracy.

Bouraoui et al. (2020) find that BERT is capable of relational induction, whilst Broscheit (2019); Petroni et al. (2020) find that BERT stores non-trivial world-knowledge.

Previous work has argued that restriction to a uni-modal context may itself impair reasoning performance (Barsalou, 2008; Li et al., 2020). In a bi-modal Vision + Language (V+L) context, datasets such as CLEVR and GQA allow for the evaluation of both model reasoning and language grounding. Within this setting, Ding et al. (2020) and Lu et al. (2020) show that appropriate neural models trained on large quantities of data can exhibit accurate reasoning.

In this paper, we propose a new method of applying a massively pretrained V+L BERT model (Chen et al., 2020) to the KVQA task (Shah et al., 2019). Our method is able to learn a set of reasoning types (confirming findings in Ding et al. (2020)) but can increase performance even more by incorporating external factual information. KVQA answers require attending to a knowledge base, allowing us to quantify the contribution of both explicit and implicit knowledge extracted from supervised training data. We also quantify the degree to which corpus bias makes certain question types harder, and outline how future datasets may be better balanced.

Our contributions are as follows:

- We perform factual integration into a V+L BERT-based model architecture VQA, leading to 19.1% accuracy improvement over previous baselines on KVQA.

August 1–6, 2021. ©2021 Association for Computational Linguistics

- We evaluate our model's reasoning capabilities through an ablation study, proposing explanations for poor performance on certain question types as well as highlighting our model's strong preference for text and facts over the image modality.

- We conduct a bias study of the KVQA dataset, revealing both strengths and potential improvements for future VQA datasets.

2 Related Work

VQA tasks explicitly encourage grounded reasoning (Antol et al., 2015), with emphasis on a variety of sub-domains, such as commonsense (Zellers et al., 2019), compositionality and grounding (Suhr et al., 2020), factual reasoning (Wang et al., 2017) or external knowledge reasoning (Wang et al., 2016; Marino et al., 2019; Shah et al., 2019).

State-of-the-art systems for external knowledge VQA are based on Memory networks (MemNet, (Weston et al., 2014)). In Shah et al. (2019), the facts are extracted from the Knowledge Graph (KG) by considering the visual (from image) and eventually textual (from Wikipedia caption) entities. They are then embedded using a Bi-LSTM encoder and fed into the memory. After the question is embedded in a similar way, the resulting representation is used to query the memory by soft attention. Several stacked memory layers are used to better model multi-hop facts.

Wang et al. (2016, 2017) introduce two datasets, KB-VQA and FVQA respectively, and address the task with systems that perform searches in a visual knowledge graph formed from the image and a KB. The question is first mapped to a query of the form ⟨visual object, relationship, answer source⟩, which is then used to extract the supporting facts from the KB. They report improved results when compared to systems using LSTM, SVM and hierarchical co-attention (Lu et al., 2016).

In Marino et al. (2019), the OK-VQA is presented with some baseline results obtained with MUTAN (Ben-younes et al., 2017), a multimodal tensor-based Tucker decomposition which models interactions between visual (from CNN) and textual (from RNN) representations. Those systems exhibit rather low performance compared to those obtained on standard VQA, demonstrating that the corpus requires external knowledge to be solved correctly.

Recent work has introduced methods to incorporate visual information to create Vision+Language BERT models through joint multimodal embeddings (Chen et al., 2020; Su et al., 2019; Lu et al., 2019). First, image and text are embedded into the same space, and then Transformer networks are applied as in the standard BERT model (Devlin et al., 2019).

Our work is most similar to that of Shah et al. (2019) since the same preprocessing pipeline is used. However, our system does not use a memory network, and instead relies on on a BERT-based model (UNITER, see section 3) to model the relationship between question, facts, and image with self-attention layers.

3 Methodology

To answer KVQA with Neural models, we first take the V+L BERT model UNITER (Chen et al., 2020) with the highest score on the commonsense VQA task, VCR (Zellers et al., 2019).

In order to allow UNITER to accept external KG facts, we cast these facts to a textual form 'Entity_1 Relation Entity_2'. To keep the input facts count small, we perform a *conditional search* of the KG. The KVQA task consists in finding a^*:

$$a^* = \underset{a \in A}{\operatorname{argmax}}\, p(a|q, i, K) \approx \underset{a \in A}{\operatorname{argmax}}\, p(a|q, i, k_{i,q}) \quad (1)$$

where a^* is the correct answer out of candidate set A; and q, i, and K are a question, image and knowledge base, respectively. As shown, we may reduce the KG through a conditional search to find the relevant subset of facts $k_{i,q}$.

To define the subset $k_{i,q}$, we follow Shah et al. (2019) in extracting all facts from the knowledge base that are up to two hops from any entities detected by the textual entity linking or the face detection.

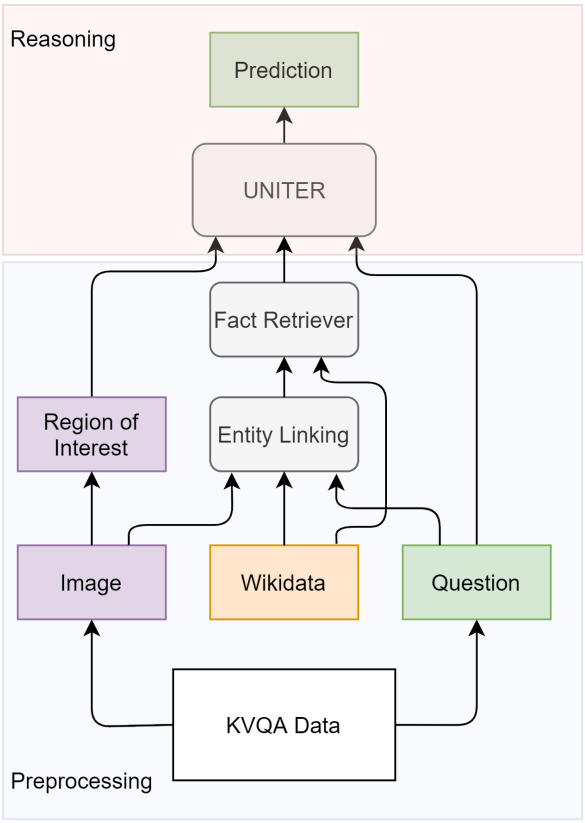

Figure 1: Our Model

Our model, as presented in section 2 consists of two stages: preprocessing, which implements relevant fact extraction, and reasoning, which selects an answer from the question, facts, and image features.

3.1 Preprocessing Stage

For preprocessing and fact acquisition, we broadly reproduce the fact and feature extraction process used in Shah et al. (2019). We perform object detection with the Faster R-CNN network (Ren et al., 2017). A seven-dimensional normalised size and location vector is concatenated with the Faster R-CNN features.

For person detection, we use MTCNN (Zhang et al., 2016) and Facenet (Schroff et al., 2015) models, pretrained on the MS-celeb-1M (Guo et al., 2016) dataset, to generate 128-dimensional embeddings. We predict names by nearest-neighbour comparison with the KVQA reference dataset. We treat the name identification as a multi-class classification problem, achieving a Micro-F1 of 0.539. Since this is lower than reported in Shah et al. (2019), we follow them in applying a textual entity linker (van Hulst et al., 2020) over supplied image descriptions. This setup achieves a per-image Micro-F1 of 0.686.

Normalised image location facts are generated from these detections, such as 'Barack Obama at 42 78', which would indicate that the centre bounding box for Barack Obama is at normalised (0-100) position x=42, y=78 of the image. We use the names of identified entities to query Shah et al.'s 2019 reduced Wikidata graph (Vrandečić and Krötzsch, 2014) up to two hops. The extracted facts are finally cast to the form 'subject relation object'.

3.2 Reasoning Stage

The neural model we use, UNITER, is pretrained on MS COCO (Lin et al., 2014), Visual Genome (Krishna et al., 2016), Conceptual Captions (Sharma et al., 2018), and SBU Captions (Ordonez et al., 2011). It is a multi-task system that is trained on performing Masked Language Modeling, Image-Text Matching, and Masked Region Modeling (Chen et al., 2020).

4 Experimental Setup

We select the KVQA dataset for two reasons: to our knowledge, it is the largest external knowledge dataset (with 183k questions), and the questions are annotated with their reasoning types. We use accuracy as the evaluation metric and provide results over both the entire dataset and also for each question type as provided in the KVQA dataset.

The baseline systems for KVQA are those presented in (Shah et al., 2019) and discussed in section 2. The first baseline is a stacked BLSTM encoder, operating over question and facts. This system has an overall accuracy of 48.0% . The second is the MemNet architecture and has the previously highest performing baseline accuracy at 50.2%.

We use the UNITER_BASE pretrained model available at the ChenRocks GitHub repository[2] with custom classification layers (MLP +softmax output layer). For task training, we merge retrieved facts with the question, dividing each statement with the '[SEP]' token, following research that indicates that this token induces partitioning and pipelining of information across attention layers (Clark et al., 2019). The textual input stream is tokenised with the HuggingFace 'bert-base-uncased' tokeniser (Wolf et al., 2020). We set the maximum WordPiece sequences length to 412, the maximum visual objects count to 100, the learning rate to

8×10^{-5} and use AdamW (Loshchilov and Hutter, 2017) as optimizer. Once preprocessing is completed, we train the UNITER model with the cross-entropy objective function for 80,000 iterations, which we empirically found to guarantee convergence.

5 Results

Table 1 shows the results of our system (UNITER), using a question label break-down similar to Shah et al. (2019). Overall, we observe that our system outperforms the previous baseline MemNet setting (see 'World+WikiCap+ORG' in Shah et al. (2019)) with an absolute improvement of 19%.

Our results show that UNITER is learning to perform reasoning more accurately than MemNet in all but two cases. In the question types involving multiple entities ('Multi-Entity', 'Multi-Hop', 'Multi-Relation'), the increase is the greatest, suggesting that UNITER is able to robustly learn these reasoning here. We speculate that stacked self-attention layers in BERT are able to better attend to the many involved entities than MemNet.

We now discuss the performance of our model on its weakest categories, namely 'Subtraction' and 'Spatial'. The poor performance on 'Subtraction' questions confirms previous results that BERT-like models require specialised pretraining for numerical reasoning tasks (Geva et al., 2020). In the case of our model specifically, we note the lack of numerical reasoning tasks in UNITER's pretraining regime. 'Spatial' is the model's least accurate question type (21.4%) and the biggest absolute decrease from MemNet (-26.7%). This question type requires two-hop reasoning where the second hop is a numerical operation of the form $\underset{y}{\text{argmin}}(x_i - y_i)$. Both of these have been shown to be problematic for BERT (Kassner et al., 2020; Geva et al., 2020).

6 Analysis

UNITER performs well at the reasoning tasks in general, with the most surprising result being that it apparently does better at multi-hop reasoning than one-hop. We believe that this can be explained by the presence of unbalanced distribution of answer types in the dataset perturbing the results (see Table 1). We discuss this in Section 6.1.

In order to better understand the reasoning capability of our model and the impact of each input modality, we perform an inference time ablation study, presented in Table 2.

Ablation of Image features (column 'Q+F') does not change the performance, suggesting that the model is not attending to image features. To confirm this hypothesis, we performed an experiment with adversarial images, obtaining very similar results for each question type and the same overall score (69.30%). We explain this behaviour by the fact that the preprocessing pipeline extracts all the required information as explicit facts which the model prefers over the more ambiguous visual features. We leave a deeper analysis for further work.

An interesting case is the 'Spatial' questions, where facts alone are able to correctly answer 13% of the questions. This is likely the result of the answers to this question type being entities present in the facts. Again, we observe that the model is not able to learn this information from the visual features.

	Train Ablation		Adversarial Modality*	
Question Type	Q+I	Q	I	F
1-Hop	47.09	38.5	65.9	31.3
1-Hop Counting	66.1	61.5	75.2	50.5
1-Hop Subtraction	29.4	29.7	28.1	26.2
Boolean	83.9	67.3	94.1	57.5
Comparison	83.4	60.3	90.6	47.8

Table 3: Further Ablation and Adversarial Studies. *Adversarial Modality indicates that the sample from that modality was randomly assigned from the entire data split

6.1 Bias Studies

We briefly discuss the corpus bias, a well-known concern in VQA (Goyal et al., 2019). We consider question difficulty across three parameters: reasoning difficulty, task design, and corpus bias. Certain question types are inherently more complex, as discussed in Section 5. Additionally, the task may have different numbers of answer classes per task, effectively weakening any priors models might form (see Entropy column in Table 1). Finally, an unbalanced dataset may cause certain reasoning types to be underrepresented, making it harder for models to learn for them. 'Spatial' and 'Substraction' questions are among the least represented in the training dataset, which increase their difficulty for the model.

Unseen answer classes are also an issue. For 'Spatial' questions, only 54.2% of the test answers (output classes) are actually seen during training, placing an upper bound on accuracy. We find 98.4% of 'Spatial' questions the model answered correctly and 95.7% of 'Spatial' question the model answered incorrectly were supplied with adequate facts by the preprocessing pipeline.

Training time ablation and adversarial experiments To further probe the task, we perform a training time ablation with first facts, and then facts and images removed (see Table 3). In this we seek to exhibit the capability of our model to leverage the available modalities and to compensate for the missing ones.

Through comparing the training time and inference time ablations, we can better understand the importance of a modality to solving the task.

Through comparing train and inference ablation of facts ('Q+I' column of Table 3 and of Table 2) we observe that when facts are unavailable at train time, the model attends to images to obtain 47.0% accuracy, which is 15.4% more than the 31.6% obtained by the corresponding inference time ablation. This indicates that the visual modality can provide useful information for this task.

We observe a similar trend in the fact and image ablation setting ('Q' column of Table 3 and of Table 2) that the model is able to greater leverage questions to make accurate predictions when additional modalities are never available.

We also perform adversarial checks, where random images or facts from the data split are presented at inference time. These align closely with the ablation study, with adversarial images (Column 'I' of Table 3) performing within 0.1% of blanked images (Column 'Q+F' of Table 3) and adversarial facts (Column 'F' of Table 3) performing within 1% of blanked facts (Column 'Q+I' of Table 3). These results confirm the importance of factual data and the unimportance of raw image features to a model trained on the full data.

7 Conclusion and Future Work

We evaluated our model and found that it improves on the previous state of the art by a substantial margin (19.1%). An ablation study revealed the specific strengths and weaknesses of our model on certain question categories when evaluated on the KVQA dataset. We show that the UNITER model is not actually using the visual input.

In the future, we seek to create a large external knowledge dataset designed following KVQA with more entities besides persons to encourage grounded reasoning, and better calibration of answer types. We will also consider pretraining our model on closely related tasks. This will help to form a model capable of learning robust reasoning with a high degree of spatial specificity and entity discrimination.

Acknowledgements

Peter Vickers is supported by the Centre for Doctoral Training in Speech and Language Technologies (SLT) and their Applications funded by the UK Research and Innovation grant EP/S023062/1.

Ethical Statement

This work is based on the open-source KVQA dataset, an English multimodal dataset, and the Wikidata knowledge base (also in English). No English-specific preprocessing was used for this research and the UNITER model is language agnostic, which tends to suggest that this could generalize to other languages. We will make our code publicly available to ensure the reproducibility of our experiments in the following repository

Abstract

Neural models for automated fact verification have achieved promising results thanks to the availability of large, human-annotated datasets. However, for each new domain that requires fact verification, creating a dataset by manually writing claims and linking them to their supporting evidence is expensive. We develop QACG, a framework for training a robust fact verification model by using automatically-generated claims that can be supported, refuted, or unverifiable from evidence from Wikipedia. QACG generates question–answer pairs from the evidence and then convert them into different types of claims. Experiments on the FEVER dataset show that our QACG framework significantly reduces the demand for human-annotated training data. In a zero-shot scenario, QACG improves a RoBERTa model's F_1 from 50% to 77%, equivalent in performance to 2K+ manually-curated examples. Our QACG code is publicly available.[1]

1 Introduction

Fact verification aims to validate a claim in the context of evidence. This task has attracted growing interest with the rise in disinformation in news and social media. Rapid progress has been made by training large neural models (Zhou et al., 2019; Liu et al., 2020b; Zhong et al., 2020) on the FEVER dataset (Thorne et al., 2018), containing more than 100K human-crafted (evidence, claim) pairs based on Wikipedia.

Fact verification is demanded in many domains, including news articles, social media, and scientific documents. However, it is not realistic to assume that large-scale training data is available for every new domain that requires fact verification. Creating training data by asking humans to write claims and search for evidence to support/refute them can be extremely costly.

We address this problem by exploring the possibility of automatically *generating* large-scale (evidence, claim) pairs to train the fact verification model. We propose a simple yet general framework **Q**uestion **A**nswering for **C**laim **G**eneration (QACG) to generate three types of claims from any given evidence: 1) claims that are `supported` by the evidence, 2) claims that are `refuted` by the evidence, and 3) claims that the evidence does Not have Enough Information (`NEI`) to verify.

To generate claims, we utilize *Question Generation (QG)* (Zhao et al., 2018; Liu et al., 2020a; Pan et al., 2020), which aims to automatically ask questions from textual inputs. QG has been shown to benefit various NLP tasks, such as enriching QA corpora (Alberti et al., 2019), checking factual consistency for summarization (Wang et al., 2020), and data augmentation for semantic parsing (Guo et al., 2018). To the best of our knowledge, we are the first to employ QG for fact verification.

As illustrated in Figure 1, given a passage P as the evidence, we first employ a *Question Generator* to generate a question–answer pair (Q, A) for the evidence. We then convert (Q, A) into a claim C (*QA-to-Claim*) based on the following logical assumptions: a) if P can answer Q and A is the correct answer, then C is a `supported` claim; b) if P can answer Q but A is an incorrect answer, then C is a `refuted` claim; c) if P cannot answer Q, then C is a `NEI` claim. The Question Generator and the QA-to-Claim model are off-the-shelf BART models (Lewis et al., 2020), finetuned on SQuAD (Rajpurkar et al., 2016) and QA2D (Demszky et al., 2018) datasets.

We generate 100K (evidence, claim) pairs for each type of claim, which we then use to train a RoBERTa (Liu et al., 2019) model for fact verification. We evaluate the model on three test sets

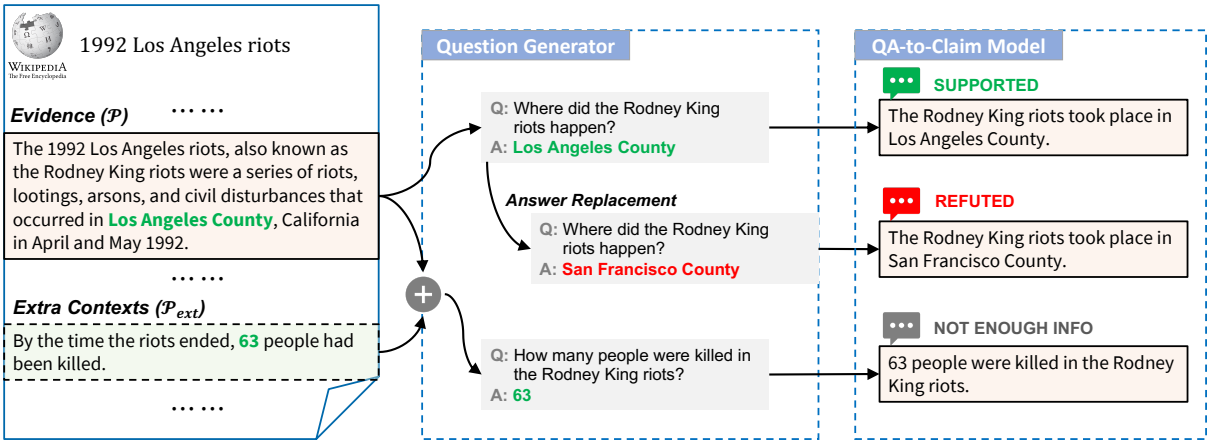

Figure 1: Overview of our QACG framework, consisting of two modules: 1) *Question Generator* generates questions from the evidence $\mathcal{P}$ and the extra contexts $\mathcal{P}_{ext}$ given different answers extracted from the passage (in green), and 2) *QA-to-Claim* converts question-answer pairs into claims with different labels.

based on the FEVER dataset. Although we do not use any human-labeled training examples, the model achieves over 70% of the F_1 performance of a fully-supervised setting. By finetuning the model with only 100 labeled examples, we further close the performance gap, achieving 89.1% of fully-supervised performance. The above results show that pretraining the fact verification model with generated claims greatly reduces the demand for in-domain human annotation. When evaluating the model on an unbiased test set for FEVER, we find that training with generated claims also produces a more *robust* fact verification model.

In summary, our contributions are:

- To the best of our knowledge, this is the first work to investigate zero-shot fact verification.
- We propose QACG, a novel framework to generate high-quality claims via question generation.
- We show that the generated training data can greatly benefit the fact verification system in both zero-shot and few-shot learning settings.

2 Methodology

Given a claim $\mathcal{C}$ and a piece of evidence $\mathcal{P}$ as inputs, a *fact verification* model $\mathcal{F}$ predicts a label $\mathcal{Y} \in \{\texttt{supported}, \texttt{refuted}, \texttt{NEI}\}$ to verify whether $\mathcal{C}$ is supported, refuted, or can not be verified by the information in $\mathcal{P}$.

For the *zero-shot* setting, we assume no human-annotated training example is available. Instead, we generate a synthetic training set based on our QACG framework to train the model.

2.1 Question Generator and QA-to-Claim

As illustrated in Figure 1, our claim generation model QACG has two major components: a *Question Generator* $\mathcal{G}$, and a *QA-to-Claim* model $\mathcal{M}$.

The **Question Generator** takes as input an evidence $\mathcal{P}$ and a text span A from the given evidence and aims to generate a question Q with A as the answer. We implement this with the BART model (Lewis et al., 2020), a large transformer-based sequence-to-sequence model pretrained on 160GB of text. The model is finetuned on the SQuAD dataset processed by Zhou et al. (2017), where the model encodes the concatenation of the SQuAD passage and the answer text and then learns to decode the question. We evaluate the question generator using automatic and human evaluation and investigate its impact on fact verification in Appendix A.

The **QA-to-Claim Model** takes as inputs Q and A, and outputs the declarative sentence C for the (Q, A) pair, as shown in Figure 1. We also treat this as a sequence-to-sequence problem and finetune the BART (Lewis et al., 2020) model on the QA2D dataset (Demszky et al., 2018), which contains the human-annotated declarative sentence for each (Q, A) pair in SQuAD.

2.2 Claim Generation

Given the pretrained question generator $\mathcal{G}$ and the QA-to-Claim model $\mathcal{M}$, we then formally introduce how we generate claims with different labels.

`Supported` claim generation. Given an evidence P, we use named entity recognition to identify all entities within P, denoted as $\mathcal{E}$. For each

entity $a \in \mathcal{E}$, we treat each a in turn as an answer and generate a question $q = \mathcal{G}(\mathcal{P}, a)$ with the question generator. The question–answer pair (q, a) are then sent to the QA-to-Claim model to generate the `supported` claim $c = \mathcal{M}(q, a)$.

`Refuted` claim generation. To generate a `refuted` claim, after we generate the question–answer pair (q, a), we use *answer replacement* (shown in Figure 1) to replace the answer a with another entity a' with the same type such that a' becomes an incorrect answer to the question q. Using a as the query, we randomly sample a phrase from the top-5 most similar phrases in the pretrained Sense2Vec (Trask et al., 2015) as the replacing answer a'. The new pair (q, a') is then fed to the QA-to-Claim model to generate the `refuted` claim.

To avoid the case that a' is still the correct answer, we define rules to ensure that the a' has less lexical overlap with a. However, this problem is sometimes non-trivial and cannot be completely avoided. For example, for the QA pair: ("Who is the producer of Avatar?"; "James Cameron"), another valid answer a' is "Jon Landau", who happens to be another producer of Avatar. However, we observe that such coincidences rarely happen: among the 100 randomly sampled claims, we only observed 2 such cases. Therefore, we leave them as the natural noise of the generation model.

`NEI` claim generation. We need to generate a question q' which is relevant but cannot be answered by $\mathcal{P}$. To this end, we link $\mathcal{P}$ back to its original Wikipedia article $\mathcal{W}$ and expand the evidence with additional contexts $\mathcal{P}_{ext}$, which are five randomly-retrieved sentences from $\mathcal{W}$ that are not present in $\mathcal{P}$. In our example in Figure 1, one additional context retrieved is "By the time the riots ended, 63 people had been killed". We then concatenate $\mathcal{P}$ and $\mathcal{P}_{ext}$ as the expanded evidence, based on which we generate a `supported` claim given an entity in $\mathcal{P}_{ext}$ as the answer (*e.g.*, "63"). This results in a claim relevant to but unverifiable by the original evidence $\mathcal{P}$.

3 Experiments

By applying our QACG model to each of the $18,541$ Wikipedia articles in the FEVER training set, we generate a total number of $176,370$ `supported` claims, $360,924$ `refuted` claims, and $258,452$ `NEI` claims. Our generated data is around five times the size of the human-annotated claims in FEVER. We name this generated dataset as QACG-*Full*. We then create a balanced dataset QACG-*Filtered* by randomly sampling $100,000$ samples for each class. Statistics of the FEVER and the generated dataset are in Appendix B.

Evaluation Datasets. We evaluate fact verification on three different test sets based on FEVER: **1) FEVER-S/R**: Since only the `supported` and `refuted` claims are labeled with gold evidence in FEVER, we take the claim–evidence pairs of these two classes from the FEVER test set for evaluation. **2) FEVER-Symmetric**: this is a carefully-designed unbiased test set designed by Schuster et al. (2019) to detect the robustness of the fact verification model. Note that only `supported` and `refuted` claims are present in this test set. **3) FEVER-S/R/N**: The full FEVER test set are used for a three-class verification. We follow Atanasova et al. (2020) to use the system of Malon (2019) to retrieve evidence sentences for `NEI` claims.

Fact Verification Models. As shown in Table 1, we take a BERT model (S1) and a RoBERTa model (S2) fine-tuned on the FEVER training set as the *supervised* models. Their corresponding *zero-shot* settings are Rows U5 and U6, where the models are trained on our generated QACG-*Filtered* dataset. Note that for binary classification (FEVER-S/R and FEVER-Symmetric), only the `supported` and `refuted` claims are used for training, while for FEVER-S/R/N, the full training set is used.

We employ four baselines that also do not need any human-annotated claims to compare with our method. *Random Guess* (U1) is a weak baseline that randomly predicts the class label. *GPT2 Perplexity* (U2) predicts the class label based on the perplexity of the claim under a pretrained GPT2 (Radford et al., 2019) language model, following the assumption that "misinformation has high perplexity" (Lee et al., 2020a). *MNLI-Transfer* (U3) trains a BERT model for natural language inference on the MultiNLI corpus (Williams et al., 2018) and applies it for fact verification. *LM as Fact Checker* (Lee et al., 2020b) (U4) leverages the implicit knowledge stored in the pretrained BERT language model to verify a claim. The implementation details are given in Appendix C.

3.1 Main Results

Table 1 summarizes the fact verification performance, measured by the macro Precision (P), Recall (R), and F1 Score (F_1).

	Model	FEVER -Symmetric	FEVER-S/R	FEVER-S/R/N
		P / R / F_1	P / R / F_1	P / R / F_1
Supervised	S1. BERT-base (Devlin et al., 2019)	81.5 / 81.3 / 81.2	92.8 / 92.6 / 92.6	85.7 / 85.6 / 85.6
	S2. RoBERTa-large (Liu et al., 2019)	**85.5 / 85.5 / 85.5**	**95.2 / 95.1 / 95.1**	**88.0 / 87.9 / 87.8**
Zero-shot	U1. Random Guess	50.0 / 50.0 / 50.0	50.0 / 50.0 / 50.0	33.3 / 33.3 / 33.3
	U2. GPT2 Perplexity	52.7 / 52.7 / 52.7	55.6 / 55.6 / 55.6	35.3 / 35.3 / 35.3
	U3. MNLI-Transfer	62.2 / 55.5 / 58.7	63.6 / 60.5 / 61.8	41.4 / 39.6 / 40.7
	U4. LM as Fact Checker (Lee et al., 2020b)	71.2 / 64.5 / 67.8	77.9 / 65.6 / 70.2	64.3 / 54.6 / 49.8
	U5. QACG (BERT-base)	73.2 / 73.0 / 72.9	74.2 / 74.0 / 74.1	56.5 / 55.7 / 55.9
	U6. QACG (RoBERTa-large)	**77.3 / 77.0 / 77.1**	**78.1 / 78.1 / 78.1**	**64.6 / 62.0 / 62.6**

Table 1: Fact verification performance for supervised models and zero-shot models on three different settings.

Comparison with supervised settings. The zero-shot setting with RoBERTa-large (U6) attains 78.1 F_1 on the FEVER-S/R and 62.6 F_1 on the FEVER-S/R/N. The F_1 gap to the fully-supervised RoBERTa-large (S2) is only 17.0 and 15.2 on these two settings, respectively. These results demonstrate the effectiveness of QACG in generating good (evidence, claim) pairs for training the fact verification model. The RoBERTa model (S2, U6) is more effective than the BERT model (S1, U5) for both the zero-shot and the supervised setting.

Comparison with zero-shot baselines. Our model (U6) achieves the best results among all the zero-shot baselines across all three test sets. We find that validating a claim by its perplexity (U2) only works slightly better than random guess (U1) (+3.43 F_1), showing that misinformation does not necessary to have high perplexity. Although natural language inference seems highly correlated with fact verification, directly transferring the model trained on the MNLI dataset (U3) only outperforms random guess by 9.30 F_1. We believe this is due to the domain gap between FEVER (from Wikipedia) and the MNLI (from fiction, letters, etc.) dataset. As a generation framework, our model can avoid the domain gap issue by generating pseudo training data from the same domain (Wikipedia). Another reason is the "task gap" between NLI and fact verification, in which the former makes inference about the situation described in a sentence, while the latter focuses on claims about entities in Wikipedia.

Model Robustness. We observe a large performance drop when the supervised model is evaluated on the FEVER-Symmetric test set for both the BERT model (-11.4 F_1) and the RoBERTa model (-9.6 F_1). However, the models trained with our generated data (U2, U3) drop only 1.2 and 1.0 F_1 drop. This suggests that the wide range of different claims we generate as training data helps eliminate some of the annotation artifacts present in FEVER, leading to a more robust fact verification model.

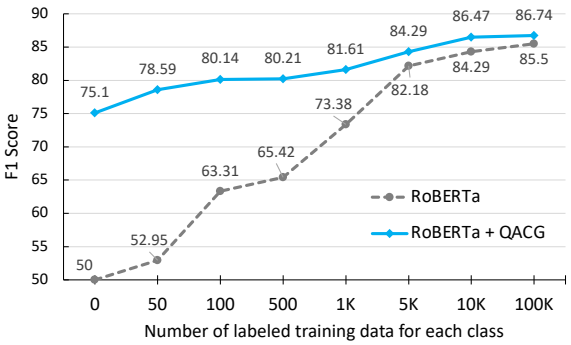

Figure 2: The few-shot learning experiment. The figure shows the F_1 score on FEVER-Symmetric for progressively larger training dataset sizes.

3.2 Few-shot Fact Verification

We then explore QACG's effectiveness in the few-shot learning setting where only a few human-labeled (evidence, claim) pairs are available. We first train the RoBERT-large fact verification model with our generated dataset QACG-Filtered. Then we fine-tune the model with a limited amount of human-labeled claims in FEVER. The blue solid line in Figure 2 shows the F_1 scores on FEVER-Symmetric after finetuning with different numbers of labeled training data. We compare this with training the model from scratch with the human-labeled data (grey dashed line).

Our model performs consistently better than the model without pretraining, regardless of the amount of labeled training data. The improvement is especially prominent in data-poor regimes; for example, our approach achieves 78.6 F_1 with only 50 labeled claims for each class, compared with 52.9 F_1 without pretraining (+25.7). This only leaves a 7.9 F_1 gap to the fully-supervised setting (86.5 F_1) with over 100K training samples. The results show pretraining fact verification with QACG

Evidence	Generated Claim
Budapest is cited as one of the most beautiful cities in Europe, ranked as the most liveable Central and Eastern European city on EIU's quality of life index, ranked as "the world's second best city" by Conde Nast Traveler, and "Europe's 7th most idyllic place to live" by Forbes.	**SUPPORTED claims** Budapest is ranked as the most liveable city in central Europe. Budapest ranks 7th in terms of idyllic places to live in Europe. **REFUTED claims** Budapest ranks in 11th in terms of idyllic places to live in Europe. Budapest is ranked the most liveable city in Asia. **NEI claims** Budapest is one of the largest cities in the European Union. Budapest is the capital of Hungary.
Alia Bhatt received critical acclaim for portraying emotionally intense characters in the road drama Highway (2014), which won her the Filmfare Critics Award for Best Actress, and the crime drama Udta Punjab (2016), which won her the Filmfare Award for Best Actress.	**SUPPORTED claims** Bhatt won the Filmfare Award for Best Actress in Udta Punjab. Bhatt received the Filmfare Critics Award for her role in Highway. **REFUTED claims** Alia Bhatt won the Best Original Screenplay award in Highway. 2 States (2014) won Alia Bhatt the Filmfare Award for Best Actress. **NEI claims** Alia Bhatt made her acting debut in the 1999 thriller Sangharsh. Bhatt played her first leading role in Karan Johar's romantic drama.

Table 2: Examples of evidence and claims generated by QACG, categorized by class labels. In the evidence, the identified answers for question generation are highlighted in blue. For claims, the correct answers are highlighted in blue for SUPPORTED claims and the replaced wrong answers are in red for REFUTED claims.

Evidence:	Roman Atwood is best known for his vlogs, where he posts updates about his life.
Claim:	Roman Atwood is a content creator.
Evidence:	In 2004, Slovenia entered NATO and the European Union.
Claim:	Slovenia uses the euro.
Evidence:	He has traveled to Chad and Uganda to raise awareness about conflicts in the regions.
Claim:	Ryan Gosling has been to a country in Africa.

Table 3: Examples of claims in FEVER that require commonsense or world knowledge (underlined).

greatly reduces the demand for in-domain human-annotated data. Our method can provide a "warm start" for fact verification system when applied to a new domain where training data are limited.

3.3 Analysis of Generated Claims

Table 2 shows representative claims generated by our model. The claims are fluent, label-cohesive, and exhibit encouraging language variety. However, one limitation is that our generated claims are mostly *lack of deep reasoning over the evidence*. This is because we finetune the question generator on the SQuAD dataset, in which more than 80% of its questions are shallow factoid questions.

To better understand whether this limitation brings a domain gap between the generated claims and the human-written claims, we randomly sampled 100 `supported` claims and 100 `refuted` and analyze whether reasoning is involved to verify those claims. We find that 38% of the `supported` claims and 16% of the `refuted` claims in FEVER require either commonsense reasoning or world knowledge to verify. Table 3 show three typical examples. Therefore, we believe this domain gap is the main bottleneck of our system. Future studies are required to generate more complex claims which involves multi-hop, numerical, and commonsense reasoning, such that we can apply our model to more complex fact checking scenario.

4 Conclusion and Future Work

We utilize the question generation model to ask different questions for given evidence and convert question–answer pairs into claims with different labels. We show that the generated claims can train a well-performing fact verification model in both the zero-shot and the few-shot learning setting. Potential future directions could be: 1) generating more complex claims that require deep reasoning; 2) extending our framework to other fact checking domains beyond Wikipedia, *e.g.*, news, social media; 3) leveraging generated claims to improve the robustness of fact checking systems.

Ethical Considerations

We discuss two potential issues of claim generation, showing how our work sidesteps these issues. While individuals may express harmful or biased claims, our work only focuses on generating factoid claims from a corpus. In this work, we take Wikipedia as the source for objective fact. Practicing this technique thus requires the identification of an appropriate source of objective truth to generate claims from. Another potential misuse of claim generation is to generate `refuted` claims and subsequently spread such misinformation. We caution practitioners to treat the generated claims with care. In our case, we use the generated claims only to optimize for the downstream fact verification task. We advise against releasing generated claims for public use — especially on public websites, where they may be crawled and then subsequently used for inference. As such, we will release the model code but not the output in our work. Practitioners can re-run the training pipeline to replicate experiments accordingly.

A Evaluation of Question Generation

To implement the question generator, we finetune the pretrained BART model provided by HuggingFace library on the SQuAD dataset. The codes are based on the SimpleTransformers[2] library. The success of our QACG framework heavily rely on whether we can generate fluent and answerable questions given the evidence. Therefore, we separately evaluate the question generator using both automatic and human evaluation and investigate its impact to zero-shot fact verification.

A.1 Automatic Evaluation

We employ BLEU-4 (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007), and ROUGE-L (Lin, 2004) to evaluate the performance of our implementation. We compare the BART model with several state-of-the-art QG models, using their reported performance on the Zhou split of SQuAD.

Table 4 shows the evaluation results comparing against all baseline methods. The BART model achieves a BLEU-4 of 21.32, outperforming NQG++, S2ga-mp-gsa, and CGC-QG by large margins. This is as expected since these three baselines are based on Seq2Seq and do not apply language model pretraining. Compared with the current state-of-the-art model UniLM, the BART model achieves comparable results, with slightly lower BLEU-4 but higher METEOR.

Model	B4	MR	R_L
NQG++ (Zhou et al., 2017)	13.5	18.2	41.6
S2ga-mp-gsa (Zhao et al., 2018)	15.8	19.7	44.2
CGC-QG (Liu et al., 2020a)	17.6	21.2	44.5
UniLM (Dong et al., 2019)	**23.8**	25.6	**52.0**
BART (Lewis et al., 2020)	21.3	**27.1**	43.6

Table 4: Performance evaluation of the *Question Generator* with different model implementations. We adopt the BART model in our QACG framework. *B4*: BLEU-4, *MR*: METEOR, R_L: ROUGE-L.

A.2 Impact of Answerability

Given the evidence P and the answer A, the generated question Q must be answerable by P and

[2]https://github.com/ThilinaRajapakse/simpletransformers

Model	Answerable Rate	FV Performance P / R / F_1
NQG++	63.0%	62.2 / 62.4 / 62.3
BART	89.5%	76.3 / 76.0 / 76.1

Table 5: *Answerable Rate*: the ratio of answerable questions generated by the NQG++ and the BART model. *FV Performance*: the zero-shot fact verification performance on the FEVER-Symmetric.

Dataset		Supported	Refuted	NEI
FEVER	Train	80,035	29,775	35,517
	Test	6,666	6,666	6,666
FEVER-Symmetric		710	710	–
QACG	Full	176,370	360,924	258,452
	Filtered	100,000	100,000	100,000

Table 6: Basic statistics of the FEVER dataset and the dataset generated by QACG.

take A as its correct answer. This is the premise of generating a correct SUPPORTED claim. Therefore, we specially evaluate this *answerability* property via human ratings. We randomly sample 100 generated question-answer pairs with their corresponding evidence and ask two workers to judge the answerability of each sample. We do this for both the NQG++ model and the BART model. To investigate the impact of question quality on the fact verification performance, we separately use the NQG++ and BART as the question generator to generate claims and train the RoBERTa model. The performance is summarized in Table 5.

We find that the ratio of answerable questions generated by the BART model is 89.5%, significantly outperforms the 63.5% achieved by the NQG++ model. When switching the question generator to NQG++, the fact verification F_1 drops to 62.3 (-22.1% compared with BART). This shows that answerability plays an important role in ensuring the validity of the generated claims and has a huge impact on the fact verification performance.

B Dataset Statistics

Table 6 shows the basic data statistics of the FEVER, FEVER-Symmetric, and our generated dataset by QACG. We use the balanced dataset QACG-*Filtered* sampled from QACG-*Full* to train the fact verification model in the zero/few-shot setting. Compared with the original FEVER dataset, our generated QACG-*Filtered* dataset has a balanced number of claims for each class. Moreover, because QACG can generate three different types of claims for the same given evidence (shown in Figure 1), it results in a more "unbiased" dataset in which the model must rely on the *(evidence, claim)* pair rather than the *evidence* itself to make an inference of the class label.

C Model Implementation Details

BERT-base and RoBERTa-large (S1, S2, U5, U6). We use the `bert-base-uncased` (110M parameters) and the `roberta-large` (355M parameters) model provided by HuggingFace library to implement the BERT model and the RoBERTa model, respectively. The model is fine-tuned with a batch size of 16, learning rate of 1e-5 and for a total of 5 epochs, where the epoch with the best performance is saved.

GPT2 Perplexity (U2). To measure the perplexity, we use the HuggingFace implementation of the medium GPT-2 model (`gpt2-medium`, 345M parameters). We then rank the claims in the FEVER test set by their perplexity under the GPT-2 model. We then predict the label for each claim based on the assumption that misinformation has high perplexity. However, manually setting the perplexity threshold is difficult. Since the FEVER test set contains an equal number of claims for each class, we predict the claims in the top 1/3 of the ranking list as `refuted`, and the bottom 1/3 as `supported`. The rest claims are set as `NEI`. Therefore, the number of predicted labels for each class is also equal.

MNLI-Transfer (U3). We use the HuggingFace – BERT base model (110M parameters) fine tuned on the Multi-Genre Natural Language Inference (MNLI) corpus[3], a crowd-sourced collection of 433K sentence pairs annotated with textual entailment information. We then directly apply this model for fact verification in the FEVER test set. The class label `entailment`, `contradiction`, and `neutral` in the NLI task is mapped to `supported`, `refuted`, and `NEI`, respectively, for the fact verification task.

LM as Fact Checker (U4). Since there is no public available code for this model, we implement our own version following the settings described in Lee et al. (2020b). We use HuggingFace's `bert-base` as the language model to predict the masked named entity, and use the NLI model described in U3 as the entailment model.

Thank you BART!
Rewarding Pre-Trained Models Improves Formality Style Transfer

Huiyuan Lai, Antonio Toral, Malvina Nissim
CLCG, University of Groningen / The Netherlands
{h.lai, a.toral.ruiz, m.nissim}@rug.nl

Abstract

Scarcity of parallel data causes formality style transfer models to have scarce success in preserving content. We show that fine-tuning pre-trained language (GPT-2) and sequence-to-sequence (BART) models boosts content preservation, and that this is possible even with limited amounts of parallel data. Augmenting these models with rewards that target style and content –the two core aspects of the task– we achieve a new state-of-the-art.

1 Introduction and Background

Style transfer is the task of automatically converting a text of one style into another, such as turning the formal "*I viewed it and I believe it is a quality program.*" into the informal "*I've watched it and it is AWESOME!!!!*". This task, which can be used for, e.g., personalised response generation, translation of ancient text into modern text, and text simplification, is particularly challenging since style must be changed while ensuring that content is preserved. Accordingly, the performance of style transfer systems is commonly assessed on both style strength and content preservation.

Due to the general scarcity of parallel data, unsupervised approaches are popular. These include disentangling style and content by learning a distinct representation for each (Shen et al., 2017; Fu et al., 2018; John et al., 2019), and back translation (Zhang et al., 2018; Lample et al., 2019; Luo et al., 2019; Prabhumoye et al., 2018). A common strategy to enhance style accuracy is to introduce a reward in the form of a style classifier (Lample et al., 2019; Gong et al., 2019; Luo et al., 2019; Wu et al., 2019; Sancheti et al., 2020). As a result, unsupervised models achieve good accuracy in style strength. Content preservation is however usually unsuccessful (Rao and Tetreault, 2018).

Parallel data can help to preserve content, but is limited. Niu et al. (2018) combine the train sets of two different domains and incorporate machine translation to train their models with a multi-task learning schema, plus model ensembles. Sancheti et al. (2020) use it to train a supervised sequence-to-sequence model, and in addition to the commonly used style strength reward, they include a reward based on BLEU (Papineni et al., 2002) to enhance content preservation. Shang et al. (2019) propose a semi-supervised model combining parallel data with large amounts of non-parallel data.

Pre-trained models, successful in a variety of NLP tasks, have recently been used in formality style transfer. Zhang et al. (2020) propose several data augmentation methods for pre-training a transformer-based (Vaswani et al., 2017) model and then used gold data for fine-tuning. Using GPT-2 (Radford et al., 2019), Wang et al. (2019) and Wang et al. (2020) propose a harness-rule-based preprocessing method, and joint training of bi-directional transfer and auto-encoding with two auxiliary losses. Contemporary work by Chawla and Yang (2020) develops a semi-supervised model based on BART large (Lewis et al., 2020).

Contributions Focusing specifically on *formality transfer*, for which parallel data is available, (i) we take the contribution of pre-trained models a step further by augmenting them with reward strategies that target content and style, thereby achieving new state-of-the-art results. (ii) We analyse separately the contribution of pre-trained models on content and style, showing that they take care of preserving content (the hardest part of style transfer to date), while ensuring style strength. (iii) Moreover, experimenting with training size, we show that while parallel data contributes to content preservation, fine-tuning pre-trained models with 10% of parallel data is more successful than training on 100% of data from scratch. Reducing the need for parallel data opens up the applicability of

(a) Architecture of the GPT-2-based model

(b) Architecture of the BART-based model

Figure 1: Model architectures. We use three special symbols: [BOS] in front of every source sentence, [SEP] between the source and target sentences (only in GPT-2), and [EOS] at the end of every target sentence.

supervised style transfer to new scenarios: tasks, domains, languages.[1]

2 Method

We propose a framework to control the style of output text for style transfer atop pre-trained models. Given a source sentence $\boldsymbol{x} = \{x_1, \cdots, x_n\}$ of length n with style s_1 and a target style sentence $\boldsymbol{y} = \{y_1, \cdots, y_m\}$ of length m with style s_2, our model aims to learn two conditional distributions, altering the style of a sentence while preserving its original content. Our framework consists of (i) fine-tuning pre-trained models on a formality transfer parallel corpus; (ii) incorporating rewards to enhance style change and content preservation.

2.1 Models

GPT-2 This model (Radford et al., 2019) is a transformer-based network (Vaswani et al., 2017). Given a sentence of tokens $\boldsymbol{x} = \{x_1, \cdots, x_l\}$, the standard language modeling objective is to minimize the following negative log likelihood:

$$L_(\phi) = -\Sigma_i \log(p(x_i|x_{i-k:i-1}; \phi)) \quad (1)$$

where k is the size of the context window.

To make GPT-2 rephrase a text in the target style, the input pair ⟨Source Sentence, Target Sentence⟩ is represented as a single sequence with three special tokens to mark beginning [BOS] and end [EOS] of every sequence, and to separate source and target sentences [SEP] (Fig. 1(a)). During inference, we feed to GPT-2 the source sentence with [BOS] and [SEP] to infer the target sentence.

[1]All code at https://github.com/laihuiyuan/Pre-trained-formality-transfer.

BART This is a denoising autoencoder for pre-training sequence-to-sequence models (Lewis et al., 2020). Given a source sentence $\boldsymbol{x}$ and a target sentence $\boldsymbol{y}$, the loss function is the cross-entropy between the decoder's output and the target sentence:

$$L_(\phi) = -\Sigma_i \log(p(y_i|y_{1:i-1}, \boldsymbol{x}; \phi)) \quad (2)$$

2.2 Rewards

Atop the models, we implement two rewards, used in isolation and together, to enhance style strength (Style Classification Reward) and content preservation (BLEU Score Reward).

Style Classification Reward As often done in previous work (see Section 1), we use a classification confidence reward to encourage larger change in the confidence of a style classifier (SC). We pre-train the binary style classifier TextCNN (Kim, 2014) and use it to evaluate how well the transferred sentence $\boldsymbol{y}'$ matches the target style. SC's confidence is formulated as

$$p(s_i|\boldsymbol{y}') = softmax_i(TextCNN(\boldsymbol{y}', \theta)) \quad (3)$$

where i = {1,2}, and represent source and target style respectively. θ are the parameters of the style classifier, fixed during fine-tuning. The reward is

$$R_{cls} = \lambda_{cls}[p(s_2|\boldsymbol{y}') - p(s_1|\boldsymbol{y}')] \quad (4)$$

where $\boldsymbol{y}'$ is the generated target sentence sampled from the model's distribution at each time step in decoding. For the GPT-2 based model, we also add a classification confidence reward to the source sentence, similar to Eq. 4, since the model generates sentence $\boldsymbol{x}'$ with the original style while generating the target sentence:

$$R_{cls_{source}} = \lambda_{cls}[p(s_1|\boldsymbol{x}') - p(s_2|\boldsymbol{x}')] \quad (5)$$

		0 ⟶ 1		1 ⟶ 0	
Domain	Train	Valid	Test	Valid	Test
F&R	51,967	2,788	1,332	2,247	1,019
E&M	52,595	2,877	1,416	2,356	1,082

Table 1: GYAFC dataset. 0 = informal; 1 = formal.

BLEU Score Reward Following Sancheti et al. (2020), we introduce a BLEU-based reward to foster content preservation as in Eq. 6, where $\boldsymbol{y}'$ is the target style text obtained by greedily maximizing the distribution of model outputs at each time step, and $\boldsymbol{y}^s$ is sampled from the distribution.

$$R_{bleu} = \lambda_{bleu}[bleu(\boldsymbol{y}', \boldsymbol{y}) - bleu(\boldsymbol{y}^s, \boldsymbol{y})] \quad (6)$$

Gradients and Objectives The rewards are used for policy learning. The policy gradient[2] is

$$\nabla_\phi J(\phi) = E[R \cdot \nabla_\phi log(P(\boldsymbol{y}^s|\boldsymbol{x}; \phi))] \quad (7)$$

where R is the SC reward and/or the BLEU reward, $\boldsymbol{y}^s$ is sampled from the distribution of model outputs at each decoding time step, and ϕ are the parameters of the model. Similarly, we add the policy gradient regarding the source sentence for the SC reward (only for the GPT-2-based model).

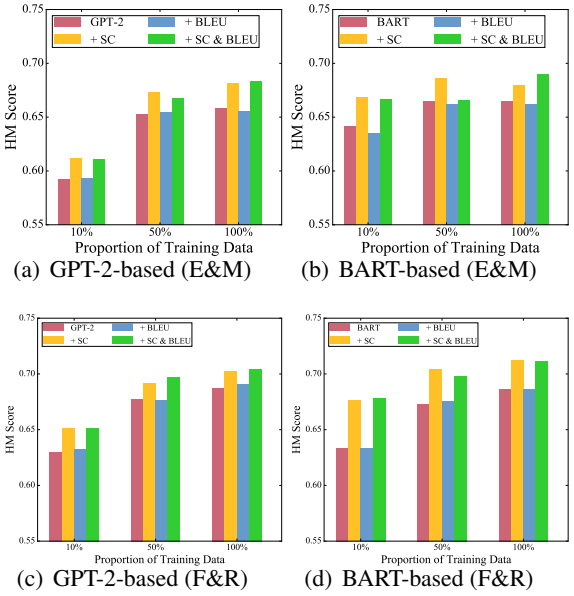
The overall objectives for ϕ are the loss of the base model (Eq. 1 or Eq. 2) and the policy gradient of the different rewards (Eq. 7).

3 Experiments

Dataset Grammarly's Yahoo Answers Formality Corpus (GYAFC) (Rao and Tetreault, 2018) is a formality style transfer dataset with parallel formal and informal sentences from two domains: Entertainment & Music (E&M) and Family & Relationships (F&R). Table 1 shows the number of sentences in train, validation, and test. Four human references exist for every valid/test sentence.

Setup All experiments are implemented atop Huggingface's transformers (Wolf et al., 2020). Our base models are the GPT-2-based model (117M parameters) and BART-based model (base with 139M parameters and large with 406M). We fine-tune them with the Adam optimiser (Kingma and Ba, 2015) with batch size 32; the initial learning rates are $5e^{-5}$ (GPT-2) and $3e^{-5}$ (BART). The final values for λ are set to 1 for SC and 0.2 for BLEU based on validation results. We use early stopping (patience 3) if validation performance does not improve. Test results are reported with the best validation settings.

[2]Additional details are provided in the Appendix.



(a) GPT-2-based (E&M) (b) BART-based (E&M)

(c) GPT-2-based (F&R) (d) BART-based (F&R)

Figure 2: HM score of x%-sized training sets of GPT-2-/BART-based models with different rewards (none, +SC, +BLEU, +SC & BLEU) for the two domains (E&M and F&R).

Evaluation Following previous work (Luo et al., 2019; He et al., 2020; Sancheti et al., 2020), we adopt the following strategies. The binary classifier TextCNN (Kim, 2014) is pre-trained to evaluate style strength; on the human references it has an accuracy of 87.0% (E&M) and 89.3% (F&R). Based on the four human references, we calculate BLEU[3] for content preservation. As overall score we compute the harmonic mean (HM) of style accuracy and BLEU. For our evaluation we also test BLEURT, a recent metric for content preservation which correlates better with human judgments than other metrics that take semantic information into account, e.g. METEOR (Sellam et al., 2020).

Baselines We train a basic supervised model (a Bi-LSTM with attention from OpenNMT (Klein et al., 2017)), to assess the impact of the size of parallel training data. We compare our models to the five baselines from Rao and Tetreault (2018), and to the best performing formality style transfer methods that report results on the datasets we use. These are mentioned in Section 1 and summarised as follows: Bi-directional FT (Niu et al.,

[3]We use `multi-bleu.perl` with default settings.

Table 2: Comparison of our models to previous work. The best score for each metric in each block is boldfaced. Notes: (i) if the output of previous work is available, we re-calculate the scores using our evaluation metrics. Otherwise, scores are from the paper and we mark this with (*); (ii) (B) shows our results on informal-to-formal to compare with Wang et al. (2019) and Chawla and Yang (2020), who only transfer in this direction; (iii) in (C) we train on the concatenated data from both domains, to compare against Niu et al. (2018); (iv) in (E&M (D)) we re-evaluate our system against the first reference only, as done by Sancheti et al. (2020).

2018), CPLS (Shang et al., 2019), GPT-CAT (Wang et al., 2019), S2S-SLS (GPT-2) (Wang et al., 2020), Transformer (data augmentation) (Zhang et al., 2020), TS→CP (Sancheti et al., 2020), and Chawla's (Chawla and Yang, 2020). Since supervised methods significantly outperform unsupervised approaches, results for the latter are not considered as the baseline in our experiment.. Disentanglement-based methods are not included since Lample et al. (2019) provide evidence that they are surpassed.

Results Figure 2 shows the HM score of x%-sized training sets on the E&M and the F&R domains. Increasing train set size from 10% to 50% has a greater boost on GPT-2-based models than BART's. However, BART-based models obtain the highest results. Table 2 reports a selection of our models [4] and previous state-of-the-art work. Zooming in on the single measures, we see in Table 2 how varying training size reveals the impact of parallel data on content preservation: OpenNMT's BLEU score on E&M increases from 0.231 with 10% of the data to 0.403 with 100%. Style accuracy appears instead easier to achieve even with limited supervision. Increasing training size for fine-tuning either pre-trained model does not however yield dramatic improvements in content preservation (e.g. from 0.547 to 0.577 BLEU for BART base on E&M). In fact, fine-tuning a pre-trained model (either GPT-2 or BART) with just 10% of parallel data, leads to better content preservation (0.547 BLEU with BART on E&M) than OpenNMT with 100% (0.403). This suggests that content preservation is largely taken care of by the pre-trained models, already, and can explain why the BLEU-based reward does not help too much in isolation (see Fig. 2). Conversely, the SC reward consistently boosts style accuracy in both BART and GPT-2. Nevertheless, combining rewards can be beneficial. Overall, BART-based models perform better on content preservation while results on style strength are mixed.

Given the experimental setup of some previous work, we ran additional comparisons (blocks (B), (C), and (D) of Table 2). In all cases, our results are higher than the previous state-of-the-art. For example, in F&R (D) our model with 10% parallel data outperforms Shang et al. (2019)'s semi-supervised model, which uses about 9.5% parallel data and large amounts of non-parallel data (BLEU 0.571 vs 0.379). Fine-tuning BART on both domains (C)[5] leads to the best results to date on both datasets (E&M: 0.719; F&R: 0.728).

With respect to the two evaluation metrics used for content preservation (BLEU and BLEURT), we can observe in Table 2 that they follow a similar trend. In fact, they correlate very highly (Pearson's $r = .951$, p<.001, $n = 14$ for E&M, and $r = .951$,

[4] In the table we report results for the models that use both rewards (BLEU and SC) since this setting mostly leads to best results. Complete results for all models (and sample outputs) are in the Appendix.

[5] Following Kobus et al. (2017), we add a token to each training instance that specifies its domain.

Table 3: Sample model outputs and their sentence-level scores on the E&M domain, where red denotes improperly generated words or content. Note that ACC indicates style confidence here.

$p<.001$, $n = 13$ for F&R).

Finer-grained Analysis Table 3 shows example outputs and their evaluation according to the metrics we use; the outputs are produced by existing systems we compare to, and our own models.[6]

In the "Informal to Formal" example, we can see that text generated by most systems is assessed with a high confidence in style conversion, except for PBMT-Combined (Rao and Tetreault, 2018) and Transformer (Zhang et al., 2020) (the name "omarionhe" should be "Omarion", and the word "he" at the beginning of the sentence should be "He"). However, the sentences generated by previous systems are not so fluent, and some of them fail in preserving content (Transformer (Zhang et al., 2020) ("omarionhe") and Chawla's (Chawla and Yang, 2020) ("Marion")). For our models, the Bi-LSTM based model fails in content preservation while the systems based on pre-trained models are much better at this task. Our model based on BART Large generates this specific sentence accurately in terms of content preservation, style strength, and fluency.

When looking at the "Formal to Informal" example in Table 3, we observe that the two previously existing systems replace very little (one comma by the Bi-directional FT (Niu et al., 2018)) or nothing at all (PBMT-Combined (Rao and Tetreault, 2018)). Conversely, our systems make substantial modifications, resulting in output sentences that are noticeably more informal than the input sentence. OpenNMT and the GPT-2-based models lose part of the content (the suggestion to avoid hot dogs) while the two BART-based systems manage to preserve the whole message.

[6]More examples are in Appendix.

4 Conclusions

Fine-tuning pre-trained models proves a successful strategy for formality style transfer, especially towards content preservation, thereby reducing the need for parallel data. A sequence-to-sequence pre-trained model (BART) outperforms a language model (GPT-2) in content preservation, and overall, and with the addition of rewards achieves new state-of-the-art results. The fact that GPT-2 is instead often better at style strength could be (partly) due to how the style reward is implemented in the two models (Eq. 4 and 5), and will need further investigation. For a better understanding of the different behaviour of BART and GPT-2 for this task, the next natural step is to include human evaluation.

Acknowledgments

This work was partly funded by the China Scholarship Council (CSC). The anonymous ACL reviewers provided us with useful comments which contributed to improving this paper and its presentation, so we're grateful to them. We would also like to thank the Center for Information Technology of the University of Groningen for their support and for providing access to the Peregrine high performance computing cluster.

Impact Statement

All work that automatically generates and/or alters natural text could unfortunately be used maliciously. While we cannot fully prevent such uses once our models are made public, we do hope that writing about risks explicitly and also raising awareness of this possibility in the general public are ways to contain the effects of potential harmful uses. We are open to any discussion and suggestions to minimise such risks.

A Appendices

This Appendices include: 1) detailed results for all experiments (A.1); 2) more details on policy gradient (A.2); 3) some example outputs of various models and their sentence-level scores, to give an idea of what the generated sentences look like when style transfer is applied. We specifically focus on the 100% parallel data settings for our models (A.3).

A.1 Detailed Results of Models

We report here the full set of results for all our models and previous work.

Table A.1.1: Evaluation results of x%-sized training sets (10%, 50% and 100%) on the E&M domain. The best score for each metric in each table section is boldfaced. BLEURT scores are calculated based on the BLEURT-base model with 128 tokens. Note that (i) Both BLEURT and BLEU are calculated against the four human references; (ii) ACC is the accuracy of the output labeled as the target style by the binary classifier; and (iii) HM is the harmonic mean of ACC and BLEU.

Table A.1.2: Evaluation results of x%-sized training sets (10%, 50% and 100%) on the F&R domain. The best score for each metric in each table section is boldfaced. BLEURT scores are calculated based on the BLEURT-base model with 128 tokens. Note that (i) Both BLEURT and BLEU are calculated against the four human references; (ii) ACC is the accuracy of the output labeled as the target style by the binary classifier; and (iii) HM is the harmonic mean of ACC and BLEU.

Table A.1.3: Comparison of our models with the other models. The best score for each metric in each block is boldfaced. BLEURT scores are calculated based on the BLEURT-base model with 128 tokens. Notes: (i) if the output of a previous work is available, we re-calculate the scores using our evaluation metrics. Otherwise we take the scores from the paper and mark this with a (*); (ii) in (B) we report our results on informal-to-formal alone to compare with several systems which only transfer in this direction; (iii) in (C) we train systems on the concatenated data from both domains, to compare against Niu et al. (2018); (iv) in (E&M (D)) we re-evaluate our system against the first reference only, as this is what Sancheti et al. (2020) do.

A.2 Policy Gradient

Reinforcement learning (RL) is a sub-field of machine learning that is concerned with how intelligent agents ought to take actions in an environment in order to maximize the cumulative reward. Here, we employ the policy gradient algorithm (Williams, 1992) to maximize the expected reward (style strength and/or content preservation) of the generated sequence $\boldsymbol{y}^s$, whose gradient with respect to the parameters ϕ of the neural network model is estimated by sampling as:

$$\begin{aligned}
\nabla_\phi J(\phi) &= R \cdot \nabla_\phi \sum_i P(\boldsymbol{y}_i^s|\boldsymbol{x}_i;\phi) \\
&= \sum_i P(\boldsymbol{y}_i^s|\boldsymbol{x}_i;\phi) R_i \nabla_\theta \log(P(\boldsymbol{y}_i^s|\boldsymbol{x}_i;\phi)) \\
&\simeq \frac{1}{N}\sum_{i=1}^{N} R_i \nabla_\phi \log(P(\boldsymbol{y}_i^s|\boldsymbol{x}_i;\phi)) \\
&= E[R \cdot \nabla_\phi log(P(\boldsymbol{y}^s|\boldsymbol{x};\phi))]
\end{aligned} \tag{8}$$

where $J(\cdot)$ is the objective function, $\nabla_\phi J(\cdot)$ is the gradient of $J(\cdot)$ with respect to ϕ, R_i is the reward of the i_{th} sequence $\boldsymbol{y}^s$ that is sampled from the distribution of model outputs at each decoding time step, ϕ are the parameters of the model, N is the sample size, and $E(\cdot)$ is the expectation.

Regarding the reward of style classification for GPT-2 based model, we design two rewards (Eq. 4 and Eq. 5) for source sentence and target sentence, respectively. The policy gradient is then

$$\begin{aligned}
\nabla_\phi J(\phi) = &E[R_{cls_{source}} \cdot \nabla_\phi log(P(\boldsymbol{y}^s_{source}|\boldsymbol{x}_{source};\phi))] \\
&+ E[R_{cls_{target}} \cdot \nabla_\phi log(P(\boldsymbol{y}^s_{target}|\boldsymbol{x}_{source,target};\phi))]
\end{aligned} \tag{9}$$

Abstract

Existing works for aspect-based sentiment analysis (ABSA) have adopted a unified approach, which allows the interactive relations among subtasks. However, we observe that these methods tend to predict polarities based on the literal meaning of aspect and opinion terms and mainly consider relations implicitly among subtasks at the word level. In addition, identifying multiple aspect–opinion pairs with their polarities is much more challenging. Therefore, a comprehensive understanding of contextual information w.r.t. the aspect and opinion are further required in ABSA. In this paper, we propose Deep Contextualized Relation-Aware Network (DCRAN), which allows interactive relations among subtasks with deep contextual information based on two modules (i.e., Aspect and Opinion Propagation and Explicit Self-Supervised Strategies). Especially, we design novel self-supervised strategies for ABSA, which have strengths in dealing with multiple aspects. Experimental results show that DCRAN significantly outperforms previous state-of-the-art methods by large margins on three widely used benchmarks.

1 Introduction

Aspect-based sentiment analysis (ABSA) is a task of identifying the sentiment polarity of associated aspect terms in a sentence. Generally, ABSA is composed of three subtasks, 1) aspect term extraction (ATE), 2) opinion term extraction (OTE), and 3) aspect-based sentiment classification (ASC). Given the sentence "*Food is good, but service is dreadful.*", ATE aims to identify two-aspect terms "*food*" and "*service*", and OTE aims to determine two-opinion terms "*good*" and "*dreadful*". Then, ASC assigns a sentiment polarity of each aspect: "*food* (*positive*)" and "*service* (*negative*)".

	Examples (Ground Truth)	Model	Aspect (Polarity)	Opinion
E1	I've had *better Japanese food* (neg) at a mall food court.	RACL	Japanese food (pos)	better
		DCRAN	Japanese food (neg)	better
E2	The *sushi* (neg) is cut in blocks *bigger* than my cell phone.	RACL	sushi (neu)	bigger
		DCRAN	sushi (neg)	bigger
E3	While the *smoothies* (neg) are a little *bigger* for me, the *fresh juices* (pos) are the *best* I have ever had !	RACL	smoothies (pos) fresh juices (pos)	bigger fresh best
		DCRAN	smoothies (neg) fresh juices (pos)	bigger best

Table 1: Examples of ABSA results comparing to previous approach (Chen and Qian, 2020) that we reimplement. All the results are based on BERT$_{base}$ model for a fair comparison. The polarity labels pos, neu, and neg, denote positive, neutral, and negative, respectively.

Existing works for ABSA have adopted a two-step approach, which considers each subtask separately (Tang et al., 2016; Xu et al., 2018). However, most recently, unified approaches have achieved significant performance improvements in ABSA task. Luo et al. (2020) focused on modeling the interactions between aspect terms and Chen and Qian (2020) exploited dyadic and triadic relations between subtasks (i.e., ATE, OTE, ASC).

Despite the impressive results, their methods have two limitations. First, they only consider relations among subtasks at the word level and do not explicitly utilize contextualized information of the whole sequence. For example, E1 in Table 1, the opinion term "*better*" seems to represent positive opinion of "*Japanese food*". However, the authentic meaning of E1 is "*The Japanese food I have had at the food court was more delicious than the one I had at this restaurant*". Thus, previous approaches tend to assign polarities based on the literal meaning of aspect and opinion terms (E2). Second, identifying multiple aspect–opinion pairs and their polarities is much more challenging as the model needs to not only detect multiple aspects and

opinions but also correctly predict each polarity of the aspect (E3).

To address the aforementioned issues, we propose Deep Contextualized Relation-Aware Network (DCRAN) for ABSA. DCRAN not only implicitly allows interactive relations among the subtasks of ABSA, but also explicitly considers their relations by using contextual information. Our main contributions are as follows: 1) We design aspect and opinion propagation decoder so that the model has a comprehensive understanding of the whole context, and thus it results in better prediction of the polarity. 2) We propose novel self-supervised strategies for ABSA, which are highly effective in dealing with multiple aspects and considering deep contextualized information with the aspect and opinion terms. To the best of our knowledge, it is the first attempt to design explicit self-supervised methods for ABSA. 3) Experimental results demonstrate that DCRAN significantly outperforms previous state-of-the-art methods on three widely used benchmarks.

2 DCRAN: Deep Contextualized Relation-Aware Network

2.1 Task Definition

Given a sentence $S = \{w_1, w_2, ..., w_n\}$, where n denotes the number of tokens, we aim to solve three subtasks: aspect term extraction (ATE), opinion term extraction (OTE), and aspect-based sentiment classification (ASC) as sequence labeling problems. ATE task aims to identify a sequence of aspect terms $Y^a = \{y_1^a, y_2^a, ..., y_n^a\}$, where $y_i^a \in \{B, I, O\}$, and OTE task aims to identify a sequence of opinion terms $Y^o = \{y_1^o, y_2^o, ..., y_n^o\}$, where $y_i^o \in \{B, I, O\}$ of aspect and opinion terms, respectively. Likewise, ASC task aims to assign a sequence of polarities $Y^p = \{y_1^p, y_2^p, ..., y_n^p\}$, where $y_i^p \in \{POS, NEU, NEG, O\}$. The labels *POS*, *NEU*, and *NEG* denote *positive*, *neutral*, and *negative*, respectively.

2.2 Task-Shared Representation Learning

Following existing works, we utilize pre-trained language models, such as BERT (Devlin et al., 2019) and ELECTRA (Clark et al., 2020) as the shared encoder to construct context representation, which is shared by subtasks: ATE, OTE, and ASC. Given a sentence $S = \{w_1, w_2, ..., w_n\}$, pre-trained language models take the input sequence, $\mathbf{X}_{\text{absa}} = [[\text{CLS}]\, w_1\, w_2 \ldots w_n\, [\text{SEP}]]$, and output a sequence of the shared context representation, $H = \{h_{[\text{CLS}]}, h_1, h_2, ..., h_n, h_{[\text{SEP}]}\} \in \mathbb{R}^{d_h \times (n+2)}$, where d_h represents a dimension of the shared encoder. We represent the parameters of the shared encoder as Θ_s. Then, we utilize a single-layer feed-forward neural network (FFNN) as,

$$\begin{aligned} Z^a &= (W_1 h_{[1:n+1]} + b_1) \\ \hat{Y}^a &= \text{softmax}(W_2 Z^a + b_2), \end{aligned} \tag{1}$$

where $W_1 \in \mathbb{R}^{d_h \times d_h}$ and $W_2 \in \mathbb{R}^{3 \times d_h}$ are trainable parameters. The parameters of a single-layer FFNN are represented as Θ_a for aspect term extraction. The objective of aspect term extraction is minimizing the negative log-likelihood (NLL) loss: $\mathcal{L}_{\text{ate}}(\Theta_s, \Theta_a) = -\sum \log p(Y^a|H)$. Likewise, Z^o and $\hat{Y}^o$ are obtained as in Equation 1. Then, the NLL loss of opinion term extraction is defined as, $\mathcal{L}_{\text{ote}}(\Theta_s, \Theta_o) = -\sum \log p(Y^o|H)$.

2.3 Aspect and Opinion Propagation

We utilize the transformer-decoder (Vaswani et al., 2017) to consider relations of aspect and opinion while predicting a sequence of polarities. Our transformer-decoder is mainly composed of a multi-head self-attention, two multi-head cross attention, and a feed-forward layer. The multi-head self-attention takes shared context representation H as,

$$U^h = \text{LN}(H + \text{SelfAttn}(H, H, H)) \tag{2}$$

and U^h, Z^a, and Z^o are fed into two steps of cross multi-head attention as,

$$U^a = \text{LN}(U^h + \text{CrossAttn}(U^h, Z^a, Z^a)) \tag{3}$$

$$U^o = \text{LN}(U^a + \text{CrossAttn}(U^a, Z^o, Z^o)) \tag{4}$$

where LN represents layer norm (Ba et al., 2016). Note that Equation 3 and 4 represent aspect and opinion propagation, respectively. Then U^o is fed into a single-layer FFNN to obtain a sequence of polarities Y^p. The objective of aspect-based sentiment analysis is minimizing the NLL loss: $\mathcal{L}_{\text{asc}}(\Theta_s, \Theta_a, \Theta_o, \Theta_p) = -\sum \log p(Y^p|H, Z^a, Z^o)$. The architecture of the aspect and opinion propagation is described in Figure 1-(a).

2.4 Explicit Self-Supervised Strategies

To further exploit the aspect–opinion relation with contextualized information of a sentence, we propose explicit self-supervised strategies consisting of two auxiliary tasks: 1) type-specific masked term

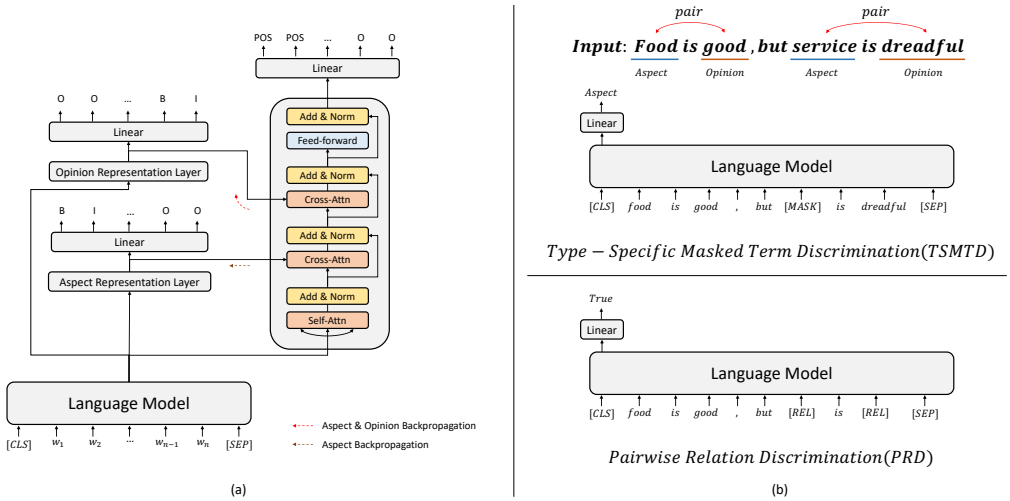

Figure 1: Overall architecture of Deep Contextualized Relation-Aware Network (DCRAN) for ABSA.

discrimination (TSMTD) and 2) pairwise relations discrimination (PRD). The examples of *Explicit Self-Supervised Strategies* are described in Figure 1-(b).

Type-Specific Masked Term Discrimination In the type-specific masked term discrimination task, we uniformly mask aspects, opinions, and terms that do not correspond to both, using the special token [MASK]. The input sequence of a masked sentence is represented as, $\mathbf{X}_{\text{tsmtd}} = [[\text{CLS}]\, w_1 \ldots [\text{MASK}]_i \ldots w_n\, [\text{SEP}]]$, and is fed into pre-trained language models. Then, the output representation of [CLS] token is used to classify which type of term is masked in a sentence as,

$$\hat{Y}^m = \text{softmax}(W_3 h_{[\text{CLS}]} + b_3),$$

where $W_3 \in \mathbb{R}^{3\times d_h}$ represents trainable parameters and $\hat{Y}^m \in \{Aspect, Opinion, O\}$. The parameters of a linear projection layer are represented as Θ_m for the type-specific masked term discrimination. Then, the NLL loss of the type-specific masked term discrimination is defined as: $\mathcal{L}_{\text{tsmtd}}(\Theta_s, \Theta_m) = -\sum \log p(Y^m|H)$. This allows the model to explicitly exploit sentence information by discriminating what kind of term is masked.

Pairwise Relations Discrimination In this task, we uniformly replace both aspects and opinion terms using the special token [REL]. The input sequence of a masked sentence is represented as, $\mathbf{X}_{\text{prd}} = [[\text{CLS}]\, w_1 \ldots [\text{REL}]_i \ldots [\text{REL}]_j \ldots w_n\, [\text{SEP}]]$, and is fed into pre-trained language models. Then, the output representation of [CLS] token is used to discriminate whether the replaced tokens have a pairwise relation as,

$$\hat{Y}^r = \text{softmax}(W_4 h_{[\text{CLS}]} + b_4),$$

where $W_4 \in \mathbb{R}^{2\times d_h}$ represents trainable parameters and $\hat{Y}^r \in \{True, False\}$. The parameters of a linear projection layer are represented as Θ_r for the pairwise relations discrimination. Then, the NLL loss of the pairwise relations discrimination is defined as: $\mathcal{L}_{\text{prd}}(\Theta_s, \Theta_r) = -\sum \log p(Y^r|H)$. We describe the negative sampling method to replace aspects and opinion terms in Appendix A.2.

2.5 Joint Learning Procedure

All these tasks are jointly trained, and the final objective is defined as,

$$\mathcal{L}_{\text{absa}} = \mathcal{L}_{\text{ate}} + \mathcal{L}_{\text{ote}} + \mathcal{L}_{\text{asc}}$$
$$\mathcal{L}_{\text{aux}} = \mathcal{L}_{\text{tsmtd}} + \mathcal{L}_{\text{prd}}$$
$$\mathcal{L}_{\text{final}} = \mathcal{L}_{\text{absa}} + \alpha \mathcal{L}_{\text{aux}}$$

where α is a hyper-parameter determining the degree of auxiliary tasks. Note that the parameters Θ_s are optimized for all subtasks. Especially, the parameters Θ_s are further optimized through $\mathcal{L}_{\text{tsmtd}}$ and $\mathcal{L}_{\text{prd}}$ to explicitly exploit the relations between aspect and opinion with context meaning.

3 Experiments

3.1 Experimental Setup

We evaluate our model on three widely used sentiment analysis benchmarks: laptop reviews (LAP14), restaurant reviews (REST14) from (Pontiki et al., 2014), and restaurant reviews (REST15)

		LAP14				REST14				REST15

Table 2: Evaluation results on the LAP14, REST14, and REST15 datasets, which are provided by Chen and Qian (2020). All the results except ours are cited from the existing works (Chen and Qian, 2020; Peng et al., 2020; Mao et al., 2021) and all the baselines are described in Appendix A.4. We report average results over five runs with random initialization. The best scores are in bold, and the second-best scores are underlined depending on the types of the pre-trained language model. '-' denotes unreported results.

from (Pontiki et al., 2015). Primitive versions of these benchmarks only provide aspect terms and sentiment polarities, while opinion terms are provided by Wang et al. (2016, 2017) later. Recently, Fan et al. (2019) provides aspect-opinion pairwise datasets (Section 2.4). Following He et al. (2019), we set four evaluation metrics: ATE-F1, OTE-F1, ASC-F1, and ABSA-F1. The ATE-F1, OTE-F1, and ASC-F1 measure each subtask's F-1 scores, and ABSA-F1 measures complete ABSA, which counts only when both ATE and ASC predictions are correct.

3.2 Quantitative Results

Table 2 reports the quantitative results on the LAP14, REST14, and REST15 datasets. Our experiments utilize two pre-trained language models such as BERT and ELECTRA, for the shared encoder. First, we observe that DCRAN-BERT$_{base}$ shows slightly lower ABSA-F1 scores than previous state-of-the-art methods, which is based on BERT$_{large}$, on the REST14 and LAP14 datasets except for the REST15 dataset. This suggests that our proposed methods are highly effective for ABSA. Overall, DCRAN-BERT$_{large}$ significantly outperforms previous state-of-the-art methods in all metrics. Another observation is that ELECTRA based models outperform BERT based models. As a result, DCRAN-ELECTRA$_{large}$ achieves absolute gains over previous state-of-the-art results by 5.5%, 4.4%, and 7.6% in ABSA-F1 on the LAP14, REST14, and REST15 datasets, respectively.

3.3 Ablation Study

To study the effectiveness of the aspect propagation (AP), opinion propagation (OP), type-specific masked term discrimination (TSMTD), and pairwise relations discrimination (PRD), we conduct ablation experiments on the REST14 dataset. We set the baseline model that did not utilize aspect and opinion propagation and explicit self-supervised strategies. When the AP and OP are not utilized, a single-layer FFNN is utilized as in Equation 1 to predict a sequence of polarities Y^p instead of transformer-decoder. As shown in Table 3, we can observe that the AP is more effective than the OP, and scores drop significantly when not utilizing the AP and OP. In the case of explicit self-supervised strategies, we can observe that the PRD is more effective than the TSMTD. As the PRD objective is discriminating whether the replace tokens have a pairwise aspect–opinion relations, it allows the model to more exploit the relations between aspect and opinion at a sentence level.

		ABSA-F1
	DCRAN-ELECTRA$_{base}$	**80.00**†

Baseline	w/o & AP & OP & TSMTD & PRD	78.61

Table 3: Ablation study on the REST14 dataset. We choose DCRAN-ELECTRA$_{base}$ as the baseline. † denotes statistical significance (p-value < 0.05).

3.4 Aspect Analysis

We conduct aspect analysis by comparing sentences with single- and multiple-aspect. As shown in Table 4, *Aspect and Opinion Propagation* signif-

		REST14		REST15	
		ABSA-F1	Sent-level Acc.	ABSA-F1	Sent-level Acc.
Single-Aspect	DCRAN_ELECTRA$_{base}$	**78.62**	**74.48**	**66.23**	**67.69**
	w/o TSMTD & PRD	78.42	73.79	64.21	66.67
	w/o TSMTD & PRD & AP & OP	77.45	73.10	62.50	64.29

	w/o TSMTD & PRD	80.22	61.70	65.16	48.60
	w/o TSMTD & PRD & AP & OP	79.88	61.39	64.84	46.73

Table 4: Aspect analysis on the REST14 and REST15 datasets. Comparisons of ABSA-F1 and sentence-level accuracy results for the case when the sentence contains single-aspect or multiple-aspect.

icantly improves performance when the sentence contains a single-aspect, while a small increase is observed w.r.t. the case of multiple-aspect. Although considering the relations between aspect and opinion implicitly can improve performance w.r.t. the case of single-aspect, it is not sufficient for inducing performance improvement for the multiple-aspect case. It suggests that additional explicit tasks are further required to identify multiple-aspect with corresponding opinions, which helps the model assign polarities correctly. In the case of multiple-aspect, *Explicit Self-Supervised Strategies* show absolute ABSA-F1 improvements of 0.97% (80.22% $\rightarrow$ 81.19%) and 3.04% (65.16% $\rightarrow$ 68.20) on the REST14 and REST15 datasets, respectively. This indicates explicit self-supervised strategies are highly effective for correctly identifying ABSA when the sentence contains multiple-aspect. In addition, the performance gain by *Explicit Self-Supervised Strategies* in Table 3 is mostly derived from the multiple-aspect cases (+0.97%), thus our proposed model has strengths in dealing with multiple aspects.

In ABSA, it is important to accurately predict all aspects and corresponding sentiment polarities in one sentence. Since ABSA-F1 is a word-level based metric, it still has a limitation to evaluate whether all aspects and corresponding polarities are correct or not. Therefore, we also evaluate our method with sentence-level accuracy; the number of sentences that accurately predicted all aspects and polarity in a sentence divided by total number of sentences. Unlike ABSA-F1, the sentence-level accuracy of multiple-aspect is lower than that of single-aspect, which implies identifying multiple aspects and their polarities is more challenging. In the case of multiple-aspect, our *Explicit Self-Supervised Strategies* leads significant sentence-level accuracy improvements of 2.54% (61.70% $\rightarrow$ 64.24%) and 3.74% (48.60% $\rightarrow$ 52.34%) on the REST14 and REST15 datasets, respectively. However, we observe only small improvements in sentence-level accuracy on both datasets when the sentence contains single-aspect. From these observations, we demonstrate that our proposed method is highly effective for the case when the sentence contains multiple aspects.

4 Conclusion

In this paper, we proposed the Deep Contextualized Relation-Aware Network (DCRAN) for aspect-based sentiment analysis. DCRAN allows interaction between subtasks implicitly in a more effective manner and two explicit self-supervised strategies for deep context- and relation-aware learning. We obtained the new state-of-the-art results on three widely used benchmarks.

A Appendix

A.1 Related Work

Existing works have studied a two-step approach for ABSA. In a two-step approach, each model for ATE, OTE, and ASC are separately trained and are merged in a pipelined manner (Wang et al., 2016; Tang et al., 2016; Wang et al., 2017; He et al., 2017; Xu et al., 2018; Yu et al., 2018; Li et al., 2018; Chen and Qian, 2019). However, the errors from other tasks can be propagated to the ASC and can degrade performance after all.

Most recently, a unified approach that comprised of joint approach (García-Pablos et al., 2018; Luo et al., 2019; He et al., 2019; Luo et al., 2020) and collapsed approach (Li and Lu, 2017; Ma et al., 2018; Wang et al., 2018; Li et al., 2019) has been proposed. A joint approach labels each word with different tag sets for each task: ATE, OTE, and ASC. On the other hand, a collapsed approach labels each word as the combined one of ATE and ASC, such as "B-POSITIVE" and "I-POSITIVE", where "B" and "I" represent the aspect term boundary, and "POSITIVE" represents polarity. However, in a collapsed approach, the relations among subtasks cannot be effectively exploited because subtasks need to share all representation without distinction of each task. Therefore, a joint training approach allows the interactive relations between subtasks, while a collapsed approach is not.

A.2 Negative Sampling Algorithm for Pairwise Relations Discrimination

Algorithm 1 describes the negative sampling procedure in pairwise relations discrimination. The get_sample function takes a list of aspect-opinion pairs in a sentence and replaces them with [REL] tokens. Then, if the replaced tokens have pairwise relations, set the target label as True, and set as False if not. The get_pair function randomly selects a pairwise aspect and opinion, and the get_neg_pair function selects aspects and opinions of different pairs when there are two or more pairs in a sentence.

Algorithm 1 Negative Sampling Algorithm for Pairwise Relations Discrimination

Input: $pairs$: list of aspect–opinion pairs in a sentence
Output: $pair, target$
  function GET_SAMPLE($pairs$)
    if count($pairs$) == 0 **then**
      return None, None
    else if count($pairs$) == 1 **then**
      return $pairs$[0], True
    else
      $random$ = $\{0 < random \leq 1\}$
      if $random \leq 0.25$ **then**
        return get_pair($pairs$), True
      else
        return get_neg_pair($pairs$), False

A.3 Implementation Details

We implemented our model by using the PyTorch (Paszke et al., 2019) deep learning library based on the open source[1] (i.e., Transformers (Wolf et al., 2020)). For the shared encoder, we adopt four types of pre-trained language models: BERT$_{base}$, BERT$_{large}$, ELECTRA$_{base}$, and ELECTRA$_{large}$. We set the batch size to 64 for the $base$ model, 12 for the BERT$_{large}$ and 32 for the ELECTRA$_{large}$. We set the initial learning rate to 5e-5 for BERT$_{base}$ and ELECTRA$_{base}$, 2e-5 for BERT$_{large}$, and 5e-6 for ELECTRA$_{large}$. For the transformer decoder, we set the number of heads in multi-head attention and hidden layers to 2 among range from 2 to 6, and hidden dimension size to 768. In the case of α, we obtained the best results when α is 1. The average runtime for each approach was about 20 seconds for BERT$_{base}$ and ELECTRA$_{base}$, and 90 seconds for BERT$_{large}$ and ELECTRA$_{large}$. We train our models using AdamP (Heo et al., 2021) optimizer and conduct experiments with Tesla V100 GPU for all the experiments.

A.4 Baselines

We compare our model with the following previous works[2].

MNN (Wang et al., 2018) is a multi-task model for ATE and ASC using attention mechanisms to learn the joint representation of aspect and polarity relations.

E2E-TBSA (Li et al., 2019) is an end-to-end model of the collapsed approach for ATE and ASC. Additionally, it introduces the auxiliary OTE task without explicit interaction.

[1] https://github.com/huggingface/transformers

[2] We do not compare our work with GRACE (Luo et al., 2020) as Luo et al. (2020) contains *conflict* tag in polarities.

	Examples (Ground Truth)	Model	Aspect (Polarity)	Opinion
E1	I have worked in restaurants and cook a lot, and there is no way a maggot should be able to get into *well prepared food* (neg).	RACL	food (pos)	well
		DCRAN w/o	food (pos)	well prepared
		DCRAN	food (neg)	well prepared
E2	All in all, I would return - as it was a *beautiful restaurant* (pos) - but I hope the *staff* (neg) pays more attention to the little details in the future.	RACL	-	-
		DCRAN w/o	restaurant (pos) staff (pos)	beautiful
		DCRAN	restaurant (pos) staff (neg)	beautiful
E3	I have never been so *disgusted* by both *food* (neg) and *service* (neg)	RACL	food (pos) service (pos)	disgusted
		DCRAN w/o	food (pos) service (neg)	disgusted
		DCRAN	food (neg) service (neg)	disgusted

Table 5: Case study on the REST15 dataset. Model comparison between previous state-of-the-art method (RACL) (Chen and Qian, 2020) and our proposed method (DCRAN). DCRAN w/o denotes DCRAN without *Explicit Self-Supervised Strategies* (Section 2.4). All models are built based on the BERT$_{base}$ model. The polarity labels pos, neu, and neg denote positive, neutral, and negative, respectively. '-' denotes that the model failed to extract corresponding terms.

DOER (Luo et al., 2019) is a dual cross-shared RNN framework that jointly trains ATE and ASC. It considers relations between aspect and polarity.

IMN (He et al., 2019) is a multi-task model for ATE and ASC with separate labels. The OTE task is fused into ATE by constructing five-class labels.

WHW (Peng et al., 2020) is a unified two-stage framework to extract (aspect, opinion, polarity) triples as a result of ATE, OTE, and ASC.

IKTN (Liang et al., 2020) is an iterative knowledge transfer network for ABSA considering the semantic correlations among the ATE, OTE, and ASC.

SPAN (Hu et al., 2019) is a pipeline approach to solve ATE and ASC using BERT$_{large}$. It uses a multi-target extractor for ATE and a polarity classifier for ASC.

RACL (Chen and Qian, 2020) defines interactive relations among ATE, OTE, and ASC. It proposes relation propagation mechanisms through the stacked multi-layer network.

Dual-MRC (Mao et al., 2021) leverages two machine reading comprehension problems to solve ATE and ASC. It jointly trains two BERT-MRC models sharing parameters.

A.5 Case Study

In E1 and E3, while all models correctly extract both aspect and opinion, RACL and DCRAN w/o make inaccurate polarities predictions based on the words having superficial meaning (i.e., *well prepared*, *disgusted*). Especially, E3 expresses a sarcastic opinion about aspect terms throughout the sentence. It suggests that these models cannot understand the authentic meaning of the sentence. On the other hand, DCRAN grasps the entire context and predicts the correct polarity corresponding to its aspect. In E2, the evidence for understanding the actual meaning of the aspect term *staff* is not specified in a word-level opinion and expressed in a sentence like "*I hope the staff pays more attention to the little details in the future*". In this case, RACL can not extract aspect and opinion terms, and DCRAN w/o make inaccurate polarities predictions for the aspect term *staff* based on the opinion term *beautiful*. However, DCRAN with *Explicit Self-Supervised Strategies* understands the sentence expressing an opinion on the *staff* and predicts correctly.

Towards Generative Aspect-Based Sentiment Analysis*

Abstract

Aspect-based sentiment analysis (ABSA) has received increasing attention recently. Most existing work tackles ABSA in a discriminative manner, designing various task-specific classification networks for the prediction. Despite their effectiveness, these methods ignore the rich label semantics in ABSA problems and require extensive task-specific designs. In this paper, we propose to tackle various ABSA tasks in a unified generative framework. Two types of paradigms, namely annotation-style and extraction-style modeling, are designed to enable the training process by formulating each ABSA task as a text generation problem. We conduct experiments on four ABSA tasks across multiple benchmark datasets where our proposed generative approach achieves new state-of-the-art results in almost all cases. This also validates the strong generality of the proposed framework which can be easily adapted to arbitrary ABSA task without additional task-specific model design.[1]

1 Introduction

Aspect-based sentiment analysis (ABSA), aiming at mining fine-grained opinion information towards specific aspects, has attracted increasing attention in recent years (Liu, 2012). Multiple fundamental sentiment elements are involved in ABSA, including the aspect term, opinion term, aspect category, and sentiment polarity. Given a simple example sentence "*The pizza is delicious.*", the corresponding elements are "*pizza*", "*delicious*", "*food quality*" and "*positive*", respectively.

The main research line of ABSA focuses on the identification of those sentiment elements such as extracting the aspect term (Liu et al., 2015; Yin et al., 2016; Li et al., 2018; Ma et al., 2019) or classifying the sentiment polarity for a given aspect (Wang et al., 2016; Chen et al., 2017; Jiang et al., 2019; Zhang and Qian, 2020). To provide more detailed information, many recent studies propose to jointly predict multiple elements simultaneously (Li et al., 2019a; Wan et al., 2020; Peng et al., 2020; Zhao et al., 2020). Taking the Unified ABSA (UABSA, also called End-to-End ABSA) task as an example, it tries to simultaneously predict the mentioned aspect terms and the corresponding sentiment polarities (Luo et al., 2019; He et al., 2019).

In general, most ABSA tasks are formulated as either sequence-level or token-level classification problems (Li et al., 2019b). By designing task-specific classification networks, the prediction is made in a discriminative manner, using the class index as labels for training (Huang and Carley, 2018; Wan et al., 2020). However, these methods ignore the label semantics, *i.e.*, the meaning of the natural language labels, during the training process. Intuitively, knowing the meaning of "*food quality*" and "*restaurant ambiance*", it can be much easier to identify that the former one is more likely to be the correct aspect category for the concerned aspect "*pizza*". Such semantics of the label can be more helpful for the joint extraction of multiple sentiment elements, due to the complicated interactions of those involved elements. For example, understanding "*delicious*" is an adjective for describing the food such as "*pizza*" could better lead to the prediction of aspect opinion pair ("*pizza*", "*delicious*"). Another issue is that different classification models are proposed to suit the need of different ABSA problems, making it difficult to adapt the model from one to another.

Motivated by recent success in formulating sev-

eral language understanding problems such as named entity recognition, question answering, and text classification as generation tasks (Raffel et al., 2020; Athiwaratkun et al., 2020), we propose to tackle various ABSA problems in a unified generative approach in this paper. It can fully utilize the rich label semantics by encoding the natural language label into the target output. Moreover, this unified generative model can be seamlessly adapted to multiple tasks without introducing additional task-specific model designs.

In order to enable the **G**enerative **A**spect-based **S**entiment analysis (GAS), we tailor-make two paradigms, namely annotation-style and extraction-style modeling to transform the original task as a generation problem. Given a sentence, the former one adds annotations on it to include the label information when constructing the target sentence; while the latter directly adopts the desired natural language label of the input sentence as the target. The original sentence and the target sentence produced by either paradigm can then be paired as a training instance of the generation model. Furthermore, we propose a prediction normalization strategy to handle the issue that the generated sentiment element falls out of its corresponding label vocabulary set. We investigate four ABSA tasks including Aspect Opinion Pair Extraction (AOPE), Unified ABSA (UABSA), Aspect Sentiment Triplet Extraction (ASTE), and Target Aspect Sentiment Detection (TASD) with the proposed unified GAS framework to verify its effectiveness and generality.

Our main contributions are 1) We tackle various ABSA tasks in a novel generative manner; 2) We propose two paradigms to formulate each task as a generation problem and a prediction normalization strategy to refine the generated outputs; 3) We conduct experiments on multiple benchmark datasets across four ABSA tasks and our approach surpasses previous state-of-the-art in almost all cases. Specifically, we obtain 7.6 and 3.7 averaged gains on the challenging ASTE and TASD task respectively.

2 Generative ABSA (GAS)

2.1 ABSA with Generative Paradigm

In this section, we describe the investigated ABSA tasks and the proposed two paradigms, namely, annotation-style and extraction-style modeling.

Aspect Opinion Pair Extraction (AOPE) aims to extract aspect terms and their corresponding opinion terms as pairs (Zhao et al., 2020; Chen et al., 2020). Here is an illustrative example of our generative formulations for the AOPE task:

`Input`: Salads were fantastic, our server was also very helpful.
`Target (Annotation-style)`: [Salads | fantastic] were fantastic here, our [server | helpful] was also very helpful.
`Target (Extraction-style)`: (Salads, fantastic); (server, helpful)

In the annotation-style paradigm, to indicate the pair relations between the aspect and opinion terms, we append the associated opinion modifier to each aspect term in the form of [*aspect* | *opinion*] for constructing the target sentence, as shown in the above example. The prediction of the coupled aspect and opinion term is thus achieved by including them in the same bracket. For the extraction-style paradigm, we treat the desired pairs as the target, which resembles direct extraction of the expected sentiment elements but in a generative manner.

Unified ABSA (UABSA) is the task of extracting aspect terms and predicting their sentiment polarities at the same time (Li et al., 2019a; Chen and Qian, 2020). We also formulate it as an (*aspect*, *sentiment polarity*) pair extraction problem. For the same example given above, we aim to extract two pairs: (*Salads*, *positive*) and (*server*, *positive*). Similarly, we replace each aspect term as [*aspect* | *sentiment polarity*] under the annotation-style formulation and treat the desired pairs as the target output in the extraction-style paradigm to reformulate the UABSA task as a text generation problem.

Aspect Sentiment Triplet Extraction (ASTE) aims to discover more complicated (*aspect*, *opinion*, *sentiment polarity*) triplets (Peng et al., 2020):

`Input`: The Unibody construction is solid, sleek and beautiful.
`Target (Annotation-style)`: The [Unibody construction | positive | solid, sleek, beautiful] is solid, sleek and beautiful.
`Target (Extraction-style)`: (Unibody construction, solid, positive); (Unibody construction, sleek, positive); (Unibody construction, beautiful, positive);

As shown above, we annotate each aspect term with its corresponding sentiment triplet wrapped in the bracket, *i.e.*, [*aspect*|*opinion*|*sentiment polarity*] for the annotation-style modeling. Note that

we will include all the opinion modifiers of the same aspect term within the same bracket to predict the sentiment polarities more accurately. For the extraction-style paradigm, we just concatenate all triplets as the target output.

Target Aspect Sentiment Detection (TASD) is the task to detect all (*aspect term*, *aspect category*, *sentiment polarity*) triplets for a given sentence (Wan et al., 2020), where the aspect category belongs to a pre-defined category set. For example,

> `Input`: A big disappointment, all around. The pizza was cold and the cheese wasn't even fully melted.
> `Target (Annotation-style)`: A big disappointment, all around. The [pizza | food quality | negative] was cold and the [cheese | food quality | negative] wasn't even fully melted [null | restaurant general | negative].
> `Target (Extraction-style)`: (pizza, food quality, negative); (cheese, food quality, negative); (null, restaurant general, negative);

Similarly, we pack each aspect term, the aspect category it belongs to, and its sentiment polarity into a bracket to build the target sentence for the annotation-style method. Note that we use a bigram expression for the aspect category instead of the original uppercase form "FOOD#QUALITY" to make the annotated target sentence more natural. As presented in the example, some triplets may not have explicitly-mentioned aspect terms, we thus use "*null*" to represent it and put such triplets at the end of the target output. For the extraction-style paradigm, we concatenate all the desired triplets, including those with implicit aspect terms, as the target sentence for sequence-to-sequence learning.

2.2 Generation Model

Given the input sentence $\boldsymbol{x}$, we generate a target sequence $\boldsymbol{y}'$, which is either based on the annotation-style or extraction-style paradigm as described in the last section, with a text generation model $f(\cdot)$. Then the desired sentiment pairs or triplets $\boldsymbol{s}$ can be decoded from the generated sequence $\boldsymbol{y}'$. Specifically, for the annotation-style modeling, we extract the contents included in the bracket "[]" from $\boldsymbol{y}'$, and separate different sentiment elements with the vertical bar "|". If such decoding fails, *e.g.*, we cannot find any bracket in the output sentence or the number of vertical bars is not as expected, we ignore such predictions. For the extraction-style paradigm, we separate the generated pairs or triplets from the sequence $\boldsymbol{y}'$ and ignore those invalid generations in a similar way.

We adopt the pre-trained T5 model (Raffel et al., 2020) as the generation model $f(\cdot)$, which closely follows the encoder-decoder architecture of the original Transformer (Vaswani et al., 2017). Therefore, by formulating these ABSA tasks as a text generation problem, we can tackle them in a unified sequence-to-sequence framework without task-specific model design.

2.3 Prediction Normalization

Ideally, the generated element $e \in \boldsymbol{s}$ after decoding is supposed to exactly belong to the vocabulary set it is meant to be. For example, the predicted aspect term should explicitly appear in the input sentence. However, this might not always hold since each element is generated from the vocabulary set containing all tokens instead of its specific vocabulary set. Thus, the predictions of a generation model may exhibit morphology shift from the ground-truths, *e.g.*, from *single* to *plural* nouns.

We propose a prediction normalization strategy to refine the incorrect predictions resulting from such issue. For each sentiment type c denoting the type of the element e such as the aspect term or sentiment polarity, we first construct its corresponding vocabulary set V_c. For aspect term and opinion term, V_c contains all words in the current input sentence $\boldsymbol{x}$; for aspect category, V_c is a collection of all categories in the dataset; for sentiment polarity, V_c contains all possible polarities. Then for a predicted element e of the sentiment type c, if it does not belong to the corresponding vocabulary set V_c, we use $\bar{e} \in V_c$, which has the smallest Levenshtein distance (Levenshtein, 1966) with e, to replace e.

3 Experiments

3.1 Experimental Setup

Datasets We evaluate the proposed GAS framework on four popular benchmark datasets including `Laptop14`, `Rest14`, `Rest15`, and `Rest16`, originally provided by the SemEval shared challenges (Pontiki et al., 2014, 2015, 2016). For each ABSA task, we use the public datasets derived from them with more sentiment annotations. Specifically, we adopt the dataset provided by Fan et al. (2019), Li et al. (2019a), Xu et al. (2020), Wan et al. (2020) for the AOPE, UABSA, ASTE, TASD task respectively. For a fair comparison, we use the same data split as previous works.

Evaluation Metrics We adopt F1 scores as the main evaluation metrics for all tasks. A prediction is correct if and only if all its predicted sentiment elements in the pair or triplet are correct.

Experiment Details We adopt the T5 base model from *huggingface* Transformer library[2] for all experiments. T5 closely follows the original encoder-decoder architecture of the Transformer model, with some slight differences such as different position embedding schemes. Therefore, the encoder and decoder of it have similar parameter size as the BERT-BASE model. For all tasks, we use similar experimental settings for simplicity: we train the model with the batch size of 16 and accumulate gradients every two batches. The learning rate is set to be 3e-4. The model is trained up to 20 epochs for the AOPE, UABSA, and ASTE task and 30 epochs for the TASD task.

[2] https://github.com/huggingface/transformers

3.2 Main Results

The main results for the AOPE, UABSA, ASTE, TASD task are reported in Tables 1, 2, 3, 4 respectively. For our proposed GAS framework, we also present the raw results without the proposed prediction normalization strategy (with the suffix "-R"). All results are the average F1 scores across 5 runs with different random seeds.

It is noticeable that our proposed methods, based on either annotation-style or extraction-style modeling, establish new state-of-the-art results in almost all cases. The only exception is on the `Rest15` dataset for the AOPE task, our method is still on par with the previous best performance. It shows that tackling various ABSA tasks with the proposed unified generative method is an effective solution. Moreover, we can see that our method performs especially well on the ASTE and TASD tasks, the proposed extraction-style method outperforms the previous best models by 7.6 and 3.7 average F1 scores (across different datasets) on them respectively. It implies that incorporating the label semantics and appropriately modeling the interactions among those sentiment elements are essential for tackling complex ABSA problems.

	BEFORE	AFTER	LABEL

Table 5: Example cases of the predictions before and after the prediction normalization.

3.3 Discussions

Annotation-style & Extraction-style As shown in result tables, the annotation-style method generally performs better than the extraction-style method on the AOPE and UASA task. However, the former one becomes inferior to the latter on the more complex ASTE and TASD tasks. One possible reason is that, on the ASTE and TASD tasks, the annotation-style method introduces too much content, such as the aspect category and sentiment polarity, into the target sentence, which increases the difficulty of sequence-to-sequence learning.

Why Prediction Normalization Works To better understand the effectiveness of the proposed prediction normalization strategy, we randomly sample some instances from the ASTE task that have different raw prediction and normalized prediction (*i.e.*, corrected by our strategy). The predicted sentiment elements before and after the normalization, as well as the gold label of some example cases are shown in Table 5. We find that the normalization mainly helps on two occasions: The first one is the morphology shift where two words have minor lexical differences. For example, the method fixes "*Bbq rib*" to "*BBQ rib*" (#1) and "*repeat*" to "*repeats*" (#2). Another case is orthographic alternatives where the model might generate words with the same etyma but different word types, *e.g.*, it outputs "*vegetarian*" rather than "*vegan*" (#6). Our proposed prediction normalization, which finds the replacement from the corresponding vocabulary set via Levenshtein distance, is a simple yet effective strategy to alleviate this issue.

We also observe that our prediction strategy may fail if the raw predictions are quite lexically different or even semantically different from the gold-standard labels (see Case #4, #7 and #8). In these cases, the difficulty does not come from the way of performing prediction normalization but the generation of labels close to the ground truths, especially for the examples containing implicit aspects or opinions (Case #4).

4 Conclusions and Future Work

We tackle various ABSA tasks in a novel generative framework in this paper. By formulating the target sentences with our proposed annotation-style and extraction-style paradigms, we solve multiple sentiment pair or triplet extraction tasks with a unified generation model. Extensive experiments on multiple benchmarks across four ABSA tasks show the effectiveness of our proposed method.

Our work is an initial attempt on transforming ABSA tasks, which are typically treated as classification problems, into text generation problems. Experimental results indicate that such transformation is an effective solution to tackle various ABSA tasks. Following this direction, designing more effective generation paradigms and extending such ideas to other tasks can be interesting research problems for future work.

Abstract

Recently, token-level adaptive training has achieved promising improvement in machine translation, where the cross-entropy loss function is adjusted by assigning different training weights to different tokens, in order to alleviate the token imbalance problem. However, previous approaches only use static word frequency information in the target language without considering the source language, which is insufficient for bilingual tasks like machine translation. In this paper, we propose a novel bilingual mutual information (BMI) based adaptive objective, which measures the learning difficulty for each target token from the perspective of bilingualism, and assigns an adaptive weight accordingly to improve token-level adaptive training. This method assigns larger training weights to tokens with higher BMI, so that easy tokens are updated with coarse granularity while difficult tokens are updated with fine granularity. Experimental results on WMT14 English-to-German and WMT19 Chinese-to-English demonstrate the superiority of our approach compared with the Transformer baseline and previous token-level adaptive training approaches. Further analyses confirm that our method can improve the lexical diversity.

1 Introduction

Neural machine translation (NMT) (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017; Chen et al., 2018; Meng and Zhang, 2019; Zhang et al., 2019; Yan et al., 2020; Liu et al., 2021) has achieved remarkable success. As a data-driven model, the performance of NMT depends on training corpus. Balanced training data is a crucial factor in building a superior model. However, natural languages conform to the Zipf's law (Zipf, 1949), the frequencies of words exhibit the long tail characteristics, which brings an imbalance in the distribution of words in training corpora. Some studies (Jiang et al., 2019; Gu et al., 2020) assign different training weights to target tokens according to their frequencies. These approaches alleviate the token imbalance problem and indicate that tokens should be treated differently during training.

However, there are two issues in existing approaches. First, these approaches believe that low-frequency words are not sufficiently trained and thus amplify the weight of them. Nevertheless, low-frequency tokens are not always difficult as the model competence increases (Wan et al., 2020). Second, previous studies only use monolingual word frequency information in the target language without considering the source language, which is insufficient for bilingual tasks, e.g., machine translation. The mapping between bilingualism is a more appropriate indicator. As shown in Table 1, word frequency of *pleasing* and *bearings* are both 847. Corresponding to Chinese, *pleasing* has multiple mappings, while *bearings* is relatively single. The more multivariate the mapping is, the less confidence in predicting the target word given the source context. He et al. (2019) also confirm this view that words with multiple mappings contribute more to the BLEU score.

To tackle the above issues, we propose bilingual mutual information (BMI), which has two characteristics: 1) BMI measures the learning difficulty for each target token by considering the strength of association between it and the source sentence; 2) for each target token, BMI can dynamically adjust according to the context. BMI-based adaptive training can dynamically adjust the learning granularity on tokens. Easy tokens are updated with coarse granularity while difficult tokens are updated with

pleasing (847)	gāoxìng (81); yúkuài (74); xǐyuè (63); qǔyuè (49) ...
bearings (847)	zhóuchéng (671) ...

Table 1: An example from the WMT19 Chinese-English training set. The Chinese words are presented in pinyin style and the word frequency is shown in brackets. The two words have the same word frequency, while the mapping of *bearings* is more stable than that of *pleasing*.

fine granularity.

We evaluate our approach on both WMT14 English-to-German and WMT19 Chinese-to-English translation tasks. Experimental results on two benchmarks demonstrate the superiority of our approach compared with the Transformer baseline and previous token-level adaptive training approaches. Further analyses confirm that our method can improve the lexical diversity. The main contributions[1] of this paper can be summarized as follows:

- We propose a training objective based on bilingual mutual information (BMI), which can reflects the learning difficulty for each target token from the perspective of bilingualism, and assigns an adaptive weight accordingly to guide the adaptive training of machine translation.
- Experimental results show that our method can improve not only the machine translation quality, but also the lexical diversity.

2 Background

2.1 Neural Machine Translation

A NMT system is a neural network that translates a source sentence $\mathbf{x}$ with n words to a target sentence $\mathbf{y}$ with m words. During the training process, NMT models are optimized by minimizing cross entropy:

$$\mathcal{L} = -\frac{1}{m}\sum_{j=1}^{m} \log p(y_j|\mathbf{y}_{<j}, \mathbf{x}), \quad (1)$$

where y_j is the ground-truth token at the j-th position and $\mathbf{y}_{<j}$ is the translation history known before predicting token y_j.

[1]Reproducible code: https://github.com/xydaytoy/BMI-NMT

BMI= 2.29	In ball **bearings**, as the radial clearance increases , the axial clearance increases as well. zài qiú **zhóu chéng**, jìng xiàng jiàn xì de zēng jiā, zhóu xiàng yóu xì zēng zhǎng.
BMI= 1.83	One of his crowd **pleasing** notions is that migrants will infect Americans with terrible diseases. tā **qǔ yuè** qún méng de gài niàn zhī yī shì yí mín huì jǐ měi guó rén dài lái kě pà de chuán rǎn bìng.

Figure 1: An example from WMT19 Chinese-to-English training set. Words with Red and Bold fonts have the same word frequency while different BMI.

2.2 Token-level Adaptive Training Objective

Following (Gu et al., 2020), the token-level adaptive training objective is

$$\mathcal{L} = -\frac{1}{m}\sum_{j=1}^{m} w_j \cdot \log p(y_j|\mathbf{y}_{<j}, \mathbf{x}), \quad (2)$$

where w_j is the weight assigned to the target token y_j . Gu et al. (2020) used monolingual word frequency information in the target language to calculate the w_j. The weight does not contain the information of the source language, and cannot be dynamically adjusted with the context.

3 BMI-based Adaptive Training

In this section, we start with the definition of the bilingual mutual information (BMI). Then we analyze the relationship between BMI and translation difficulty. Based on this, we introduce our BMI-based token-level adaptive training objective.

3.1 Definition of BMI

Mutual information measures the strength of association between two random variables by comparing the number of their individual and joint occurrences. We develop BMI, which is calculated by summarizing the mutual information of the target token and each token in the source sentence, to measure the learning difficulty of the model. Token pairs with high BMI are considered easy, since they have high co-occurrence relative to the frequency. Given the source sentence $\mathbf{x}$ and target token y_j, we define the bilingual mutual information as[2]:

$$\mathrm{BMI}(\mathbf{x}, y_j) = \sum_{i=1}^{n} \log \frac{f(x_i, y_j)}{f(x_i) \cdot f(y_j)/K}, \quad (3)$$

[2]To ensure comparability of two probability distribution, the tokens that appear multiple times in a sentence and the token pairs that appear multiple times in a sentence pair are not counted repeatedly.

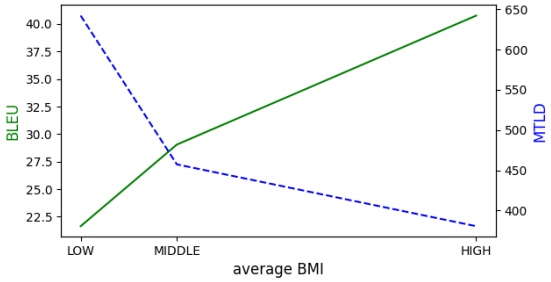

Figure 2: The BLEU (green solid line) and MTLD (blue dotted line) values on the subsets of WMT14 English-German training set, divided according to the average BMI. All target sentences of the training set are divided into three subsets according to the average BMI of the tokens in the sentence, which are equal in size and denoted as LOW, MIDDLE, and HIGH, respectively. BLEU indicates the learning difficulty of the model. The measure of textual lexical diversity (MTLD) (McCarthy and Jarvis, 2010) represents the lexical diversity of the data set. The results show that high BMI means relatively stable mapping, which is easy to be learned by the model and has low lexical diversity.

where $f(x_i)$ and $f(y_j)$ are total number of sentences in the corpus containing at least one occurrence of x_i and y_j, respectively, $f(x_i, y_j)$ represents total number of sentences in the corpus having at least one occurrence of the word pair (x_i, y_j), and K denotes total number of sentences in the corpus.

3.2 What BMI Measures?

We use an example to illustrate our idea. Figure 1 shows two sentence pairs. Words with Red and Bold fonts have the same word frequency. As shown in Table 1, *pleasing* has multiple mappings, while the mapping of *bearings* is relatively single. As a result, the appearance of corresponding English word brings different confidence of the appearance of the Chinese word, which can be reflected by BMI. Further statistical results are shown in Figure 2, high BMI means relatively stable mapping, which is easy to be learned by the model and has low lexical diversity.

3.3 BMI-based Objective

We calculate the token-level weight by scaling BMI and adjusting the lower limit as follows:

$$w_j = S \cdot \mathrm{BMI}(\mathbf{x}, y_j) + B. \quad (4)$$

The two hyperparameters S (scale) and B (base) influence the magnitude of change and the lower limit, respectively.

In training process, the loss of simple tokens will be amplified, the model updates simple tokens with coarse granularity, because our strategy thinks the model can easily predict these target tokens given the source sentence, and it needs to increase the penalty if the prediction is wrong. For difficult tokens, the model has a higher tolerance because their translation errors may not be absolute. As a result, the loss is small due to the small weight and the difficult tokens are always updated in a fine-grained way.

4 Experiments

We evaluate our method on the Transformer (Vaswani et al., 2017) and conduct experiments on two widely-studied NMT tasks, WMT14 English-to-German (En-De) and WMT19 Chinese-to-English (Zh-En).

4.1 Data Preparation

EN-DE. The training data consists of 4.5M sentence pairs from WMT14. Each word in the corpus has been segmented into subword units using byte pair encoding (BPE) (Sennrich et al., 2016) with 32k merge operations. The vocabulary is shared among source and target languages. We select newstest2013 for validation and report the BLEU scores on newstest2014.

ZH-EN. The training data is from WMT19 which consists of 20.5M sentence pairs. The number of merge operations in byte pair encoding (BPE) is set to 32K for both source and target languages. We use newstest2018 as our validation set and newstest2019 as our test set, which contain 4k and 2k sentences, respectively.

4.2 Systems

Transformer. We implement our approach with the open source toolkit THUMT (Zhang et al., 2017) and strictly follow the setting of Transformer-Base in (Vaswani et al., 2017).

Exponential (Gu et al., 2020). This method adds an additional training weights to low-frequency target tokens:

$$w_j = A \cdot e^{-T \cdot Count(y_j)} + 1. \quad (5)$$

Chi-Square (Gu et al., 2020). The weighting function of this method is similar to the form of chi-square distribution

$$w_j = A \cdot Count^2(y_j) e^{-T \cdot Count(y_j)} + 1. \quad (6)$$

	B	S	EN-DE	ZH-EN

		0.10	26.89	**23.61**
		0.15	26.93	23.49
		0.20	26.98	23.39
		0.25	26.91	23.24
		0.30	26.85	23.50
	0.9	0.15	26.93	23.31
		0.20	26.88	23.31
		0.25	26.96	23.41
	0.8	0.15	**27.01**	23.40
		0.20	26.81	23.25
		0.25	26.93	23.50
	0.7	0.15	26.92	23.44
		0.20	26.90	23.35
		0.25	26.89	23.34

Table 2: Performance of our methods on the validation sets with different hyperparameters S and B.

BMI. Our system is first trained with normal cross entropy loss (Equation 1) for 100k steps. Then the model is further trained with BMI-based adaptive objective (Equation 4) for 100k steps. The same procedure was used for the competing methods. In order to eliminate the influence of noise, we assign the weight of tokens with BMI lower than 0.4 to zero during the training process.

4.3 Hyperparameters

We introduce two hyperparameters, B and S, to adjust the weight distribution based on BMI, as shown in Equation 4. In our experiments, we fixed B to narrow search space [0.7, 1]. We tuned another hyperparameter S on the validation sets. The results are shown in Table 2. Finally, we use the best hyperparameters found on the validation set for the final evaluation of the test set. For En-De, B = 0.8 and S = 0.15, for Zh-En, B = 1.0 and S = 0.1.

4.4 Main Results

As shown in Table 3, compared with (Vaswani et al., 2017), our Transformer outperforms it by 0.67 BLEU points. We use a strong baseline system in this work in order to make the evaluation convincing. Improvement of existing methods (Gu et al., 2020) is limited over strong baseline. Exponential objective achieves 28.17 (+0.2) BLEU on En-De and Chi-Square objective achieves 24.62 (+0.25) BLEU on Zh-En. Our method yields 28.53 (+0.56) and 25.19 (+0.82) BLEU on the En-De task and Zh-En task, respectively. The significant and consistent improvement on the two large-scale dataset demonstrates the effectiveness of our method.

System	EN-DE	ZH-EN

+ BMI	**28.53(+*0.56*)***	**25.19(+*0.82*)***

Table 3: BLEU scores (%) on the WMT14 En-De test set and the WMT19 Zh-En test set. Results of our method marked with '*' are statistically significant (Koehn, 2004) by contrast to all other models ($p<0.01$).

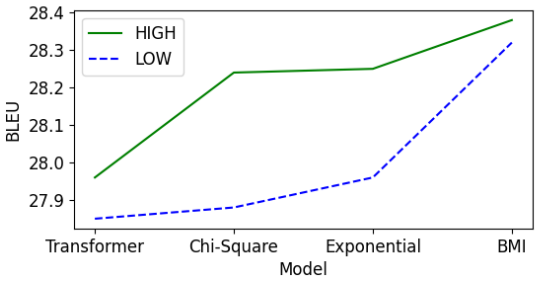

Figure 3: BLEU scores (%) on different WMT14 En-De test subsets which are grouped by their average BMI. Sentences in the HIGH subset contains more tokens with high BMI.

4.5 Results on Different BMI Intervals

We score each target sentence of newstest2014 by calculating the average BMI of each token in the sentence, and then divide newstest2014 into two subsets with equal size according to the score, denoted as HIGH and LOW, respectively. As shown in Figure 3, compared to Transformer, frequency-based methods outperform on the HIGH subset but have no obvious improvement on the LOW subset. By contrast, our method can not only bring a stable improvement on the HIGH subset, the improvement is even more obvious on the LOW subset. Low BMI means relatively rich mapping. We believe that the model should have a higher tolerance for these tokens because their translation errors may not be absolute. For example, the model outputs another token with similar meaning. Therefore, our method improves more on LOW subset.

Models	MATTR	HD-D	MTLD
Transformer	89.41	94.05	230.36
+ Chi-Square	89.37	94.02	230.02
+ Exponential	89.41	94.08	232.98
+ BMI	**89.45**	**94.10**	**236.43**
Reference	90.92	94.88	259.98

Table 4: The lexical diversity of WMT14 En-De translations measured by MATTR (%), HD-D (%) and MTLD. A larger value means a higher diversity.

4.6 Effects on Lexical Diversity

Vanmassenhove et al. (2019) suggest that the vanilla NMT systems exacerbate bias presented in corpus, resulting in lower vocabulary diversity. We use three measures of lexical diversity, namely, moving-average type-token ratio (MATTR) (Covington and McFall, 2010), the approximation of hypergeometric distribution (HD-D) and the measure of textual lexical diversity (MTLD) (McCarthy and Jarvis, 2010). Results in Table 4 show that, on improving the lexical diversity of translation, our method is superior to existing methods (Chi-Square and Exponential) based on word frequency.

4.7 Contrast with Label Smoothing

There are similarities between token-level adaptive training and label smoothing, because they both adjust the loss function of the model by token weighting. In particular, for some smoothing methods guided by prior or posterior knowledge of training data (Gao et al., 2020; Pereyra et al., 2017), different tokens are treated differently. But these similarities are not the key points of the two methods, and they are essentially different. The first and very important point is that the motivations of the two methods are different. Label smoothing is a regularization method to avoid overfitting, while our method treats samples of different difficulty differently for adaptive training. Second, the two methods work in different ways. Label smoothing is used when calculating the cross-entropy loss. It emphasizes how to assign the weight of tokens other than the golden one, and indirectly affects the training of the golden token. While our method is used after calculating the cross-entropy loss. It is calculated according to the golden token at each position in the reference, which is more direct. In all experiments, we employed uniform label smoothing of value $\epsilon_{ls} = 0.1$, the results show that the two methods does not conflict when used together.

5 Conclusion

We propose a novel bilingual mutual information based adaptive training objective, which can measure the learning difficulty for each target token from the perspective of bilingualism, and adjust the learning granularity dynamically to improve token-level adaptive training. Experimental results on two translation tasks show that our method can bring a significant improvement in translation quality, especially on sentences that are difficult to learn by the model. Further analyses confirm that our method can also improve the lexical diversity.

Abstract

This ability to learn consecutive tasks without forgetting how to perform previously trained problems is essential for developing an online dialogue system. This paper proposes an effective continual learning for the task-oriented dialogue system with iterative network pruning, expanding and masking (TPEM), which preserves performance on previously encountered tasks while accelerating learning progress on subsequent tasks. Specifically, TPEM (i) leverages network pruning to keep the knowledge for old tasks, (ii) adopts network expanding to create free weights for new tasks, and (iii) introduces task-specific network masking to alleviate the negative impact of fixed weights of old tasks on new tasks. We conduct extensive experiments on seven different tasks from three benchmark datasets and show empirically that TPEM leads to significantly improved results over the strong competitors. For reproducibility, we submit the code and data at: https://github.com/siat-nlp/TPEM.

1 Introduction

Building a human-like task-oriented dialogue system is a long-term goal of AI. Great endeavors have been made in designing end-to-end task-oriented dialogue systems (TDSs) with sequence-to-sequence (Seq2Seq) models (Eric and Manning, 2017; Madotto et al., 2018; Gangi Reddy et al., 2019; Qin et al., 2020; Mi et al., 2019; He et al., 2020; Wang et al., 2020; Qin et al., 2021), which have taken the state-of-the-art of TDSs to a new level. Generally, Seq2Seq models leverage an encoder to create a vector representation of dialogue history and KB information, and then pass this representation into a decoder so as to output a response word by word. For example, GLMP (Wu et al., 2019) is a representative end-to-end TDS, which incorporates KB information into Seq2Seq model by using a global memory pointer to filter irrelevant KB knowledge and a local memory pointer to instantiate entity slots.

Despite the remarkable progress of previous works, the current dominant paradigm for TDS is to learn a Seq2Seq model on a given dataset specifically for a particular purpose, which is referred to as isolated learning. Such learning paradigm is theoretically of limited success in accumulating the knowledge it has learned before. When a stream of domains or functionalities are joined to be trained sequentially, isolated learning faces catastrophic forgetting (McCloskey and Cohen, 1989; Yuan et al., 2020, 2021). In contrast, humans retain and accumulate knowledge throughout their lives so that they become more efficient and versatile facing new tasks in future learning (Thrun, 1998). If one desires to create a human-like dialogue system, imitating such a lifelong learning skill is quite necessary.

This paper is motivated by the fact that a cognitive AI has continual learning ability by nature to develop a task-oriented dialogue agent that can accumulate knowledge learned in the past and use it seamlessly in new domains or functionalities. Continual learning (Parisi et al., 2019; Wu et al., 2018; Yuan et al., 2020, 2021) is hardly a new idea for machine learning, but remains as a non-trivial step for building empirically successful AI systems. It is essentially the case for creating a high-quality TDS. On the one hand, a dialogue system is expected to reuse previously acquired knowledge, but focusing too much on stability may hinder a TDS from quickly adapting to a new task. On the other hand, when a TDS pays too much attention to plasticity, it may quickly forget previously-acquired abilities (Mallya and Lazebnik, 2018).

In this paper, we propose a continual learning

method for task-oriented dialogue system with iterative network pruning, expanding and masking (TPEM), which preserves performance on previously encountered tasks while accelerating learning progress on the future tasks. Concretely, TPEM adopts the global-to-local memory pointer networks (GLMP) (Wu et al., 2019) as the base model due to its powerful performance in literature and easiness for implementation. We leverage iterative pruning to keep old tasks weights and thereby avoid forgetting. Meanwhile, a network expanding strategy is devised to gradually create free weights for new tasks. Finally, we introduce a task-specific binary matrix to mask some old task weights that may hinder the learning of new tasks. It is noteworthy that TPEM is model-agnostic since the pruning, expanding and binary masking mechanisms merely work on weight parameters (weight matrices) of GLMP.

We conduct extensive experiments on seven different domains from three benchmark TDS datasets. Experimental results demonstrate that our TPEM method significantly outperforms strong baselines for task-oriented dialogue generation in continual learning scenario.

2 Our Methodology

2.1 Task Definition

Given the dialogue history X and KB tuples B, TDS aims to generate the next system response Y word by word. Suppose a lifelong TDS model that can handle domains 1 to k has been built, denoted as $\mathcal{M}_{1:k}$. The goal of TDS in continual learning scenario is to train a model $\mathcal{M}_{1:k+1}$ that can generate responses of the $k+1$-th domain without forgetting how to generate responses of previous k domains. We use the terms "domain" and "task" interchangeably, because each of our tasks is from a different dialogue domain.

2.2 Overview

In this paper, we adopt the global-to-local memory pointer networks (GLMP) (Wu et al., 2019) as base model, which has shown powerful performance in TDS. We propose a continual learning method for TDS with iterative pruning, expanding, and masking. In particular, we leverage pruning to keep the knowledge for old tasks. Then, we adopt network expanding to create free weights for new tasks. Finally, a task-specific binary mask is adopted to mask part of old task weights, which may hinder the learning of new tasks. The proposed model is model-agnostic since the pruning, expanding and binary masking mechanisms merely work on weight parameters (weight matrices) of the encoder-decoder framework. Next, we will introduce each component of our TPEM framework in detail.

2.3 Preliminary: The GLMP Model

GLMP contains three primary components: external knowledge, a global memory encoder, and a local memory decoder. Next, we will briefly introduce the three components of GLMP. The readers can refer to (Wu et al., 2019) for the implementation details.

External Knowledge To integrate external knowledge into the Seq2Seq model, GLMP adopts the end-to-end memory networks to encode the word-level information for both dialogue history (dialogue memory) and structural knowledge base (KB memory). Bag-of-word representations are utilized as the memory embeddings for two memory modules. Each object word is copied directly when a memory position is pointed to.

Global Memory Encoder We convert each input token of dialogue history into a fixed-size vector via an embedding layer. The embedding vectors go through a bi-directional recurrent unit (BiGRU) (Chung et al., 2014) to learn contextualized dialogue representations. The original memory representations and the corresponding implicit representations will be summed up, so that these contextualized representations can be written into the dialogue memory. Meanwhile, the last hidden state of dialogue representations is used to generate two outputs (i.e., global memory pointer and memory readout) by reading out from the external knowledge. Note that an auxiliary multi-label classification task is added to train the global memory pointer as a multi-label classification task.

Local Memory Decoder Taking the global memory pointer, encoded dialogue history and KB knowledge as input, a sketch GRU is applied to generate a sketch response Y^s that includes the sketch tags rather than slot values. If a sketch tag is generated, the global memory pointer is then passed to the external knowledge and the retrieved object word will be picked up by the local memory pointer; otherwise, the output word is generated by the sketch GRU directly.

To effectively transfer knowledge for subsequent tasks and reduce the space consumption, the global memory encoder and external knowledge in GLMP are shared among all tasks, while a separate local memory decoder is learned by each task.

2.4 Continual Learning for TDS

We employ an iterative network pruning, expanding and masking framework for TDS in continual learning scenario, inspired by (Mallya and Lazebnik, 2018; Mallya et al., 2018).

Network Pruning To avoid "catastrophic forgetting" of GLMP, a feasible way is to retain the acquired old-task weights and enlarge the network by adding weights for learning new tasks. However, as the number of tasks grows, the complexity of model architecture increases rapidly, making the deep model difficult to train. To avoid constructing a huge network, we compress the model for the current task by releasing a certain fraction of neglectable weights of old tasks (Frankle and Carbin, 2019; Geng et al., 2021).

Suppose that for task k, a compact model $\mathcal{M}_{1:k}$ that is able to deal with tasks 1 to k has been created and available. We then free up a certain fraction of neglectable weights (denoted as $\mathbf{W}_k^F$) that have the lowest absolute weight values by setting them to zero. The released weights associated with task k are extra weights which can be utilized repeatedly for learning newly coming tasks. However, pruning a network suddenly changes the network connectivity and thereby leads to performance deterioration. To regain its original performance after pruning, we re-train the preserved weights for a small number of epochs. After a period of pruning and re-training, we obtain a sparse network with minimal performance loss on the performance of task k. This network pruning and re-training procedures are performed iteratively for learning multiple subsequent tasks. When inferring task k, the released weights are masked in a binary on/off fashion such that the network state keeps consistent with the one learned during training.

Network Expanding The amount of preserved weights for old tasks becomes larger with the growth of new tasks, and there will be fewer free weights for learning new tasks, resulting in slowing down the learning process and making the found solution non-optimal. An intuitive solution is to expand the model while learning new tasks so as to increase new capacity of the GLMP model for subsequent tasks (Hung et al., 2019b,a).

To effectively perform network expansion while keeping the compactness of network architecture, we should consider two key factors: (1) the proportion of free weights for new tasks (denoted as F_k) and (2) the number of training batches (denoted as N_k). Intuitively, it is difficult to optimize the parameters that are newly added and randomly initialized with a small number of training data. To this end, we define the following strategy to expand the hidden size H_k for the k-th task from H_{k-1}:

$$H_k = H_{k-1} + \alpha * (P_{k-1} - F_k) * \log(1 + N_k/\beta) \quad (1)$$

where α and β are two hyperparameters. P_{k-1} is the pruning ratio of task $k-1$. In this way, we are prone to expand more weights for the tasks that have less free weights but more training data.

Network Masking The preserved weights $\mathbf{W}_k^P$ of old tasks are fixed so as to retain the performance of learned tasks and avoid forgetting. However, not all preserved weights are beneficial to learn new tasks, especially when there is a large gap between old and new tasks. To resolve this issue, we apply a learnable binary mask $\mathbf{M}^k$ for each task k to filter some old weights that may hinder the learning of new tasks. We additionally maintain a matrix $\tilde{\mathbf{M}}^k$ of real-valued mask weights, which has the same size as the weight matrix $\mathbf{W}$. The binary mask matrix $\mathbf{M}^k$, which participates in forward computing, is obtained by passing each element of $\tilde{\mathbf{M}}^k$ through a binary thresholding function:

$$\mathbf{M}_{ij}^k = \begin{cases} 1, & \text{if } \tilde{\mathbf{M}}_{ij}^k > \tau \\ 0, & \text{ortherwise} \end{cases} \quad (2)$$

where τ is a pre-defined threshold. The real-valued mask $\tilde{\mathbf{M}}^k$ will be updated in the backward pass via gradient descent. After obtaining the binary mask $\mathbf{M}^k$ for a given task, we discard $\tilde{\mathbf{M}}^k$ and only store $\mathbf{M}^k$. The weights selected are then represented as $\mathbf{M}^k \odot \mathbf{W}_k^P$, which get along with free weights $\mathbf{W}_k^F$ to learn new tasks. Here, $\odot$ denotes element-wise product. Note that old weights $\mathbf{W}_k^P$ are "picked" only and keep unchanged during training. Thus, old tasks can be recalled without forgetting. Since a binary mask requires only one extra bit per parameter, TPEM only introduces an approximate overhead of 1/32 of the backbone network size per parameter, given that a typical network parameter is often represented by a 32-bit float value.

Table 1: BLEU/Entity F1 results evaluated on the final model after all 7 tasks are visited. We use Avg. to represent the average performance of all tasks for each method.

3 Experimental Setup

Datasets Since there is no authoritative dataset for TDS in continual learning scenario, we evaluate TPEM on 7 tasks from three benchmark TDS datasets: (1) In-Car Assistant (Eric and Manning, 2017) that contains 2425/302/304 dialogues for training/validation/testing, belonging to calendar scheduling, weather query, and POI navigation domains, (2) Multi-WOZ 2.1 (Budzianowski et al., 2018) that contains 1,839/117/141 dialogues for training/validation/testing, belonging to restaurant, attraction, and hotel domains, and (3) CamRest (Wen et al., 2016) that contains 406/135/135 dialogues from the restaurant reservation domain for training/validation/testing.

Implementation Details Following (Wu et al., 2019), the word embeddings are randomly initialized from normal distribution $\mathcal{N}(0, 0.1)$ with size of 128. We set the size of encoder and decoder as 128. We conduct one-shot pruning with ratio $P = 0.5$. The hyperparameters α and β are set to 32 and 50, respectively. We use Adam optimizer to train the model, with an initial learning rate of $1e^{-3}$. The batch size is set to 32 and the number of memory hop k is set to 3. We set the maximum re-training epochs to 5. That is, we adopt the same re-training epochs for different tasks. We run our model three times and report the average results.

Baseline Methods First, we compare TPEM with three widely used TDSs: **Ptr-Unk** (Eric and Manning, 2017), **Mem2Seq** (Madotto et al., 2018), and **GLMP** (Wu et al., 2019). In addition, we also compare TPEM with **UCL** (Ahn et al., 2019) which is a popular continual learning method. Furthermore, we report results obtained by the base model when its parameters are optionally re-initialized after a task has been visited (denoted as **Re-init**). We also report the results of Re-init with network expansion (denoted as **Re-init-expand**). Different from GLMP that keeps learning a TDS by utilizing parameters learned from past tasks as initialization for the new task, both Re-init and Re-init-expand save a separate model for each task in inference without considering the continual learning scenario.

4 Experimental Results

Main Results We evaluate TPEM and baselines with BLEU (Papineni et al., 2002) and entity F1 (Madotto et al., 2018). We conduct experiments by following the common continual learning setting, where experimental data from 7 domains arrives sequentially. The results of each task are reported after all 7 tasks have been learned. That is, each model keeps learning a new task by using the weights learned from past tasks as initialization. The evaluation results are reported in Table 1. The typical TDSs (i.e., Ptr-Unk, Mem2Seq, GLMP) perform much worse than the continual learning methods (UCL and TPEM). This is consistent with our claim that conventional TDSs suffer from catastrophic forgetting. TPEM achieves significantly better results than baseline methods (including Re-init and Re-init-expand) on both new and old tasks. The improvement mainly comes from the iterative network pruning, expanding and masking.

Ablation Study To investigate the effectiveness of each component in TPEM, we conduct ablation test in terms of removing network pruning (w/o Pruning), network expansion (w/o Expansion), and network masking (w/o Masking). The experimental results are reported in Table 1. The performance

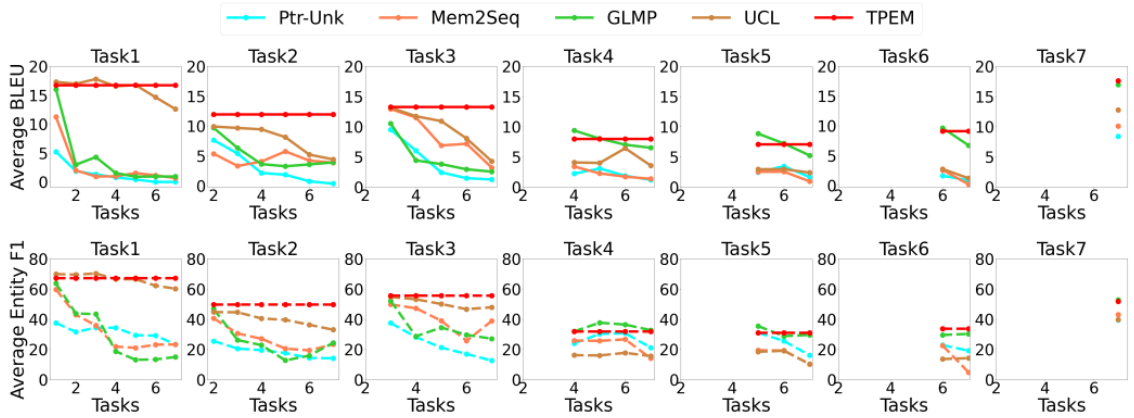

Figure 1: The change of BLEU/Entity F1 scores for each task during the whole learning process (i.e., after learning new tasks).

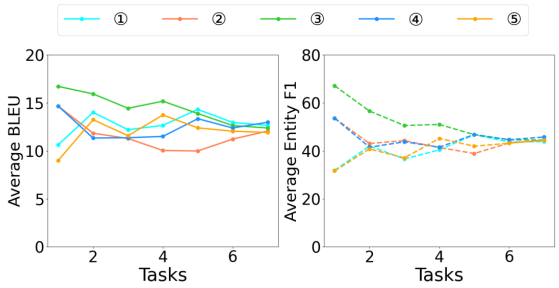

Figure 2: The average results of TPEM over 7 domains with 5 different orderings randomly sampled from the 7 domains.

of TPEM drops more sharply when discarding network pruning than discarding the other two components. This is within our expectation since the expansion and masking strategies rely on network pruning, to some extent. Not surprisingly, combining all the components achieves the best results. Furthermore, by comparing the results of Re-init and Re-init-expand, we can observe that only using network expanding cannot improve the performance of Re-init.

Case Study We provide visible analysis on the middle states of all the models. Figure 1 shows how the results of each task change as new tasks are being learned subsequently. Taking the third task as an example, we observe that the performance of conventional TDSs and UCL starts to decay sharply after learning new tasks, probably because the knowledge learned from these new tasks interferes with what was learned previously. However, TPEM achieves stable results over the whole learning process, without suffering from knowledge forgetting.

Effect of Task Ordering To explore the effect of task ordering for our TPEM model, we randomly sample 5 different task orderings in this experiment. The average results of TPEM over 7 domains with 5 different orderings are shown in Figure 2. We can observe that although our method has various behaviors with different task orderings, TPEM is in general insensitive to orders because the results show similar trends, especially for the last 2 tasks.

5 Conclusion

In this paper, we propose a continual learning method for task-oriented dialogue systems with iterative network pruning, expanding and masking. Our dialogue system preserves performance on previously encountered tasks while accelerating learning progress on subsequent tasks. Extensive experiments on 7 different tasks show that our TPEM method performs significantly better than compared methods. In the future, we plan to automatically choose the pruning ratio and the number of re-training epochs in the network pruning process for each task adaptively.

Abstract

We present **TIMERS** - a **TIME**, **R**hetorical and **S**yntactic-aware model for document-level temporal relation classification. Our proposed method leverages rhetorical discourse features and temporal arguments from semantic role labels, in addition to traditional local syntactic features, trained through a Gated Relational-GCN. Extensive experiments show that the proposed model outperforms previous methods by 5-18% on the TDDiscourse, TimeBank-Dense, and MATRES datasets due to our discourse-level modeling.

1 Introduction

Temporal relation extraction (TempRel) is a challenging task that involves determining the temporal order between two events in a text (Pustejovsky et al., 2003). Understanding the temporal ordering of events in a document plays a key role in downstream tasks such as timeline creation (Leeuwenberg and Moens, 2018), time-aware summarization (Noh et al., 2020), temporal question-answering (Ning et al., 2020), and temporal information extraction (Leeuwenberg and Moens, 2019).

Prior work focuses on extracting temporal relations between event pairs (a.k.a., *TLINKS*) present in the same sentence (*Intra-sentence TLINKS*) or adjacent sentences (*Inter-sentence TLINKS*), mostly ignoring document-level pairs (*Cross-document TLINKS*) (Reimers et al., 2016). Past works have used RNN (Cheng and Miyao, 2017; Meng et al., 2017; Goyal and Durrett, 2019; Ning et al., 2019; Han et al., 2019a,c,b, 2020b) and Transformer networks (Ballesteros et al., 2020; Zhao et al., 2020b) for encoding a few sentences or a short paragraph but do not capture long-range dependencies and multi-hop reasoning at the document-level. This shortcoming is shown in the TDDiscourse dataset (Naik et al., 2019), which was designed to highlight global discourse-level challenges, e.g., multi-hop chain reasoning, future or hypothetical events, and reasoning requiring world knowledge.

We propose **TIMERS** - a **TIME**, **R**hetorical, and **S**yntactic-aware model for document-level temporal relation extraction. TIMERS uses discourse features in the form of connections from Rhetorical Structure Theory (RST) parsers (Bhatia et al., 2015) to leverage long-range inter-sentential relationships. It also extends existing contextual embeddings with structural and syntactic dependency parse connections. Lastly, it uses timex-timex relations, *dct* (document creation date)-timex relations, and temporal arguments obtained via sentence-level semantic role labeling. These rhetorical, syntactic, and temporal features are learned through a modified version of Relational Graph Convolutional Networks (R-GCN) with a gating mechanism (GR-GCN) (Schlichtkrull et al., 2018), which learns highly relational data relationships in densely-connected graph networks.

Our **main contribution** is a document-level model that incorporates these three features to improve temporal relationship extraction. We obtain state-of-the-art performance across three datasets with **5-18% relative improvement**, showing improvement for events that require chain reasoning, causal prerequisite links, and future events.

2 Methodology

Let document D be defined as a sequence of n tokens $w_i \in W = \{w_1, \cdots, w_n\}$. The entire document is a list of m sentences $V = [v_1, \cdots, v_m]$. Each document has a set of p events $E = \{e_1, \cdots, e_p\}$ and q timexes $T = \{t_1, \cdots, t_q\}$, where $p, q \leq n$. The creation date of the document is represented by timestamp t_{DCT}. We denote the source and target events by e_s and e_t, respec-

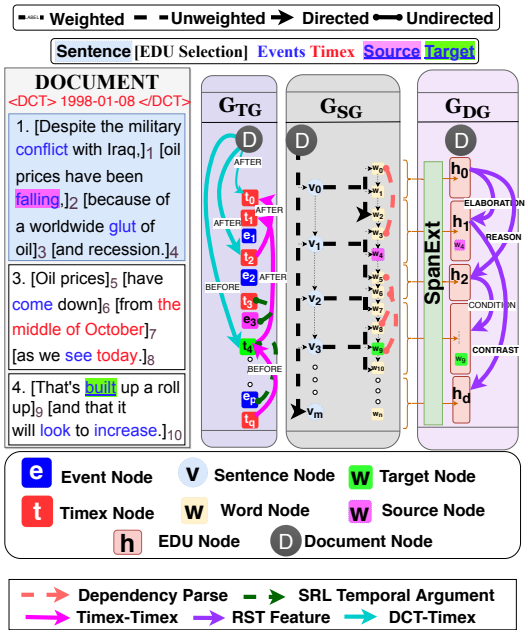

Figure 1: Three graphs are created from the input document. Time-aware Graph (G_{TG}): DCT-Timex associations, Timex-Timex associations, and Temporal Argument connections from semantic role labels; Syntactic-aware Graph (G_{SG}): structural and syntactic connections; and Rhetoric-aware Graph (G_{DG}): rhetorical relations between EDU's (h_i).

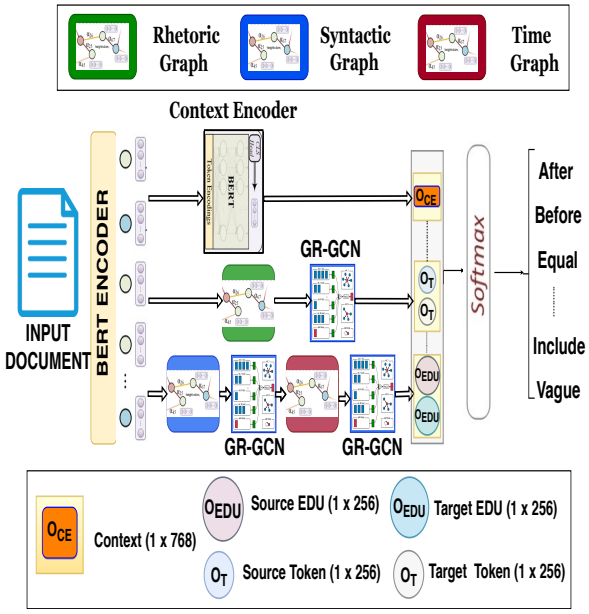

Figure 2: TIMERS learns rhetorical, syntactic, and temporal features through a Gated Relational-Graph Convolutional Networks (GR-GCN). The output of G_{SG} forms the input of G_{TG}. The output corresponding to the source and target nodes learned by G_{TG} (O_T) and G_{DG} (O_{EDU}) are concatenated with the output of the BERT based context encoder (O_{CE}), which forms the final output h_G that passes through the Softmax layer to predict the temporal relation.

tively. The task is to identify the temporal relation $y \in R$ between the source and target event in a multi-class classification setup, where R is the set of all possible temporal links (*TLINKs*).

To solve this task, our model (Fig.1) builds the **TIMERS**-graph, which consists of a Syntactic Graph (Sec.2.1), a Time Graph (Sec. 2.2), and a Rhetorical Graph (Sec.2.3). Each graph is learned through GR-GCN to extract the embeddings used for temporal relation extraction (Fig.2, Sec.2.4).

2.1 Syntactic-Aware Graph

The syntactic graph captures the document structure and word dependency. Our syntactic-aware graph ($\mathcal{G}_{SG}$) is made of separate nodes to represent the document D, each of its inherent sentences $v_i \in V$, and all the constituent words $w_i \in W$ of each sentence. The edges of the Syntactic Graph encode five relations: **(1) Document-Sentence Affiliation** and **(2) Sentence-Word Affiliation** model the hierarchical structure of the document through a directed edge from the document node to each sentence node and from a sentence node to each word in the sentence. **(3) Sentence-Sentence Adjacency** and **(4) Word-Word Adjacency** to preserve sequential ordering for consecutive sentence and word nodes. **(5) Word-Word Dependency** encodes the syntactical nature of the word-level relationships by adding an undirected edge between two word nodes if they share a parent-child relationship in the sentence-level dependency tree.

We use BERT to encode each w_i and obtain sentence embeddings $v_i^{'}$ by averaging the second-to-last hidden layer of BERT for each token. The document vector embedding $D_i^{'}$ was calculated as the average of all sentence embedding ($D_i^{'} = \sum_{i=0}^{m} v_i^{'}$).

2.2 Time-Aware Graph

When events are anchored to a specific time, it becomes easier to infer event relationships from their associated date and time. The time-aware graph ($\mathcal{G}_{TG}$) exploits this intuition and propagates relational information among events, timexes, and the Document Creation Time (*DCT*). The document node D is the node corresponding to the document creation date while the timexes t_i and events e_i are characterized by their corresponding word nodes in the Syntactic Graph. We design three types of edge connections: **(1) *DCT*-Timex Association:** exploit the ordering of timexes with respect to the document creation time through directed weighted edges from *DCT* to timexes. **(2) Timex-Timex Association:** capture inherent non-local timeline ordering between timex pairs by a

directed weighted edge. **(3) Predicate-Temporal Argument:** anchor local temporal relations at the sentence level by connecting each event verb predicate to its temporal argument with a directed edge. The connections formed between temporal entities help navigate information from the source event to the target event while exploring interactions with other events, timexes, *dct*, and temporal arguments.

We calculate timestamps for timexes and the *DCT* from the annotated TimeML format of input documents. The weight of the *DCT*-timex and timex-timex edges is determined based on the temporal order of the entities $\{After, Before, Simultaneous, None\}$. We added *None* as a relation when one of the timestamps cannot be anchored in time.

2.3 Rhetorical-Aware Graph

We use discourse features based on Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) to leverage long-range inter-dependencies through a discourse tree. The rhetorical discourse tree of a document contains nodes of phrases, where each phrase (a.k.a, Elementary Discourse Unit or EDU) is contiguous, adjacent and non-overlapping. The interdependencies among EDUs are represented by conventional rhetorical relations (Mann, 1987), e.g. *Elaboration, Span, Condition, Attribution*. Prior work showed discourse features in the form of RST connections help leverage long-range document-level interactions between phrase units (Bhatia et al., 2015) and identify background-foreground events (Aldawsari et al., 2020).

Elementary Discourse Unit (EDU), a sub-sentence phrase unit, is the minimal selection unit for discourse segmentation of a document. We generate the document vector representations at EDU-level $h_i \in H = \{h_1, \cdots, h_d\}$ via the Self-Attentive Span Extractor (SpanExt) from Lee et al. (2017) over the BERT token embeddings. We use the converted dependency version of the tree to build the Rhetorical-aware graph ($\mathcal{G}_{DG}$) by treating every discourse dependency from the i-th EDU to the j-th EDU as a directed edge weighted by the type of the rhetorical relation.

2.4 Temporal Relation Extraction

Each graph is instantiated as a gated variant of Relational Graph Convolutional Networks (R-GCN) (Schlichtkrull et al., 2018), which we term as Gated Relational Graph Convolution Network (GR-GCN). GR-GCN propagates messages among the nodes to obtain a learned node representation and is inspired by (Zhang et al., 2020). Fig. 2 shows how the learned representations obtained from the syntactic-aware graph forms the input to the time-aware graph. For the time-aware graphs, the learned representations of nodes corresponding to the source event e_s and target event e_t are extracted (O_T). In the case of the rhetorical graphs, the span representations of the EDU span nodes corresponding to the source event (h_e) and target event (h_s) are extracted (O_{EDU}).

The output corresponding to the source and target nodes learnt by G_{TG} (O_T) and G_{DG} (O_{EDU}) are concatenated with output of BERT based context encoder (O_{CE}) (similar to BERT encoding in (Zhao et al., 2020a)): $z_G = \text{ReLU}(W[O_T; O_{EDU}; O_{CE}]+b)$. This is followed by a Softmax layer to predict temporal relations.

3 Experiments

3.1 Data

We train and test our proposed model using the TDDMan and TDDAuto subsets of the TDDiscourse corpus (Naik et al., 2019), which was designed to explicitly focus on global discourse-level temporal ordering. We also train and evaluate our method on the MATRES and TimeBank-Dense datasets, both of which primarily consist of local TLINKs that occur in either the same or adjacent

Table 3: Results comparing performance of TIMERS with baselines and ablative components on TDDMan, TDDAuto, MATRES and TimeBank-Dense datasets. We adopt the BERT and RoBERTa implementation from (Ballesteros et al., 2020). * indicates statistical significance over BERT Transformer ($p \leq 0.005$) under Wilcoxon's Signed Rank test. Darker green represents better F1 performance on ablation studies. Bold denotes the best performing model. TIMERS improves substantially over all datasets. The ablation shows that context, discourse ($\mathcal{G}_{DG}$), and time-aware ($\mathcal{G}_{TG}$) graph encoders prove to be most beneficial.

sentences. Table 1 reports the data statistics and label distributions. (Naik et al., 2019) shows the distribution of the distance between event-pairs for all TLINKs in the TDD test set and explains that nearly 53% TLINKs in the TDD dataset comprise of event pairs that are more than 5 sentences apart. Like Cheng and Miyao (2017), we report results on non-vague labels of TimeBank-Dense. MATRES has no standard validation set. Hence, we follow the split used in (Ning et al., 2019).

3.2 Experimental Settings

Token Encoding:The word-level token representations are obtained by summing the corresponding BERT embeddings from the last 4 layers of pre-trained BERT-base encoder. **Syntactic Dependency Parser**: The dependency parse tree of individual sentences is obtained via SpaCy[1] to form word-word dependency connections in the syntactic-aware graph. **Semantic Role Labeller**: We extract semantic role labels using AllenNLP's SRL parser[2] that internally uses SRL-BERT (Shi and Lin, 2019) to obtain the temporal arguments corresponding to each verb event. **Timex Normalization**: Timex phrases are treated as a single unit for the purpose of graph construction by average pooling their BERT tokenized representations. Microsoft Recognizers-Text[3] is employed to normalize timexes and DCT date-time values. The normalized timex expressions are compared through Allen's interval algebra, where each timex has a start and an endpoint. The comparison is then made on the basis of the endpoints of the timexes, forming an edge going from earlier to later ending timex. **RST Discourse Parser**: We used the shift-reduce discourse parser proposed by Ji and Eisenstein (2014) to build the discourse tree [4], which is post-processed using *discoursegraphs* library[5] (Neumann, 2015) to build the rhetorical dependencies graph. Further implementation details can be found in the appendix.

3.3 Results

Table 3 compares our work to the baseline methods reported on the TDDMan, TDDAuto, MATRES, and TimeBank-Dense datasets. We also include results for BERT-based Transformer (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) following Ballesteros et al. (2020). To prevent truncation or memory errors otherwise caused by multi-sentence spans, we concatenate only sentences containing source and events as input to Transformer baselines. These methods outperform the existing reported results and provide strong benchmarks but still perform similarly to a majority class baseline for the TDDMan dataset. Our model shows a significant gain of 8.0 F1 and 8.8 F1 over the BERT baseline on the TDDMan and TDDAuto datasets. Table 2 compares TIMERS to additional rigorous state-of-the-art methods for TimeBank-Dense and MATRES. TIMERS achieves state-of-the-art performance on all four datasets, showing that it successfully handles intra-sentence, inter-sentence, and cross-sentence TLINK pairs through the same architecture.

[4] Implementation used: https://github.com/jiyfeng/DPLP
[5] https://pypi.org/project/discoursegraphs/

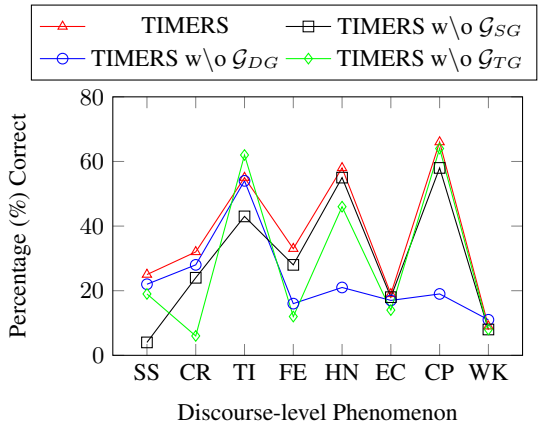

Figure 3: Error analysis on manually annotated discourse-level phenomena in the test set of TDDMan. SS: Single-Sent, CR: Chain Reasoning, TI: Tense Indicator, FE: Future Events, HN: Hypothetical/Negated, EC: Event Coreference, CP: Causal/Prereq, WK: World Knowledge. TIMERS handles CR and CP phenomena but struggles on EC and WK.

3.4 Ablation Study

To assess the contribution of discourse, syntactic, and time-aware graphs, we performed an ablation experiment with different configurations (Table 3). Removing the context encoder significantly degrades performance, indicating that the graph components themselves cannot replace the contextual encoding. Removing any of the graph encoders hurts the model performance, motivating the need for all the constituent graph components. We also analyzed the relative importance of $\mathcal{G}_{DG}$, $\mathcal{G}_{SG}$, and $\mathcal{G}_{TG}$ represented by color shading in the table. The results show that the syntactic graph is least important for document level pairs in TDDMan and TDDAuto, which we believe is due to the longer range dependencies present in this dataset. However, removing the discourse graph for TimeBank-Dense and MATRES datasets leads to the least performance deterioration as inter and intra-sentence pairs do not fully utilize document-level rhetorical relations. TIMERS outperforms the BERT baseline even without $\mathcal{G}_{TG}$, demonstrating its useful in cases where document creation date or timexes cannot be obtained easily.

3.5 Error Analysis

The error analysis results of TIMERS and its ablations for TDDMan are shown in Fig. 3 (the results on TDDAuto are in Appendix Fig.1). The results provide evidence that the syntactic-aware graph ($\mathcal{G}_{SG}$) is most important for relations that can be extracted from a single sentence (SE). The time-aware graph ($\mathcal{G}_{TG}$) plays an important role in improving relationships requiring chain reasoning (multi-hop) and relationship determined by future events. We also note the role of the rhetorical-aware graph ($\mathcal{G}_{DG}$) for modeling future possibility (FE), hypothetical events (HN) and causal conditions for event occurrences (CP). This can be attributed to rhetorical relational features that extract plausible inter-dependencies such as *cause, explanation, contrast* (Lioma et al., 2012). None of the experimented models show improved performance on TLINK pairs which depend on world knowledge (WK) or event coreference (EC).

4 Conclusion

This work presents a neural architecture that utilizes local syntactic features, rhetorical discourse features, and temporal arguments in semantic role labels through a Gated Relational-GCN for document-level temporal relation extraction on TDDiscourse, MATRES, and TimeBank-Dense datasets. Experiments show that TIMERS shows substantial improvement for events that require chain reasoning and causal prerequisite links. Future work will focus on exploring real-world scenarios in which the temporal extraction task suffers from absent or erroneous event and timex annotations. We believe our proposed methods can also be adapted for other languages as well by overcoming possible limitations such as dependency parsing, semantic parsing, Timex normalization for the non-English corpora.

Ethics Statement

This work does not collect or release any new data resource. Moreover, all four of the datasets used in experiments (TDDiscourse, TimeBank-Dense and MATRES) are publicly available and free to use, hence do not intrude user privacy. During the course of this work, no human judgements were exploited nor any user-level data was collected, stored or processed. Our methods do not add to any pre-existing data biases. Potential applications of this work include extracting event timelines from news, contractual documents, and digitizing patient electronic health records. We acknowledge that temporal information extraction finds applications in clinical NLP (Lin et al., 2019; Tourille et al., 2017). Hence, we would like to caution about shortcomings of the proposed system in terms of misclassifications on event pairs requiring real-world common sense reasoning and domain shift.

A Experiment Settings

A.1 Node Connections

We detail the node connections present in each graph of our proposed model along with edge attributes in Table 4.

A.2 Edge Relations

Table 6 lists rhetorical relations used in Rhetoric-aware graph G_{DG}in the TIMERS model, along with the definitions as provided by Mann (1987). The weights of the Rhetoric graph G_{DG} are determined based on the RST relations described in this table. Table 7 details the type of relations between timex-timex and DCT-timex nodes of the Time-aware graph G_{TG}.

A.3 Training Setup

Hyperparameter: Hyper-parameters for our model were tuned on the respective validation set to find the best configurations for different datasets. We summarize the range of our model's hyper parameters such as: number of hidden layers in GR-GCN $\{1, 2, 3\}$, size of hidden layers in GR-GCN $\{64, 128, 256, 512\}$, BERT embedding size, dropout $\delta \in \{0.2, 0.3, 0.4, 0.5.0.6\}$, learning rate $\lambda \in \{1e-5, 1e-4, 1e-3, 1e-2, 1e-1\}$, weight decay $\omega \in \{1e-6, 1e-5, 1e-4, 1e-3\}$, batch size $b \in \{16, 32, 64\}$ and epochs (≤ 100).

Contextual Encoder: We used BERT-base-uncased for generating token embedding of size 1x 768. As BERT-base Transformer provides a stronger baseline as compared to RoBERTa, we utilized BERT Transformer for Contextual Encoder in TIMERS architecture. We use the default dropout rate (0.1) on BERT's self attention layers but do not use additional dropout at the top linear layer The output from the Contextual Encoder is a 1-D vector of size 768.

Loss Function and Inference: TIMERS is trained end to end using Binary Cross Entropy loss with Adam optimizer. Across all four datasets, we found the best results correspond with the use of Adam optimiser set with default values $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$, weight-decay of $5e-4$ and an initial learning rate of 0.001. We evaluate the performance of temporal relation extraction systems in terms of F1, precision and recall score.

Computing Infrastructue: TIMERS is written in PyTorch library and was trained on Nvidia GeForce RTX 2080 GPU. **Average Runtime**: The model takes a maximum of approximately 6,500 seconds to train on either of the four datasets.

Dataset Access Links to download TDDiscourse (Naik et al., 2019) dataset: https://github.com/aakanksha19/TDDiscourse Link to download MATRES (Ning et al., 2018a) dataset: https://github.com/qiangning/MATRES Link to download TimeBank-Dense (Cassidy et al., 2014) dataset: https://github.com/muk343/TimeBank-dense

A.4 Reproducibility

Table 5 lists the range ad best values of the hyperparameters used in TIMERS model for different data settings. We used grid search to choose the best set of training configurations across each dataset. We run 5 rounds of hyper-parameter search trials and report average of observed results.

B Additional Results

We observe from Figure 4 a similar trend to TDDMan, although with a stronger support for SS, CR, TI and and FE. This is partly due to the fact that TDDAuto was generated automatically (Naik et al., 2019) using weakly annotated time relations. Moreover, 90% of samples in TDDAuto require SS. Hence, TIMERS trained exclusively on TDDAuto performs worse on challenging phenomenon like HN and CP. Consistent with results on TDDMan, TIMERS and its ablations trained on TDDAuto struggle on EC and WK.

Consistent with results on TDDMan, TIMERS and its ablations trained on TDDAuto struggle on EC and WK.

Relation Label	Definition
Temporal	Relating to time
Summary	Shorter restatement
Same-unit	Part of the same phrasal unit
Span	Extending to multiple phrasal units
Purpose	Initiation in order to realize a goal
Example	Specific subtypes
Elaboration	Providing additional details
Reason	Justification with intent to defend a stance
Sequence	Subject-matter sequence
Condition	Realization of dependency
Means	Method or instrument to improve likelihood
Consequence	Intended or unintended end goal
Topic	Central idea
Attribution	Contributing factor
Textual Organization	Part of formal text span
Contrast	Opposing phenomenon
Manner	Semantic course of occurrence
Antithesis	Incompatibility due to contrast
Concession	Potential Incompatibility
Explanation	Providing clarification to an established fact
Circumstance	Framework for interpretation

Abstract

Arabic diacritization is a fundamental task for Arabic language processing. Previous studies have demonstrated that automatically generated knowledge can be helpful to this task. However, these studies regard the auto-generated knowledge instances as gold references, which limits their effectiveness since such knowledge is not always accurate and inferior instances can lead to incorrect predictions. In this paper, we propose to use regularized decoding and adversarial training to appropriately learn from such noisy knowledge for diacritization. Experimental results on two benchmark datasets show that, even with quite flawed auto-generated knowledge, our model can still learn adequate diacritics and outperform all previous studies, on both datasets.[1]

1 Introduction

Modern standard Arabic (MSA) is generally written without diacritics, which poses a challenge to text processing and understanding in downstream applications, such as text-to-speech generation (Drago et al., 2008) and reading comprehension (Hermena et al., 2015). Restoration of such diacritics, known as diacritization, becomes an important task for Arabic natural language processing (NLP). Among different diacritization methods (Pasha et al., 2014; Shahrour et al., 2015; Zitouni et al., 2006; Habash and Rambow, 2007; Darwish et al., 2017), the neural ones (Abandah et al., 2015a; Fadel et al., 2019a,b; Zalmout and Habash, 2019, 2020; Darwish et al., 2020) achieve the best performance due to their better capability in incorporating contextual features. To further improve diacritization, automatically generated knowledge from off-the-shelf toolkits, such as morphological features, parts-of-speech tags, and automatic diacritization results, have been extensively applied to this task (Zitouni et al., 2006; Arabiyat, 2015; Darwish et al., 2017, 2020). However, current models treat such knowledge instances as gold references and always directly concatenate them with input embeddings (Arabiyat, 2015; Darwish et al., 2020), which may lead to inferior results since the knowledge may be inaccurate, especially if the toolkits were trained on data with different criteria.

Diacritization can be performed by character-based sequence labeling (Zitouni et al., 2006; Belinkov and Glass, 2015; Fadel et al., 2019b). We follow this paradigm and propose a neural approach in this paper, using regularized decoding and adversarial training to incorporate auto-generated knowledge (i.e., the diacritization results generated from off-the-shelf toolkits). Specifically, the regularized decoder treats the auto-generated knowledge as separate gold labels and learns to predict them in a separate decoding process, which is then used to update the main model. The adversarial training is applied to the encoding process by determining whether the diacritization for an input follows the gold label or the auto-generated knowledge. In doing so, our model can dynamically distinguish between auto-generated knowledge instances instead of treating them all as gold references, so as to effectively identify what knowledge should be leveraged for different inputs. Importantly, regularized decoding and adversarial training are exclusively applied to the training stage; we only need the main tagger for inference once the model has been trained. Experimental results and further analyses illustrate the effectiveness of our approach, where our model outperforms strong baselines and achieves state-of-the-art results on two benchmark datasets: Arabic Treebank (ATB) (Maamouri et al., 2004) and Tashkeela (Zerrouki and Balla, 2017).

2 The Proposed Approach

As shown in Figure 1, our approach for diacritization follows the sequence labeling paradigm, where it has two training stages for the main tagger ($\mathcal{M}$). In the **first training stage** (presented in the orange box in Figure 1), $\mathcal{M}$ is enhanced by regularized decoding ($\mathcal{RD}$) and adversarial training ($\mathcal{AT}$) to discriminatively learn from the auto-generated labels. Specifically, given an input Arabic character sequence $\mathcal{X} = x_1 \cdots x_i \cdots x_n$, $\mathcal{M}$ and $\mathcal{RD}$ aim to predict two types of diacritization labels, $\widehat{\mathcal{Y}}$ and $\widehat{\mathcal{Y}}^K$, which follow the gold and auto-generated label criteria, respectively. $\mathcal{AT}$ ensures that the main tagger only learns useful information from either gold or auto-generated labels. Therefore, the first training stage can be conceptually formalized by

$$\widehat{\mathcal{Y}}, \widehat{\mathcal{Y}}^K = f(\mathcal{M}(\mathbf{H}^S, \mathcal{X}), \mathcal{RD}(\mathbf{H}^S, \mathcal{X}), \mathcal{AT}(\mathbf{H}^S)) \quad (1)$$

where $\mathbf{H}^S$ denotes the output vectors of the shared encoder $\mathcal{SE}$ (whose input is $\mathcal{X}$) that is designed to learn the information shared by the gold and auto-generated labels. As a result, the goal of this training stage is to minimize the loss defined by

$$\mathcal{L} = \mathcal{L}_\mathcal{M} + \mathcal{L}_\mathcal{K} + \mathcal{L}_\mathcal{A} \quad (2)$$

where $\mathcal{L}_\mathcal{M}$, $\mathcal{L}_\mathcal{K}$ and $\mathcal{L}_\mathcal{A}$ refer to the losses that come from $\mathcal{M}$, $\mathcal{RD}$, and $\mathcal{AT}$, respectively.

Afterwards, in the **second training stage** (presented in the green box in Figure 1), $\mathcal{M}$ is further trained alone on the gold labels $\widehat{\mathcal{Y}}$ without using auto-generated $\widehat{\mathcal{Y}}^K$, $\mathcal{RD}$ and $\mathcal{AT}$, to fine-tune its parameters, where all parameters in $\mathcal{SE}$ obtained through the first training stage are fixed. For inference, only $\mathcal{M}$ is used without requiring any additional input other than $\mathcal{X}$ to obtain the diacritization results. In the following sections, we first describe $\mathcal{M}$, then elaborate the details of $\mathcal{RD}$ and $\mathcal{AT}$.

2.1 The Main Tagger

The main tagger uses an encoder-decoder architecture, as shown in Figure 1, in which a shared encoder $\mathcal{SE}$ and a private encoder $\mathcal{PE}^\mathcal{M}$ are applied to model the contextual information. Particularly, $\mathcal{SE}$ is proposed to facilitate the process of leveraging auto-generated knowledge, which is excepted to learn information shared by the gold labels and the auto-generated knowledge. It takes the character embeddings of $\mathcal{X}$ (the embedding of x_i is denoted as $\mathbf{e}_i$) as input and encodes them to the shared hidden vectors (denoted as $\mathbf{h}_i^S$ for x_i) by

$$[\mathbf{h}_1^S, \cdots, \mathbf{h}_n^S] = \mathcal{SE}([\mathbf{e}_1, \cdots, \mathbf{e}_n]) \quad (3)$$

Similarly, $\mathcal{PE}^\mathcal{M}$ is also applied to the word embeddings and produces the result $\mathbf{h}_i^M$. Then, we concatenate $\mathbf{h}_i^S$ and $\mathbf{h}_i^M$ and map the resulting vector to the output space with a fully connected layer: $\mathbf{o}_i^M = \mathbf{W}^M \cdot (\mathbf{h}_i^M \oplus \mathbf{h}_i^S) + \mathbf{b}^M$, where $\oplus$ is concatenation and $\mathbf{W}^M$ and $\mathbf{b}^M$ are the trainable matrices and bias vector, respectively. Finally, a *softmax* decoder is applied to $\mathbf{o}_i^M$ to predict the label $\widehat{y}_i$:

$$\widehat{y}_i = \arg\max \frac{exp(o_i^{M,t})}{\sum_{t=1}^{|\mathcal{T}|} exp(o_i^{M,t})}, \quad (4)$$

where $\mathcal{T}$ denotes the set of all diacritization labels and $o_i^{M,t}$ is the value at dimension t in $\mathbf{o}_i^M$. Therefore the loss for $\mathcal{M}$ is

$$\mathcal{L}_\mathcal{M} = -\sum_{i=1}^{n} \log p(y_i^* | \mathcal{X}), \quad (5)$$

where $p(y_i^* | \mathcal{X})$ denotes the probability of labeling x_i by the gold label y_i^*.

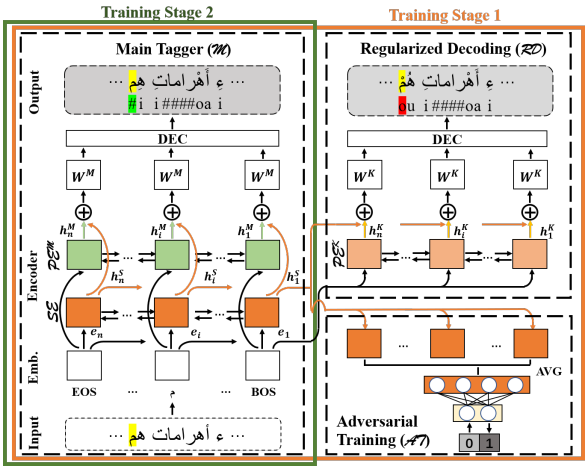

Figure 1: The architecture of our model, where the left shows the main tagger ($\mathcal{M}$) and the right shows the regularized decoding ($\mathcal{RD}$) and adversarial training ($\mathcal{AT}$) modules. The diacritization labels for an example following different criteria are illustrated in $\mathcal{M}$ and $\mathcal{RD}$, with the mismatching labels marked in green and red. E.g., for "م" (highlighted in yellow), its gold and auto-generated labels are "#" (*null*) and "o" (*sukun*).[2]

2.2 Regularized Decoding

When leveraging auto-generated knowledge, it is important to note that such knowledge may be inaccurate or follow different annotation criteria, which is required to be appropriately addressed to pre-

[2]We use a set of symbols to label different diacritization results, which are illustrated in Appendix A.

(b) ZEN 2.0

Table 1: Experimental results (i.e., DER and WER with and without the case ending being considered and accuracy) of baselines and our models with $\mathcal{RD}$ and $\mathcal{AT}$ using AraBERT (a) and ZEN 2.0 (b) on the test sets of ATB and Tashkeela, "BiLSTM" and "Transformer" denote the encoders (i.e., $\mathcal{SE}$ and $\mathcal{PE}$) used in the models.

vent the noise in the auto-generated knowledge from significantly hurting the model performance (Tang et al., 2020; Nie et al., 2020; Chen et al., 2020; Mandya et al., 2020; Tian et al., 2020a,b, 2021a,b; Chen et al., 2021). To tackle this challenge, we propose to learn from a special decoding process, which is integrated into the main diacritization model, in order to reduce error propagation compared to directly using the knowledge instances or their features. As shown in Figure 1, the proposed regularized decoding is an extra output process separated from the main tagger and performed on another sequence of labels $\mathcal{Y}^{K^*}$, which are the auto-generated knowledge instances (diacritization labels) annotated by an existing toolkit. Therefore, the loss $\mathcal{L}_\mathcal{K}$ from $\mathcal{RD}$ is computed through

$$\mathcal{L}_\mathcal{K} = -\sum_{i=1}^{n} \log p(y_i^{K^*}|\mathcal{X}) \quad (6)$$

and in the first training stage, all trainable parameters in $\mathcal{SE}$ are updated through the information back-propagated from $\mathcal{RD}$.

2.3 Adversarial Training

Although auto-generated knowledge can be back-propagated through $\mathcal{RD}$, it could be overwhelmed by the information directly learned from the gold label. We further improve our model by balancing the information learned from both $\mathcal{M}$ and $\mathcal{RD}$ with $\mathcal{AT}$, which is proposed to equalize both sides and emphasize the shared information from them.[3] In doing so, we connect a discriminator, which is a binary classifier, to $\mathcal{SE}$. The discriminator takes all $\mathbf{h}_i^S$ from $\mathcal{SE}$, averages them by $\mathbf{h}^S = \frac{1}{n}\sum_{i=1}^{n}\mathbf{h}_i^S$, and then passes the resulting vector to a fully connected layer with a *softmax* function to compute its bias towards either type (i.e., the gold or auto-generated) of diacritization labels:

$$[p_m, p_k] = softmax(\mathbf{W}^D \cdot \mathbf{h}^S + \mathbf{b}^D) \quad (7)$$

where $\mathbf{W}^D$ and $\mathbf{b}^D$ are the trainable matrix and bias vector, respectively, that map $\mathbf{h}^S$ to a two-dimensional vector, with p_m and p_k representing normalized probabilities that satisfy $p_m + p_k = 1$ and indicating the bias of $\mathcal{SE}$ towards gold and auto-generated labels, respectively. Then we apply a negative log-likelihood loss function to the discriminator, formalized as

$$\mathcal{L}_\mathcal{D} = -\log p_m - \log p_k \quad (8)$$

and an adversarial loss to the parameters in $\mathcal{SE}$ via

$$\mathcal{L}_\mathcal{S} = -p_m \log p_m - p_k \log p_k \quad (9)$$

As a result, the goal of $\mathcal{AT}$ is to minimize the loss

$$\mathcal{L}_\mathcal{A} = \mathcal{L}_\mathcal{D} - \lambda\mathcal{L}_\mathcal{S} \quad (10)$$

[3] $\mathcal{AT}$ follows the idea that the $\mathcal{SE}$ should have no bias towards the information learned from $\mathcal{M}$ and $\mathcal{RD}$.

where λ is a positive coefficient that controls the influence of $\mathcal{L}_{\mathcal{S}}$ in the adversarial training, so that to minimize $\mathcal{L}_{\mathcal{D}}$ and maximize $\mathcal{L}_{\mathcal{S}}$ synchronously.

3 Experiments

3.1 Settings

In our experiments, We use two benchmark datasets, i.e., ATB (Arabic Treebank Part 1, 2, and 3) (Maamouri et al., 2004) and Tashkeela (Zerrouki and Balla, 2017), following the same settings in previous studies.[4] For implementation, we run Farasa[5] (Abdelali et al., 2016) on the two datasets and collect their diacritization results for regularized decoding. Since the quality of text representation normally dominates the model performance (Pennington et al., 2014; Song et al., 2017, 2018; Peters et al., 2018; Song and Shi, 2018; Devlin et al., 2019), in our experiments, we test two types of widely used and powerful encoders, i.e., BiLSTM and Transformer (Vaswani et al., 2017), for $\mathcal{SE}$ and $\mathcal{PE}$. For the embeddings, we use AraBERT (Antoun et al., 2020) and the large version of ZEN 2.0 (Song et al., 2021) with their default settings (i.e. 12 layers of multi-head attentions with 768 dimensional hidden vectors for AraBERT and 24 layers of multi-head attentions with 1024 dimensional hidden vectors for ZEN 2.0) to perform the initialization (we use the output of the last layer).[6] We train our model for 20 epochs in total, with the first 10 for the first training stage and the rest for the second stage. Particularly, in the second training stage, we evaluate our model on the development set for every 100 steps to locate the best performing model. For evaluation, we follow previous studies (Abandah et al., 2015b; Fadel et al., 2019b) to use diacritization error rate (DER) and word error rate (WER) with and without considering the case ending.[7] We also use diacritization accuracy following Zalmout and Habash (2017, 2019, 2020).[8]

3.2 Overall Results

In the main experiment, we run the baselines and our models using different configurations (i.e., using AraBERT or ZEN 2.0 embeddings and using BiLSTM or Transformer encoders) with and without $\mathcal{RD}$ and $\mathcal{AT}$. The experimental results (DER and WER with and without considering the case endings, and accuracy) on the test sets of ATB and Tashkeela are reported in Table 1.[9]

There are several observations. First, under different configurations (i.e., using AraBERT or ZEN 2.0 and with BiLSTM or Transformer encoders), $\mathcal{RD}$ improves the baseline on both datasets, which shows that $\mathcal{RD}$ is effective to help diacritization with auto-generated knowledge even if they follow different criterion. Second, further consistent improvement can be observed when $\mathcal{AT}$ is applied on top of $\mathcal{RD}$, with only 3K (0.015‰ of the entire model size) more trainable parameters required to achieve this effect.[10] These observations confirm the effectiveness of forcing $\mathcal{SE}$ to learn from the information shared by gold and auto-generated labels with an appropriate model design.

[4] We illustrate the dataset details in Appendix B.

[5] http://qatsdemo.cloudapp.net/farasa/

[6] We obtain the pre-trained official AraBERT model from https://github.com/aub-mind/arabert and the Arabic version of ZEN 2.0 (large) from https://github.com/sinovation/ZEN2.

[7] We show details of DER and WER in Appendix C.

[8] We report the hyper-parameter settings of different models and the best combinations of them in Appendix D.

[9] Their dev set's results and the mean and standard deviation of test set results are reported in Appendix E and F.

[10] Model sizes are reported in Appendix G.

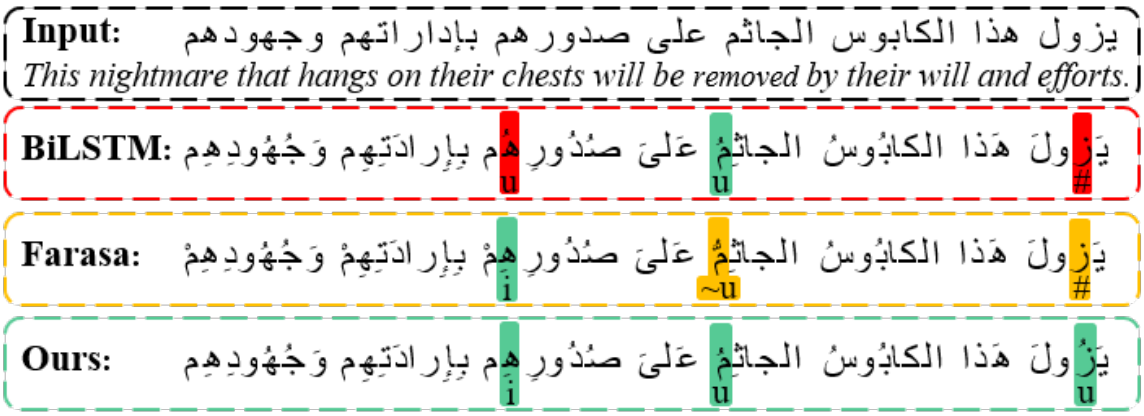

Figure 2: An example input sentence and its diacritization results ("$\sim u$", "#", "i" and "u") from Farasa, BiLSTM, and our approach (BiLSTM+$\mathcal{RD}$+$\mathcal{AT}$) with AraBERT. All results matching gold labels are highlighted in green; the mismatching results from Farasa and BiLSTM are in orange and red, respectively.

In addition, we also compare the results of our best models (with $\mathcal{RD}$ and $\mathcal{AT}$) with previous studies (including Farasa's results) on the test sets of both datasets. The results are shown in Table 2, where our model with BiLSTM encoder outperforms previous models and achieves state-of-the-art performance on both datasets.

3.3 Case Study

To explore how our approach with $\mathcal{RD}$ and $\mathcal{AT}$ leverage auto-generated knowledge, we conduct a case study on an example sentence from the test set of ATB. The input and its diacritization results from Farasa, the BiLSTM baseline, and our approach with AraBERT (BiLSTM+$\mathcal{RD}$+$\mathcal{AT}$) are illustrated in Figure 2, where the correct diacritization results are highlighted in green, and the incorrect ones from Farasa and BiLSTM are highlighted in orange and red, respectively. It is clearly observed that our approach leverages the necessary information learned from Farasa (i.e., the "$\sim u$" label) and prevents its unreliable results from affecting the final diacritics. Specifically, for the highlighted Arabic character "ه", where the Farasa output suggests the diacritic "i" (*kasra*), our approach leverages this knowledge and corrects the BiLSTM baseline. For the other two highlighted characters, although the Farasa output (i.e., "$\sim u$" (*Shadda+Damma*) for "م" and "#" (*No Diacritic*) for "ز") also produces diacritization results that are different from the BiLSTM baseline and do not match the gold standard, our approach is able to learn from their patterns and make correct predictions. Therefore, although Farasas output does not match the gold labels in most cases (see the Farasa results in Table 2), the proposed $\mathcal{RD}$ and $\mathcal{AT}$ can leverage such knowledge and improve the main tagger accordingly.

4 Conclusion

In this paper, we propose to incorporate auto-generated knowledge (diacritization labels in another criterion) for Arabic diacritization with regularized decoding and adversarial training. In detail, the regularized decoding treats the auto-generated knowledge as separate "gold" labels and learns to predict them in another decoding process; the adversarial training is used to ensure that the shared information from gold and auto-generated labels are learned to help diacritization. With the regularized decoding and adversarial training, the main tagger in our approach is able to smartly leverage auto-generated knowledge provided by an existing diacritization tagger. Experimental results on two benchmark datasets illustrate the validity and effectiveness of our model, where state-of-the-art performance is obtained on both datasets.

Appendix A. Diactritization Labels

Table 3 presents the 15 diacritization labels used in our study, following Fadel et al. (2019b).

Class Label	Class Name	Class Shape	Class Label	Class Name	Class Shape
#	No diacritics	بـ	~	Shadda	بّ
a	Fatha	بَ	~a	Shadda+Fatha	بَّ
i	Kasra	بِ	~i	Shadda+Kasra	بِّ
o	Sukun	بْ	~u	Shadda+Damma	بُّ
u	Damma	بُ	~K	Shadda+Kasratan	بٍّ
K	Kasratan	بٍ	~F	Shadda+Fathatan	بًّ
F	Fathatan	بً	~N	Shadda+Dammatan	بٌّ
N	Dammatan	بٌ			

Table 3: Diactritization labels used in this study.

Appendix B. Datasets

In our experiments, We use two benchmark datasets, i.e., ATB (Arabic Treebank Part 1, 2, and 3)[11] (Maamouri et al., 2004) and Tashkeela[12] (Zerrouki and Balla, 2017). For ATB, we follow the same data split policy as Diab et al. (2013), which is based on the 10-80-10 rule. That is, we firstly split each part of ATB into three portions (with each portion containing 10%, 80%, and 10% of documents, respectively). Then, we combine the first, second, and third portion of all three parts to form the development, training, and test set, respectively. For Tashkeela, we use the cleaned version[13] from Fadel et al. (2019b) with the standard train/dev/test split. The statistics of the datasets in terms of the number of words, lines, and the average number of characters in each word are reported in Table 4.

	ATB			Tashkeela		
	Train	Dev	Test	Train	Dev	Test
Word #	503K	63K	63K	2.1M	102K	107K
Line #	15.7K	1.9K	1.9K	50K	2.5K	2.5K
C/W	4.37	4.31	4.35	3.97	3.97	3.97

Table 4: Statistics of the benchmark datasets, where the number of words and lines, and average characters per word (C/W) are reported.

[13] We download the data from https://github.com/AliOsm/arabic-text-diacritization/tree/master/dataset.

Appendix C. Evaluation of DER and WER

It is worth noting that previous studies (Zitouni et al., 2006; Arabiyat, 2015; Fadel et al., 2019a; Abandah and Abdel-Karim, 2019; Alqahtani et al., 2019, 2020) use different methods to compute diacritic error rate (DER) for ATB and Tashikeela datasets. Therefore, we follow the schema in Zitouni et al. (2006); Arabiyat (2015); Abandah and Abdel-Karim (2019) to compute DER for ATB and follow Fadel et al. (2019a); Alqahtani et al. (2019, 2020) to compute that for Tashikeela.

Specifically, for ATB, we compute DER by: (1) all words are counted including numbers and punctuators; (2) each latter or digit in a word is a potential host for a set of diacritics; and (3) all diacritics on a single letter are counted as a single binary (True or False) choice. For Tashikeela, the schema is similar to the one for ATB but all non-Arabic letters are ignored in computing DER because they do not hold a diacritic. For word error rate (WER), the way to compute it is identical for both datasets, where the diacritization result for an Arabic word is regarded as incorrect if there is s at least one incorrectly restored diacritic. We follow previous studies (Abandah et al., 2015b; Fadel et al., 2019a) to evaluate our results in terms of diacritic error rate (DER) and word error rate (WER). We use the implementation[14] provided by Fadel et al. (2019a) to compute DER (with two criteria) and WER of different models on both datasets, where the DER and WER with and without considering the case endings are both included in our evaluation.

Appendix D. Hyper-parameter Settings

Table 5 reports the hyper-parameters tested in training our models. We test all combinations of them for each model and use the one achieving the highest F1 score in our final experiments.

Hyper-parameters	Values
Learning Rate	$1e-5, \mathbf{3e-5}, 5e-5$
Warmup Rate	**0.06**
Dropout Rate	**0.1**
Batch Size	$16, \mathbf{32}, 64$

Table 5: The hyper-parameters tested in tuning our models. The best ones used in our final experiments are highlighted in boldface.

[14] https://github.com/AliOsm/arabic-text-diacritization/blob/master/helpers/diacritization_stat.py.

Appendix E. Experimental Results on the Development Set

Table 6 reports the DER and WER (with case ending) of different models evaluated on the development set of ATB and Tashkeela.

	ATB		Tashkeela	
	DER	WER	DER	WER
BiLSTM	2.52	7.00	2.58	7.66
+$\mathcal{RD}$	2.46	6.47	2.20	6.47

(b) ZEN 2.0

Table 6: DER and WER (with case ending) of models with different configurations (i.e., based on BiLSTM and Transformer) evaluated on the development set of ATB and Tashkeela.

Appendix F. Mean and Deviation of the Results

In the experiments, we test models with different configurations. For each model, we train it with the best hyper-parameter setting using five different random seeds. We report the mean (μ) and standard deviation (σ) of DER and WER (with case ending) on the test set of ATB and Tashkeela in Table 7.

Appendix G. Model Size and Running Speed

Table 8 reports the number of trainable parameters and the inference speed (lines per second) of the baseline (i.e., BiLSTM and Transformer encoder with and without regularized decoding ($\mathcal{RD}$)) and our models with both $\mathcal{RD}$ and adversarial training ($\mathcal{AT}$) on ATB and Tashkeela. All models are performed on NVIDIA Quadro RTX 6000 GPUs.

Abstract

Subword segmentation algorithms have been a *de facto* choice when building neural machine translation systems. However, most of them need to learn a segmentation model based on some heuristics, which may produce suboptimal segmentation. This can be problematic in some scenarios when the target language has rich morphological changes or there is not enough data for learning compact composition rules. Translating at fully character level has the potential to alleviate the issue, but empirical performances of character-based models has not been fully explored. In this paper, we present an in-depth comparison between character-based and subword-based NMT systems under three settings: translating to typologically diverse languages, training with low resource, and adapting to unseen domains. Experimental results show strong competitiveness of character-based models. Further analyses show that compared to subword-based models, character-based models are better at handling morphological phenomena, generating rare and unknown words, and more suitable for transferring to unseen domains.

1 Introduction

Neural machine translation (NMT) has achieved great success in recent years. Modern NMT systems typically operate on subword level, using segmentation algorithms such as *byte pair encoding* (BPE) (Sennrich et al., 2016) or Morfessor (Creutz and Lagus, 2002). Compared to word-level models, subword segmentation helps overcome the out-of-vocabulary (OOV) problem and make better use of morphological information in the surface form.

Despite their empirical effectiveness, subword algorithms may produce improper segmentation due to their data-dependent nature. NMT models are typically robust to such errors when trained on large corpora or the target language is regular in morphological changes, like French or German. However, the problem will arise when such conditions are not met, i.e. there is not enough data for learning compact composition rules or the target language is morphologically rich and complex.

An alternative segmentation choice is to use fully character-level (CHAR) models (Lee et al., 2017; Cherry et al., 2018; Gupta et al., 2019; Gao et al., 2020; Banar et al., 2020), which has the potential to alleviate above issues. CHAR does not need to *learn* any segmentation rules and keeps all available information in the surface form, avoiding the risk of information loss due to improper segmentation. What is more, the main pain point of CHAR that it takes too long to train is less obvious in above settings since there is not as much data as in the rich resource setting. However, there has not been a comprehensive study in these settings.

In this paper, we conduct a systematic comparison between CHAR and other subword algorithms, e.g. BPE and Morfessor. Experiments show strong competitiveness of CHAR under three settings: translating to typologically diverse languages (Section 2), training with low resource (Section 3), and adapting to distant domains (Section 4). Further analyses show that compared to subword algorithms, the benefits of CHAR mainly come from better capture of the morphological phenomena, better generation of rare and unknown words, and better translation of domain-specific words.

2 Translation Across Typologically Diverse Languages

Human languages are known to exhibit diverse morphological phenomena, which could serve as a principle to classify languages into different morphological categories, such as *fusional*, *agglutinative*, *introflexive* and *isolating*. While previous

works only focus on performances of character-level models when translating to fusional and agglutinative languages (Gupta et al., 2019; Libovický and Fraser, 2020), we conduct a comprehensive study covering all four morphological categories.

2.1 Experiment Setup

Dataset We consider the translation from English to eight target languages representing four morphological categories, i.e. French (**Fr**) and Romanian (**Ro**) for *fusional*, Finnish (**Fi**) and Turkish (**Tr**) for *agglutinative*, Hebrew (**He**) and Arabic (**Ar**) for *introflexive*, and Vietnamese (**Vi**) and Malaysian (**Ml**) for *isolating*. We use OPUS-100 corpus[1] (Tiedemann, 2012), which consists of 1M parallel sentences for each language pair.

Model and Hyperparameters We use the Transformer architecture (Vaswani et al., 2017) throughout all experiments. To ensure results' reliability , we run an exhaustive search of hyperparameters including batch size and learning rate. Detailed hyperparameters can be found in Appendix A.

2.2 Results

The results are listed in Table 1. We can see that CHAR outperforms other algorithms in 7 out of 8 languages in terms of BLEU (Papineni et al., 2002) and chrF3 (Popović, 2015), showing strong competitiveness of CHAR's ability across languages. The only exception is the En-Fr language pair, which are known to be quite similar and is beneficial for BPE to learn a joint segmentation model.

It is intuitive that BPE and Morfessor cannot outperform CHAR on introflexive languages (Hi, Ar). Introflexive languages follows non-concatenative morphology (McCarthy, 1981), i.e. grammatical information is conveyed by directly modifying the root words. This makes it hard for linear segmenting methods such as BPE and Morfessor to work well. This finding is also consistent with previous research on other tasks (Zhu et al., 2019).

For isolating languages (Vi, Ml), there are rare morphological phenomena indicating grammatical relations, so segmentation algorithms do not greatly affect the performance. We can see that the two open-vocabulary segmentation algorithms (CHAR, BPE) show comparable performances.

Surprisingly, even for highly agglutinative languages such as Finnish and Turkish, which has very regular morphological changes by adding affixes or suffixes, CHAR still achieves better performance.

2.3 Analysis on MorphEval

To understand where the advantages of CHAR model come from, we take Finnish as an example and evaluate the morphological competence of different models using MorphEval test suites (Burlot et al., 2018). MorphEval generates pairs of source sentences that differ by one kind of morphological phenomena, and assesses a MT system's ability by computing the percentage of its generated target sentences that convey as the source sentences. Higher accuracy means the model is more sensitive to the current morphological phenomenon.

As shown in Table 2, CHAR performs the best in 10 out of 14 tests. Among these 10 tests, in comparative adjectives, possessive determiner, local postposition case, preposition case, plural nouns, CHAR surpasses other algorithms notably by at least 5% accuracy. This indicates CHAR's strong ability to capture the fine-grained morphological

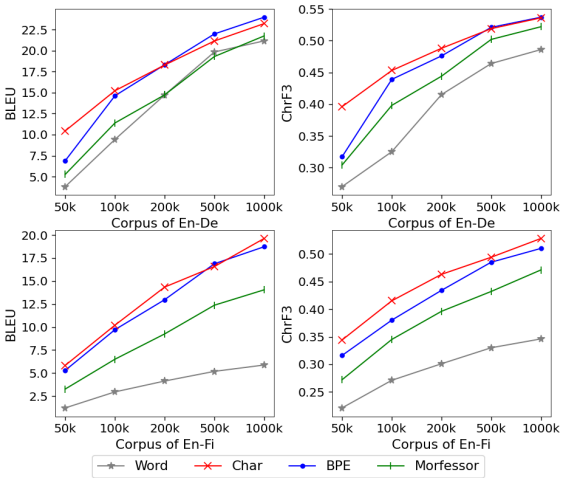

Figure 1: BLEU and chrF3 score curves using different amount of parallel data for training En-De (above) and En-Fi (below) translation systems.

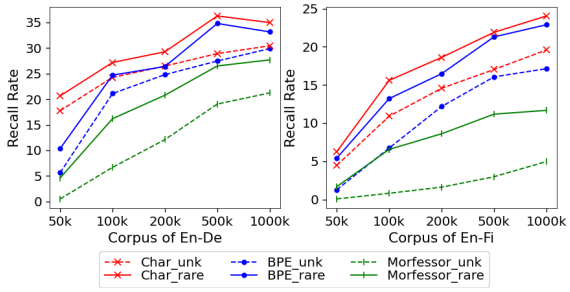

Figure 2: Recall rates of unknown and rare words generated by systems based on different tokenizers models. Words appearing no more than 5 times in the training set are considered as rare words.

phenomena, which is crucial for MT models when translating into morphologically rich languages.

Interestingly, three of four morphological phenomena on which CHAR falls behind are so-called *stability* features (Burlot et al., 2018), which are expressed differently in the source language but should be expressed identically in the target language[2]. The disadvantage of CHAR in this kind of phenomena shows CHAR-based model may be less robust to lexical changes to source-side changes, and the reason needs to be further researched.

3 Translation with Low Resource

Subword algorithms help alleviate the OOV problem. However, most of them are based on heuristics and may produce wrong segmentation. While this problem is not so evident when there is enough data to learn robust composition rules, in low-resource setting it could be a different story and their effectiveness should be examined. While for CHAR, pure character sequences can directly provide all the information to the model for learning the composition rules. Therefore a prudent choice of segmentation should be studied in this setting.

3.1 Experiment Setup

We perform evaluation on WMT14 En-De[3] and WMT17 En-Fi[4] dataset. Datasets of size 50k, 100k, 200k, 500k and 1000k are subsampled from the original training dataset and serve as training data of different resource conditions. For validation and test, we use the original development and test split.

Previous works (Sennrich and Zhang, 2019; Nguyen and Chiang, 2017) show that in low resource settings the evaluation results can be sensitive to model size (e.g. hidden dimension, layer number) and the number of BPE merges k, so we run an additional search of hidden dimension, layer number and k, and report the best results in this section. See Appendix A for details.

3.2 Results

We evaluate models with BLEU and chrF3. The results are showed in Figure 1. In general, the performances of CHAR and BPE are on par, and are better than Word and Morfessor. In different data conditions, the results varies.

medium-resource When there are plenty resources, e.g. 500k and 1000k, the performance of CHAR and BPE are comparable but different for different language pairs. For En-Fi, CHAR is better than BPE. It is because morphological changes in Finnish are quite complex. More fine-grained segmentation like CHAR is needed to learn corresponding rules. Conversely, German's morphological changes are so regular that BPE can learn most of merging rules, making them performing better.

low-resource When the corpus size is 50k to 200k, CHAR performs the best among four segmentation methods. BPE and Morfessor usually regard frequently occurring words as single tokens, many of which contain rich morphological information. This, together with the improper segmentation problem, prevents NMT models from learning correct composition rules, damaging the model's generalization ability on rare and unknown words. In low resource setting this problem would be more se-

[2]For example, English uses *he/she* to convey the masculine/feminine contrast, but Finnish uses the same pronoun *hän* regardless of the gender of the antecedent.

vere, since there are much more rare and unknown words but not enough data for learning compact composition rules.

Compared with subwords, character-based models learn combinations directly from character sequences. Not limited to fixed char sequence patterns in subwords, more words with different morphological changes can be generated through CHAR. Therefore, CHAR can learn more correct composition rules than subword-based model, leading to better translation of rare and unknown words.

3.3 Analysis on Rare and Unknown Words

To further support the above analysis, we evaluate the translation quality of rare and unknown words by calculating their recall rates. The results are showed in Figure 2. We can see that CHAR has achieved the highest recall rates of rare and unknown words. Although, as the resource increases, the gap between CHAR and BPE is shrinking gradually, the results can still prove that CHAR can capture more morpheme information, performing better at generating rare and unknown words.

4 Translation Across Distant Domains

Domain robustness (Müller et al., 2020), which refers to models' generalization ability on unseen domains, is important for NMT applications. However, subword algorithms need to learn segmentation rules from a given corpus, which may be domain-specific. When applied to a new domain, they may improperly segment target-domain specific words, hurting the domain robustness. In contrast, CHAR does not suffer from the issue. In this section, we investigate how different segmentation algorithms affect NMT models' domain robustness.

4.1 Experiment Setup

We use the same corpora as (Koehn and Knowles, 2017), which is a De-En dataset covering subsets of four domains: *Law*, *Medical*, *IT* and *Koran*. Following Koehn and Knowles (2017), each time we train a source domain model on one of four subsets and report results on test sets of the other three domain. We experiment in two settings: **No Adapt** and **Finetune**. The first one involves no target domain data, while the latter uses randomly sampled 100k sentence pairs from target domain data to finetune the source domain model.

4.2 Results

We report the average out-of-domain (OOD) BLEU scores of NMT systems based on different segmentation algorithms in Figure 3a and Figure 3b. As can be seen from the figure, CHAR surpasses other algorithms in almost all settings, except when finetuning from Medical to others. This illustrates the suitability of CHAR for domain robustness, especially when there is no enough data for adaptation.

4.3 Analysis on Different Types of Words

To understand the advantages of CHAR, we take the setting of finetuning from *IT* to *Medical* as an example and analyze performances on different types of words. Specifically, we divide words in the test set into three types: **(1) Domain-specific** words occur only in the target domain training data; **(2) Common** words occur in both the source and target domain training data; **(3) OOV** words *do not* occur in both training data.

The result can be seen in Figure 3c. CHAR achieves better performance on OOV words, which is consistent with findings in Section 3. While performances of CHAR and subword-based algorithms are on par on common words, CHAR outperforms the others by a large margin on domain-specific words. This suggests that the advantage of CHAR mainly comes from the correct translation of domain-specific and OOV words, which may be segmented improperly by subword algorithms.

	Word	Char	BPE	Morf.	BPE-D
No adapting	11.03	**12.46**	9.02	9.74	11.11
Finetune	30.26	**40.53**	39.53	38.49	40.26

Table 3: Average OOD BLEU of models based on different subword algorithms when adapting from *Law* to other domains. BPE-D: BPE-dropout (Provilkov et al., 2020)

4.4 Comparison with Advanced Segmentation Algorithms

Although we focus on deterministic segmentation algorithms in this paper, there are more advanced ones such as BPE-dropout (Provilkov et al., 2020) and subword regularization (Kudo, 2018), which produce multiple segmentation candidates when training and show improved performance. Therefore, we also conduct experiments comparing CHAR with BPE-dropout in terms of domain adaptation performance. We take the setting of adapting from *Law* to other domains and report results in Table 3. As can be seen, although BPE-dropout surpasses BPE by a large margin, CHAR still achieves the best performance, which again shows the superiority of CHAR.

5 Related Work

Character-level neural machine translation has received growing attention in recent years. Lee et al. (2017) first propose a fully character-level NMT model based on recurrent encoder-decoder architecture and convolutional layers, which shows a promising results. Gao et al. (2020) propose to incorporate convolution layers in the more advanced Transformer architecture and show their model can learn more robust character-level alignments.

However, translating at character level may incur significant computational overhead. Therefore, later works on character-level NMT (Cherry et al., 2018; Banar et al., 2020) mainly focus on reducing computation cost of them. Cherry et al. (2018) show that by employing source sequence compression techniques, the quality and efficiency of character-based models can be properly balanced. Banar et al. (2020) share the same idea as Cherry et al. (2018) but build their models using Transformer architecture. Our work differs from theirs in that we aim to analyze the performance of existing models instead of exploring novel architectures.

There are also several researches on comparison between CHAR and other subword algorithms (Durrani et al., 2019; Gupta et al., 2019). Durrani et al. (2019) compare character-based models and subword-based models in terms of representation quality, and find that representation learned by the former are more suitable for modeling morphology, and more robust to noisy input. Gupta et al. (2019) investigate the performance of different segmentation algorithms when using Transformer architecture, and find that character-based models can achieve better performance when translating noisy text or text from a different domain. Our finds are consistent with them, yet we conduct a more large-scale and in-depth analysis by covering language pairs from more language families and explaining where the advantage of character-based models comes from.

6 Conclusion

We conduct a comprehensive study and show advantages of CHAR over subword algorithms in three settings: translating to typologically diverse languages, translating with low resource, and adapting to distant domains. Note that although we have tried our best to take as much language pairs as possible into consideration, there are certainly a lot of languages remaining uncovered in this paper. However, we believe our experimental results can serve as an evidence of character-based NMT models' strong competitiveness. We hope more attention will be drawn to them, including exploring their more benefits and reducing the possibly higher computation cost in practice.

A Hyperparameters

We conduct a grid search of hyperparameters for the training of Transformer models, including batch size (tokens per batch) and learning rate. For batch size, the searching range is $\{4096, 8192, 16384, 32768\}$. For learning rate, the searching range is $\{5e-5, 1e-4, 5e-4, 1e-3\}$.

Besides, we also experiment with diffrent model size and number of bpe merges k in the low resource settings(50k, 100k, 200k). The searching range of k is $\{2000, 10000\}$. We consider four kinds of model size, i.e. *tiny*, *mini*, *small* and *base*, which differ in their hidden size and transformer layers. The details can be found in Table 4.

	hidden size	layer
tiny	128	2
mini	256	4
small	512	4
base	512	6

Abstract

Chinese word segmentation (CWS) is undoubtedly an important basic task in natural language processing. Previous works only focus on the textual modality, but there are often audio and video utterances (such as news broadcast and face-to-face dialogues), where textual, acoustic and visual modalities normally exist. To this end, we attempt to combine the multi-modality (mainly the converted text and actual voice information) to perform CWS. In this paper, we annotate a new dataset for CWS containing text and audio. Moreover, we propose a time-dependent multi-modal interactive model based on Transformer framework to integrate multi-modal information for word sequence labeling. The experimental results on three different training sets show the effectiveness of our approach with fusing text and audio.

1 Introduction

Word segmentation is a fundamental task in Natural Language Processing (NLP) for those languages without word delimiters, e.g., Chinese and many other East Asian languages (Duan and Zhao, 2020). In this paper, we mainly take Chinese language as investigating object, namely CWS. As we know, CWS has been applied as an essential preprocessing step for many other NLP tasks (Zhou et al., 2019; Qiu et al., 2020), such as named entity recognition, sentiment analysis, machine translation, etc.

In the literature, some popular approaches to CWS systems report a high performance at the level of 96%–98%, and these systems typically require a large scale of pre-segmented textual dataset for training. However, the collection of a specific scenario on such large scale is very time-consuming and resource-intensive, such as video monologues and audio broadcast. In these scenarios, there are multiple modalities: text, audio and vision, thus if only using the text seems not a good choice. For example, as shown in Figure 1, if we only read the text"必须不忘初心牢记使命" with no punctuation, it is not easy to make word segmentation immediately. However, if there is the acoustic information, we can observe the obvious stop in spectrum and sonic wave at the middle of "心" and "牢", which provides the facility for CWS.

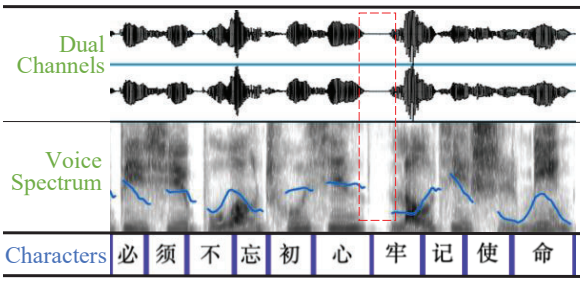

Figure 1: A multi-modal example for CWS. 必须(must) 不(not) 忘(forget) 初(original) 心(heart) 牢记(remember) 使命(mission).

Therefore, in this paper, we propose to performing CWS with multi-modality, namely MCWS, by a time-dependent multi-modal interactive network. Specifically, we first collect a new dataset from an audio and video news broadcast platform and annotate the word boundaries of audio transcription text. Second, we make the text and the audio align as the time stamp of each character, then encode both modalities [1] by Transformer-based framework to capture the intra-modal dynamics. Third, we design a time-dependent multi-modal interaction module for each character step to generate the multi-modal hybrid character representation.

*Corresponding author: lishoushan@suda.edu.cn

[1]Since each video in this platform mainly describe the specific news scene, not the face of the speaker, the visual modality is not useful for word segmentation. Therefore, for the sake of simplicity, we only utilize text and audio to perform CWS.

Finally, we leverage the CRF to perform sequence labeling on the basis of the above character representation.

We evaluate our approach on the newly annotated small-scale dataset with different size of training sets. The experimental results demonstrate that our approach performs significantly better than the single-modal state-of-the-art and the multi-modal approaches with early fused features of CWS.

2 Related Work

Xu (2003) first formalize CWS as a sequence labeling task, considering CWS as a supervised learning from annotated corpus with human segmentation. Peng et al. (2004) further adopt standard sequence labeling tool CRFs for CWS modeling, achieving a best performance in their same period. Then, a large amount of approaches based on above settings are proposed for CWS (Li and Sun, 2009; Sun and Xu, 2011; Mansur et al., 2013; Zhang et al., 2013).

Recently, deep neural approaches have been widely proposed to minimize the efforts in feature engineering for CWS (Zheng et al., 2013; Pei et al., 2014; Chen et al., 2015; Cai and Zhao, 2016; Zhou et al., 2017; Yang et al., 2017; Zhang et al., 2017; Ma et al., 2018; Li et al., 2019; Wang et al., 2019a; Fu et al., 2020; Ding et al., 2020; Tian et al., 2020a; Zhao et al., 2020). Among these studies, most of them follow the character-based paradigm to predict segmentation labels for each character in an input sentence. To enhance CWS with neural models, there were studies leverage external information, such as vocabularies from auto-segmented external corpus and weakly labeled data (Wang and Xu, 2017; Higashiyama et al., 2019; Gong et al., 2020).

To our best knowledge, we are first to perform CWS with multi-modality, which can deal with multi-modal scenarios and offers an alternative solution to robustly enhancing neural CWS models.

3 Data Collection and Annotation

We collect the multi-modal data for CWS from a Chinese news reporting platform "Xuexi"[2]. We mainly focus on the audios equipped with machine transcription text. In total, we crawl 120 short videos and segment them into about 2000 sentences. To avoid the contextual influence and augment the robust of designed computing model, we randomly select 250 sentences to annotate the word boundaries, and the remaining data are used to perform semi-supervised or unsupervised learning in the future.

[2]https://www.xuexi.cn/

Items	Size
Sentences	250
Avg. Length (Character)	50.56
Avg. Length (Word)	26.95
Avg. Length (Time)(s)	10.63
Max Length (Character)	382
Max Length (Word)	231
Max Length (Time)(s)	95.06
Total Characters	12640
Total Words	6736
Total Time(s)	2658.16

Table 1: The statistics summary for used data.

We annotate these Chinese audio transcriptions following the CTB word segmentation guidelines by Xia (2000). Two annotators are asked to annotate the data. Due to the clear annotation guideline, the annotation agreement is very high, reaching 98.3%. The disagreement instances are judged by an expert. The statistics of our annotated data are summarized in Table 1.

4 Time-dependent Multi-modal Interactive Network for CWS

In this section, we introduce our proposed multi-modal approach for CWS, namely Time-dependent Multi-modal interactive Network (TMIN), which can capture the interactive semantics between text and audio for better word segmentation. This approach mainly consists of three modules: time-dependent uni-modal interaction, time-dependent multi-modal interaction and CRF labeling. Figure 2 shows the overall architecture of our TMIN.

4.1 Time-dependent Uni-modal Interaction

To better capture the temporal correspondences between different modalities (Zhang et al., 2019; Ju et al., 2020), we first align two modalities by extracting the exact time stamp of each phoneme and character using Montreal Forced Aligner (McAuliffe et al., 2017).

For machines to understand human utterance, they must be first able to understand the intra-modal dynamics (Zadeh et al., 2018; Wang et al., 2019b; Tsai et al., 2019) in each modality, such as the word order and grammar in text, breathe and

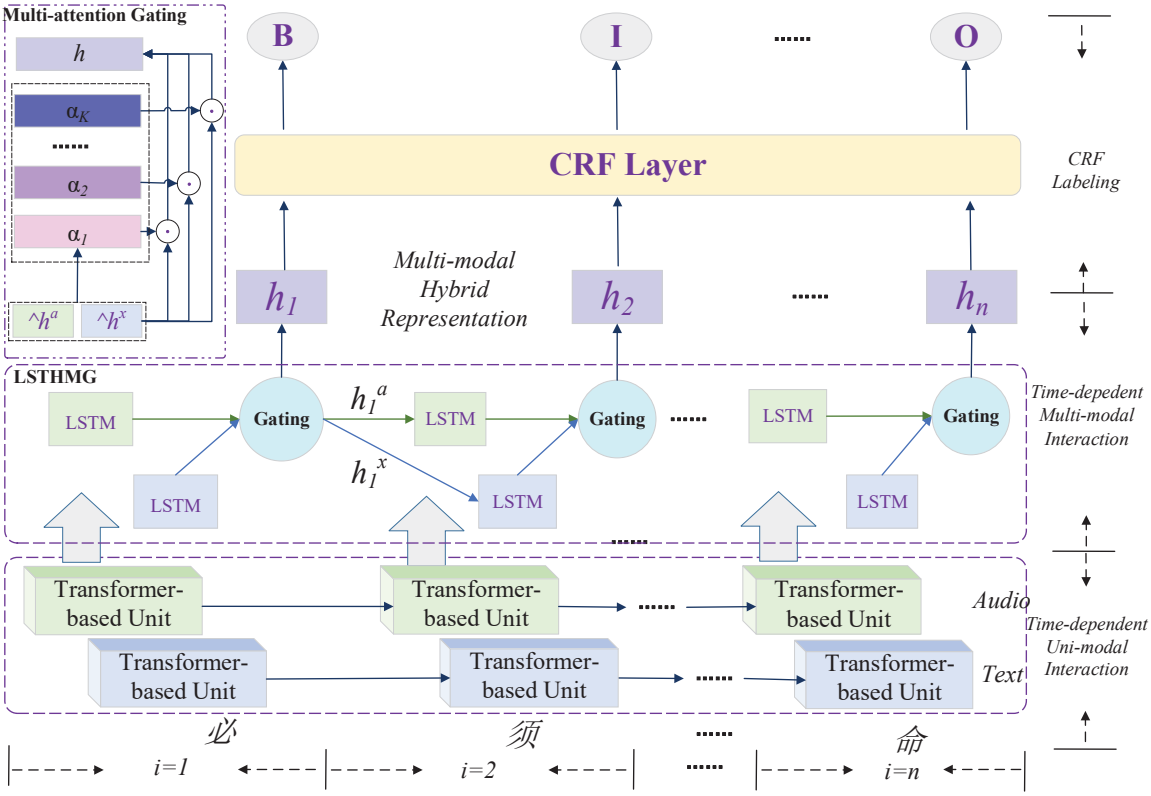

Figure 2: The overview of our proposed TMIN.

tone in audio.

Textual Modality. We use BERT (Devlin et al., 2019) as encoder to perform intra-modal interactions and obtain the contextual character representation. Then, each character of text transcripts can be represented as: $X = (x_1, x_2, \cdots, x_n) \in \mathbb{R}^{n \times d_1}$.

Acoustic Modality. We use a famous audio processing tool, i.e., OpenSMILE (Eyben et al., 2010), to extract the MFCC, LP-coefficients, pure FFT spectrum, etc. from dual channels (Jayram et al., 2002; Sakran et al., 2017), and leverage multiple Transformer layers (Vaswani et al., 2017) to perform intra-modal interactions. Then, each character-level audio feature can be represented as: $A = (a_1, a_2, \cdots, a_n) \in \mathbb{R}^{n \times d_2}$.

4.2 Time-dependent Multi-modal Interaction

To better capture the cross-modal semantic correspondences (Wu et al., 2020; Zhang et al., 2020), we design a long- and short-term hybrid memory gating (LSTHMG) block, which is a extension of standard LSTM.

We first obtain the current memory of each character-level representation for both modalities.

$$\hat{h}_i^x, c_i^x = \text{LSTM}_i^x(x_i, h_{i-1}^x, c_{i-1}^x) \quad (1)$$

$$\hat{h}_i^a, c_i^a = \text{LSTM}_i^a(a_i, h_{i-1}^a, c_{i-1}^a) \quad (2)$$

where LSTM denotes the standard LSTM (Graves et al., 2013).

After current updating, we employ multi-attention to control the different contributions of each hidden state.

$$h_i = \hat{h}_i + \text{MA}(\hat{h}_i^x, \hat{h}_i^a) \quad (3)$$

$$= \hat{h}_i + \sum_{l=0}^{L} (\text{softmax}(\frac{Q^l (K^l)^\top}{\sqrt{d}}) V^l) \quad (4)$$

where MA denotes the multi-attention gating mechanism, which is considered to mine multiple potential dimension-aware importance for each modality (Zadeh et al., 2018). $\hat{h}_i \in \mathbb{R}^{(d_1+d_2)\times 1}$ is the unsqueezed concatenation of $\hat{h}_i^x$ and $\hat{h}_i^a$. L denotes the max times for attentions. The query Q^l, key K^l and value V^l at the l-th time are defined similarly to self-attention (Vaswani et al., 2017):

$$Q^l = \hat{h}_i W_q^l, K^l = \hat{h}_i W_k^l, V^l = \hat{h}_i W_v^l \quad (5)$$

Note that h_i denotes the sum of L times attentional state concatenation for multi-modal representation at character-level step i, which is then used to perform word segmentation by CRF. Besides, we split each part for each modality as its own dimension: h_i^x and h_i^a, and input them into the next LSTHMG step.

Table 2: Performance (the overall F-score and the recall of OOV) comparison of different approaches on different training size. We perform a Friedman test on model- (row-) wise p-value< 0.05.

4.3 CRF Labeling

Since the textual and acoustic semantics of each character have been integrated by time-dependent uni-modal and multi-modal interactions, we allow h_i to perform conditional sequence labeling. Instead of decoding each label independently, we model them jointly using a CRF to consider the correlations between labels in neighborhoods. Formally,

$$p(y|\hat{X}) = \frac{\prod_{i=1}^{n} \mathcal{S}_i(y_{i-1}, y_i, \hat{X})}{\sum_{y' \in Y} \prod_{i=1}^{n} \mathcal{S}_i(y'_{i-1}, y'_i, \hat{X})} \quad (6)$$

where $\mathcal{S}_i(y_{i-1}, y_i, \hat{X})$ and $\mathcal{S}_i(y'_{i-1}, y'_i, \hat{X})$ are potential functions. $\hat{X}$ denotes the input of CRF. Y denotes the output label space.

We use the maximum conditional likelihood estimation for CRF training. The logarithm of likelihood is given by: $\sum_i \log p(y|\hat{X})$. In the inference phase, we predict the output sequence that obtains the maximum score given by: $\text{argmax}_{y' \in Y} p(y|\hat{X})$.

5 Experimentation

In this section, we provide the exploratory experimental results and a case analysis.

5.1 Experimental Setting

Data Split. We evaluate our approach on the different size of training sets and the same validation set and test set, i.e., 50, 100 and 150 sentences for training, the remaining 50 and 50 sentences for validation and test, respectively. For different training sets, the Out-of-vocabulary (OOV) rate in test set is 92.89%, 46.73% and 30.93%, respectively.

Implementation Details. The character embeddings of text X are initialized with the cased BERT_{base} model pre-trained with dimension of 768, and fine-tuned during training. The character-level embeddings of audio A are encoded by Transformer with dimension of 124. The learning rate, the dropout rate, and the tradeoff parameter are respectively set to 1e-4, 0.5, and 0.5, which can achieve the best performance on the development set of both datasets via a small grid search over the combinations of [1e-5, 1e-4], [0.1, 0.5], and [0.1, 0.9] on two pieces of NVIDIA GTX 2080Ti GPU with pytorch 1.7. Based on best-performed development results, the Transformer layers for audio encoding and the multi-attention times L in gating is set 2 and 4, respectively. To motivate future research, the dataset, aligned features and code will be released [3].

Baselines. For a thorough comparison, we implement the following approaches with F1 as metric: 1) BERT and CRF framework, **BC**: **BC(Text)** , **BC(Audio)**, and **BC(Text+Audio)**. 2) A representative state-of-the-art, **WMSEG** (Tian et al., 2020b): **WMSEG(Text)**, **WMSEG(Audio)**, and **WMSEG(Text+Audio)**. Note that the approaches with (Text) take character-level text as input, the approaches with (Audio) take character-level audio as input, and the approaches with (Text+Audio) take character-level concatenation of text and audio as input.

5.2 Main Results

Table 2 shows the performance of different baselines compared with our approach, where the overall F-score and the recall of OOV are reported. From this table we can see that:

1) **WMSEG** performs much better than the general framework **BC**. This indicates that it is effective for **WMSEG** to incorporate wordhood information with several popular encoder-decoder com-

[3] https://github.com/MANLP-suda/MCWS

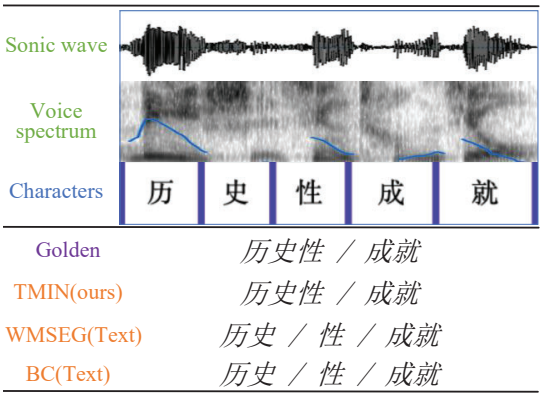

Figure 3: A case of the predicted results by different approaches. 1) 历史性(historic) 2) 历史(history), 性(sex) 3)成就(achievement).

binations and it is suitable as a competitive baseline.

2) The approach with only audio perform significantly worse than the approaches with text only, suggesting that it is confusing of the various acoustic features and we should utilize audio modality properly.

3) In most cases, the baselines with both text and audio bring in a poor performance compared with uni-modal approach, which suggests that simply concatenation of time-dependent character-level features for CWS seems a bad choice.

4) Among all approaches, our **TMIN** performs best, and significantly outperforms the competitive baselines (p-value<0.05). Moreover, with regard to R_{oov}, we can observe that our **TMIN** is able to recognize new words more accurately. This is mainly because our approach can obtain effective multi-modal information by time-dependent fusion against only textual, acoustic or early fused approaches.

5.3 Case Study

Figure 3 illustrates a real instance of the predicted boundaries by different approaches. From this figure, we can see that both **WMSRG** and **BC** give the wrong prediction of the boundary in "史" and "性" though they determine the correct segmentation for "历史" and "成就". However, our **TMIN** achieves all exact segmentation of this instance. This is mainly because it is very effective for audio, where there are a continuous breathing in the character " 性", thus "历史性" is a complete word.

6 Conclusion and Future Work

This paper proposes a new dataset for multi-modal Chinese word segmentation (MCWS), which is the first attempt to explore the multi-modality for traditional CWS. Meanwhile, we propose a time-dependent multi-modal interactive network (TMIN) to effectively integrate textual and acoustic features. The preliminary experimental results and case analysis demonstrate the reliability of our motivation and the effectiveness of the proposed approach.

In the future, we will annotate more samples at the current setting, and collect new samples with more modalities, such as visual information in social media, monologues and dialogues with continuous front face. Moreover, we will employ the neural active learning approaches for MCWS to reduce the annotation and achieve the best performance.

Abstract

Discrimination between antonyms and synonyms is an important and challenging NLP task. Antonyms and synonyms often share the same or similar contexts and thus are hard to make a distinction. This paper proposes two underlying hypotheses and employs the mixture-of-experts framework as a solution. It works on the basis of a divide-and-conquer strategy, where a number of localized experts focus on their own domains (or subspaces) to learn their specialties, and a gating mechanism determines the space partitioning and the expert mixture. Experimental results have shown that our method achieves the state-of-the-art performance on the task.

1 Introduction

Antonymy-synonymy discrimination (ASD) is a crucial problem in lexical semantics and plays a vital role in many NLP applications such as sentiment analysis, textual entailment and machine translation. Synonymy refers to semantically-similar words (having similar meanings), while antonymy indicates the oppositeness or contrastiveness of words (having opposite meanings). Although telling apart antonyms and synonyms looks simple on the surface, it actually poses a hard problem because of their interchangeable substitution.

A few research efforts have been devoted to computational solutions of ASD task, which comprises two mainstreams: *pattern-based* and *distributional* approaches. The underlying idea of pattern-based methods exists in that antonymous word pairs co-occur with each other in some antonymy-indicating lexico-syntactic patterns within a sentence (Roth and im Walde, 2014; Nguyen et al., 2017). In spite of their high precision, pattern-based methods suffer from limited recall owing to the sparsity of lexico-syntactic patterns and the lexical variations.

Distributional methods work on the basis of *distributional hypothesis* stating that "the words similar in meaning tend to occur in similar contexts" (Harris, 1954). Traditional distributional methods are based on discrete context vectors. Scheible et al. (2013) verified that using only the contexts of certain classes can help discriminate antonyms and synonyms. Santus et al. (2014) thought that synonyms are expected to have broader and more salient intersection of their top-K salient contexts than antonyms, and proposed an Average-Precision-based unsupervised measure.

With the advent of word embeddings as the continuous representations (Mikolov et al., 2013; Mnih and Kavukcuoglu, 2013; Pennington et al., 2014), several neural methods have been proposed to elicit ASD-specific information from pretrained word embeddings in a supervised manner. Etcheverry and Wonsever (2019) used a siamese network to ensure the symmetric, reflexive and transitive properties of synonymy and a parasiamese network to model the antitransitivity of antonymy. Ali et al. (2019) projected word embeddings into the synonym and antonym subspaces respectively, and then trained a classifier on the features from these distilled subspaces, where the trans-transitivity of antonymy was taken into consideration.

This paper follows the distributional approach and studies the ASD problem on the basis of pretrained word embeddings. Two hypotheses underlie our method: (a) antonymous words tend to be similar on most semantic dimensions but be different on only a few salient dimensions; (b) the salient dimensions may vary significantly for different antonymies throughout the whole distributional semantic space. With respect to the hypothesis (b), we find that a tailored model of mixture-of-experts (MoE) (Jacobs et al., 1991) fits it well. The semantic space is divided into a number of subspaces, and each subspace has one specialized expert to elicit

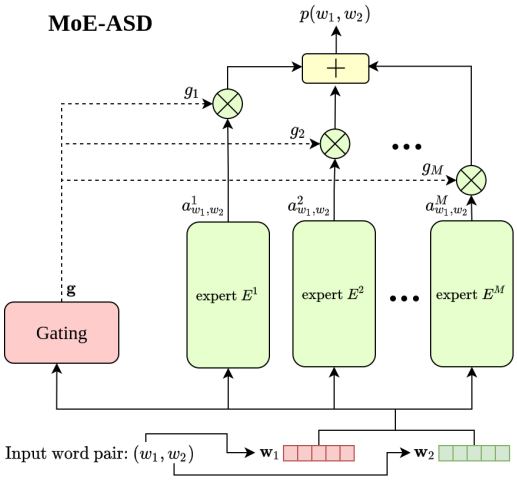

Figure 1: The architecture of MoE-ASD

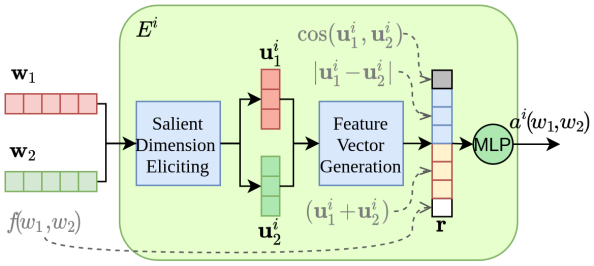

Figure 2: A localized expert

the salient dimensions and learn a discriminator for this subspace. As to the hypothesis (a), a similar opinion was also expressed by Cruse (1986) that antonymous words tend to have many common properties, but differ saliently along one dimension of meaning. In addition, our experimental results have shown that each expert requires only four salient dimensions to achieve the best performance.

Finally, we would like to point out the main difference of our method from the existing ones. Firstly, our MoE-ASD model adopts a divide-and-conquer strategy, where each subspace is in the charge of one relatively-simple localized expert that focuses on only a few salient dimensions; while existing methods rely on a global model which must grasp all the salient dimensions across all the subspaces. Secondly, our method simply enforces the symmetric property of synonymy and antonymy, but ignores the other algebraic properties such as the transitivity of synonymy and trans-transitivity of antonymy, because these algebraic properties do not always hold on the word level for the polysemy characteristic of words.

2 Method

This paper proposes a novel ASD method based on the mixture-of-experts framework (called **MoE-ASD**)[1]. Its architecture is illustrated in Figure 1. It solves the problem in a divide-and-conquer manner by dividing the problem space into a number of subspaces and each subspace is in the charge of a specialized expert. The expert focuses on the salient dimensions of the subspace and makes the decision for word pairs. A gating module is trained jointly with these experts. The details are as follows.

2.1 Localized Experts

All the experts are homogeneous, and they have the same network architecture but with different parameter values. Given a word pair (w_1, w_2) as input, each expert E^i computes its unnormalized probability $a^i(w_1, w_2)$ of being antonymy. As stated in Section 1, our method adopts the hypothesis that antonymous words tend to be similar on most semantic dimensions but be different on a few salient dimensions. Each expert has to first elicit the salient dimensions, and then makes a decision based on a feature vector constructed from them. Figure 2 illustrates how an expert works.

Let $\mathbf{w}_1$ and $\mathbf{w}_2$ denote the pre-trained word embeddings of words w_1 and w_2 respectively, whose dimensionality is d_e. Each expert E^i distills d_u salient dimensions from them by projecting them from $\mathbb{R}^{d_e}$ into $\mathbb{R}^{d_u}$:

$$\mathbf{u}^i_1 = \mathbf{w}_1 \cdot \mathbf{M}^i_u + \mathbf{b}^i_u \text{ and } \mathbf{u}^i_2 = \mathbf{w}_2 \cdot \mathbf{M}^i_u + \mathbf{b}^i_u \quad (1)$$

where $\mathbf{M}^i$ is a matrix of size $d_e \times d_u$ and $\mathbf{b}^i$ is a vector of length d_u. Next, a relational feature vector $\mathbf{r}$ is constructed by concatenating the sum $(\mathbf{u}^i_1 + \mathbf{u}^i_2)$, the absolute difference $|\mathbf{u}^i_1 - \mathbf{u}^i_2|$, the cosine similarity $\cos(\mathbf{u}^i_1, \mathbf{u}^i_2)$ and the prefix feature f_{w_1,w_2}:

$$\mathbf{r} = (\mathbf{u}^i_1 + \mathbf{u}^i_2) \oplus |\mathbf{u}^i_1 - \mathbf{u}^i_2| \oplus \cos(\mathbf{u}^i_1, \mathbf{u}^i_2) \oplus f_{w_1,w_2} \quad (2)$$

Here, f_{w_1,w_2} is the Negation-Prefix feature that denotes whether w_1 and w_2 differ only by one of the known negation prefixes: {*de*, *a*, *un*, *non*, *in*, *ir*, *anti*, *il*, *dis*, *counter*, *im*, *an*, *sub*, *ab*}, following Ali et al. (2019) and Rajana et al. (2017).

It is evident that the feature vector is symmetric with respect to the input word pair. This is,

[1] Our code and data are released at https://github.com/Zengnan1997/MoE-ASD

the word pairs (w_1, w_2) and (w_2, w_1) lead to the same feature vector. It is worth noting that the absolute difference is used instead of the difference, in order to preserve the symmetric properties of both synonymy and antonymy. We note that Roller et al. (2014) used the difference between two word vectors as useful features for detecting hypernymy which is asymmetric.

The relational feature vector $\mathbf{r}$ goes through an MLP to get the antonymy-score $a^i(w_1, w_2)$:

$$a^i(w_1, w_2) = (\mathbf{m}_o^i)^\top \cdot \text{ReLU}(\mathbf{r} \cdot \mathbf{M}_h^i + \mathbf{b}_h^i) + b_o^i \quad (3)$$

where the hidden layer has d_h units, $\mathbf{M}_h^i$ is a matrix of size $(2d_u + 2) \times d_h$, $\mathbf{b}_h^i$ and $\mathbf{m}_o^i$ are two vectors of length d_h, and b_o^i is the bias.

2.2 Gating Mechanism for Expert Mixture

Assume there are M localized experts in the MoE-ASD model. For an input word pair (w_1, w_2), we shall get M antonymy-scores $\mathbf{a} = [a^i(w_1, w_2)]_{1 \le i \le M}$, where each $a^i(w_1, w_2)$ is obtained from the expert E^i. Now, the problem is how to derive the final score for antonymy detection.

In our MoE-ASD model, the *final score* is a weighted average of the M scores from the localized experts:

$$s(w_1, w_2) = \mathbf{g}^\top \cdot \mathbf{a} \quad (4)$$

where $\mathbf{g}$ is located in the M-dimensional simplex, and denotes the proportional contributions of the experts to the final score. A gating mechanism is used to calculate $\mathbf{g}$ for each specific word pair (w_1, w_2), fulfilling a dynamic mixture of experts:

$$\mathbf{g} = \text{softmax}\left((\mathbf{w}_1 + \mathbf{w}_2)^\top \cdot \mathbf{M}_g\right) \quad (5)$$

where $\mathbf{M}_g \in \mathbb{R}^{d_e \times M}$ is the parameter matrix of the gating module. The i-th column of $\mathbf{M}_g$ can be thought of as the representative vector of the i-the expert, and the dot product between the sum of two word embeddings and the representative vector is the attention weight of the expert E^i. Softmax is then applied on the attention weights to get $\mathbf{g}$. It is evident that the gating module is also symmetric with respect to the input word pair. The symmetric properties of both the gating module and the local expert module endow our model with symmetry that make it distinct from the other state-of-the-arts such as **Parasiam** (Etcheverry and Wonsever, 2019) and **Distiller** (Ali et al., 2019).

Table 1: Antonym/Synonym Dataset

2.3 Model Prediction and Loss Function

Given word pair (w_1, w_2), the probability of being antonymy is obtained by simply applying sigmoid function to the final score:

$$p(w_1, w_2) = \sigma(s(w_1, w_2)) \quad (6)$$

Let A denote the training set of N word pairs, $A = \{(w_1^{(n)}, w_2^{(n)})\}_{n=1}^N$, $t^{(n)}$ denote the gold label of the n-th word pair, and $p^{(n)}$ the predicted probability of being antonymy. Our model uses the cross-entropy loss function:

$$L = \frac{1}{N} \sum_{n=1}^{N} \left[t^{(n)} \log p^{(n)} + \left(1 - t^{(n)}\right) \log \left(1 - p^{(n)}\right) \right] \quad (7)$$

3 Evaluation

Dataset. We evaluate our method on the dataset (Nguyen et al., 2017) that was previously created from WordNet (Miller, 1995) and Wordnik[2]. The word pairs of antonyms and synonyms were grouped according to the word class (*Adjective*, *Noun* and *Verb*). The ratio of antonyms to synonyms in each group is 1:1. The statistics of the dataset are shown in Table 1. In order to make a fair comparison with previous algorithms, the dataset is splitted into training, validation and testing data the same as previous works.

Methods for Comparison: We make a comparison against the following ASD methods: (1) **Concat** - a baseline method that concatenates two word vectors and feeds it into an MLP with two hidden layers (with 400 and 200 hidden units respectively) and ReLU activation functions. (2) **AntSynNET** (Nguyen et al., 2017) is a pattern-based method that encodes the paths connecting the joint occurrences of candidate pairs using a LSTM; (3) **Parasiam** (Etcheverry and Wonsever, 2019) used a siamese network and a parasiamese network to ensure the algebraic properties of synonym and antonym, respectively. (4) **Distiller** (Ali et al., 2019) is a two-phase method that first distills

task-specific information and then trains a classifier based on distilled sub-spaces.

3.1 Experimental Settings

We use the 300-dimension FastText word embeddings (Bojanowski et al., 2017)[3]. The model is optimized with the Adam algorithm (Kingma and Ba, 2015). We run our algorithm 10 times and record the average Precision, Recall and F-scores. The number of salient dimensions (d_u) and the number of localized experts (M) are tuned on the validation data by grid search, with $M \in \{2^i\}_{1 \leq i \leq 8}$ and $d_u \in \{2^i\}_{1 \leq i \leq 8}$. The best configuration is ($d_u = 4, M = 256$) for both *Noun* and *Verb*, while ($d_u = 4, M = 128$) for *Adjective*.

3.2 Comparison with SOTA methods

Table 2 compares our method with the state-of-the-arts, which are restricted to pretrained vanilla word embeddings. Both the Parasiam method and our MoE-ASD method use FastText embeddings (Bojanowski et al., 2017), while *Distiller* uses Glove embeddings (Pennington et al., 2014).

It is observed that our model consistently outperforms the state-of-the-arts on all the three subtasks, which manifests the effectiveness of the mixture-of-experts model for ASD and validates the hypothesis (b) that the salient dimensions may vary significantly throughout the whole space.

We also find that the performance on *Noun* class is relatively low when compared with *Verb* and *Adjective* classes, which coincide with the observations obtained in (Scheible et al., 2013; Ali et al., 2019), possibly for the reason that polysemy phenomenon is more significant among nouns.

F1-score	Adjective	Verb	Noun
Our full method	0.892	0.908	0.869
–prefix feature	0.886	0.905	0.868
–cosine sim	0.883	0.905	0.856
–absolute diff	0.890	0.897	0.866
–sum	0.888	0.903	0.867

Table 4: Ablation analysis of the features

Besides vanilla word embeddings, existing ASD methods also used dLCE (Nguyen et al., 2016) embeddings, and often obtained better results. However, a large number of antonymies and synonymies have been used in the process of learning dLCE embeddings, which may lead to severe overfitting. In spite of this concern, we also test our method with dLCE embeddings on the dataset and find that it outperforms these competitors with dLCE and list the results in Table 3.

3.3 Ablation Analysis of Features

We also make an ablation analysis about the four kinds of features, by removing each of them from our model. It can be seen from Table 4 that all the features are making their own contributions to the ASD. Different parts of speech have different sensitivities to different features. Specifically, verb is most sensitive to "*absolute difference*", while both adjective and noun are most sensitive to "*cosine*". The reason behind the observations deserves further exploration.

newdataset	Model	Adjective			Verb			Noun		
		P	R	F1	P	R	F1	P	R	F1
FastText	Parasiam	0.694	**0.866**	0.769	0.642	**0.824**	0.719	0.740	**0.759**	0.748
	MoE-ASD	**0.808**	0.810	**0.809**	**0.830**	0.693	**0.753**	**0.846**	0.722	**0.776**

	MoE-ASD	**0.877**	0.908	**0.892**	**0.860**	0.835	**0.847**	**0.912**	0.869	**0.890**

Table 5: Performance of our model and the baseline models on the lexical-split datasets

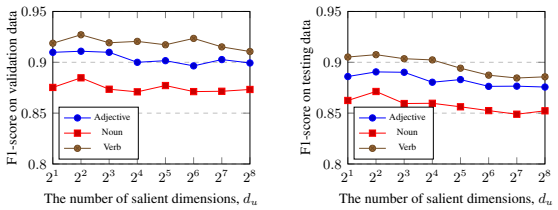

Figure 3: The effect on performance by varying the number of salient dimensions (fixing $M = 256$)

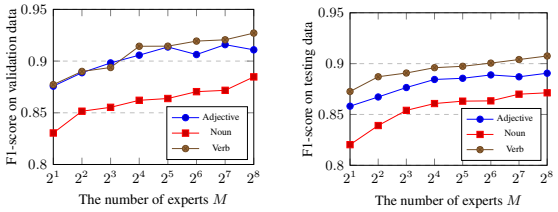

Figure 4: The effect on performance by varying the number of experts (fixing $d_u = 4$)

3.4 Hyperparameter Analysis

The number of salient dimensions (d_u) and the number of experts (M) are two prominent hyper-parameters in our MOE-ASD model. By varying their values, we study their influence on the performance.

Firstly, by fixing $M = 256$, we vary d_u from 2^1 to 2^8 and plot the F1-scores on the validation data and the testing data in Figure 3. It is observed that all the three subtasks (*Adjective*, *Noun* and *Verb*) arrive at the best performance at $d_u = 4$ on both validation data and testing data. It validates our hypothesis (a) that antonymous words tend to be different on only a few salient dimensions.

Secondly, by fixing $d_u = 4$, we vary M from 2^1 to 2^8 and plot the F1-scores in Figure 4. Overall, the performance becomes better with the larger number of experts. We conjecture that marginal improvement will be obtained by increasing the number of experts further, but we do not make such experiments.

Category	Train	Dev	Test	Total
Adjective	4227	303	1498	6028
Verb	2034	146	712	2892
Noun	2667	191	954	3812

Table 6: The datasets after lexical split

3.5 Lexical Memorization

To eliminate the bias introduced by the lexical memorization problem (Levy et al., 2015), we perform lexical splits to obtain train and test datasets with zero lexical overlap. The statistics of the lexical-split datasets are listed in Table 6. Table 5 shows the results of our method and Parasiam on the lexical-split datasets by using FastText and dLCE pretrained word embeddings. It can be seen that our MoE-ASD model outperforms Parasiam on all three lexical-split datasets. However, significant decreases in the F1 scores are also observed.

4 Conclusions

This paper first presents two hypotheses for ASD task (i.e., antonymous words tend to be different on only a few salient dimensions that may vary significantly for different antonymies) and then motivates an ASD method based on mixture-of-experts. Finally, experimental results have manifested its effectiveness and validated the two underlying hypotheses. It is worth noting that our method is distinct from the other state-of-the-arts in two main aspects: (1) it works in a *divide-and-conquer* strategy by dividing the whole space into multiple subspaces and having one expert specialized for each subspace; (2) it is *inherently symmetric* with respect to the input word pair.

{fl399, iv250, alk23, nhc30}cam.ac.uk

Abstract

Injecting external domain-specific knowledge (e.g., UMLS) into pretrained language models (LMs) advances their capability to handle specialised in-domain tasks such as biomedical entity linking (BEL). However, such abundant expert knowledge is available only for a handful of languages (e.g., English). In this work, by proposing a novel cross-lingual biomedical entity linking task (XL-BEL) and establishing a new XL-BEL benchmark spanning 10 typologically diverse languages, we first investigate the ability of standard knowledge-agnostic as well as knowledge-enhanced monolingual and multilingual LMs beyond the standard monolingual English BEL task. The scores indicate large gaps to English performance. We then address the challenge of transferring domain-specific knowledge from resource-rich languages to resource-poor ones. To this end, we propose and evaluate a series of cross-lingual transfer methods for the XL-BEL task, and demonstrate that general-domain bitext helps propagate the available English knowledge to languages with little to no in-domain data. Remarkably, we show that our proposed domain-specific transfer methods yield consistent gains across all target languages, sometimes up to 20 Precision@1 points, without any in-domain knowledge in the target language, and without any in-domain parallel data.

1 Introduction

Recent work has demonstrated that it is possible to combine the strength of 1) Transformer-based encoders such as BERT (Devlin et al., 2019; Liu et al., 2019), pretrained on large general-domain data with 2) external linguistic and world knowledge (Zhang et al., 2019; Levine et al., 2020; Lauscher et al., 2020). Such expert human-curated knowledge is crucial for NLP applications in specialised domains such as biomedicine. There, Liu et al. (2021) recently proposed *self-alignment pretraining* (SAP), a technique to fine-tune BERT on phrase-level synonyms extracted from the Unified Medical Language System (UMLS; Bodenreider 2004).[1] Their SAPBERT model currently holds state-of-the-art (SotA) across all major English biomedical entity linking (BEL) datasets. However, this approach is not widely applicable to other languages: abundant external resources are available only for a few languages, hindering the development of domain-specific NLP models in all other languages.

Simultaneously, exciting breakthroughs in cross-lingual transfer for language understanding tasks have been achieved (Artetxe and Schwenk, 2019; Hu et al., 2020). However, it remains unclear whether such transfer techniques can be used to improve domain-specific NLP applications and mitigate the gap between knowledge-enhanced models in resource-rich versus resource-poor languages. In this paper, we thus investigate the current performance gaps in the BEL task beyond English, and propose several cross-lingual transfer techniques to improve domain-specialised representations and BEL in resource-lean languages.

In particular, we first present a novel cross-lingual BEL (XL-BEL) task and its corresponding evaluation benchmark in 10 typologically diverse languages, which aims to map biomedical names/mentions in any language to the controlled UMLS vocabulary. After empirically highlighting the deficiencies of multilingual encoders (e.g, MBERT and XLMR; Conneau et al. 2020) on XL-BEL, we propose and evaluate a multilingual extension of the SAP technique. Our main results suggest that expert knowledge can be transferred from English to resource-leaner languages, yielding huge gains over vanilla MBERT and XLMR, and English-only SAPBERT. We also show that

[1] UMLS is a large-scale biomedical knowledge graph containing more than 14M biomedical entity names.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 565–574

leveraging general-domain word and phrase translations offers substantial gains in the XL-BEL task.

Contributions. **1)** We highlight the challenge of learning (biomedical) domain-specialised cross-lingual representations. **2)** We propose a novel multilingual XL-BEL task with a comprehensive evaluation benchmark in 10 languages. **3)** We offer systematic evaluations of existing knowledge-agnostic and knowledge-enhanced monolingual and multilingual LMs in the XL-BEL task. **4)** We present a new SotA multilingual encoder in the biomedical domain, which yields large gains in XL-BEL especially on resource-poor languages, and provides strong benchmarking results to guide future work. The code, data, and pretrained models are available online at: `github.com/cambridgeltl/sapbert`.

2 Methodology

Background and Related Work. Learning biomedical entity representations is at the core of BioNLP, benefiting, e.g., relational knowledge discovery (Wang et al., 2018) and literature search (Lee et al., 2016). In the current era of contextualised representations based on Transformer architectures (Vaswani et al., 2017), biomedical text encoders are pretrained via Masked Language Modelling (MLM) on diverse biomedical texts such as PubMed articles (Lee et al., 2020; Gu et al., 2020), clinical notes (Peng et al., 2019; Alsentzer et al., 2019), and even online health forum posts (Basaldella et al., 2020). However, it has been empirically verified that naively applying MLM-pretrained models as entity encoders does not perform well in tasks such as biomedical entity linking (Basaldella et al., 2020; Sung et al., 2020). Recently, Liu et al. (2021) proposed SAP (**S**elf-**A**lignment **P**retraning), a fine-tuning method that leverages synonymy sets extracted from UMLS to improve BERT's ability to act as a biomedical entity encoder. Their SAPBERT model currently achieves SotA scores on all major English BEL benchmarks.

In what follows, we first outline the SAP procedure, and then discuss the extension of the method to include multilingual UMLS synonyms (§2.1), and then introduce another SAP extension which combines domain-specific synonyms with general-domain translation data (§2.2).

2.1 Language-Agnostic SAP

Let $(x, y) \in \mathcal{X} \times \mathcal{Y}$ denote the tuple of a name and its categorical label. When learning from UMLS synonyms, $\mathcal{X} \times \mathcal{Y}$ is the set of all *(name, CUI*[2]*)* pairs, e.g., (*vaccination*, `C0042196`). While Liu et al. (2021) use only English names, we here consider names in other UMLS languages. During training, the model is steered to create similar representations for synonyms regardless of their language.[3] The learning scheme includes 1) an online sampling procedure to select training examples and 2) a metric learning loss that encourages strings sharing the same CUI to obtain similar representations.

Training Examples. Given a mini-batch of N examples $\mathcal{B} = \mathcal{X}_\mathcal{B} \times \mathcal{Y}_\mathcal{B} = \{(x_i, y_i)\}_{i=1}^{N}$, we start from constructing all possible triplets for all names $x_i \in \mathcal{X}_\mathcal{B}$. Each triplet is in the form of (x_a, x_p, x_n) where x_a is the *anchor*, an arbitrary name from $\mathcal{X}_\mathcal{B}$; x_p is a positive match of x_a (i.e., $y_a = y_p$) and x_n is a negative match of x_a (i.e., $y_a \neq y_n$). Let $f(\cdot)$ denote the encoder (i.e., MBERT or XLMR in this paper). Among the constructed triplets, we select all triplets that satisfy the following constraint:

$$\|f(x_a) - f(x_p)\|_2 + \lambda \geq \|f(x_a) - f(x_n)\|_2,$$

where λ is a predefined margin. In other words, we only consider triplets with the positive sample further to the negative sample by a margin of λ. These 'hard' triplets are more informative for representation learning (Liu et al., 2021). Every selected triplet then contributes one positive pair (x_a, x_p) and one negative pair (x_a, x_n). We collect all such positives and negatives, and denote them as $\mathcal{P}, \mathcal{N}$.

Multi-Similarity Loss. We compute the pairwise cosine similarity of all the name representations and obtain a similarity matrix $\mathbf{S} \in \mathbb{R}^{|\mathcal{X}_\mathcal{B}| \times |\mathcal{X}_\mathcal{B}|}$ where each entry $\mathbf{S}_{ij}$ is the cosine similarity between the i-th and j-th names in the mini-batch $\mathcal{B}$. The Multi-Similarity loss (MS, Wang et al. 2019), is then used for learning from the triplets:

$$\mathcal{L} = \frac{1}{|\mathcal{X}_\mathcal{B}|} \sum_{i=1}^{|\mathcal{X}_\mathcal{B}|} \left(\frac{1}{\alpha} \log \left(1 + \sum_{n \in \mathcal{N}_i} e^{\alpha(\mathbf{S}_{in} - \epsilon)} \right) + \frac{1}{\beta} \log \left(1 + \sum_{p \in \mathcal{P}_i} e^{-\beta(\mathbf{S}_{ip} - \epsilon)} \right) \right). \quad (1)$$

α, β are temperature scales; ϵ is an offset applied on the similarity matrix; $\mathcal{P}_i, \mathcal{N}_i$ are indices of positive and negative samples of the i-th *anchor*.

[2] In UMLS, "CUI" means **C**oncept **U**nique **I**dentifier.

[3] For instance, *vaccination* (EN), *active immunization* (EN), *vacunación* (ES) and 予防接種 (JA) all share the same Concept Unique Identifier (CUI; `C0042196`); thus, they should all have similar representations.

Table 1: Construction of the XL-BEL benchmark; key statistics. See the App. §A.1 for further details.

2.2 SAP with General-Domain Bitext

We also convert word and phrase translations into the same format (§2.1), where each 'class' now contains only two examples. For a translation pair (x_p, x_q), we create a unique pseudo-label y_{x_p,x_q} and produce two new name-label instances (x_p, y_{x_p,x_q}) and (x_q, y_{x_p,x_q}),[4] and proceed as in §2.1. This allows us to easily combine domain-specific knowledge with general translation knowledge within the same SAP framework.

3 The XL-BEL Task and Evaluation Data

A general cross-lingual entity linking (EL) task (McNamee et al., 2011; Tsai and Roth, 2016) aims to map a mention of an entity in free text of *any language* to a controlled English vocabulary, typically obtained from a knowledge graph (KG). In this work, we propose XL-BEL, a cross-lingual *biomedical* EL task. Instead of grounding entity mentions to English-specific ontologies, we use UMLS as a language-agnostic KG: the XL-BEL task requires a model to associate a mention in any language to a (language-agnostic) CUI in UMLS. XL-BEL thus serves as an ideal evaluation benchmark for biomedical entity representations: it challenges the capability of both 1) representing domain entities and also 2) associating entity names in different languages.

Evaluation Data Creation. For English, we take the available BEL dataset WikiMed (Vashishth et al., 2020), which links Wikipedia mentions to UMLS CUIs. We then follow similar procedures as WikiMed and create an XL-BEL benchmark covering 10 languages (see Table 2). For each language, we extract all sentences from its Wikipedia dump, find all hyperlinked concepts (i.e., words and phrases), lookup their Wikipedia pages, and retain only concepts that are linked to UMLS.[5] For each UMLS-linked mention, we add a triplet *(sentence, mention, CUI)* to our dataset.[6] Only one example per surface form is retained to ensure diversity. We then filter out examples with mentions that have the same surface form as their Wikipedia article page.[7] Finally, 1k examples are randomly selected for each language: they serve as the final test sets in our XL-BEL benchmark. The statistics of the benchmark are available in Table 1.

4 Experiments and Results

UMLS Data. We rely on the UMLS (2020AA) as our SAP fine-tuning data, leveraging synonyms in all available languages. The full multilingual fine-tuning data comprises ≈15M biomedical entity names associated with ≈4.2M individual CUIs. As expected, English is dominant (69.6% of all 15M names), followed by Spanish (10.7%) and French (2.2%). The full stats are in App. §A.3.

Translation Data. We use (a) "muse" word translations (Lample et al., 2018), and (b) the parallel Wikipedia article titles (phrase-level translations; referred to as "wt"). We also list results when using "muse" and "wt" combined ("wt+ muse").

Training and Evaluation Details. Our SAP fine-tuning largely follows Liu et al. (2021); we refer to the original work and the Appendix for further tech-

[4] These pseudo-labels are not related to UMLS, but are used to format our parallel translation data into the input convenient for the SAP procedure. In practice, for these data we generate pseudo-labels ourselves as 'LANGUAGE_CODE+index'. For instance, `ENDE2344` indicates that this word pair is our 2,344th English-German word translation. Note that the actual coding scheme does not matter as it is only used for our algorithm to determine what terms belong to the same (in this case - translation) category.

[5] For instance, given a sentence from German Wikipedia *Die [Inkubationszeit] von COVID-19 beträgt durchschnittlich fünf bis sechs Tage.*, we extract the hyperlinked word *Inkubationszeit* as an UMLS-linked entity mention. Since Wikipedia is inherently multilingual, if *Inkubationszeit* is linked to UMLS, its cross-lingual counterparts, e.g., *Incubation period* (EN), are all transitively linked to UMLS.

[6] Note that though each mention is accompanied with its context, we regard it as out-of-context mention following the tradition in prior work (Sung et al., 2020; Liu et al., 2021; Tutubalina et al., 2020). According to Basaldella et al. (2020), biomedical entity representations can be easily polluted by its context. We leave contextual modelling for future work.

[7] Otherwise, the problem is easily solved by comparing surface forms of the mention and the article title.

Table 3: Results when applying SAP with 1) UMLS knowledge + 2) word and/or phrase translations.

nical details. The evaluation measure is standard Precision@1 and Precision@5. In all experiments, SAP always denotes fine-tuning of a base LM with UMLS data. `[CLS]` of the last layer's output is used as the final representation (Liu et al., 2021). Without explicit mentioning, we use the BASE variants of all monolingual and multilingual LMs. At inference, given a query representation, a nearest neighbour search is used to rank all candidates' representations. We restrict the target ontology to only include CUIs that appear in WikiMed (62,531 CUIs, 399,931 entity names).

4.1 Main Results and Discussion

Multilingual UMLS Knowledge Always Helps (Table 2). Table 2 summarises the results of applying multilingual SAP fine-tuning based on UMLS knowledge on a wide variety of monolingual, multilingual, and in-domain pretrained encoders. Injecting UMLS knowledge is consistently beneficial to the models' performance on XL-BEL across all languages and across all base encoders. Using multilingual UMLS synonyms to SAP-fine-tune the biomedical PUBMEDBERT (SAPBERT$_{all_syn}$) instead of English-only synonyms (SAPBERT) improves its performance across the board. SAP-ing monolingual BERTs for each language also yields substantial gains across all languages; the only exception is Thai (TH), which is not represented in UMLS. Fine-tuning multilingual models MBERT and XLMR leads to even larger relative gains.

Performance across Languages (Table 2). UMLS data is heavily biased towards Romance and Germanic languages. As a result, for languages more similar to these families, monolingual LMs (upper half, Table 2) are on par or outperform multilingual LMs (lower half, Table 2). However, for other (distant) languages (e.g., KO, ZH, JA, TH), the opposite holds. For instance, on TH, XLMR+SAP$_{all_syn}$ outperforms THBERT+SAP$_{all_syn}$ by 20% Precision@1.

General Translation Knowledge is Useful (Table 3). Table 3 summarises the results where we

Table 4: Varying UMLS synonymy sets.

continue training on general translation data (§2.2) after the previous UMLS-based SAP. With this variant, base multilingual LMs become powerful multilingual biomedical experts. We observe additional strong gains (cf., Table 2) with out-of-domain translation data: e.g., for MBERT the gains range from 2.4% to 12.7% on all languages except ES. For XLMR, we report Precision@1 boosts of >10% on RU, TR, KO, TH with XLMR+SAP$_{en_syn}$, and similar but smaller gains also with XLMR+SAP$_{all_syn}$.

We stress the case of TH, not covered in UMLS. Precision@1 rises from 11.5% (XLMR+SAP$_{en_syn}$) to 30.9%$^{\uparrow 19.4\%}$ (XLMR+SAP$_{all_syn}$(+en-th wt+ muse)), achieved through the synergistic effect of both knowledge types: **1) UMLS synonyms in other languages** push the scores to 20.6%$^{\uparrow 9.1\%}$; **2) translation knowledge** increases it further to 30.9%$^{\uparrow 10.3\%}$. In general, these results suggest that both external in-domain knowledge and general-domain translations boost the performance in resource-poor languages.

The More the Better (Table 4)? According to Table 4 (lower half), it holds almost universally that all_syn > en+{$LANG}_syn > en_syn/{$LANG}_syn on XLMR, that is, it seems that more in-domain knowledge (even in non-related languages) benefit cross-lingual transfer. However, for MBERT (Table 4, upper half), the trend is less clear, with en+{$LANG}_syn sometimes outperforming the all_syn variant. Despite modest performance differences, this suggests that the choice of source languages for knowledge transfer also plays a role; this warrants further investigations in future work.

Are Large Models (Cross-Lingual) Domain Experts (Table 5)? We also investigate the LARGE variant of XLMR, and compare it to its BASE variant. On English, XLMR$_{LARGE}$ gets 73.0% Precision@1, being in the same range as SAPBERT (78.7%), without SAP-tuning (Table 5). The scores without SAP fine-tuning on XLMR$_{LARGE}$, although much higher than of its BASE variant, decrease on other ('non-English') languages. At the same time, note that XLMR BASE achieves random-level performance without SAP-tuning. After SAP fine-tuning, on average, XLMR$_{LARGE}$+SAP still outperforms BASE models, but the gap is much smaller: e.g., we note that the performance of the two SAP-ed models is on par in English. This suggests that with sufficient knowledge injection, the underlying base model is less important (English); however, when the external data are scarce (other languages beyond English), a heavily parameterised large pretrained encoder can boost knowledge transfer to resource-poor languages.

data split→	EN		**avg**	
model↓	@1	@5	@1	@5
XLMR	1.0	2.0	0.2	0.5
+ SAP$_{all_syn}$	78.2	81.0	34.3	39.3
XLMR$_{LARGE}$	73.0	75.0	12.3	13.3
+ SAP$_{all_syn}$	**78.3**	**81.3**	**39.0**	**44.2**

Table 5: Comparing BASE and LARGE models on XL-BEL. Both EN results and **avg** across all languages are reported. Full table available in Appendix Table 9.

5 Conclusion

We have introduced a novel cross-lingual biomedical entity task (XL-BEL), establishing a wide-coverage and reliable evaluation benchmark for cross-lingual entity representations in the biomedical domain in 10 languages, and have evaluated current SotA biomedical entity representations on XL-BEL. We have also presented an effective transfer learning scheme that leverages general-domain translations to improve the cross-lingual ability of domain-specialised representation models. We hope that our work will inspire more research on multilingual *and* domain-specialised representation learning in the future.

A Appendix A

A.1 XL-BEL: Full Statistics

Table 1 in the main paper summarises the key statistics of the XL-BEL benchmark. It was extracted from the `20200601` version of Wikipedia dump. "sentences" refers to the number of sentences that contain biomedical mentions in the Wiki dump. "unique titles (Wiki page)" denotes the number of unique Wikipedia articles the biomedical mentions link to. "mentions" denotes the number of all biomedical mentions in the Wikipedia dump. "unique mentions" refers to the number of mentions after filtering out examples containing duplicated mention surface forms. "unique $\text{mentions}_{\text{mention!=title}}$" denotes the number of unique mentions that have surface forms different from the Wikipedia articles they link to. The 1k test sets for each language are then randomly selected from the examples in "unique $\text{mentions}_{\text{mention!=title}}$".

A.2 XL-BEL: Selection of Languages

Our goal is to select a diverse and representative sample of languages for the resource and evaluation from the full set of possibly supported languages. For this reason, we exclude some Romance and Germanic languages which were too similar to some languages already included in the resource (e.g., since we include Spanish as a representative of the Romance language, evaluating on related languages such as Portuguese or Italian would not yield additional and new insights, while it would just imply running additional experiments). The language list covers languages that are close to English (Spanish, German); languages that are very distant from English (Thai, Chinese, etc.); and also languages that are *in the middle* (e.g., Turkish, which is typologically different, but shares a similar writing script with English).

The availability of biomedical texts in Wikipedia also slightly impacted our choice of languages. The overlapping entities of Wikipedia and UMLS are not evenly distributed in the biomedical domain. For example, since animal species are comprehensively encoded in UMLS, they become rather dominant for certain low-resource languages. We manually inspected the distribution of the covered entities in each language to ensure that they are indeed representative biomedical concepts. Languages with heavily skewed entity distributions are filtered out. E.g., biomedical concepts in Basque Wikipedia are heavily skewed towards plant and animal species (which are valid UMLS concepts but not representative enough). As a result, we dropped Basque as our evaluation language. The current 10 languages all have a reasonably fair distribution over biomedical concepts categories.

A.3 UMLS Data Preparation

All our UMLS fine-tuning data for SAP is extracted from the `MRCONSO.RRF` file downloaded at https://www.nlm.nih.gov/research/umls/licensedcontent/umlsarchives04.html#2020AA. The extracted data includes 147,706,62 synonyms distributed in more than 20 languages. The detailed statistics are available in Table 6.

code	language	# synonyms	percentage
EN	English	10,277,246	69.6%
ES	Spanish	1,575,109	10.7%
JA	Japanese	329,333	2.2%
RU	Russian	291,554	2.0%
DE	German	231,098	1.6%
KO	Korean	145,865	1.0%
ZH	Chinese	80,602	0.5%
TR	Turkish	51,328	0.3%
FI	Finnish	24,767	0.2%
TH	Thai	0	0.0%
FR	French	428,406	2.9%
PT	Portuguese	309,448	2.1%
NL	Dutch	290,415	2.0%
IT	Italian	242,133	1.3%
CS	Czech	196,760	0.7%
NO	Norwegian	63,075	0.4%
PL	Polish	51,778	0.4%
ET	Estonian	31,107	0.2%
SV	Swedish	29,716	0.2%
HR	Croatian	10,035	0.1%
EL	Greek	2,281	<0.1%
LV	Latvian	1,405	<0.1%
	Total	147,706,62	100%

Table 6: The amount of UMLS synonyms per language. The first 10 languages are included in our XL-BEL test languages. However, note that Thai has no UMLS data.

A.4 Translation Data

The full statistics of the used word and phrase translation data are listed in Table 7. The "muse" word translations are downloaded from https://github.com/facebookresearch/MUSE while the Wikititle pairs ("wt") are extracted by us, and are made publicly available.

A.5 Pretrained Encoders

A complete listing of URLs for all used pretrained encoders hosted on huggingface.co is provided in Table 8. For monolingual models of each language,

#↓, language→	EN-ES	EN-DE	EN-FI	EN-RU	EN-TR	EN-KO	EN-ZH	EN-JA	EN-TH
muse	112,583	101,931	43,102	48,714	68,611	20,549	39,334	25,969	25,332
wt	1,079,547	1,241,104	338,284	886,760	260,392	319,492	638,900	547,923	107,398

Table 7: Statistics of muse word translations ("muse") and Wikipedia title pairs ("wt").

we made the best effort to select the most popular one (based on download counts).

A.6 Full Table for Comparing with LARGE Models

Table 9 list results across all languages for comparing BASE and LARGE models.

A.7 Future Work

Investigating Other Cross-Lingual Transfer Learning Schemes. We also explored adapting multilingual sentence representation transfer techniques like Reimers and Gurevych (2020) that leverage parallel data. However, we observed no improvement comparing to the main transfer scheme reported in the paper. We plan to investigate existing techniques more comprehensively, and benchmark more results on XL-BEL in the future.

Comparison with in-Domain Parallel Data. While we used general-domain bitexts to cover more resource-poor languages, we are aware that in-domain bitexts exist among several "mainstream" languages (EN, ZH, ES, PT, FR, DE, Bawden et al. 2019).[8] In the future, we plan to also compare with biomedical term/sentence translations on these languages to gain more insights on the impact of domain-shift.

A.8 Number of Model Parameters

All BASE models have ≈110M parameters while LARGE models have ≈340M parameters.

A.9 Hyperparameter Optimisation

Table 10 lists the hyperparameter search space. Note that the chosen hyperparameters yield the overall best performance, but might be suboptimal in any single setting. We used the same random seed across all experiments.

A.10 Software and Hardware Dependencies

All our experiments are implemented using PyTorch 1.7.0 with Automatic Mixed Precision (AMP)[9] turned on. The hardware we use is listed in Table 11. On this machine, the SAP fine-tuning procedure generally takes 5-10 hours with UMLS data. SAP fine-tuning with translation data takes 10 minutes to 5 hours, depending on the amount of the data. Inference generally takes <10 minutes.

A Cluster-based Approach for Improving Isotropy in Contextual Embedding Space

Sara Rajaee[1] and **Mohammad Taher Pilehvar**[1,2]

Abstract

The representation degeneration problem in Contextual Word Representations (CWRs) hurts the expressiveness of the embedding space by forming an anisotropic cone where even unrelated words have excessively positive correlations. Existing techniques for tackling this issue require a learning process to re-train models with additional objectives and mostly employ a global assessment to study isotropy. Our quantitative analysis over isotropy shows that a local assessment could be more accurate due to the clustered structure of CWRs. Based on this observation, we propose a local cluster-based method to address the degeneration issue in contextual embedding spaces. We show that in clusters including punctuations and stop words, local dominant directions encode structural information, removing which can improve CWRs performance on semantic tasks. Moreover, we find that tense information in verb representations dominates sense semantics. We show that removing dominant directions of verb representations can transform the space to better suit semantic applications. Our experiments demonstrate that the proposed cluster-based method can mitigate the degeneration problem on multiple tasks.[1]

1 Introduction

Despite their outstanding performance, CWRs are known to suffer from the so-called *representation degeneration problem* that makes the embedding space anisotropic (Gao et al., 2019). In an anisotropic embedding space, word vectors are distributed in a narrow cone, in which even unrelated words are deemed to have high cosine similarities. This undesirable property hampers the representativeness of the embedding space and limits the diversity of encoded knowledge (Ethayarajh, 2019).

To better understand the representation degeneration problem in pre-trained models, we analyzed the embedding space of GPT-2 (Radford et al., 2019), BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019). We found that, despite being extremely anisotropic in all non-input layers from a global sight, the embedding space is significantly more isotropic from a local point of view (when embeddings are clustered and each cluster is made zero-mean). Motivated by this observation and based on previous studies that highlight the clustered structure of CWRs (Reif et al., 2019; Michael et al., 2020), we extend the technique of Mu and Viswanath (2018) with a further clustering step. In our proposal, we cluster embeddings and apply PCA on individual clusters to find the corresponding principal components (PCs) which indicate the dominant directions for each specific cluster. Nulling out these PCs for each cluster renders a more isotropic space. We evaluated our cluster-based method on several tasks, including Semantic Textual Similarity (STS) and Word-in-Context (WiC). Experimental results indicate that our cluster-based method is effective in enhancing the isotropy of different CWRs, reflected by the significant performance improvements in multiple evaluation benchmarks.

In addition, we provide an analysis on the reasons behind the effectiveness of our cluster-based technique. The empirical results show that most clusters contain punctuation tokens, such as periods and commas. The PCs of these clusters encode structural information about context, such as sentence style; hence, removing them can improve CWRs performance on semantic tasks. A similar structure exists in other clusters containing stop words. The other important observation is about verb distribution in the contextual embedding space. Our experiments reveal that verb representations are separated across the tense dimension in distinct

[1]The code for our experiments is available at https://github.com/Sara-Rajaee/clusterbased_isotropy_enhancement/

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 575–584

sub-spaces. This brings about an unwanted peculiarity in the semantic space: representations for different senses of a verb tend to be closer to each other in the space than the representations for the same sense that are associated with different tenses of the same verb. Indeed, removing such PCs improves model's ability in downstream tasks with dominant semantic flavor.

2 Isotropy in CWRs

Isotropy is a desirable property of word embedding spaces and arguably any other vector representation of data in general (Huang et al., 2018; Cogswell et al., 2016). From the geometric point of view, a space is called isotropic if the vectors within that space are uniformly distributed in all directions. Lacking isotropy in the embedding space affects not only the optimization procedure (e.g., model's accuracy and convergence time) but also the expressiveness of the embedding space; hence, improving the isotropy of the embedding space can lead to performance improvements (Wang et al., 2020; Ioffe and Szegedy, 2015).

We measure the isotropy of embedding space using the partition function of Arora et al. (2016):

$$F(u) = \sum_{i=1}^{N} e^{u^T w_i} \quad (1)$$

where u is a unit vector, w_i is the corresponding embedding for the i^{th} word in the embedding matrix $\mathrm{W} \in \mathbb{R}^{\mathrm{N}\times\mathrm{D}}$, N is the number of words in the vocabulary, and D is the embedding size. Arora et al. (2016) showed that $F(u)$ can be approximated using a constant for isotropic embedding spaces. Therefore, for the set U, which is the set of eigenvectors of $\mathrm{W}^T\mathrm{W}$, in the following equation, I(W) would be close to one for a perfectly isotropic space (Mu and Viswanath, 2018).

$$\mathrm{I(W)} = \frac{min_{u\in U} F(u)}{max_{u\in U} F(u)} \quad (2)$$

2.1 Analyzing Isotropy in pre-trained CWRs

Using the above metric, we analyzed the representation degeneration problem globally and locally.

Global assessment. We quantified isotropy in all layers for GPT-2, BERT, and RoBERTa on the development set of STS-Benchmark (Cer et al., 2017). Figure 1 shows the trend of isotropy in all layers based on I(W). Clearly, all CWRs are extremely anisotropic in all non-input layers. While

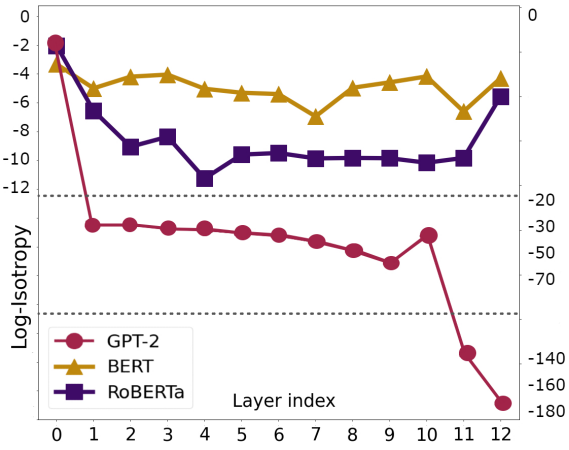

Figure 1: Layer-wise isotropy for different CWRs on the STS-B dev set (↑ log-isotropy: ↑ isotropy). Given the large difference, BERT and RoBERTa are shown on the left axis and GPT-2 on the right.

the isotropy of GPT-2 decreases consistently in upper layers, that for RoBERTa has a semi-convex form in which the last layer (except for the input layer) has the highest isotropy. Also, interestingly, the input layer in GPT-2 is more isotropic than those for the other two models. This observation contradicts with what has been previously reported by Ethayarajh (2019).

Local assessment. In the light of the clustered structure of the embedding space in CWRs (Reif et al., 2019), we carried out a local investigation of isotropy. To this end, we clustered the space using k-means and measured isotropy after making each cluster zero-mean (Mu and Viswanath, 2018). Table 1 shows the results for different number of clusters (each being the average of five runs). When the embedding space is viewed closely, the distribution of CWRs is notably more isotropic. Clustering significantly enhances isotropy for BERT and RoBERTa, making their embedding spaces almost isotropic. However, GPT-2 is still far from being isotropic. This contradicts with the observation of Cai et al. (2021).

A possible explanation for these contradictions is the different metric used by Ethayarajh (2019) and Cai et al. (2021) for measuring isotropy: cosine similarity. Randomly sampled words in an anisotropic embedding space should have high cosine similarities (a near-zero similarity denotes isotropy). However, there are exceptional cases where this might not hold (an anisotropic embedding space where sampled words have near-zero cosine similarities). In Figure 2, we illustrate GPT-

	GPT-2	BERT	RoBERTa
Baseline	5.02E-174	5.05E-05	2.70E-06
$k = 1$	2.49E-220	0.010	0.015
$k = 3$	9.42E-66	0.040	0.290
$k = 6$	**1.40E-41**	0.125	0.453
$k = 9$	1.18E-41	0.131	0.545
$k = 20$	4.06E-47	**0.262**	**0.603**

Table 1: CWRs isotropy after clustering and making each cluster zero-mean separately (results for different number of clusters (k) on STS-B dev set).

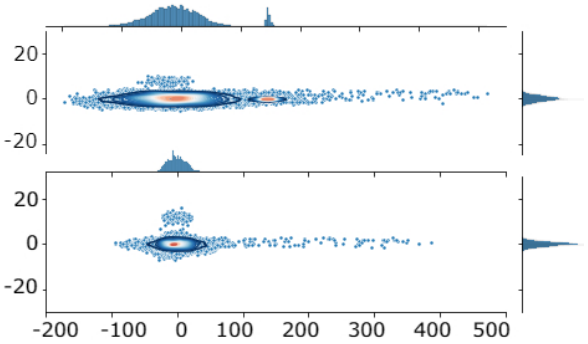

Figure 2: GPT-2 embeddings on STS-B dev set before (top) and after (bottom) a local zero-mean operation.

2 embedding space as an example for such an exceptional cases. Making individual clusters zero-mean (bottom) improves isotropy over the baseline (top). However, the embeddings are still far from being uniformly distributed in all directions. Instead, they are distributed around a horizontal line. This leads to a near-zero cosine similarity for randomly sampled words while the embedding space is anisotropic. Hence, cosine similarity might not be a proper metric for computing isotropy.

3 Cluster-based Isotropy Enhancement

The degeneration problem in the embedding space can be attributed to the training procedure of the underlying models, which are often language models trained through likelihood maximization with the weight tying trick (Gao et al., 2019). Maximizing the likelihood of a specific word embedding (minimizing that for others) requires pushing it towards the direction of the corresponding hidden state, which results in the accumulation of the learnt word embeddings into a narrow cone.

Previous work has shown that nulling out dominant directions of an anisotropic embedding space can make the space isotropic and improve its expressiveness (Mu and Viswanath, 2018). We refer to this as the *global* approach. This method was proposed for static embeddings. Hence, it might not be optimal for contextual embeddings, especially in the light that the latter tends to have a clustered structure. For instance, recent work suggests that word types (e.g., verbs, nouns, punctuations), entities (e.g., personhood, nationalities, and dates), and even word senses (Michael et al., 2020; Loureiro et al., 2021; Reif et al., 2019) create local distinct clustered areas in the contextual embedding space. Moreover, our local assessment shows that it is not necessarily the case that all clusters share the same dominant directions. Hence, discarding dominant directions that are computed globally is not efficient for removing local degenerated directions. Consequently, it is more logical to have a cluster-specific dropping of dominant directions.

Based on these observations, we propose a cluster-based approach for isotropy enhancement. Specifically, instead of determining dominant directions globally, we obtain them separately for different sub-spaces and discard for each cluster only the corresponding cluster-specific dominant directions. To this end, we employ Principal Component Analysis (PCA) to compute local dominant directions in clusters. Geometrically, principal components (PCs) represent those directions in which embeddings have the most variance (maximum elongation). In our proposed method, we first cluster word embeddings using a simple k-means algorithm. After making each cluster zero-mean, the top PCs of every cluster are removed separately. Adding a clustering step helps us to eliminate the local dominant directions of each cluster. We will show in Section 5 that different linguistic knowledge is encoded in the dominant directions of various clusters. Moreover, numerical results show that in comparison with the global approach, our method can make the embedding space more isotropic, even when the fewer number of PCs are nulled out.

4 Experiments

We carried out experiments on the following benchmarks. As for Semantic Textual Similarity (STS), which is the main benchmark for our experiments, we experimented with STS 2012-2016 datasets (Agirre et al., 2012, 2013, 2014, 2015, 2016), the SICK-Relatedness dataset (SICK-R) (Marelli et al., 2014), and the STS benchmark (STS-B). For the STS task, we report results for GPT-2, BERT, and RoBERTa. We also experimented with a number

	Model	STS 2012	STS 2013	STS 2014	STS 2015	STS 2016	SICK-R	STS-B
Baseline	GPT-2	26.49	30.25	35.74	41.25	46.40	45.05	24.8
	BERT-base	42.87	59.21	59.75	62.85	63.74	58.69	47.4

Table 3: Results on the classification tasks (BERT) in terms of accuracy (except for CoLA: Matthew's correlation).

of classification tasks: Recognizing Textual Entailment from the GLUE benchmark (Wang et al., 2018, RTE), the Corpus of Linguistic Acceptability (Warstadt et al., 2019, CoLA), Stanford Sentiment Treebank (Socher et al., 2013, SST-2), Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005, MRPC), Word-in-Context (Pilehvar and Camacho-Collados, 2019, WiC), and BoolQ (Clark et al., 2019). For the classification tasks, we limit our experiments to BERT and extract features to train an MLP. Further details on the datasets and system configuration can be found in Appendix B.

We benchmark our cluster-based approach with the pre-trained CWRs (baseline) and the global method. As it was mentioned before, this method is similar to ours in its elimination of a few top dominant directions but with the difference that these directions are computed globally (in contrast to our local cluster-based computation). The best setting for each model is selected based on performance on the STS-B dev set. The reported results are the average of five runs.

4.1 Results

Tables 2 and 3 report experimental results. As can be seen, globally increasing isotropy can make a significant improvement for all the three pre-trained models. However, our cluster-based approach can achieve notably higher performance compared to the global approach. We attribute this improvement to our cluster-specific discarding of dominant directions. Both global and cluster-based methods null out the optimal number of top dominant directions (tuned separately, cf. Appendix B), but the latter identifies them based on the specific structure of a sub-region in the embedding space (which might not be similar to other sub-regions).

5 Discussion

In this section, we provide a brief explanation for reasons behind the effectiveness of the cluster-based approach through investigating the linguistic knowledge encoded in the dominant local directions. We also show that enhancing isotropy reduces convergence time.

5.1 Linguistic knowledge

Punctuations and stop words. We observed that local dominant directions for the clusters of punctuations and stop words carry structural and syntactic information about the sentences in which they appear. For example, the two sentences "A man is crying." and "A woman is dancing." from STS-B do not have much in common in terms of semantics but are highly similar with respect to their style. To quantitatively analyze the distribution of this type of tokens in CWRs, we designed an experiment based on the dataset created by Ravfogel et al. (2020). The dataset consists of groups in which sentences are structurally and syntactically similar but have no semantic similarity. We picked 200 different structural groups in which each group has six semantically different sentences. Then, using the k-NN algorithm, we calculated the percentage of

Model	Baseline				Removed PCs			
	ST-SM	ST-DM	DT-SM	*Isotropy*	ST-SM	ST-DM	DT-SM	*Isotropy*
GPT-2	48.82	48.19	50.86	2.26E-05	9.32	9.53	9.49	0.17
BERT	13.44	14.24	14.87	2.24E-05	10.31	10.50	10.32	0.32
RoBERTa	5.89	6.31	6.86	1.22E-06	4.78	5.00	4.89	0.73

Table 4: The mean Euclidean distance of a sample occurrence of a verb to all other occurrences of the same verb with the Same-Tense and the Same-Meaning (ST-SM), the Same-Tense but Different-Meaning (ST-DM), and a Different-Tense but the Same-Meaning (DT-SM). Semantically, it is desirable for DT-SM to be lower than ST-DM.

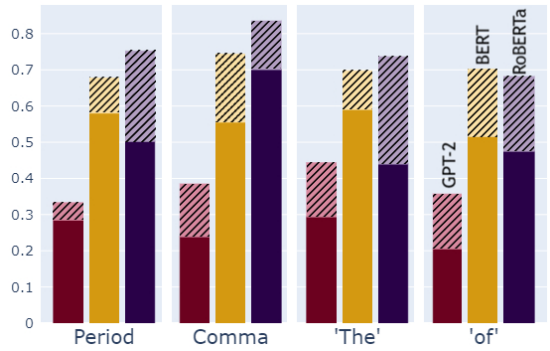

Figure 3: The percentage of nearest neighbours that share similar structural and syntactic knowledge, before (lighter, pattern-filled) and after removing dominant directions in pre-trained CWRs.

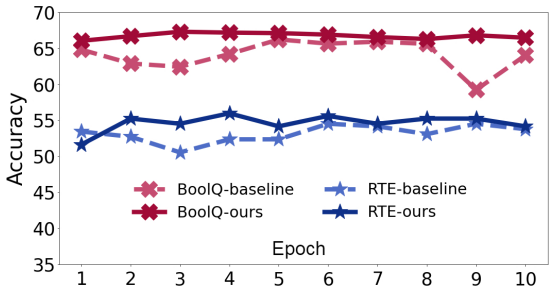

Figure 4: The impact of our cluster-based isotropy enhancement on per-epoch performance for two tasks.

nearest neighbours which are in the same group before and after removing local dominant directions. We evaluated this for period and comma, which are the most frequent punctuations, and "the" and "of" as the most contextualized stop words (Ethayarajh, 2019). The reported results in Figure 3 show that the representations for punctuations and stop words are biased toward structural and syntactic information of sentences; hence, removing their dominant directions reduces the number of same-group nearest neighbours. The improvement from our local isotropy enhancement can be partially attributed to attenuating this type of bias.

Verb Tense. Our experiments show that tense is more dominant in verb representations than sense-level semantic information. To have a precise examination of this hypothesis, we used SemCor (Miller et al., 1993), a dataset comprising around 37K sense-annotated sentences. We collected representations for polysemous verbs that had at least two senses occurring a minimum of 10 times. Then, for each individual verb, we calculated Euclidean distance to the contextual representation of the same verb: (1) with the same tense and the same meaning, (2) with the same tense but a different meaning, and (3) with a different tense and the same meaning. The experimental results reported in Table 4 confirm the hypothesis and show the effectiveness of the cluster-based approach in bringing together verb representations that correspond to the same sense, even if they have different tense.

5.2 Convergence time

In the previous experiments, we showed that the contextual embeddings are extremely anisotropic and highly correlated. Such embeddings can slow down the learning process of deep neural networks. Figure 4 shows the trend of convergence for the BoolQ and RTE tasks (dev sets). By decreasing the correlation between embeddings, our method can reduce convergence time.

6 Conclusions

In this paper, we proposed a cluster-based method to address the representation degeneration problem in CWRs. We empirically analyzed the effect of clustering and showed that, from a local sight, most clusters are biased toward structural information. Moreover, we found that verb representations are distributed based on their tense in distinct sub-spaces. We evaluated our method on different semantic tasks, demonstrating its effectiveness in removing local dominant directions and improving performance. As future work, we plan to study the effect of fine-tuning on isotropy and on the encoded linguistic knowledge in local regions.

A Isotropy statistics

Table 5 shows isotropy statistics for GPT-2, BERT, and RoBERTa. GPT-2's embedding space is extremely anisotropic in upper layers. Hence, more PCs are required to be eliminated to make this embedding space isotropic in comparison to BERT and RoBERTa, both in the cluster-based approach and the global one (Mu and Viswanath, 2018). Also, in almost all layers, BERT has higher a isotropy than RoBERTa.

Model	GPT-2	BERT	RoBERTa
layer 0	1.5E-02	4.6E-04	9.1E-03
layer 1	9.9E-24	9.9E-06	2.7E-07
layer 2	**2.8E-23**	6.3E-05	8.7E-10
layer 3	6.1E-26	8.8E-05	4.2E-09

Table 5: Per-layer isotropy on the STS-B dev set. Numbers have been calculated based on I(W).

B Experimental Setup

B.1 Dataset details

STS. In the Semantic Textual Similarity task, the provided labels are between 0 and 5 for each paired sentence. We first calculate sentence embeddings by averaging all word representations in each sentence and then compute the cosine similarity between two sentence representations as a score of semantic relatedness of the pair.

RTE. The Recognizing Textual Entailment dataset is a classification task from the GLUE benchmark (Wang et al., 2018). Paired sentences are collected from different textual entailment challenges and labeled as *entailment* and *not-entailment*.

CoLA. The Corpus of Linguistic Acceptability (Warstadt et al., 2019) is a binary classification task in which sentences are labeled whether they are grammatically acceptable.

SST-2. The Stanford Sentiment Treebank (Socher et al., 2013) is a binary sentiment classification task.

MRPC. The Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) consists of paired sentences, and the goal is determining whether, in a pair, sentences share similar semantics or not.

WiC. Word-in-Context (Pilehvar and Camacho-Collados, 2019) is a binary classification task in which it should be determined if a target word in two different contexts refers to the same meaning.

BoolQ. Boolean Questions (Clark et al., 2019) is a Question Answering classification task. Every sample includes a passage and a yes/no question about the passage.

B.2 Configurations

For the classification tasks, we trained a simple MLP on the features extracted from BERT. The proposed cluster-based approach has two hyperparameters: the number of clusters and the number of PCs to be removed. We selected both of them from range [5, 30] and tuned them on the STS-B dev set. In the cluster-based approach,The optimal number of clusters for GPT-2, BERT, and RoBERTa are respectively 10, 27, and 27. For BERT and RoBERTa, 12 top dominant directions have been removed, while the number is 30 for GPT-2 regarding its extremely anisotropic embedding space. The tuning of the number of PCs to be eliminated in the global method has been done similarly to the cluster-based approach (on the STS-B dev set): 30, 15, and 25 for GPT-2, BERT, and RoBERTa, respectively.

C Isotropy on STS datasets

In Table 6, we present the isotropy of the contextual embedding spaces calculated using I(W) on the STS benchmark. The results reveal the effectiveness of the proposed method in enhancing the isotropy of the embedding space.

D Word frequency bias in CWRs

CWRs are biased towards their frequency information, and words with similar frequency create local regions in the embedding space (Gong et al., 2018; Li et al., 2020). From the semantic point of view, this is certainly undesirable given that words with similar meanings but different frequencies could be

Unsupervised Enrichment of Persona-grounded Dialog with Background Stories

Abstract

Humans often refer to personal narratives, life experiences, and events to make a conversation more engaging and rich. While persona-grounded dialog models are able to generate responses that follow a given persona, they often miss out on stating detailed experiences or events related to a persona, often leaving conversations shallow and dull. In this work, we equip dialog models with 'background stories' related to a persona by leveraging fictional narratives from existing story datasets (e.g. ROCStories). Since current dialog datasets do not contain such narratives as responses, we perform an unsupervised adaptation of a retrieved story for generating a dialog response using a gradient-based rewriting technique. Our proposed method encourages the generated response to be *fluent* (i.e., highly likely) with the dialog history, *minimally different* from the retrieved story to preserve event ordering and *consistent* with the original persona. We demonstrate that our method can generate responses that are more diverse, and are rated more engaging and human-like by human evaluators, compared to outputs from existing dialog models.

1 Introduction

Humans often rely on specific incidents and experiences while conversing in social contexts (Dunbar et al., 1997). Responses from existing chitchat dialog agents often lack such specific details. To mitigate this, some prior work has looked into assigning personas to dialog agents (Zhang et al., 2018; Majumder et al., 2020). However, persona descriptions are often shallow and limited in scope, and while they lead to improvements response specificity, they still lack the level of detail with which humans share experiences.

In this work, we propose methods to enrich dialog personas with relevant background events using fictional narratives from existing story datasets such as ROCStories (Mostafazadeh et al., 2016). For example, for a persona attribute 'I have two children and a dog,' we are able to identify a relevant narrative from a story corpus (Figure 1). However, such stories may not directly fit fluently in the dialog context. Thus, retrieved stories should be adapted to construct a response that is fluent and relevant to the context. Since existing datasets (such as PersonaChat (Zhang et al., 2018)) do not contain responses with such background stories, such adaptation has to be done in an unsupervised fashion with decoders trained to generate responses conditioned only on a dialog history and persona.

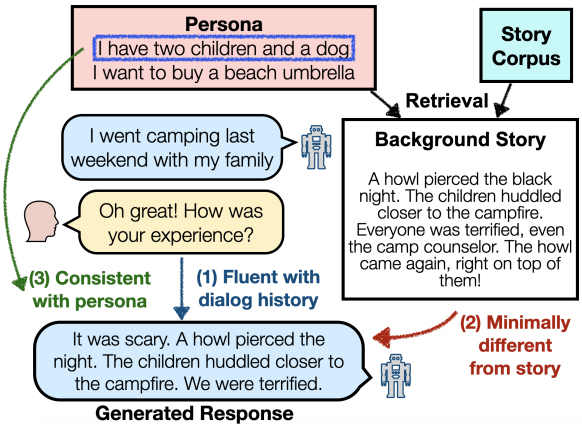

Figure 1: We enrich agent personas with 'background stories' from an existing corpus. We propose a gradient-based technique which encourages the generated response to be fluent with the dialog history, minimally different from the retrieved story, and consistent with the persona. The proposed approach leads to more specific and interesting responses.

To adapt a retrieved narrative incident as a relevant background story, we use a decoding procedure which encourages the generated response to (1) be fluent with the dialog history, (2) be consistent with the original persona, and (3) be minimally different from the retrieved story. While fluency with dialog context is encouraged directly by the likelihood as per the underlying language model

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 585–592

the remaining two constraints are incorporated via iterative updates to the decoder output distributions at inference time. Our inference-time decoding method is different from the only recent effort by Su et al. (2020) that leverages non-dialog data (forum comments, book snippets) as distant labels to train dialog systems with supervision. Our contributions can be summarized as follows:

- We propose a novel approach to enrich dialog agent personas with relevant backstories, relying only on existing story datasets.
- We propose to use an unsupervised back-propagation based decoding procedure[1] to adapt the relevant stories such that the resulting response is fluent with the dialog history and consistent with the dialog agent persona. Our method works with a model trained just with dialog data i.e. without access to story corpus at training time.
- Our experiments demonstrate that the proposed approach results in much more engaging and specific dialog outputs in a persona-grounded dialog setup. This fills a gap in existing dialog models which often lack the capability to generate responses about specific events and experiences relevant to persona attributes.

2 Unsupervised Persona Enrichment with Background Stories

Given dialog history h and persona C consisting of several (typically 3-5, example shown in Figure 1) attributes, our goal is to construct a dialog response x. Our underlying model is based on the discrete persona attribute choice model from Majumder et al. (2020). To generate a dialog utterance x, we first sample a persona attribute $c \sim p(c|h)$ conditioned on the dialog history h. x is then generated conditioned on the dialog history and the chosen persona attribute. The underlying dialog model's decoder is initialized with a pretrained GPT-2 model, and is fine-tuned on the PersonaChat dataset (Zhang et al., 2018). However, in our current setup, we also have to identify relevant background stories and use them to construct fluent responses at decoding time. Therefore, we propose a different decoding procedure.

To generate a response, we first sample a persona attribute $c \sim p(c|h)$. Next we retrieve stories corresponding to the persona attribute c (Section 2.1). However, the underlying dialog model is trained to generate responses conditioned only on the dialog history and persona. To incorporate the retrieved story in the response, we perform gradient-based inference (Section 2.2), that only assumes a left-to-right language model trained on dialog context and responses, and the story is handled at decoding time in an unsupervised fashion. We refer to the proposed method as **PABST** (Unsupervised **P**erson**A** enrichment with **B**ackground **ST**ories).

2.1 Retrieving Relevant Stories

For a persona attribute c, we aim to identify relevant stories from a story corpus. Toward this goal, we rank the stories using the F1 component of BERT-score (Zhang et al., 2020) based retrieval using the persona attribute c as the query and the highest scoring story is chosen. Note that many of the stories are written in the third person. For use as background stories, we must first transform them to first–person. Following prior work (Brahman and Chaturvedi, 2020), we identify the protagonist of such stories as the most frequently occurring character. Thereafter, we use co-reference resolution (Lee et al., 2017) to identify all words or phrases that refer to the protagonist. Finally, all words or phrases so identified are replaced with suitable first person pronouns (e.g. 'his books' to 'my books').

2.2 Gradient-based Inference

Our underlying dialog model is not trained to condition on a retrieved story, and cannot be directly used to construct a desirable response using s. To tackle this, we consider a decoding strategy which, in addition to fluency with history h, encourages response x to follow two soft constraints: (1) be minimally different from story s, and (2) be consistent with persona c.

First, we generate an initial response based only on the dialog history. Then we perform an iterative procedure which alternates between performing a forward pass on the language model to encourage fluency, and a backward pass which updates the response via back-propagation to respect the two soft constraints. However, x is discrete, and cannot be directly updated using gradients from back-propagation. Instead, we maintain and update a soft representation o of x, where o_i corresponds to the last hidden state representation for the i^{th} token position, i.e., $p(x_i) \sim \text{softmax}(Wo_i/\tau)$, where τ is the temperature parameter, W is the embedding

[1] Code can be found at https://github.com/majumderb/pabst

matrix, and $Wo_i \in \mathcal{R}^V$ (V is the vocabulary size). Our approach is inspired by recent works that use gradient-based decoding for text generation with soft constraints (Dathathri et al., 2020; Qin et al., 2020). Next we describe the backward and forward passes of the iterative procedure.

Backward Pass with Soft Constraints We define the following soft constraints on response x:
(1) **Divergence from story:** We want to encourage x to be *minimally different* from the story s. Following prior work (Qin et al., 2020), we compute a cross entropy loss (denoted by cross-entr henceforth) with story $s = \{s_1, \ldots, s_T\}$ tokens as labels and $Wo_1, \ldots, Wo_T$ as the logits.
(2) **Consistency to persona:** We want x to be *consistent with persona attribute* c. Consider a classifier $q_\phi(o, c)$ which predicts the probability of x (or rather the soft representation o of x) entailing c. The classifier $q_\phi(o, c)$ is a bag-of-words classification head on decoder hidden states o, fine-tuned on the Dialogue-NLI dataset (Welleck et al., 2019) to predict whether pairs of persona attributes and responses are entailed or not. The objective to maximize can be written as:

$$\mathcal{L}(c, s; o) = \lambda_c \log q_\phi(o, c) - \lambda_d \,\text{cross-entr}(s, Wo)$$

where λ_c and λ_d are hyper-parameters. We update o through back-propagation by computing the gradient $\nabla_o \mathcal{L}(c, s; o)$, while keeping the model parameters constant. Let the resulting o after the gradient-based updates be denoted by o^b.

Forward Pass to Encourage Fluency Next we perform a forward pass of the underlying dialog model, with the goal of regularizing the hidden states towards the unmodified language model values. On computing the forward pass at the j^{th} token, we mix the final hidden states o_j^f from the forward pass with o_j^b computed in the backward pass, via weighted addition to get the resulting $o_j = \gamma \times o_j^f + (1 - \gamma) \times o_j^b$, where $\gamma \in (0, 1)$ is a hyperparameter. The resulting o_j is used for computing the logits at the next time step $j + 1$.

We initialize the output response by performing greedy decoding from the underlying dialog model, conditioned on the dialog history and persona attribute. Then we iteratively update o by alternate backward and forward passes. We sample the final response $x \sim \text{softmax}(Wo/\tau)$. In practice, we found that 5 iterations are sufficient to generate good quality outputs.

Method	Training	Decoding	D-1	D-2	ENTR
W/o Story Data					
TRANSFERO	PERSONA	Nucleus	0.05	0.11	1.21

Table 1: Diversity metrics on the PersonaChat test set. D-1/2 is the % of distinct uni- and bi-grams. ENTR is the geometric mean of n-gram entropy. Grad. Inf. is the unsupervised gradient-based decoding as opposed to Nucleus sampling (Holtzman et al., 2020).

3 Experiments

We evaluate methods in terms of their capability to generate diverse, fluent and engaging responses. Hyperparameters are noted in Appendix §A.

Datasets We experiment with the PersonaChat dialog dataset (Zhang et al., 2018) consisting of 131,438 utterances for training, 15,602 for validation, and 15,024 for testing. For stories, we use the training split of the ROCStories dataset (Mostafazadeh et al., 2016), that consists of 78,529 stories, each typically of 4 to 5 sentences.

Baselines We consider two broad groups of models as baselines: **(1)** ***Without access to story corpus***: We use finetuned GPT2 (**TRANSFERO**) on PersonaChat, and the discrete persona attribute choice model (**DISCCHOICE**) from Majumder et al. (2020). We also consider a version of DISCCHOICE which enriches personas with inferences from a commonsense knowledge base (**CS-KB**). **(2)** ***Baselines using story corpus*:** To allow DISCCHOICE models to generate story-like responses, we adapt an alternative training regime (**PSEUDO**) from (Su et al., 2020), where we randomly replace some of the target dialog responses with retrieved stories—treating them as pseudo labels. Finally, we also consider a **MULTITASK** training setup from (Su et al., 2020), wherein the decoder is trained on PersonaChat as well as with a language modeling objective on ROCStories. We additionally consider a **RETRIEVAL** baseline that uses the retrieved story verbatim as the dialog response.

3.1 Automatic Evaluation

We hypothesize that that the proposed approach to leverage external non-dialog data can increase the diversity of the generated responses. Following

PABST vs.	TRANSFERO		DISCCHOICE		RETRIEVAL		PSEUDO		MULTITASK		w/o DNLI		Gold	
Aspect	win	loss	win	loss	win	loss	win	loss	win	loss	win	loss	win	loss
Sensible	**83.8**	5.6	**71.4**	10.1	**72.7**	15.7	**94.3**	3.1	**92.8**	1.5	**81.7**	6.8	29.1	**33.6**
Engaging	**96.7**	1.8	**82.6**	6.7	**87.2**	5.3	**94.7**	2.1	**94.1**	2.6	**70.9**	14.8	**70.2**	15.6

Table 2: Pairwise comparison (% win/loss cases, ties not reported) between responses from PABST and from other baselines as well as gold. All differences are significant with $p < 0.05$. Cohen's Kappa (Cohen, 1960) for sensibility and engagement were 0.79 and 0.82 respectively. Complete details of the human evaluations are in Appendix §B.

Dialog History Agent: How was your last trip? User: It was great. I went to Utah and saw the Canyonlands.	**Dialog History** Agent: I work as stunt double. What about you? User: I'm an engineer. I just got back from work. How's yours?
Retrieved Story: I went on a trip. I went to Florida. When we got there, there was no air conditioning. I was irritated. It was too hot.	**Retrieved Story:** I was a working actor. For my new role I was a stunt double. I started working on new stunts. When I jumped off a building yesterday I got hurt. I had to be rushed to the hospital.
DISCCHOICE: That's great. You must be adventurous.	**DISCCHOICE:** That's great. I am looking for a job.
RETRIEVAL: I went on a trip. I went to Florida. When we got there, there was no air conditioning. I was irritated. It was too hot.	**RETRIEVAL:** I was a working actor. For my new role I was a stunt double. I started working on new stunts. When I jumped off a building yesterday I got hurt. I had to be rushed to the hospital.
PSEUDO: I have a house in Florida.	**PSEUDO:** I got a new job. I am an actor.
MULTITASK: I like Florida. I went to the beaches.	**MULTITASK:** I started a new role. I got hurt.
PABST ($\lambda_d = 5$): I went on a trip. I went to Florida. I have a house there. We do not have air condition. It was hot.	**PABST ($\lambda_d = 5$):** I was working as a stunt double. I jumped off a building. I got hurt. I had to be rushed to the hospital.
PABST ($\lambda_d = 1$): That's great. I frequently go to Florida. I have a house there but it gets hot in summer.	**PABST ($\lambda_d = 1$):** Yesterday while I was working, I jumped off a building and I got hurt. I had to be taken to the hospital.

Table 3: Generations from different models. More examples are in Appendix §C.

prior work (Li et al., 2016), we report the percentage of distinct uni-grams and bi-grams (**D-1** and **D-2** respectively). Note that these values do not capture the actual frequency distribution of different word types. Therefore, we also report the geometric mean of entropy values of empirical frequency distributions of n-grams of words (n $\in \{1, 2, 3\}$) (Jhamtani et al., 2018), denoted by **ENTR**.

We observe that methods that use story data show much higher diversity compared to methods that do not (Table 1). Among methods using story data, gradient-based decoding (PABST) performs better than DISCCHOICE trained with PSEUDO or MULTITASK. Note that just using RETRIEVAL outputs as-is leads to even more diverse outputs than PABST. However, they are much less sensible with the context, as shown in human evaluations.

3.2 Human Evaluation

Since we do not have ground truth story-like responses in the dialog dataset, we perform human evaluation with 150 test examples to investigate if PABST generates responses that are 1) **sensible** with the dialog history and 2) **engaging**. We hired two Anglophone (Lifetime HIT acceptance % > 85) annotators for every test sample. The order of the systems present in the interface is randomized. A snapshot of the human evaluation interface is provided in Appendix §C. All differences in values from human evaluations are significant with $p < 0.05$ from bootstrap tests on 1000 subsets of size 50. Cohen's Kappa (Cohen, 1960) to measure inter-annotator agreement for sensibility and engagement were 0.79 and 0.82 respectively.

From the results (shown in Table 3), we note that in comparison to responses from baselines, responses from PABST are more engaging and more sensible with respect to the dialog history. We further make following observations. Firstly, using the gradient-based decoding approach with retrieved stories (PABST) works significantly better than using distant supervision with stories data (PSEUDO and MULTITASK). Secondly, background stories provide sufficient detail for an engaging conversation compared to DISCCHOICE which expands persona attributes using commonsense knowledge (Majumder et al., 2020). Finally, we also observe that PABST performs worse when we do not use the consistency constraint (w/o DNLI).

Choice of λ_d We also experiment with different values of the weight for the divergence term (λ_d) in $\mathcal{L}$: High ($\lambda_d = 5$), Moderate ($\lambda_d = 1$),

and Low ($\lambda_d = 0.05$). We consider 100 samples for this experiment. We attribute a high λ_d to responses strictly copying the story. We find that PABST (moderate λ_d) wins wins 81.2% and 69.1% cases against PABST (high λ_d) on 'sensible' and 'engaging' response criteria respectively. Similarly, PABST (moderate λ_d) wins 93.2% and 84.7% cases against PABST (low λ_d) in terms of sensibility and engagement respectively.

Qualitative Analysis Table 3 shows responses generated by different baselines. We observe that PABST is able to follow the retrieved story (same as output from RETRIEVAL) while modifying the response to be conversation-like and sensible with dialog history. Responses from other baselines remain verbose or incoherent. Mirroring the human evaluation, we observe that choosing a higher λ_d makes the model to almost repeat the retrieved story but a lower value smooths the output to make it more sensible with the ongoing dialog.

4 Related Work

A desired impact of the proposed approach is increase in diversity of the generated responses. To tackle the issue of diversity in dialog model outputs, prior work has focused on decoding strategies such as diversity-promoting sampling (Holtzman et al., 2020); training strategies such as discouraging undesirable responses via unlikelihood training (Li et al., 2020); model changes such as using stochastic variables (Serban et al., 2017); and using external data such as forum data (Su et al., 2020) or external knowledge bases (Majumder et al., 2020). In contrast to these, our proposed method generates responses with background stories using a gradient-based decoding approach.

One of the steps in our proposed approach is to retrieve relevant stories from an external corpus. Prior work has explored using retrieval of similar dialog instances as an initial step in improving response diversity and other human-like desiderata in dialog (Roller et al., 2020; Weston et al., 2018). Distant supervision by using retrieved text snippets as pseudo responses has been explored in prior work (Su et al., 2020; Roller et al., 2020). We use an external data source to improve dialog responses, a theme shared with some efforts in other tasks such as machine translation (Khandelwal et al.). The use of narrative text in dialog has been explored in prior work, mostly as a 'script' or template for conversation (Xu et al., 2020; Zhu et al., 2020). We adapted a BERT-based retrieval method (Zhang et al., 2020) in our case to retrieve relevant story given dialog context and use retrieved story in the decoding phase.

Gradient-based for text generation with soft constraints has been explored in prior work (Dathathri et al., 2020; Qin et al., 2020). Song et al. (2020) focused on generating response which are consistent to given persona. Differently, we use a gradient-based decoding to generate a dialog response while honoring constraints such as consistency to persona and similarity to retrieved story.

5 Conclusion

We propose a method to enrich persona-grounded dialog with background stories at the inference time only using an existing corpus of non-conversational narratives—opening up new ways to generate enriched and engaging responses. One of the limitations of PABST is the assumption of the background story at every turn. As future work, we can include a decision step to decide if we need to incorporate a background story or not, given the dialog history. We can further explore ways to use retrieved stories over multiple turns instead of a single turn.

Impact Statement

In this work, we discuss ways to make a dialog system to generate more engaging responses. Since we use a finetuned version of a pretrained generative model, we inherit the general risk of generating biased or toxic language, which should be carefully filtered. Furthermore, the generations may incorporate biases that are already present in the dialog dataset and story dataset due to crowd-sourced data collection. Hence, we cautiously advise any developer who wishes to use a different story dataset for the background stories to be aware of the biases present in the dataset. Finally, we also note that experiments in this paper are limited only to English language.

A Implementation Details

We obtain the PersonaChat dataset from ParlAI repository[2]. ROCStories dataset is obtained from the repository of original release[3]. We adapted codes from original PPLM (Dathathri et al., 2020) repository[4] and modified them for our own objective function.

Network architecture For the generator network, we use GPT2 (Transformer with 12 layers, 768 hidden size, 12 heads— `gpt2-small`[5]) following the state-of-the-art model (Wolf et al., 2019) from Conv-AI2 competition. The decoder has total of 124 Million parameters. We used the pre-trained decoder model obtained from (Majumder et al., 2020).

Hyperparameters PABST does not require any training since we perform gradient-based decoding at the inference time. For our best method, in objective function $\mathcal{L}$, we use λ_d as 1 and λ_c as 1. We keep generation length to be 100 to encourage longer generations. We train the consistency classifier using code from PPLM repository[6]. The weight γ for mixing forward and backward passes was set to 0.45. For PSEUDO, we substitute a random 30% of the original target responses with retrieved stories.

B Human Evaluations Setup

Figure 2 shows a sample question for the pairwise comparison between response generated by PABST and a baseline for sensibility and engagingness. A similar setup was used to measure performance between PABST variants with different λ_d values $(0.5, 1, 5)$.

C Qualitative Examples

Tables 4 and 5 show generations from PABST and baselines for sampled text examples.

Abstract

The famous "laurel/yanny" phenomenon references an audio clip that elicits dramatically different responses from different listeners. For the original clip, roughly half the population hears the word "laurel," while the other half hears "yanny." How common are such "polyperceivable" audio clips? In this paper we apply ML techniques to study the prevalence of polyperceivability in spoken language. We devise a metric that correlates with polyperceivability of audio clips, use it to efficiently find new "laurel/yanny"-type examples, and validate these results with human experiments. Our results suggest that polyperceivable examples are surprisingly prevalent, existing for $>2\%$ of English words.[1]

1 Introduction

How robust is human sensory perception, and to what extent do perceptions differ between individuals? In May 2018, an audio clip of a man speaking the word "laurel" received widespread attention because a significant proportion of listeners confidently reported hearing *not* the word "laurel," but rather the quite different sound "yanny" (Salam and Victor, 2018). At first glance, this suggests that the decision boundaries for speech perception vary considerably among individuals. The reality is more surprising: almost everyone has a decision boundary between the sounds "laurel" and "yanny," without a significant "dead zone" separating these classes. The audio clip in question lies close to this decision boundary, so that if the clip is slightly perturbed (e.g. by damping certain frequencies or slowing down the playback rate), individuals switch from confidently perceiving "laurel" to confidently perceiving "yanny," with the exact point of switching varying slightly from person to person.

[1]This research was conducted under Stanford IRB Protocol 46430.

How common is this phenomenon? Specifically, what fraction of spoken language is "polyperceivable" in the sense of evoking a multimodal response in a population of listeners? In this work, we provide initial results suggesting a significant density of spoken words that, like the original "laurel/yanny" clip, lie close to unexpected decision boundaries between seemingly unrelated pairs of words or sounds, such that individual listeners can switch between perceptual modes via a slight perturbation.

The clips we consider consist of audio signals synthesized by the Amazon Polly speech synthesis system *with a slightly perturbed playback rate* (i.e. a slight slowing-down of the clip). Though the resulting audio signals are not "natural" stimuli, in the sense that they are very different from the result of asking a human to speak slower (see Section 5), we find that they are easy to compute and reliably yield compelling polyperceivable instances. We encourage future work to investigate the power of more sophisticated perturbations, as well as to consider natural, ecologically-plausible perturbations.

To find our polyperceivable instances, we (1) devise a metric that correlates with polyperceivability, (2) use this metric to efficiently sample candidate audio clips, and (3) evaluate these candidates on human subjects via Amazon Mechanical Turk. We present several compelling new examples of the "laurel/yanny" effect, and we encourage readers to listen to the examples included in the supplementary materials (also available online at https://theory.stanford.edu/~valiant/polyperceivable/index.html). Finally, we estimate that polyperceivable clips can be made for $>2\%$ of English words.

2 Method

To investigate polyperceivability in everyday auditory input, we searched for audio clips of single spoken words that exhibit the desired effect. Our method consisted of two phases: (1) sample a large number of audio clips that are likely to be polyperceivable, and (2) collect human perception data on those clips using Amazon Mechanical Turk to identify perceptual modes and confirm polyperceivability.

2.1 Sampling clips

To sample clips that were likely candidates, we trained a simple autoencoder for audio clips of single words synthesized using the Amazon Polly speech synthesis system. Treating the autoencoder's low-dimensional latent space as a proxy for *perceptual* space, we searched for clips that travel through more of the space as the playback rate is slowed from $1.0\times$ to $0.6\times$. Intuitively, a longer path through encoder space should correspond to a more dramatic change in perception as the clip is slowed down (Section 3 presents some data supporting this).

Concretely, we computed a score S proportional to the length of the curve swept by the encoder E in latent space as the clip is slowed down, normalized by the straight-line distance traveled: that is, we define $S(c) = \frac{\int_{r=1.0\times}^{0.6\times} ||dE(c,r)/dr||dr}{||E(c,0.6\times)-E(c,1.0\times)||}$. Then, with probability proportional to $e^{0.2 \cdot S}$, we importance-sampled 200 clips from the set of audio clips of the top 10,000 English words, each spoken by all 16 voices offered by Amazon Polly (spanning American, British, Indian, Australian, and Welsh accents, and male and female voices). The distributions of S in the population and our sample is shown in Figure 2.

Autoencoder details Our autoencoder operates on one-second audio clips sampled at 22,050 Hz, which are converted to spectrograms with a window size of 256 and then flattened to vectors in $\mathbb{R}^{90,000}$. The encoder is a linear map to $\mathbb{R}^{512}$ with ReLU activations, and the decoder is a linear map back to $\mathbb{R}^{90,000}$ space with pointwise squaring. We used an Adam optimizer with lr=0.01, training on a corpus of 16,000 clips (randomly resampled to between 0.6x and 1.0x the original speed) for 70 epochs with a batch size of 16 ($\approx$ 8 hours on an AWS c5.4xlarge EC2 instance).

2.2 Mechanical Turk experiments

Each Mechanical Turk worker was randomly assigned 25 clips from our importance-sampled set of 200. Each clip was slowed to either 0.9x, 0.75x, or 0.6x the original rate. Workers responded with a perceived word and a confidence score for each clip. We collected responses from 574 workers, all of whom self-identified as US-based native English speakers. This yielded 14,370 responses ($\approx$ 72 responses per clip).

Next, we manually reviewed these responses and selected the most promising clips for a second round with only 11 of the 200 clips. Note that because these selections were made by manual review (i.e. listening to clips ourselves), there is a chance we passed over some polyperceivable clips — this means that our computations in Section 3 are only a conservative lower bound. For this round, we also included clips of the 5 words identified by Guan and Valiant (2019), 12 potentially-polyperceivable words we had found in earlier experiments, and "laurel" as controls. We collected an additional 3,950 responses among these 29 clips ($\approx$ 136 responses per clip) to validate that they were indeed polyperceivable.

Finally, we took the words associated with these 29 clips and produced a new set of clips using each of the 16 voices, for a total of 464 clips. We collected 4,125 responses for this last set ($\approx$ 3 responses for each word/voice/rate combination).

3 Results

Are the words we found polyperceivable? To identify cases where words had multiple perceptual "modes," we looked for clusters in the distribution of responses for each of the 29 candidate words. Concretely, we treated responses as "bags of phonemes" and then applied K-means. Though this rough heuristic discards information about the order of phonemes within a word, it works sufficiently well for clustering, especially since most of our words have very few syllables (more sophisticated models of phonetic similarity exist, but they would not change our results).

We found that the largest cluster typically contained the original word and rhymes, whereas other clusters represented significantly different perceptual modes. Some examples of clusters and their relative frequency are available in Table 1, and the relative cluster sizes as a function of playback rate are shown in Figure 1. As the rate is perturbed,

Table 1: Some polyperceivable words (bold) and their alternate perceptual modes (below). Each row gives representative elements from the mode, and the proportion of workers whose response fell in that mode.

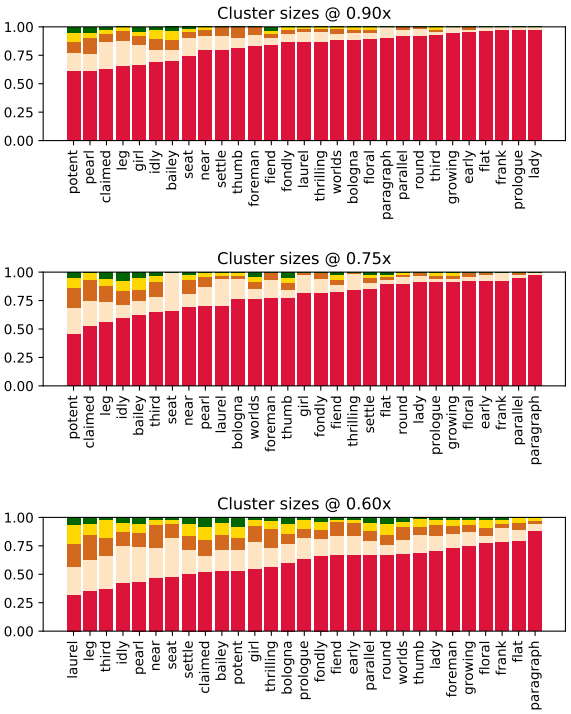

Figure 1: Relative cluster sizes across different playback rates. When the rate is slightly perturbed, the prevalence of alternate modes increases.

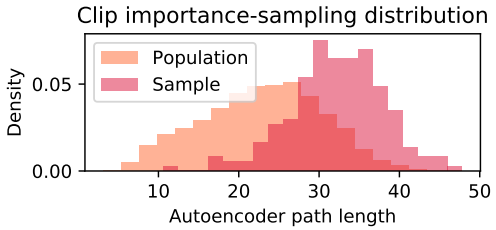

Figure 2: Distribution of path lengths (the S metric) in the population (top 10k English words, all 16 voices) and our sample of 200.

the prevalance of alternate modes among our clips increases.

How prevalent are polyperceivable words? Of our initial sample of 200 words, 11 ultimately yielded compelling demonstrations. To compute the prevalence of polyperceivable words in the population of the top 10k words, we have to account for the importance sampling weights we used when sampling in Section 2.1. After scaling each word's contribution by the inverse of the probability of including that word in our nonuniform sample of 200, we conclude that polyperceivable clips exist for at least 2% of the population: that is, of the 16 voices under consideration, at least one yields a polyperceivable clip for >2% of the top 10k English words.

We emphasize that this is a conservative lower bound, because it assumes that there were no other polyperceivable words in the 200 words we sampled, besides the 11 that we selected for the second round. We did not conduct an exhaustive search among those 200 words, instead focusing our Mechanical Turk resources on only the most promising candidates.

Is S a good metric? We consider the metric S to be successful because it allowed us to efficiently find several new polyperceivable instances. If the 200 words were sampled uniformly instead of being importance-sampled based on S, we would only have found 4 polyperceivable words in expectation (2% of 200). Thus, importance sampling increased our procedure's recall by almost 3×.

For a more quantitative understanding, we analyzed the relationship between "autoencoder path length" S and "perceptual path length" T. Our measure T of "perceptual path length" for a clip is *change in average distance between source word and response* as we slow the clip down from 0.75× to 0.6×. As with clustering above, distance

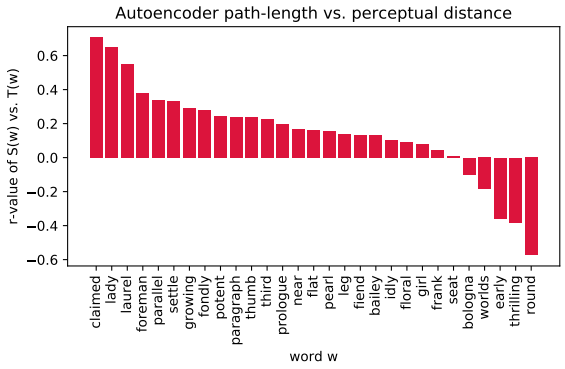

Figure 3: Correlation between S and T across the $n = 16$ voices for each of our 29 words. Nearly all words correlate positively, though with varying strengths (note that "laurel" correlates quite strongly).

is measured in bag-of-phonemes space. For each word, we computed the correlation between S and T among the 16 voices (both S and T vary significantly across voices). For all but 5 of our 29 words these metrics correlated positively, though with varying strength (Figure 3). This suggests that S indeed correlates with polyperceivability.

4 Discussion: Why study quirks of human perception in an ACL paper?

Perceptual instability in human sensory systems offers insight into ML systems. The question of what fraction of natural inputs lie close to decision boundaries for trained ML systems has received enormous attention. The surprising punchline that has emerged over the past decade is that *most* natural examples (including points in the training set) actually lie extremely close to unexpected decision boundaries. For most of these points, a tiny but carefully-crafted perturbation can lead the ML system to change the label. Such perturbations are analogous to the slight perturbation in playback speed for the polyperceivable clips we consider. In the ML literature, these perturbations, referred to as "adversarial examples" seem pervasive across complex ML systems (Szegedy et al., 2013; Goodfellow et al., 2014; Nguyen et al., 2015; Moosavi-Dezfooli et al., 2016; Madry et al., 2017; Raghunathan et al., 2018; Athalye et al., 2017).

While the initial work on adversarial examples focused on computer vision, more recent work shows the presence of such examples across other settings, including reinforcement learning (Huang et al., 2017), reading comprehension (Jia and Liang, 2017), and speech recognition (Carlini and Wagner, 2018; Qin et al., 2019). Studying perceptual illusions would provide a much-needed reference when evaluating ML systems in these domains. For vision tasks, for example, human vision provides the only evidence that current ML models are far from optimal in terms of robustness to adversarial examples. However, while humans are certainly not *as* susceptible to adversarial examples as ML systems, we lack quantified bounds on human robustness. More broadly, understanding which systems (both biological and ML) have decision boundaries that lie surprisingly close to many natural inputs may inform our sense of what settings are amenable to adversarially robust models, and what settings inherently lead to vulnerable classifiers.

Perceptual instability in ML systems offers insight into human sensory systems. Recent research on adversarial robustness of ML models has provided a trove of new tools and perspectives for probing classifiers and exploring the geometry of decision boundaries. These tools cannot directly be applied to study the decision boundaries of biological classifiers (e.g. we cannot reasonably do "gradient descent" on human subjects). However, using standard data-driven deep learning techniques to *model* human perceptual systems can allow us to apply these techniques by proxy.

An example can be found in the study of "transferability." Adversarial examples crafted to fool a specific model often also fool other models, even those trained on disjoint training sets (Papernot et al., 2016a; Tramèr et al., 2017; Liu et al., 2016). This prompts the question of whether adversarial examples crafted for an ML model might also transfer to *humans*. Recent surprising work by Elsayed et al. (2018) explores this question for vision. Humans were shown adversarial examples trained for an image classifier for $\approx$ 70ms, and asked to choose between the correct label and the classifier's (incorrect) predicted label. Humans selected the incorrect label more frequently when shown adversarial examples than when shown unperturbed images. Similarly, Hong et al. (2014) trained a low-dimensional representation of "perceptual space," and used the decision boundaries of the model to find images that confused human subjects.

5 Related work

An enormous body of work from cognitive sciences communities explores the quirks of human/animal sensory systems (Fahle et al., 2002). These works

often have the explicit goal of exploring isolated "illusions" that provide insights into our perceptual systems (Davis and Johnsrude, 2007; Fritz et al., 2005). However, there are few efforts to quantify the extent to which "typical" instances are polyperceivable or lie close to decision boundaries.

Miller (1981) studies the effect of speaking rate on how listeners perceive phonemes. The perceptual shifts studied therein are between phonetically adjacent perceptions (e.g. "pip" vs. "peep") rather than dramatically different perceptions (e.g. "laurel" vs. "yanny"). The "perturbation" of increasing human *speaking* rate is much more complex than simply linearly scaling the *playback* rate of an audio clip. Speaking-rate induced shifts also seem to hold more universally across voices, as opposed to the polyperceivable instances we examine.

6 Future work

Priming effects It is possible to use additional stimuli to alter perceptions of the "laurel/yanny" audio clip. For example, Bosker (2018) demonstrates the ability to control a listener's perception by "priming" them with a carefully crafted recording before the polyperceivable clip is played. Similarly, Guan and Valiant (2019) investigated the "McGurk effect" (McGurk and MacDonald, 1976), where what one "sees" affects what one "hears." The work estimated the fraction of spoken words that, when accompanied by a carefully designed video of a human speaker, would be perceived as significantly different words by listeners. Such phenomena raise questions about how our autoencoder-based method can be extended to search for "priming-sensitive" polyperceivability.

Security implications Just as adversarial examples for DNNs have security implications (Papernot et al., 2016b; Carlini and Wagner, 2017; Liu et al., 2016), so too might adversarial examples for sensory systems. For example, if a video clip of a politician happens to be polyperceivable, an adversary could lightly edit it with potentially significant ramifications. A thorough treatment of such security implications is left to future work.

7 Conclusion

In this paper, we leveraged ML techniques to study polyperceivability in humans. By modeling perceptual space as the latent space of an autoencoder, we were able to discover dozens of new polyperceivable instances, which were validated with Mechanical Turk experiments. Our results indicate that polyperceivability is surprisingly prevalent in spoken language. More broadly, we suggest that the study of perceptual illusions can offer insight into machine learning systems, and vice-versa.

Abstract

Event language models represent plausible sequences of events. Most existing approaches train autoregressive models on text, which successfully capture event co-occurrence but unfortunately constrain the model to follow the *discourse order* in which events are presented. Other domains may employ different discourse orders, and for many applications, we may care about different notions of ordering (e.g., temporal) or not care about ordering at all (e.g., when predicting related events in a schema). We propose a simple yet surprisingly effective strategy for improving event language models by perturbing event sequences so we can relax model dependence on text order. Despite generating completely synthetic event orderings, we show that this technique improves the performance of the event language models on both applications and out-of-domain events data.

1 Introduction

Event-level language models (LMs) provide a way to reason about events, and to approximate schematic and script-like knowledge (Schank and Abelson, 1977; Balasubramanian et al., 2013; Nguyen et al., 2015) about them (Modi and Titov, 2014; Pichotta and Mooney, 2016; Weber et al., 2018). These models aim to learn high-level representations of complex events (e.g., an arrest) and possibly their entity roles from raw text (e.g., a suspect). However, a major limitation is their reliance on the *discourse* order of event mentions when training the LM. Although powerful, these event LMs capture information we don't want in true world knowledge. For instance, a script of events may be weakly ordered in real life, but the system instead learns to strongly rely on the text order in which the events were described. Figure 1 shows an example where discourse and actual temporal order are different: a model trained on newswire may learn the pattern on the left from obituaries, but will fail to generalize to biographical or other narrative descriptions of someone's life.

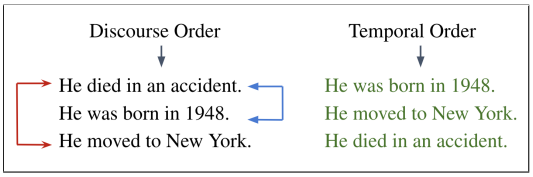

Figure 1: Example of an event schema for which the discourse order is different from the temporal order.

In this paper, we aim to improve event-level LMs in order to make them more suitable for general knowledge learning. While a range of possible modifications to the model can be imagined, such as set transformers (Lee et al., 2019), we want to leverage autoregressive pre-trained LMs. We instead find that we can encode the necessary invariances via data augmentation: namely, we apply a set of event sequence perturbations to sequences in the training data to relax the model's dependence on discourse order. By considering the next event based on shuffled sequences of events, we encourage the model to treat the input more as a set of events rather than strictly as a discourse sequence.

Surprisingly, despite our disruption of discourse order, experiments show how perturbations can improve event language modeling of text, particularly when evaluating the model on other domains which present events in different orders (e.g., novels or blogs present data in more of a "narrative" fashion than news datasets common in NLP (Yao and Huang, 2018)). Our experiments evaluate accuracy on the Inverse Narrative Cloze task on in-domain newswire, as well as out-domain novels and blogs[1].

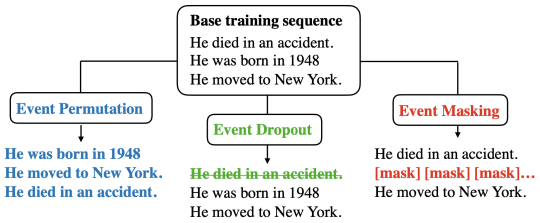

Figure 2: Sequence perturbations strategies.

2 Perturbing Discourse Sequences

Event language modeling tasks are typically defined over sequences of events as they appear in text. The events can be represented either as a sequence of words annotated with predicate-argument structure (e.g., semantic roles (Pichotta and Mooney, 2016), Open IE tuples (Weber et al., 2018; Rudinger et al., 2015) or with compositional embeddings (Modi, 2016). Generative models are trained to predict subsequent events in a sequence conditioning on previously observed events. Naturally, these models learn the order in which events appeared in text (Manshadi et al., 2008).

However, relying on discourse order may not be necessary and can potentially limit generalization of event LMs. For some event related tasks such as schema learning (Weber et al., 2018), the discourse order is not directly relevant. For other tasks such as event ordering (Pustejovsky et al., 2003; Chambers et al., 2014; Wang et al., 2018), temporal or logical order of events is most critical – discourse order, at best, is a noisy proxy. In fact, the first systems for schema learning were noticeably *not* language models (Mooney and DeJong, 1985; Chambers and Jurafsky, 2009, 2011). We introduce three simple perturbation techniques shown in Figure 2 that relax the reliance on discourse sequences.

2.1 Event Permutation

One way to reduce reliance on discourse order is to expose the model to random permutations of the input sequences, as shown in Figure 2. Using all possible permutations of a sequence is impractical, so we introduce three specific shuffles that force the model to pay attention to long-term dependencies and avoid the over-reliance on local dependencies/order:

- Reversed order: given a set of events as `ABCD`, the reverse of the sequence is created as `DCBA`.
- Concatenation of events in the odd positions followed by the even positions of the sequence: the permuted sequence is `BDAC`.
- Concatenation of event tuples in the odd positions followed by those in the even positions of the *reverse* order of the original sequence. The new sequence is: `CADB`

These shuffle patterns were selected to minimize the chance of repetition across permutations.

2.2 Event Dropout

We also consider event dropout as another perturbation to the original discourse sequence. For each sequence, we remove a small random subset of events (Event Dropout in Figure 2). We create multiple reduced sequences for each original sequence. The reduced sequences are treated in the same way as the original sequences for training the model. This perturbation is a type of regularization against overfitting on any specific event in a sequence, much like standard dropout procedures.

2.3 Event Masking

When dropping events, we can provide additional information to the model about where events were dropped. This forces the model to capture longer-term dependencies among events in the sequence. We randomly select a number of event tuples and replace their tokens with a `<mask>` token (Masking in Figure 2). For each sequence in the training set, we generate its masked sequences with each having a fixed proportion of its events masked.

3 Experimental Setup

Data We train event language models on the Annotated NYT corpus using Open IE event tuples extracted by Ollie (Schmitz et al., 2012). The dataset contains a total of around 1.8 million articles. After preprocessing steps, 1,467,366 articles are used as the training set, 6k articles as test set and 4k articles as the dev set. Each event is a 4-tuple `(v,s,o,p)` containing the verb, subject, object and preposition. We follow the same preprocessing steps outlined in Weber et al. (2018) to create event sequences.

The components of the events (the verb, subject, etc.) are all individual tokens, and are treated like normal text. For example, the events (truck packed with explosives), (police arrested suspect), would be given to the model as: packed truck explosives with [TUP] arrested police suspect _NULL_, where

NULL is the null preposition token and [TUP] is a special separator token between events.

Each document is first partitioned into segments of four sentences each. All events extracted from each segment are concatenated (in discourse order) to form an event sequence. This is a simple heuristic to avoid considering event sequences that can drift or connect otherwise unrelated events. Tuples with common verbs (is, are, be, ...) and repeating predicates are also ignored.

The training, development, and test splits have 7.1M, 19K, and 29K event sequences respectively. During training, depending on the perturbation strategy used, a number of sequences are added to the initial sets. The numbers are hyperparameters, selected differently for each model. Details are given in the following sections.

Autoregressive Models Our baseline autoregressive event LM is a pretrained GPT-2 model (Radford et al., 2019) fine-tuned on the event sequences.

Once the perturbations are applied to the original sequence, the modified sequence is used as both the input and the output of the model. We trained variants of GPT-2 with different sequence perturbations as shown in Figure 2 in our experiments. For the dropout and masked versions, we created $n/3$ new sequences with n being the number of events in the sequence. Each sequence has $n/3$ of its events either dropped or masked.

Autoencoding Models We use HierarchicAl Quantized Autoencoder (HAQAE) (Weber et al., 2018) as a strong autoencoding model. HAQAE is an LSTM-based autoencoder, which uses a hierarchical latent space to model event sequences. HAQAE uses categorical global latent variables to represent a tree-structured hierarchy which allow it to model different types of schemas and their possible tracks. Different levels of this hierarchical structure capture different levels of features of the schemas.

For training the HAQAE model, instead of reconstructing a perturbed sequence, we explore a denoising style training objective, where we *only* perturb the input part of the sequence keeping the output the same as the original. Our hypothesis is that these models learn a perturbation-invariant latent space representation in both cases, which will help break the dependence on discourse order. We use the denoising variant in our experiments as it worked better than the standard reconstruction objective in our initial experiments.

	Type of System	PPL Val	PPL Test	INC Val	INC Test
	Random Baseline	-	-	16.60	16.60
Auto regressive	RNNLM	91.84	90.92	25.30	26.30
	GPT-2 Baseline	85.13	84.13	26.80	28.30
	GPT-2 Masked	87.96	87.26	26.30	27.10
	GPT-2 Dropout	83.46	82.56	26.70	27.70
	GPT-2 Permuted	**83.18**	**82.26**	**27.45**	**28.90**
Auto encoding	HAQAE-Baseline	142.22	140.89	31.80	33.85
	HAQAE-Masked	148.07	147.03	33.80	36.80
	HAQAE-Dropout	**122.69**	**122.30**	31.25	32.25
	HAQAE-Permuted	143.39	142.07	**34.75**	**38.55**

Table 1: Perplexity and the accuracy of Inverse Narrative Cloze task. Lower is better for perplexity while higher is better for INC.

For each sequence in the permutation model, we generated permuted sequences for 10% of the original sequences. As for the dropout and masked models, we created $n/4$ new sequences with n being the number of events in the sequence. Each sequence has $n/3$ of its events either dropped or masked. Preliminary experiments showed little difference between using all the data vs a subset.

Models Hyperparameters The GPT-2 model uses the implementation from Huggingface library (Wolf et al., 2020) using a pre-trained gpt-2 small model and tokenizer. Adam optimizer (Kingma and Ba, 2014) is used with an initial learning rate of $6.25e-5$.

The HAQAE model uses 5 discrete latent variables. Each variable can initially take on K = 512 values, with an embeddings dimension of 256. The encoder is a bidirectional, single layer RNN with GRU cell (Cho et al., 2014) with a hidden dimension of size 512. The embeddings size is 300 which are initialized with pretrained GloVe (Pennington et al., 2014) vectors. The decoder is also a single layer RNN with GRU cells with a hidden dimension of 512 and 300 dimensional word embeddings (initialized) as inputs. All experiments use a vocabulary size of 50k. Adam optimizer with a learning rate of 0.0005 is used.

4 Evaluation

We ran different experiments to answer the following questions:

How do sequence perturbation techniques improve event language modeling? We evaluate perplexity as is standard in Table 1, but aside from

System	Blogs	Novels	News
HAQAE-baseline	24.31	25.10	32.25
HAQAE-permuted	**31.95**	**28.45**	**38.75**

Table 2: INC accuracy on external data

Legitimate Sequence	Confounding Sequence
↓	↓
he issued estimates	he issued estimates
he received extension	homes assess ability
candidate pledged before primary	department specify information
return release in august	provisions govern training
griffin president of investments	promise of laws unfulfilled
lauder pay income	promise remains unfulfilled

Figure 3: A legitimate sequence and its confounding.

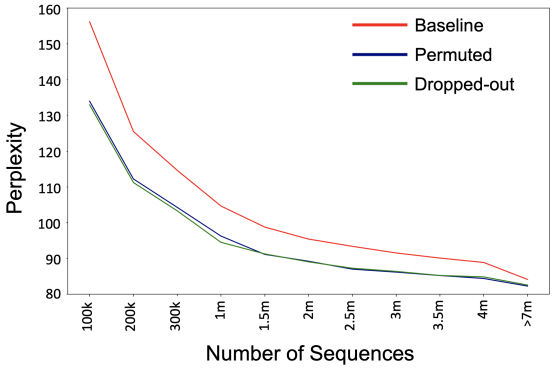

Figure 4: Perplexity of different GPT-2 models with respect to the number of training sequences.

perplexity, we want to see how well event LMs capture schematic knowledge. We thus evaluate on the inverse narrative cloze (INC) task (Weber et al., 2018). Given the first event from an original discourse sequence and a set of candidate event sequences, the task is to identify the true event sequence completion. This evaluation is closer to our ultimate goal: identifying realistic event schemas rather than discourse-focused metrics like perplexity.

The INC evaluation starts with a gold sequence of events from a real document, and then includes 5 other event sequences pulled from confounding documents. You insert the first gold event artificially at the start of each of these. The gold event sequence should have high probability compared to the confounding event sequences. Figure 3 shows a gold sequence and one confounding sequence generated for it. The six sequences are ranked based on the probabilities assigned by the model, and then the accuracy is the number of predictions where the gold sequence is ranked first. A random model will uniformly choose one among the six sequences and thus will have an accuracy of 16.6%.

The perplexity[2] and the INC accuracy of different variants of both autoregressive and autoencoding models are shown in Table 1.

Using sequence perturbations improves the INC accuracy on both test and validation sets for both categories of models. Further, the sequence perturbations gain in terms of INC accuracy is much higher with HAQAE.

[2]For autoencoders we report generative perplexity with the KL-term, while the original paper (Weber et al., 2018) has the lower reconstructive perplexity without the KL-term.

How do models trained with perturbation techniques perform on out-of-domain data? The NYT corpus used for training the models in this study is newswire. The journalistic writing style does not always follow the temporal ordering of events, but represents the events in various orders going backwards or forward in time. One might argue that the reason the sequence perturbations work better in terms of INC accuracy is that the events extracted from news do not necessarily follow the temporal order and therefore the perturbations will not create an issue. To show the effectiveness of our approach, we evaluated the performance of our models on the event sequences extracted from narratives coming from different domains: novels, blogs and news (Yao and Huang, 2018).

We used the OpenIE extraction system in a similar fashion to extract the event tuples from the narrative sequences. We used our best-performing model from the previous section and with no fine-tuning applied the models to see how our sequence perturbations performed in terms of INC accuracy on these narrative texts. The results of this analysis are presented in Table 2. The numbers show that the proposed sequence perturbations perform better on out-of-domain data (with explicit temporal links) compared to the baseline model.

How effective are the sequence perturbation techniques with respect to the number of training instances? Our sequence perturbations can be seen as data augmentation strategies which will help models learn new aspects of data that can not be learned from the original sequences. As the number of training samples increases, the model has more opportunities to learn these aspects. Therefore, the sequence perturbations will be more useful for domains with fewer training samples.

	seed	generated events	ppl(g—s)	ppl(g—ps)
HAQAE-Baseline	people reported fire, fire spread to forest	people died in fire, fire caused fires	4.49	6.49
	fire spread to forest, people reported fire	person spokesman for department, firefighters taken to hospital	5.21	6.30
HAQAE-permuted	people reported fire, fire spread to forest	fires began today, people working in area	5.75	5.58
	fire spread to forest, people reported fire	fires began today, people working in area	5.58	5.75

Table 3: Generated schemas for two-event seeds. The second row for each model shows the generated schemas for permuted seed events. ppl(g—s) and ppl(g—ps) are the perplexity of generated events given the seed events and the perplexity of events given permuted seeds. The lower the difference the more robust the model is to permutations.

	seed	generated events
HAQAE-baseline	fire spread to neighborhood, people reported fire	people fire to floor, person spokesman for department
	fire spread to forest, people reported fire	firefighters fire to floor, person spokesman for department
HAQAE-permuted	fire spread to neighborhood, people reported fire	Fire spread through floors, fire came from floor
	fire spread to forest, people reported fire	fires began today, people working in area

Table 4: Generated schemas for two-event seeds. The second event is the same while the first event shows a different branch.

We plotted the perplexity with respect to the number of training sequences for the GPT-2 baseline system as well as permuted and dropout models. As can be seen in Figure 4, the gap between the perplexity scores are higher when the number of sequences are lower. This observation suggests that our approach will result in better language models for domains with limited data.

How do schemas generated by different models differ from each other? We generated schemas for 46 two-event seeds using the HAQAE baseline and permuted models. We wanted to see how the generated schemas differ in two different aspects: First, for each seed, we permuted the events and generated schemas for both models. We expect the permuted model to have less variation in generating events for original and permuted seeds. We calculated the perplexity of the generated events for both the original order of events as well as the permuted order. Table 3 shows an example of such scenario where the HAQAE-permuted model has lower variation in perplexity for permuted seed events.

Second, we want to see how dependent the generation is upon the most recent event in the sequence. We generated schemas for two-event seeds in which the last event is the same while the first event indicates a different path. Table 4 shows an example where the permuted model generates more diverse events.

5 Conclusion

We proposed a set of simple sequence perturbations to relax the model's reliance on the discourse order of event mentions for event language modeling. By predicting the next event based on perturbed sequences, the model is encouraged to treat the input as a *set* of events. Our experiments show that these perturbations can improve identifying event schemas measured by INC accuracy both on in-domain and out-of-domain data.

The Curse of Dense Low-Dimensional Information Retrieval for Large Index Sizes

Nils Reimers and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technical University of Darmstadt
www.ukp.tu-darmstadt.de

Abstract

Information Retrieval using dense low-dimensional representations recently became popular and showed out-performance to traditional sparse-representations like BM25. However, no previous work investigated how dense representations perform with large index sizes. We show theoretically and empirically that the performance for dense representations decreases quicker than sparse representations for increasing index sizes. In extreme cases, this can even lead to a tipping point where at a certain index size sparse representations outperform dense representations. We show that this behavior is tightly connected to the number of dimensions of the representations: The lower the dimension, the higher the chance for false positives, i.e. returning irrelevant documents.

1 Introduction

Information retrieval traditionally used sparse representations like TF-IDF or BM25 to retrieve relevant documents for a given query. However, these approaches suffer from the lexical gap problem (Berger et al., 2000).

To overcome this issue, dense representations have been proposed (Gillick et al., 2018): Queries and documents are mapped to a dense vector space and relevant documents are retrieved e.g. by using cosine-similarity. Out-performance over sparse lexical approaches has been shown for various datasets (Gillick et al., 2018; Guo et al., 2020; Guu et al., 2020; Gao et al., 2020).

Previous work showed the out-performance for fixed, rather small indexes. The largest dataset where it has been shown is the MS Marco (Bajaj et al., 2018) passage retrieval dataset, where retrieval is done over an index of 8.8 million text passages. However, in production scenarios, index sizes quickly reach 100 millions of documents.

We show in this paper, that the performance for dense representations can decrease quicker for increasing index sizes than for sparse representations. For a small index of e.g. 100k documents, a dense approach might clearly outperform sparse approaches. However, with a larger index of several million documents, the sparse approach can outperform the dense approach.

We show theoretically and empirically that this effect is closely linked to the number of dimensions for the representations: Using fewer dimensions increases the chances for false positives. This effect becomes more severe with increasing index sizes.

2 Related Work

A common choice for dense retrieval is to fine-tune a transformer network like BERT (Devlin et al., 2018) on a given training corpus with queries and relevant documents (Guo et al., 2020; Guu et al., 2020; Gao et al., 2020; Karpukhin et al., 2020; Luan et al., 2020). Recent work showed that combining dense approaches with sparse, lexical approaches can further boost the performance (Luan et al., 2020; Gao et al., 2020). While the approaches have been tested on various information and question answering retrieval datasets, the performance was only evaluated on fixed, rather small indexes. Guo et al. (2020) evaluated approaches for eight different datasets having index sizes between 3k and 454k documents.

We are not aware of previous work that compares sparse and dense approaches for increasing index sizes and the connection to the dimensionality. The only work we are aware of that systematically studies the encoding size for dense approaches is (Luan et al., 2020), but they only studied the connection to the document length.

3 Theory

Dense retrieval approaches map queries and documents[1] to a fixed size dense vector. The most relevant documents for a given query can then be found using cosine-similarity.

Using as few dimensions as possible is desirable, as it decreases the memory requirement to store (an index) of millions of vectors and leads to faster retrieval. However, as we show, lower-dimensional representations can have issues with large indices.

Given a query vector $q \in \mathbb{R}^k$, we search our index of document vectors $d_1, ..., d_n \in \mathbb{R}^k$ for the documents that maximizes:

$$\text{cossim}(q, d_i) = \cos(\theta) = \frac{q \cdot d_i}{\|q\| \, \|d_i\|}$$

Note: In the following we just show the case for cosine similarity. The proof extends to other similarity functions like dot-product and any p-norm (Manhatten, Euclidean) as long as the vector space is finite. A finite n-dimensional vector space can be mapped to an $n+1$-dimensional vectors space with vectors of unit length. In that case, dot-product in n dimensions is equivalent to cosine-similarity in $n+1$ dimensions. Similar, any p-norm in n dimensions can be re-written as cosine-similarity in $n+1$ dimensions.

Theorem: The probability for false positives (I) increases with the index size n and (II) with the decreasing dimensionality k.

Proof (I): Given a query q and the relevant document d_r. For simplicity, we assume only a single relevant document. If multiple documents are relevant, we consider only the one with the highest cosine similarity. In order that no false positive is returned, $\text{cossim}(q, d_r)$ must be greater than $\text{cossim}(q, d_i)$ for all $i \neq r$. Assume the possible vectors are independent. Then, the probability for a false positive is

$$P(\text{false positive}) = 1-(1-P(\text{false positive}_i))^{n-1}$$

for an index with $n-1$ negative elements and $P(\text{false positive}_i)$ the probability that a single element is a false positive, i.e. $\text{cossim}(q, d_i) > \text{cossim}(q, d_r)$.

Proof (II): While the previous proof is straightforward, that the chance of false positives increases with larger index sizes, the more interesting aspect is the relation to the dimensionality, i.e., what is the probability $P(\text{false positive}_i)$ = $P(\text{cossim}(q, d_i) > \text{cossim}(q, d_r))$ for a random d_i? We show that this probability decreases with more dimensions.

Without loss of generality, we assume that the vectors are of unit length. The vectors are then on an k-dimensional sphere with radius 1. A false positive happens if $\text{cossim}(q, d_i) > \text{cossim}(q, d_r)$, or, equivalent if $1-\text{cossim}(q, d_i) < 1-\text{cossim}(q, d_r)$. I.e., we intersect the sphere in k dimensions with a hyperplane in $k-1$ dimensions. The area of the cut-off portion is defined by $1-\text{cossim}(q, d_r)$. All vectors within the cut-off portion (i.e. spherical cap) are false positives. The probability that a random vector will be returned as false positive is:

$$P(\text{false positive}_i) = A_{cap}/A_{sphere}$$

with A_{cap} the surface area of the spherical cap and A_{sphere} the surface area of the sphere in k dimensions. Define the surface area of the sphere in k dimensions as A_k, then the surface area of A_{cap} is (Li, 2011):

$$A_{cap} = \frac{1}{2} A_k I_{sin^2\theta}\left(\frac{k-1}{2}, \frac{1}{2}\right)$$

with $I_x(a, b)$ the regularized incomplete beta function and θ the polar angle, i.e. the angle between q and the relevant document d_r. Hence:

$$P(\text{false positive}_i) = \frac{1}{2} I_{sin^2\theta}\left(\frac{k-1}{2}, \frac{1}{2}\right) \quad (1)$$

For constant cosine similarity between query q and relevant document d_r, $I_{sin^2\theta}\left(\frac{k-1}{2}, \frac{1}{2}\right)$ is a monotonically decreasing function with increasing dimension k. In conclusion, more dimensions decrease the probability for false positives.

Combining (I) and (II) shows that a low dimensional representation might work well for small index sizes. However, with more indexed documents, the probability of false positives increases faster for low dimensional representations than for higher dimensional representations. Hence, at some index size, higher dimensional representations might outperform the lower-dimensional representation.

4 Empirical Investigation

In the proof, we have assumed that vectors are independent and uniformly distributed over the space, which gives us a lower bound on the false positive rate. However, in practice, dense representations are neither independent nor uniformly

[1] We use *document* as a cover-term for text of any length.

distributed. As shown in (Ethayarajh, 2019; Li et al., 2020), dense representations derived from pre-trained Transformers like BERT map to an anisotropic space, i.e., the vectors occupy only a narrow cone in the vector space. This drastically increases the chance that an irrelevant document is closer to the query embedding than the relevant document. Hence, we study how actual dense models are impacted by increasing index sizes and lower-dimensional representations.

4.1 Dataset

We conduct our experiments on the MS MARCO passage dataset (Bajaj et al., 2018). It consists of over 1 million unique real queries from the Bing search engine, together with 8.8 million paragraphs from heterogeneous web sources. Most of the queries have only 1 passage judged as relevant, even though more can exist. The development set consists of 6980 queries and the performance is evaluated using mean reciprocal rank MRR@10.

To better compare the relative performance differences, we compute a rank-aware error rate:

$$\text{Err} = \frac{1}{n}\sum_{i=1}^{n}\left(1 - \frac{1}{\text{rank}_i}\right)$$

with rank_i being the rank of the relevant document for the i-th query. To be compatible with MRR@10, we set $\text{rank}_i = \infty$ for $\text{rank}_i > 10$. We then define the relative error rate as $\text{Err}_{\text{Dense}}/\text{Err}_{\text{BM25}}$. A relative error rate of 50% indicates that the dense approach makes only 50% of the errors compared to BM25 retrieval.

4.2 Model

For sparse, lexical retrieval, we use ElasticSearch, which is based on BM25. For dense retrieval, we use a DistilRoBERTa-base model (Sanh et al., 2020) as a bi-encoder: The query and the passage are passed independently to the transformer model and the output is averaged to create fixed-sized representations. We train this using InfoNCE loss (van den Oord et al., 2018):

$$L = -\log \frac{\exp(\tau \cdot \text{cossim}(q, p_+))}{\sum_i \exp(\tau \cdot \text{cossim}(q, p_i))}$$

with q the query, p_+ the relevant passage. We use in-batch negative sampling and use the other passages in a batch as negative examples. We found that $\tau = 20$ performs well. We train the model in two setups: 1) only with random (in-batch) negatives, and 2) we provide for each query additionally one hard-negative passage. We use the hard-negative passages provided by the MS MARCO dataset, which were retrieved using lexical search. Models are trained with a batch size of 128 with Adam optimizer and a learning rate of $2e-5$.

DistilRoBERTa produces representations with 768 dimensions. We also experiment with lower-dimensional representations. There, we added a linear projection layer on-top of the mean pooling operation to down-project the representation to either 128 or 256 dimensions. Dense retrieval is performed using cosine similarity with exact search.

Models were trained using the SBERT framework (Reimers and Gurevych, 2019).[2]

5 Experiments

First, we study the impact of increasing index sizes with real text passages. Then, we study the performance when random noise is added.

5.1 Increasing Index Size

In the first experiment, we start with an index that only contains the 7433 relevant passages for the 6980 queries. Then, we add step-wise randomly selected passages from the MS MARCO corpus to the index until all 8.8 million passages are indexed.

Model	10k	100k	1M	8.8M
BM25	79.93	63.88	40.14	17.56
Trained without hard negatives				
128 dim	87.50	68.63	39.76	15.71
256 dim	88.82	70.79	41.74	17.08
768 dim	88.99	71.06	42.24	17.34
Trained with hard negatives				
128 dim	90.32	77.92	54.45	27.34
256 dim	91.10	78.90	55.51	28.16
768 dim	91.48	79.42	56.05	28.55

Table 1: Dev performance (MRR@10 $\times 100$) on MS MARCO passage dataset with different index sizes. Higher score = better.

Table 1 shows the MRR@10 performance for the different systems. Increasing the index naturally decreases the performance for all systems, as retrieving the correct passages from a larger index is more challenging. The dense approach trained without hard negatives clearly outperforms BM25 for an index with 10k - 1M entries, but with all 8.8 million passages it performs worse than BM25.

Table 2 shows the relative error rate in comparison to BM25 retrieval. For small index sizes, we

[2] https://www.SBERT.net

Model	10k	100k	1M	8.8M
Trained without hard negatives				
128 dim	62.3	86.8	100.6	102.2
256 dim	55.7	80.9	97.3	100.6
768 dim	54.9	80.1	96.5	100.3
Trained with hard negatives				
128 dim	48.2	61.1	76.1	88.1
256 dim	44.3	58.4	74.3	87.1
768 dim	42.5	57.0	73.4	86.7

Table 2: Relative error rate (%) of dense approaches in comparison to BM25 retrieval. Lower score = better.

observe that dense approaches drastically reduce the error rate compared to BM25 retrieval. With increasing index sizes, the gap closes.

5.2 Index with Random Noise

MS MARCO is sparsely labeled, i.e., there is usually only a single passage labeled as relevant even though multiple passages would be considered as relevant by humans (Craswell et al., 2020). To avoid that the drop in performance is due to the retrieval of relevant, but unlabeled passages, we perform an experiment where we add random irrelevant noise to the index. Our index consists only of the relevant passages and a large fraction of irrelevant, randomly generated strings.[3]

We also evaluate the popular DPR system by Karpukhin et al. (2020), which is a BERT-based dense retriever trained on the Natural Questions (NQ) dataset (Kwiatkowski et al., 2019). We chose the NQ dev set, consisting of 1772 questions from Google search logs. DPR encodes the passage as `Title [SEP] Paragraph`. We create a random string for the paragraph and combine it with 1) a randomly generated string as title, 2) selecting randomly one of the over 6 Million real Wikipedia article titles, 3) selecting randomly one of the 1772 article titles found in the NQ dev set.

We count for how many queries a random string is ranked higher than the relevant passage. The results are shown in Table 3. We observe that BM25 does not rank any randomly generated passage higher than the relevant passage for the MS MARCO dataset. The chance that a random passage contains words matching the query is small.

For the dense retrieval models, we observe for quite a large number of queries that a random string passage is ranked higher than the relevant passage. As proven in Section 3, the error increases with larger index sizes and fewer dimensions.

[3]Strings are generated randomly using lowercase characters a-z and space.

Model	100k	1M	10M	100M
BM25	0.00%	0.00%	0.00%	0.00%
Dense without hard negatives - MS MARCO				
128 dim	2.71%	4.41%	6.69%	9.73%
256 dim	2.39%	4.03%	6.16%	9.04%
768 dim	2.13%	3.72%	5.77%	8.52%
Dense with hard negatives - MS MARCO				
128 dim	2.87%	4.20%	6.00%	8.11%
256 dim	2.45%	3.72%	5.59%	7.38%
768 dim	2.12%	3.32%	5.09%	7.03%
DPR (Karpukhin et al., 2020) - Natural Questions				
rnd title	0.17%	0.28%	0.34%	0.51%
all titles	2.48%	5.59%	9.31%	12.08%
dev titles	4.18%	5.36%	6.66%	8.01%

Table 3: Percentage of queries for which a random string passage is ranked higher than the relevant passage. 100k/1M/10M/100M indicates the number of random passages in the index.

For DPR, we observe an extreme dependency on the title. Having 100 million entries in the index with a real Wikipedia article title and a random paragraph, results in the retrieval of those for about 12.08% of all questions at the top position.

The error numbers far exceed the estimation from equation (1), confirming that the representations are not uniformly distributed over the complete vector space and are concentrated in a small space. In the appendix (Figure 1), we plot the representations for the queries, the relevant passages, and the random strings.

6 Conclusion

We have proven and shown empirically that the probability for false positives in dense information retrieval depends on the index size and on the dimensionality of the used representations. These approaches can even retrieve completely irrelevant, randomly generated passages with high probability. It is important to understand the limitations of dense retrieval:

1) Dense approaches work better for smaller, clean indexes. With increasing index size the difference to sparse approaches can decreases.

2) Evaluation results with smaller indexes cannot be transferred to larger index sizes. A system that is state-of-the-art for an index of 1 million documents might perform badly on larger indices.

3) The false positive rate increases with fewer dimensions.

4) The empirically found error rates far exceeded the mathematical lower-bound error rates, indicating that only a small fraction of the available vector space is effectively used.

A Plot of Random Noise Index

Figure 1 shows a two-dimensional plot of the 6980 development queries in the MS MARCO passage dataset, together with the 7433 passages that are marked as relevant and 7433 representations for randomly generated strings (using lowercase characters and space with a random length between 20 and 150 characters). The representation for the random strings are concentrated, but we still observe a significant overlap with the region for queries and relevant documents. This explains why random strings are retrieved for certain queries (Table 3). We use the dense model that was trained with hard negatives with 768 dimensions. UMAP (McInnes et al., 2018) is used for dimensionality reduction to 2 dimensions.

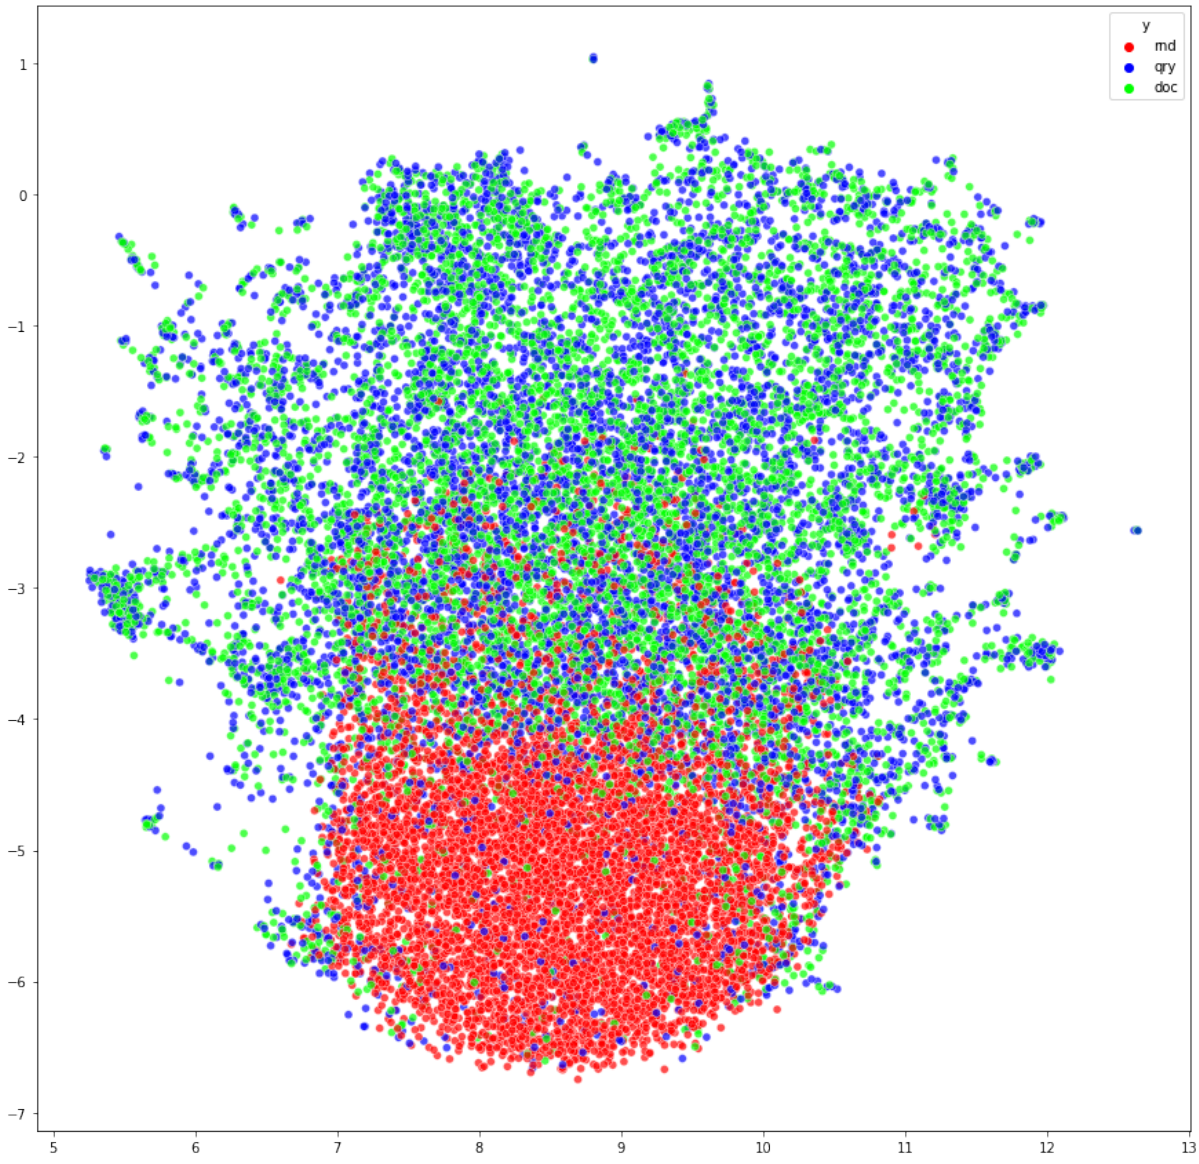

Figure 1: Plot of queries (blue), the relevant document (green) and representations from randomly generated strings (red). Dimensionality reduction via UMAP (McInnes et al., 2018). Model with hard negatives, 768 dimensions.

Cross-lingual Text Classification with Heterogeneous Graph Neural Network

Abstract

Cross-lingual text classification aims at training a classifier on the source language and transferring the knowledge to target languages, which is very useful for low-resource languages. Recent multilingual pretrained language models (mPLM) achieve impressive results in cross-lingual classification tasks, but rarely consider factors beyond semantic similarity, causing performance degradation between some language pairs. In this paper we propose a simple yet effective method to incorporate heterogeneous information within and across languages for cross-lingual text classification using graph convolutional networks (GCN). In particular, we construct a heterogeneous graph by treating documents and words as nodes, and linking nodes with different relations, which include part-of-speech roles, semantic similarity, and document translations. Extensive experiments show that our graph-based method significantly outperforms state-of-the-art models on all tasks, and also achieves consistent performance gain over baselines in low-resource settings where external tools like translators are unavailable.

1 Introduction

The success of recent deep learning based models on text classification relies on the availability of massive labeled data (Conneau et al., 2017; Tian et al., 2020; Guo et al., 2020). However, labeled data are usually unavailable for many languages, and hence researchers have developed the setting where a classifier is only trained using a resource-rich language and applied to target languages without annotated data (Xu et al., 2016; Chen and Qian, 2019; Fei and Li, 2020). The biggest challenge is to bridge the semantic and syntactic gap between languages. Most existing methods explore the semantic similarity among languages, and learn a language-agnostic representation for documents from different languages (Chen et al., 2018; Zhang et al., 2020a). This includes recent state-of-the-art multilingual pretrained language models (mPLM) (Devlin et al., 2019; Conneau and Lample, 2019), which pretrain transformer-based neural networks on large-scale multilingual corpora. The mPLM methods show superior cross-lingual transfer ability in many tasks (Wu and Dredze, 2019). However, they do not explicitly consider syntactic discrepancy between languages, which may lead to degraded generalization performance on target languages (Ahmad et al., 2019; Hu et al., 2020).

On the other hand, there usually exists sufficient unlabeled target-language documents that come naturally with rich information about the language and the task. However, only a handful of previous researches have taken advantage of the unlabeled data (Wan, 2009; Dong and de Melo, 2019).

To integrate both semantic and syntactic information within and across languages, we propose a graph-based framework named Cross-Lingual Heterogeneous GCN (CLHG). Following the work of TextGCN (Yao et al., 2019), we represent all the documents and words as graph nodes, and add different types of information into the graph. We utilize mPLM to calculate the representation of all the nodes, and connect documents nodes with semantically similar ones to extract the knowledge in mPLM. Words are connected with documents based on the co-occurrences as in previous works. However, we choose to separate different word-doc edges by part-of-speech (POS) tags of words to inject some shallow syntactic information into the graph, as POS taggers are one of the most widely accessible NLP tools, especially for low-resource languages. In-domain unlabeled documents are added to the graph if available. To further absorb

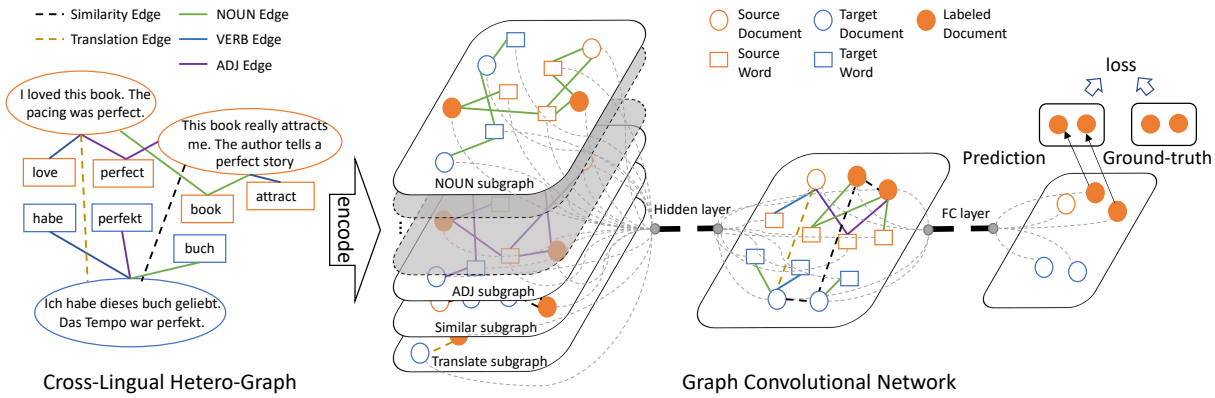

Figure 1: Illustration of our Cross-Lingual Heterogeneous GCN (CLHG) framework. For simplicity, only some POS tags are plotted in this graph. We recommend to view this figure in color as we use different colors to indicate different languages and edge types.

in-domain language alignment knowledge, we utilize machine translation to create translated text nodes. The text classification task is then formalized as node classification in the graph and solved with a heterogeneous version of Graph Convolutional Networks (Kipf and Welling, 2017). Our contributions are summarized as follows:

(1) We propose a graph-based framework to easily comprise heterogeneous information for cross-lingual text classification, and design multiple types of edges to integrate all these information. To the best of our knowledge, this is the first study to use heterogeneous graph neural networks for cross-lingual classification tasks. (2) We conduct extensive experiments on 15 tasks from 3 different datasets involving 6 language pairs. Results show that our model consistently outperforms state-of-the-art methods on all tasks without any external tool, and achieves further improvements with the help of part-of-speech tags and translations.

2 Related Works

Traditional methods for cross-lingual classification usually translate the texts (Wan, 2009) or the classifier model (Xu et al., 2016) with external aligned resources such as bilingual dictionaries (Andrade et al., 2015; Shi et al., 2010) or parallel corpora (Duh et al., 2011; Zhou et al., 2016; Xu and Yang, 2017). Recent works focus on learning a shared representation for documents of different languages, including bilingual word embeddings (Zou et al., 2013; Ziser and Reichart, 2018; Chen et al., 2018), common subword representations (Zhang et al., 2020a), and multilingual pretrained language models (mPLM) (Devlin et al., 2019; Conneau and Lample, 2019; Clark et al., 2020).

In the past few years, graph neural networks (GNN) have attracted wide attention, and become increasingly popular in text classification (Yao et al., 2019; Hu et al., 2019; Ding et al., 2020; Zhang et al., 2020b). These existing work mainly focus on monolingual text classification, except a recent work (Li et al., 2020) using meta-learning and graph neural network for cross-lingual sentiment classification, which nevertheless only uses GNN as a tool for meta-learning.

3 Method

In this section, we will introduce our CLHG framework, including how to construct the graph and how to solve cross-lingual text classification using heterogeneous GCN. In general, we first construct a cross-lingual heterogeneous graph based on the corpus and selected features, and next we encode all the texts with multilingual pre-trained language models, then we pass the encoded nodes to the heterogeneous GCN, each layer of which performs graph convolution on different subgraphs separated by different edge types, and aggregates the information together. Finally, the graph neural network outputs the predictions of doc nodes, which will be compared with groundtruth labels during training. Figure 1 shows the overall structure of the framework.

3.1 Graph Construction

Inspired by some previous works on GNN-based text classification (Yao et al., 2019; Hu et al., 2019), we construct the graph by representing both documents and words from the corpus in both languages

as graph nodes, and augment the corpus by including unlabeled in-domain documents from the target language. To extract more information of language alignments, we further use a publicly available machine translation API[1] to translate the documents in both directions. Then two categories of edges are defined in the graph.

Doc-word Edges. Like TextGCN (Yao et al., 2019), documents and words are connected by their co-occurrences. To inject syntactic information more than just co-occurrences, we add part-of-speech (POS) tags to the edges, since different POS roles have different importance in the classification tasks. Adjectives and adverbs are mostly decisive in sentiment classification, while nouns may play a more significant role in news classification. Therefore, we use POS taggers to tag each sentence and create different types of edges based on the POS roles of the words in the document, which could help GNN to learn different propagation patterns for each POS role.

Doc-doc Edges. To add more direct connections between documents, we include two types of document level edges. Firstly, we link each document with similar ones by finding K documents with the largest cosine similarity. The embeddings of the documents are calculated using mPLM. Secondly, we connect nodes created by machine translation with their original texts.

3.2 Heterogeneous Graph Convolution

After building the heterogeneous cross-lingual graph, we first encode all the nodes using mPLM by directly inputting the text to the mPLM and taking the hidden states of the first token. The encoded node features are fixed during training. Next we apply heterogeneous graph convolutional network (Hetero-GCN) (Hu et al., 2019) on the graph to calculate higher-order representations of each node with aggregated information.

Heterogeneous GCN applies traditional GCN on different sub-graphs separated by different types of edges and aggregates information to an implicit common space.

$$H^{(l+1)} = \sigma(\sum_{\tau \in \mathcal{T}} \tilde{A}_\tau \cdot H_\tau^{(l)} \cdot W_\tau^{(l)}) \qquad (1)$$

where $\tilde{A}_\tau$ is a submatrix of the symmetric normalized adjacency matrix that only contains edges with type τ, $H_\tau^{(l)}$ is the feature matrix of the neighboring nodes with type τ of each node, and $W_\tau^{(l)}$ is a trainable parameter. $\sigma(\cdot)$ denotes a non-linear activation function, which we use leaky ReLU. Initially, $H_\tau^{(0)}$ is the node feature calculated by mPLM.

Empirically, we use two graph convolution layers to aggregate information within second-order neighbors. Then a linear transformation is applied to the document nodes to get the predictions.

4 Experiments

We evaluate our framework on three different classification tasks, including Amazon Review sentiment classification (Prettenhofer and Stein, 2010), news category classification from XGLUE (Liang et al., 2020), and intent classification on a multilingual spoken language understanding (SLU) dataset (Schuster et al., 2019). More details of each dataset is provided in the appendix. For all the tasks, we use only the English samples for training and evaluate on other 6 languages, which are German (DE), French (FR), Russian (RU), Spanish (ES), Japanese (JA), and Thai (TH).

4.1 Experiment Setting

In all our experiments, we use two-layer GCN with hidden size 512 and output size 768. Each document is connected with 3 most similar documents. The model is trained using the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 2×10^{-5} and batch size 256. We train the GCN for at most 15 epochs and evaluate the model with best performance on validation set. XLM-RoBERTa (Conneau et al., 2020) is used to encode all the documents and words, which is finetuned on the English training set of each task for 2 epochs with batch size 32 and learning rate 4×10^{-5}. We set the max length as 128 for intent classification, and 512 for the other two tasks. Each experiment is repeated 3 times and the average accuracy is reported. All the experiments are conducted on an NVIDIA V100 GPU [2].

For part-of-speech tagging, we adopt different taggers for each language [3] and map all the tags to

Universal Dependency (UD) tagset [4].

4.2 Baselines

Our method is compared with different multilingual pretrained models finetuned for each task, which include multilingual BERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) and XLM-RoBERTa (Conneau et al., 2020), and also with published state-of-the-art results on each dataset.

Amazon Review. CLDFA (Xu and Yang, 2017) utilizes model distillation and parallel corpus to transform a model from source to target language. MVEC (Fei and Li, 2020) refines the shared latent space of mPLM with unsupervised machine translation and a language discriminator.

[4] https://universaldependencies.org

XGLUE News Classification. Unicoder (Huang et al., 2019) is another mPLM proposed recently, and is used as the baseline method provided alongside XGLUE benchmark.

Multilingual SLU. CoSDA-ML (Qin et al., 2020) is a data augmentation framework that automatically generates code-switching documents using a bilingual dictionary, which is used when finetuning language models on downstream tasks.

4.3 Results and Analysis

The results are provided in table 1 2 and 3 for each dataset. Our method significantly outperforms state-of-the-art baselines and achieves consistent improvements over XLM-R model. The most performance gain is achieved on the multilingual SLU dataset. Different from the other two, this dataset consists of short texts, and thus the created graph is much cleaner and more suitable for GCN to model.

To verify that the improvement does not come barely from the external data, we conduct another experiment that adds the translated data to the training set and finetunes the baseline XLM-R model on Amazon Review dataset. The results showed very slight improvement (0.09% on average), showing that XLM-R cannot directly benefit from external training data.

Ablation studies are performed on Amazon Review dataset to analyze the effectiveness of different graph structures. From the results provided in table 4, variant 1 containing a homogeneous graph with only word-doc edges (same as TextGCN) performs the worst, while adding more information leads to better performance in general. Comparing variants 4-7, similarity demonstrates to be the most important among all added information. Similarity edges help the model to converge faster and learn better as well, since they provide a "shortcut" between documents that is highly likely to be

Table 4: Ablation study results. The left-most column shows the results of finetuned XLM-R, and others each indicates a variant in graph construction. We conduct experiments on the Amazon Review dataset and report the average accuracy across three domains.

in the same category. Variant 7 shows that unlabeled corpus play an important role in EN→JA setting, but less effective when transferring between similar languages, since unlabeled data inevitably contain some noise and do not provide much help for linguistically-closer languages. Variant 4 also shows that POS tags are more helpful for distant language pairs like EN→JA, and our added experiment on EN→TH shows greater impact of POS tags (89.71→88.06 when removing POS tags). Additionally, we test a variant without any external tool that requires training resources in the target language. Variant 3 does not rely on POS tagger or translation service, and still outperforms the XLM-R baseline with a large margin. This demonstrates that our method can be adopted for real low-resource languages without good tagger or translator.

5 Conclusion

In this study, we propose a novel graph-based method termed CLHG to capture various kinds of information within and across languages for cross-lingual text classification. Extensive experiments illustrate that our framework effectively extracts and integrates heterogeneous information among multilingual corpus, and these heterogeneous relations can enhance existing models and are instrumental in cross-lingual tasks. There may exist some better semantic or syntactic features and combinations of features, which we leave as a future work to explore. We also wish to extend our GNN-based framework to different NLP tasks requiring knowledge transfer and adaptation in the future.

A Datasets

Here we introduce the three datasets we use in our experiments. A summary of the statistics for three datasets are provided in table 5.

Amazon Review [5] This is a multilingual sentiment classification dataset covering 4 languages (English, German, French, Japanese) on three domains (*Books, DVD*, and *Music*). The original dataset contains ratings of 5-point scale. Following previous works (Xu and Yang, 2017; Fei and Li, 2020), we convert the ratings to binary labels with threshold at 3 points. Since English is not used for testing, we follow the previous works and re-construct the training and validation set by combining the English training and test set. The new training set contains 3,200 randomly sampled documents. We use the training set of target languages for validation. This dataset also provides large amount of unlabeled data for each language, which is used in our framework.

XGLUE News Classification [6] This is a subtask of a recently released cross-lingual benchmark named XGLUE. This subtask aims at classifying the category of a news article, which covers 10 categories in 5 languages, including English, Spanish, French, German and Russian. This dataset does not contain unlabeled data for target languages, so we do not add unlabeled documents in our graph either.

Multilingual SLU [7] This dataset contains short task-oriented utterances in English, Spanish and Thai across weather, alarm and reminder domains. We evaluate our framework on the intent classification subtask, which has 12 intent types in total. For each target language, we use the original training set as unlabeled data added in the graph.

B Hyperparameter Search

We perform a grid search to pick the best combination of hyperparameters. The hidden size and output size are chosen among {384, 512, 768}, and the learning rate within $\{1 \times 10^{-5}, 2 \times 10^{-5}, 5 \times 10^{-5}, 1 \times 10^{-4}\}$. For the XLM-R baseline, we also tune the learning rate within $\{2 \times 10^{-5}, 4 \times 10^{-5}, 5 \times 10^{-5}\}$ and number of epochs from 2 to 5. Among all the combination of hyperparameters, we pick the values with the best performance on the German training set from *Books* domain of Amazon Review dataset, and use the same set of hyperparameters for all our experiments. The maximum length of XLM-R model is chosen based on statistics of the datasets.

Towards More Equitable Question Answering Systems: How Much More Data Do You Need?

Arnab Debnath*, **Navid Rajabi***, **Fardina Fathmiul Alam***, **Antonios Anastasopoulos**
Department of Computer Science, George Mason University
{adebnath,nrajabi,falam5,antonis}@gmu.edu

Abstract

Question answering (QA) in English has been widely explored, but multilingual datasets are relatively new, with several methods attempting to bridge the gap between high- and low-resourced languages using data augmentation through translation and cross-lingual transfer. In this project, we take a step back and study which approaches allow us to take the most advantage of *existing* resources in order to produce QA systems in *many* languages. Specifically, we perform extensive analysis to measure the efficacy of few-shot approaches augmented with automatic translations and permutations of context-question-answer pairs. In addition, we make suggestions for future dataset development efforts that make better use of a fixed annotation budget, with a goal of increasing the language coverage of QA datasets and systems.[1]

1 Introduction

Automatic question answering (QA) systems are showing increasing promise that they can fulfil the information needs of everyday users, via information seeking interactions with virtual assistants. The research community, having realized the obvious needs and potential positive impact, has produced several datasets on information seeking QA. The effort initially focused solely on English, with datasets like WikiQA (Yang et al., 2015), MS MARCO (Nguyen et al., 2016), SQuAD (Rajpurkar et al., 2016), QuAC (Choi et al., 2018), CoQA (Reddy et al., 2019), and Natural Questions (NQ) (Kwiatkowski et al., 2019), among others. More recently, heading calls for linguistic and typological diversity in natural language processing research (Joshi et al., 2020), larger efforts have produced datasets in multiple languages, such as TyDi QA (Clark et al., 2020), XQuAD (Artetxe et al., 2020), or MLQA (Lewis et al., 2020).

Despite these efforts, the linguistic and typological coverage of question answering datasets is far behind the world's diversity. For example, while TyDi QA includes 11 languages –less than 0.2% of the world's approximately 6,500 languages (Hammarström, 2015)– from 9 language families, its typological diversity is 0.41, evaluated in a [0,1] range with the measure defined by Ponti et al. (2020); MLQA provides data in 7 languages from 4 families, for a typological diversity of 0.32. The total population coverage of TyDi QA, based on population estimates from Glottolog (Nordhoff and Hammarström, 2012), is less than 20% of the world's population (the TyDiQA languages total around 1.45 billion speakers).

Obviously, the ideal solution to this issue would be to collect enough data in every language. Unfortunately, this ideal seems unattainable at the moment. In this work, we perform extensive analysis to investigate the next-best solution: using the existing resources, large multilingual pre-trained models, data augmentation, and cross-lingual learning to improve performance with just a few or no training examples. Specifically:

- we study how much worse a multilingual few-shot training setting would perform compared to training on large training datasets,
- we show how data augmentation through translation can reduce the performance gap for few-shot setting, and
- we study the effect of different fixed-budget allocation for training data creation across languages, making suggestions for future dataset creators.

[1]Code and data for reproducing our experiments are available here: https://github.com/NavidRajabi/EMQA.

*Equal contribution.

2 Problem Description and Settings

We focus on the task of simplified minimal answer span selection over a **gold passage**: The inputs to the model include the full text of an article (the *passage* or *context*) and the text of a question (*query*). The goal is to return the start and end byte indices of the minimal span that completely answers the question.

Our models follow the current state-of-the-art in extractive question answering, relying on large multilingually pre-trained language models (in our case, multilingual BERT (Devlin et al., 2019)) and the task-tuning strategy of Alberti et al. (2019), which outperforms approaches like DocumentQA (Clark and Gardner, 2018) or decomposable attention (Parikh et al., 2016). In all cases, we treat the official TyDi QA development set as our test set, since the official test set is not public.[2] We provide concrete details (model cards, hyperparmeters, etc) on our model and training/finetuning regime in Appendix A.

To simulate the scenario of data-scarce adaptation of such a model to unseen languages, we will treat the TyDi QA languages as our test, unseen ones. We will assume that we have access to (a) other QA datasets in more resource-rich languages (in particular, the SQuAD dataset which provides training data in English), and (b) translation models between the languages of existing datasets (again, English) and our target "unseen" languages.

In the experiments sections, we first focus on few- and zero-shot experiments (§3) and then study the effects of language selection and budget-restricted decisions on training data creation (§4).

Evaluation We report F1 score on the test set of each language, as well as a macro-average excluding English ($\mathbf{avg}_{\mathcal{L}}$). In addition, to measure the expected impact on actual systems' users, we follow Faisal et al. (2021) in computing a population-weighted macro-average ($\mathbf{avg}_{\mathbf{pop}}$) based on language community populations provided by Ethnologue (Eberhard et al., 2019).

3 Is Few-Shot a Viable Solution?

We first set out to explore the effect of the amount of available data on downstream performance. Starting with baselines relying solely on English-only SQuAD, we implement a few-shot setting for fine-tuning on the target languages of TyDi QA.[3] To our knowledge, this is the first study of its type on the TyDi QA benchmark.

The straightforward baseline simply provides zero-shot results on TyDi QA after training only on English. Table 1 provides our (improved) reproduction of the baseline experiments of Clark et al. (2020). The skyline results (bottom of Table 1) reflect the presumably best possible results under our current modeling approach, which trains jointly on all languages using all available TyDi QA training data. We note that for most languages the gap between the baseline and the skyline is more than 20 percentage points, with the exception of English where –unsurprisingly– there is a difference of only 3.3 percentage points. The performance gap is smallest for Russian (rus) at 10.9 percentage points, and largest for Telugu (tel) at 34 points.

We first study a *monolingual* few-shot setting. That is, we fine-tune the model trained on the English SQuAD dataset, with only a small amount of data (10, 20, or 50 training instances) in the test language. Due to space limitations, we only present results with 50 examples per language in Table 1, but the full experiments are available in Appendix C. We observe that even just 50 additional training instances are enough for significant improvements, which are consistent across all languages. For example, the improvement in Finnish (fin) exceeds 15 percentage points and covers about more than 60% of the performance gap between the baseline and the skyline.

We now turn to a *multilingual* few-shot setting. Exactly as before, we assume a scenario where we only have access to a small amount of data in each language, but now we fine-tune using that small amount of data in all languages. For example, 10 training instances in each language result in training with 90 training examples over the 9 test languages. A sample of our experimental results are presented in Table 1 under "multilingual few-shot," with complete results in Appendix C.

Simply adding 50 instances from each language we obtain an F1 score of 67.9 over the zero-shot baseline, an improvement of almost 7 percentage points which reduces the zero-full gap by 43.4%.

[2] This follows the guidelines to perform analyses over the development set to ensure the integrity of the leaderboard.

[3] We do not report results on Korean, due to a late-discovered issue: we found that parts of the Korean data use a Unicode normalization scheme different than what is expected by mBERT's vocabulary. We suspect this is responsible for our Korean results being consistently around 50% worse than previously published results.

Model	Results (F1-score) eng	ara	ben	fin	ind	swa	rus	tel	$\text{avg}_{\mathcal{L}}$ (without eng)	avg_{pop}
Baseline: SQuAD zero-shot										
(reproduction)	74.2	59.0	57.3	55.7	63.2	60.3	65.6	44.6	58.0±6.3	59.3

(+50/lang, 450 total)	73.4	69.2	65.8	69.0	73.4	68.8	67.2	66.2	68.5±2.4	68.6
(+100/lang, 900 total)	74.2	72.5	70.9	71.9	75.5	72.3	69.3	69.3	71.7±2.0	71.9
(+500/lang, 4500 total)	76.1	76.3	74.5	78.2	81.4	79.2	73.3	73.7	76.7±2.8	76.2
Data Augmentation + Multilingual Few-Shot										
+tSQuAD	74.9	65.4	58.4	66.7	65.2	69.4	60.2	44.7	61.4±7.7	61.2
+mSQuAD	75.1	65.6	68.6	71.7	70.3	66.2	75.5	49.4	66.7±7.7	67.6
+mSQuAD +500/lang	77.6	78.7	75.0	78.5	83.5	82.5	73.2	75.3	78.1±3.6	77.6
+tSQuAD +500/lang	77.9	78.8	80.0	79.5	82.8	83.6	72.5	73.5	78.7±3.9	78.6
Skyline: Full training on TyDi QA train										
(reproduction)	*77.5*	*82.4*	*78.9*	*80.1*	*85.4*	*83.8*	*76.5*	*78.3*	*80.8±3.0*	*80.9*

Table 1: Data augmentation combined with multilingual few-shot learning can reach about 98% of the skyline accuracy using only 10 times less training data on the test languages beyond English.

We note that the total 450 training instances represent less than 1% of the full TyDi QA training set! Doubling that amount of data to 100 examples per language further increases downstream performance to an average overall F1 score of 71.7. Going further to the point of adding 500 training instances per language (for a total of 4500 examples) leads to even larger improvements for an average F1 score of 76.7. That is, using less than 10% of the available training data we can reduce the average F1 score performance gap by more than 82%. For a few languages the gap reduction is even more notable, e.g., more than 92% for Finnish.

Data Augmentation through Translation Generating translations of English dataset to train systems in other languages has a long history and has been successful in the QA context as well (Yarowsky et al., 2001; Xue et al., 2020, *inter alia*). We follow the same approach, translating all SQuAD paragraphs, questions, and answers to all TyDi QA languages using Google Translate.[4] For each language, we keep between 20-50% of the question-answer pairs where the translated answer has an exact match in the translated paragraph, which becomes the target span.[5] Details of the resulting dataset (which we refer to as tSQuAD) are in Table 3 in Appendix B. A second approach translates the question of a training instance into one language, but keeps the answer and context into the original language. The result is a modified training set (which we name mSQuAD) that requires better cross-lingual modeling, as the question and contexts are in different languages.

Both approaches improve over the zero-shot baseline with F1 score of 61.4 (+3) and 66.7 (+8). Notably, though, they are not as effective as few-shot training even with just 50 instances per languages. This further strengthens the discussion of Clark et al. (2020) on the qualitative differences between the SQuAD and TyDi QA dataset. Nevertheless, combining tSQuAD (or mSQuAD) with a few examples from the TyDi QA dataset leads to our best-performing methods. In particular, augmentation through translation leads to an 1-2 percentage point improvements over the multilingual few-shot approach (cf. 76.7 to 78.1/78.7 F1 score in Table 1; full results in Appendix C). Now, using only 500 new training examples per language we are *almost* (98%) at similar performance levels as the skyline.

[4]We release the data to facilitate the reproduction of our experiments.

[5]This approach could be enhanced using word/phrase alignment techniques, which we leave for future work.

Results (F1-score)								Overall	Δ_l	avg

4 How to Spend the Annotation Budget?

In the previous section we show that the combination of data augmentation techniques with a few new annotations can reach almost 98% of the performance one would obtain by training on 10x more data. In this section we explore how one should allocate a fixed annotation budget, in order to achieve not only higher average but also more *equitable* performance across languages.

Keeping our budget fixed to 4500 instances, we study 3 scenarios. The first is **monolingual** allocation, where the whole budget is consumed by collecting training examples on a single language. We repeat the study over all 8 languages of our test set, randomly sampling training instances from the TyDi QA training set. Second, we study a **tri-lingual** budget allocation scheme, where we equally split the budget across 3 languages for 1500 training instances per language. We repeat this experiment 7 times, each time randomly selecting 3 languages. Last, the third and more **egalitarian** scenario splits the budget equally across all 8 languages, matching our previously analyzed few-shot scenario where we only have 500 additional training examples per language. In all experiments, we use our best-performing approach from the previous section, also utilizing tSQuAD for pre-training.

Our findings are summarized in Table 2. For the repeated monolingual and tri-lingual scenarios we report average performance across our experiment repetitions (full results in Appendix E). We can conclusively claim that a uniform budget allocation leads to not only better average performance, but also to more equitable performance. We report two straightforward measures for the equitability of the average accuracy across languages. First, we report the standard deviation of the accuracy across languages; the lower the standard deviation, the more equitable the performance. We also report the difference between the best and the worst performing language for each experiment, as well as the averages for the languages that are seen and unseen during fine-tuning.

Having no budget for additional annotation (essentially, attempting the task in zero-shot fashion) leads to the most inequitable performance. The monolingual scenario typically leads to the highest accuracy when evaluating on the same language as the new training examples (the *ideal* section of Table 2) but the zero-shot performance on all other languages is generally significantly worse, leading to inequity. The tri-lingual scenarios follow similar patterns, with performance close to state-of-the-art for the four languages (three plus English) that have been included in the fine-tuning process, but with the rest of the languages lagging behind: the difference between seen and unseen languages is on average 10.4 points. In our experiments we randomly sampled (without replacement) three of the seven languages, but one could potentially use heuristics or a meta-model like that of Xia et al. (2020) to find or suggest the best subset of candidate languages for transfer learning; we leave such an investigation for future work.

Encouragingly, the uniform budget allocation scenario leads to higher average performance, while also reducing the gap between worst and best performing languages from around 30 percentage points to less than 12 points (60% reduction). Note that a 8x larger budget (*ideal* scenario) with 4500 instances per language would further improve downstream accuracy and equitability. Note that in this case where some resources are available,

simple multilingual fine-tuning might not be the best approach for some languages, e.g. compared to monolingual fine-tuning or meta-learning approaches (Wang et al., 2020; Muller et al., 2021, *inter alia*). We leave an investigation of such settings for future work.

5 Discussion

We show that data augmentation through translation along with few-shot fine-tuning on new languages with a uniform budget allocation leads to a performance close to 98% of an approach using 10x more data, while producing more equitable models than other budget-constrained alternatives.

The implications of our findings become clear with a counter-factual exploration. The Gold Passage portion of the TyDi QA dataset includes around 87,000 annotated examples (50k for training across 9 languages and about 37k development and test samples). Consider the scenario where, given this annotation budget, we maintain the same evaluation standards collecting 4k development and test examples per language, but we only collect 500 training examples per language. In that case, we could have created a much more diverse resource that would include at least 19 languages! Now consider the expectation of the downstream accuracy in our counterfactual scenario: uniform budget allocation on 19 languages would lead to an average accuracy (F1 score) of around 78% (similar to our experiments). Instead, under the (currently factual) scenario where we only have training data for 9 languages, the average accuracy for these 9 languages is around 80%, but the zero-shot expected average on the other 10 languages is 10 points worse – in that case, the overall average accuracy would be around 74%, 4 points lower than that of the egalitarian allocation scenario. Hence, as long as the ideal scenario of collecting a lot of data for a lot of languages remains infeasible, we suggest that the community puts an additional focus on the linguistic diversity of our evaluation sets and use other techniques to address the lack of training data.

Acknowledgements

This work is supported by NSF Award 2040926. The authors also want to thank Fahim Faisal for helpful discussions on setting up the experiments. Most experiments were run on ARGO,[6] a research computing cluster provided by the Office of Research Computing at George Mason University, VA, and a few experiments were run on Amazon Web Services instances donated through the AWS Educate program.

A Experimental Settings

For the experiments, we've used "`bert-multi-lingual-base-uncased`" (mBERT) (Hugging Face - mBERT, 2020) as mentioned as the main baseline on TyDi QA paper (Clark et al., 2020). It is a pre-trained model on the top 102 languages with the largest Wikipedia using a masked language modeling (MLM) objective (Devlin et al., 2019). From preliminary experiments, we realized that the optimum trade-off between the highest F1 score and the least computational cost is achieved by training for 3 epochs, using batch size of 24, and learning rate of 3e-5. Therefore, we applied these hyperparameter settings for our experiments. The main script we used was a module under the Huggingface library (Wolf et al., 2020) (called run_squad), which is being used widely for fine-tuning transformers for multi-lingual question answering datasets.

B SQuAD Translation Details

We augmented the English SQuAD with *translated SQuAD* (tSQuAD) instances for each language. Here, the contexts, questions and answers from SQuAD instances are translated to the target languages using Google Translate (with the `google-trans-new` API) and only the instances where an exact match of translated answer is found in the translated context, are kept for augmentation. The total number of instances per language, we ended up with after translation is listed in Table 3.

Abstract

We propose an effective context-sensitive neural model for the task of *time to event* (TTE) prediction, which aims to predict the amount of time to/from the occurrence of given events in streaming content. We investigate this problem in the context of a multi-task learning framework, which we enrich with *time difference* embeddings. To conduct this research, we develop a multi-genre dataset of English events about soccer competitions and academy awards ceremonies, as well as their relevant tweets obtained from Twitter. Our model is 1.4 and 3.3 hours more accurate than the current state-of-the-art model in estimating TTE on English and Dutch tweets respectively. We examine different aspects of our model to illustrate its source of improvement.[1]

1 Introduction

The task of time to event (TTE) prediction aims to determine the amount of time to/from the occurrence of a well-defined event. Accurate prediction of this information is important for temporal tasks such as timeline generation (Reimers et al., 2018), news summarization (Born et al., 2020; Huang et al., 2016), and disease onset prediction in medical domain (Zeliger, 2016; Langbehn et al., 2004).

Current approaches mainly focus on news articles and expect at least one temporal expressions in each input data to predict TTE (Chambers et al., 2014; Reimers et al., 2016, 2018; Hürriyetoğlu et al., 2018; Zhou et al., 2020). These approaches cannot be readily applied to streaming content (such as Twitter data) because such data often do not carry any temporal expressions. Figure 1 show

Figure 1: Examples of tweets that don't carry any explicit time expression but indicate a future or past event due to the implicit temporal connotation in "*looking forward to*," "*must be fun to watch*," "*well done*" etc.

two examples of such tweets.[2] In addition, event-related content in data streams are heavily skewed in time distribution as they are often posted in close proximity of their corresponding events.

The above challenges and intuitions inspire our work to develop a context-sensitive model to predict TTE in streaming content. Our approach is a multi-task learning framework that uses a small fraction of temporally-rich neighbors of each input (tweet) and their time differences (learned through *time difference* embeddings) to predict (a): if the tweet has been posted *before*, *at the same time* or *after* the event, and (b): estimate the absolute value of TTE (in hours) with respect to the tweet. We learn time difference embeddings through an effective character-level sequence to sequence model that takes as input two timestamps and predicts the temporal difference between them (in hours).

The contributions of this paper are as follows: (a) an effective multi-task and context-sensitive framework that uses temporally-rich context and time difference embeddings to accurately predict TTE in streaming content, (b) publicizing a time to event dataset that includes different genres of

[*]First and second authors equally contributed to this work.
[1]Our code and data are available at https://github.com/hajipoor/time2event
[2]In fact, 89% of event-related tweets in our dataset do not carry any time expression.

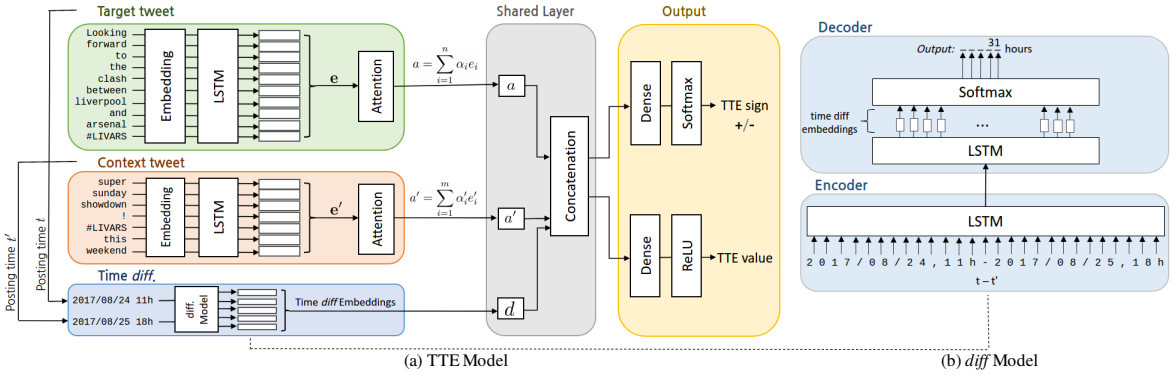

Figure 2: (a) TTE model gives the target tweet and a temporally-rich context tweet, and their time difference embedding learned through *diff* model as input and learns TTE as a combination of regression (TTE value) and classification (TTE sign) tasks. It establishes a common scale between corresponding loss values for effective training and (b) *diff* model gives two times and learns time difference embeddings via sequence to sequence model, which are used in our TTE model.

events (soccer competitions and academy awards ceremonies), their time of occurrence, their relevant tweets as well as TTE information for each tweet.

Our framework is 1.4 and 3.3 hours more accurate than the current state-of-the-art model in estimating TTE on large-scale English and Dutch tweets respectively. In addition, our time difference model achieves an accuracy of 98.3% in terms of creating embeddings that encode temporal differences between given time pairs.

2 Context-sensitive Model

Existing models often assume input data carry explicit temporal information about target events. Although informative, these information may not be available in most textual content, especially in microblogs. We propose to utilize context information (in the form of neighboring tweets) and the relative temporal differences against neighbours to estimate time to event (TTE) for given input texts.

In particular, given a tweet about an event, we propose a multi-task learning framework to predict the absolute value of TTE (in hours) for the tweet, as well as a binary sign which determines if the tweet has been posted before '(+),' or at the same time or after '(-)' the event. Figure 2(a) shows our model for predicting TTE for the target tweet t_i, given its context tweet[3], e.g. a previously posted tweet about the same event, $t_j, j < i$, and their *time difference* embeddings, which encode the time differences between tweet creation times. Our intuition for developing such embeddings is that if context tweets carry useful temporal information about events, then knowing the time differences among tweets could help the model to make more accurate prediction of TTE for the target tweet.

Our model takes as input the concatenation of attention-weighted average embeddings of the target and context tweets (a and a' in Figure 2) and their time difference embedding (d) (see section 2.1). The resulting concatenation are then used to predict *TTE sign* and *TTE value* for the target input. TTE value is a regression task while TTE sign is a binary classification task. To prevent the loss with larger gradient magnitudes dominate the training, we establish a common scale for the different loss magnitudes across the two tasks using the approach proposed in (Kendall et al., 2018), which simultaneously learns classification and regression losses of varying quantities and combines them using homoscedastic uncertainty.

2.1 Time Difference Embeddings

Motivated by recent research on neural numeracy learning (Chen et al., 2019; Wallace et al., 2019), we learn time difference embeddings–`diff embeddings`–as follows: we develop an LSTM-based character-level sequence to sequence model (based on the model presented in (Sutskever et al., 2014)) that takes as input a time pair (t and t') and predicts the difference between them (in hours). The final layer of the model is of size five, where five is determined by the maximum number of digits in the differences of any two timestamps within a 2 years period (i.e., 17520 hours). The final hidden representations of the resulting digits are then concatenated to obtain the diff embeddings, see

[3]Neighboring or context tweets are randomly sampled from the set of previously posted tweets relevant to the target event. Our model can be extended to greater context sizes.

Figure 2(b).

3 Experiments

3.1 Datasets

We develop a dataset from tweets about soccer competitions of the England Premier League (EPL) following the same approach in (Hurriyetoglu et al., 2014; Hürriyetoğlu et al., 2018). We carefully create a list of 42 distinctive hashtags for competitions between seven most famous teams [4]. These matches have the advantage that users tweet about them with distinctive hashtags by convention. We collect tweets that are sent within 14 days of match days between seven popular teams, and obtain the actual time of each event from the EPL schedule.[5]

For the regression task, the tweet label would be the absolute value of the actual time (in hours) to the start of the corresponding event. For the classification task, tweets are labeled as 'before' or 'after' depending on their time of creation against corresponding matches. Our dataset is randomly divided into 80%, 10% and 10% according to events, which are used for training, testing and validation respectively. To study the effect of temporally-rich context in a controlled situation, we divide our dataset of tweets (**All set**) into two disjoint subsets: tweets that carry at least one temporal expression (**T set**), and tweets that have no temporal expression (**N set**), where we use HeidelTime's colloquial temporal tagger (Strötgen and Gertz, 2012, 2013) to extract temporal expressions. We then introduce six new subsets of our data in X-Y format, where $X \in \{$T set, N set, All set$\}$ refers to the type of target tweets and $Y \in \{$T set, N set$\}$ refers to the type of contexts.

To investigate the generalizability of our model on other events, we evaluate our trained model on tweets about the 2018 Academy Awards ceremony. We collected 3K tweets using `#oscars`, `#oscar` and `#academyawards` hashtags in the window of 7 days before and after the date of Oscars 2018. We also use the Dutch dataset to compare our model against the baseline model proposed in (Hurriyetoglu et al., 2014) that developed a hybrid of machine learning and rule-based approach for estimating time to events.

[4]Liverpool, Manchester United, Chelsea, Arsenal, Manchester City, Newcastle United and Tottenham Hotspur

[5]https://www.premierleague.com/

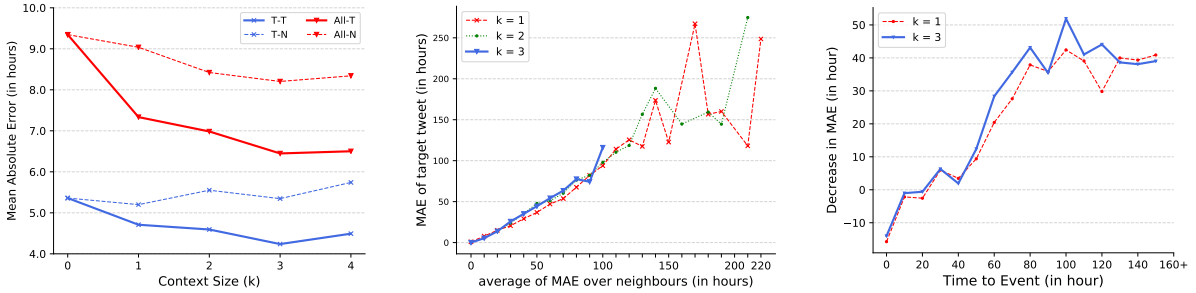
3.2 Settings and Baselines

The hyperparameters of all models are optimized on validation data using random search (Bergstra and Bengio, 2012). We consider **TenseModel** (see below), **Glove**, **BERT**, Event Time Extraction **(ETE)** (Reimers et al., 2018), and **HybridModel** (Hürriyetoğlu et al., 2018) as baselines. TenseModel uses the tense of the outermost verb of a tweet to detect whether it is posted before (+) or after the target event (-). Embedding models are used to represent input tweets and extended to address the time to event task in their last layer. The GLOVE baseline is the model with GLOVE pre-trained embeddings but without context. This baseline has only the attention-weighted average embedding of the target tweet. For BERT baseline, we fine-tuned base version of BERT by adding a linear layer on top for time to event value prediction. ETE uses sentence representation as well as event and position embeddings with a CNN to tackle the target task. They reported a high performance of 84.2% for event status classification on a balanced dataset of news articles. HybridModel is a hybrid of rule-based and data-driven methods focusing on Dutch tweets that carry temporal expressions.

4 Results

4.1 Time to Event Prediction

We compare our context-sensitive model with context size of $k \in \{0, 1, 2, 3\}$ against baseline systems. Mean and Median are heuristic baselines and indicate the mean and median of MAEs of TTE values (i.e., 27.87 and 13.91 respectively). As reported in Table 1, the TenseModel has considerably low performance in distinguishing temporal status of tweets against event times. We attribute this result to the informal language in user-generated content and multi-verb tweets which can challenge the tense model. BERT embeddings slightly improves the performance of other embedding models. However, BERT and ETE's performance are considerably lower than the performance of our model achieved by adding context information ($k \geq 1$). This result indicates that adding neighbouring tweets leads to more accurate prediction of TTE than incorporating better word embeddings. Our model achieves an MAE of 6.43 hours on *All-T* set and 4.24 on *T-T* set (see Table 1). We also compare our model against the Hybrid Model on the



(a) Effect of context size on MAE (b) Accurately-predicted neighbours (c) Farther vs. closer to event instances

Figure 3: (a): Greater context size leads to better estimation of TTE. (b): More accurately-predicted neighbours lead to more accurate estimation of TTE. (c): Context information better help farther to event target instances.

	TTE sign			TTE value
Model	**P**	**R**	**F1**	**MAE** (hours)
Trained and evaluated on the *EPL* dataset				
Mean	-	-	-	27.87
Median	-	-	-	13.91
TenseModel	0.23	0.37	0.28	-
GLOVE (Pennington et al., 2014)	0.73	0.66	0.69	8.43
BERT (Devlin et al., 2019)	0.68	0.79	0.73	7.71
ETE (Reimers et al., 2018)	0.88	0.59	0.70	7.86
Our model ($k = 0$)	0.61	0.52	0.56	9.34
Our model ($k = 1$)	0.73	0.77	0.74	7.31
Our model ($k = 2$)	0.81	**0.87**	0.83	6.98
Our model ($k = 3$)	**0.92**	0.83	**0.87**	**6.43**
Trained on *EPL* and evaluated on the *Oscars* dataset				
BERT	0.46	0.48	0.47	14.2
Our model ($k = 0$)	0.38	0.49	0.43	14.76
Our model ($k = 1$)	0.51	0.57	0.54	13.43
Our model ($k = 2$)	0.55	0.60	0.57	13.37
Our model ($k = 3$)	0.58	0.64	0.61	13.18

Table 1: Model performance in terms of macro precision, recall and F1 for sign classification (TTE sign), and Mean Absolute Error (MAE) for TTE prediction (TTE value) on EPL and Oscars datasets.

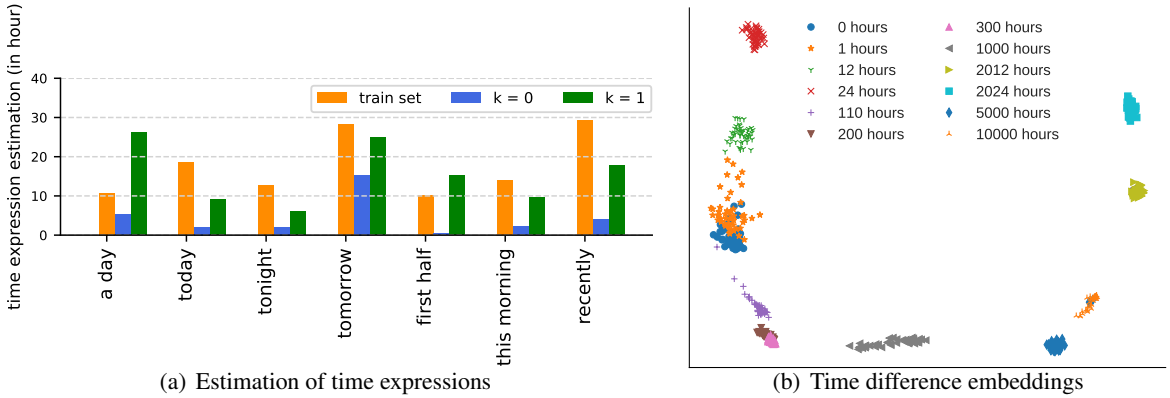
Dutch dataset (see Section 3.1).[6] Using the Dutch embeddings of (Tulkens et al., 2016), our model achieves an MAE of 4.7 hours based on leave-one-out cross validation, while the corresponding value for the Hybrid Model is 8 hours. Evaluation results on Oscars dataset reveals that the model learns how to utilize information of neighbouring tweets and time differences. The lower performance on the Oscar dataset is due to differences in training (EPL) and test (Oscar) data distributions.

Can context information help? To investigate the effect of adding context, we start with a standalone base model that predicts the time to event by just relying on its own content, i.e, $k = 0$. Figure 3(a) illustrates that the performance is higher for tweets that contain at least one time expression (*T set*) compared to *All set*. Accordingly, as we gradually add more context tweets, the performance consistently increases with greater improvement with the *T set* as context. The best preforming model is achieved by adding context of size 3 from *T set*, leading to the lowest time to event estimation error of 4.24 hours.

We also note that context tweets that do not contain any temporal expression (the *N set*) slightly increase the performance; see the dashed lines in Figure 3(a). We conjecture that these tweets add lexical clues that carry implicit temporal information about events. In addition, Figure 3(b) shows a strong correlation between the average error in model prediction performance on context and target tweets. This result shows that neighboring tweets that are more accurately learned by the network are better candidates to use as context for other tweets.

Does context information lead to more accurate estimation of time expressions? To answer this question, we compute the average time to event for each time expression from both training tweets and predictions for test tweets as $H(\text{TIMEX}_i) = \frac{1}{N}\sum_{t_j \in \mathcal{S}, \text{TIMEX}_i \in t_j} \text{TTE}_{t_j}$ where $\mathcal{S} \in \{train, test\}$, TTE_{t_j} indicates time to event for tweet t_j, and N is normalization factor; for training data we use gold values and for test data we use predicted values. Figure 4(a) shows the baseline and estimated values for a range of time expressions. The results show that the value of time expressions are better estimated by adding context. Give that the most frequent time expressions often refer to points in time close to the event (such as *now*) (Hurriyetoglu et al., 2014), our model improves rare time expressions more than the frequent ones, leading to improved prediction of farthest tweets from events.

[6] Note only 71% of 138k tweets are returned by the Twitter API, the rest were deleted or made private by their users.



(a) Estimation of time expressions

(b) Time difference embeddings

Figure 4: (a): Estimation of some selected time expressions. (b): Time differences in the embedding space. Each sample point shows the embedding of time difference between two randomly selected times t_1 and t_2. This figure shows that if $t_1 - t_2 \approx t_1^{'} - t_2^{'}$, their *diff* embeddings are closer in the time difference space.

4.2 Time Difference Embeddings

We generate a synthetic dataset of $2m$ time pairs to evaluate the time difference approach in terms of accurate prediction of time differences between given time pairs, where possible predictions range between 0 to 17520 hours, which corresponds to a maximum difference of two years. Evaluation on $200k$ number of test time pairs shows that the model achieves 98.3% accuracy. In addition, Figure 4(b) shows t-SNE representation of time differences in the embedding space for different randomly selected time pairs. Data points with the same color shows the diff embeddings of the same time differences. The result shows for two random times (t_1, t_2) and $(t_1^{'}, t_2^{'})$, if $t_1 - t_2 \approx t_1^{'} - t_2^{'}$, their *diff* embeddings are very close in the time difference embedding space, indicating the high quality of the resulting space. In addition, Table 2 shows time difference embeddings are useful for TTE estimation since removing them increases the MAE of our full model by a significant amount of 0.8 hours.

4.3 Early prediction

Given that *early* prediction of TTE is more valuable and challenging (due to scarcity of data at earlier times and often imprecise temporal information in earlier tweets), we investigate the performance of our model on target tweets that were posted much earlier than the occurrences of their corresponding events. The results in Figure 3(c) shows that context tweets help farther-to-event instances better than closer ones. This result provides insights for future research on the task of early TTE prediction.

Configuration	MAE (absolute increase)
Full System	6.43
Random diff embeddings	6.64 (+0.21)
No diff embeddings	7.23 (+0.80)
No TTE sign	6.71 (+0.28)

Table 2: Ablation analysis showing changes in Mean Absolute Error (MAE) obtained from removing individual components of the model.

5 Conclusion and Future Work

We developed a context-sensitive neural model that used rich-neighbouring tweets as well as time difference embeddings between target tweets and their neighbors for effective prediction of time to event. We evaluated our and current models on events and tweets of different genres (soccer competitions and academy award ceremonies) and languages (English and Dutch). Future works include expansion to temporal tasks that particularly focus on early prediction of time to events. In addition, it's worth investigating if user or social network information could be helpful for better time to event prediction.

Acknowledgments

We sincerely thank anonymous reviewers for their insightful comments. In addition, this research was completed during the spread of the COVID-19 virus, while the world was in quarantine fearing the epidemic. We would like to dedicate this work to all researchers who contributed to the discovery of the COVID-19 vaccine.

Broader Impact Statement

Our research affects applications that deal with time, and time difference can be an effective feature for them. For example, our work enables automatic creation of calendar of events, which helps keeping individuals informed about potential relevant events. It also help researchers to benchmark their models using our dataset.

In addition, the process of collecting our dataset followed the Twitter policy[7]. We crawled data using the Twitter API and we did not make any attempt to identify any information that have not been volunteered by our user base (e.g., gender, race, wealth, etc.,). We also will just publish the Tweet IDs.

Improving Compositional Generalization in Classification Tasks via Structure Annotations

Juyong Kim **Pradeep Ravikumar**

{jainslie,santiontanon}@google.com

Abstract

Compositional generalization is the ability to generalize systematically to a new data distribution by combining known components. Although humans seem to have a great ability to generalize compositionally, state-of-the-art neural models struggle to do so. In this work, we study compositional generalization in classification tasks and present two main contributions. First, we study ways to convert a natural language sequence-to-sequence dataset to a classification dataset that also requires compositional generalization. Second, we show that providing structural hints (specifically, providing parse trees and entity links as attention masks for a Transformer model) helps compositional generalization.

1 Introduction

Compositional generalization is the ability of a system to systematically generalize to a new data distribution by combining known components or primitives. For example, assume a system has learned the meaning of "jump" and that "jump twice" means that the action "jump" has to be repeated two times. Upon learning the meaning of the action "jax", it should be able to infer what "jax twice" means. Although modern neural architectures are pushing the state of the art in many complex natural language tasks, these models still struggle with compositional generalization (Hupkes et al., 2020).

In order to advance research in this important direction, in this paper we present two main contributions [1]. First, we present a binary classification dataset which is hard in a compositional way. This allows for studying the compositional generalization ability of a larger range of models than sequence generation tasks, since the task only requires an encoder, and not a decoder. Specifically, we present a methodology to convert an existing semantic parsing dataset, CFQ (Keysers et al., 2019), into a binary classification dataset that is also compositionally hard.

Our second and main contribution is showing that a transformer-based model can better generalize compositionally if we provide hints on the structure of the input. Specifically, we do so by modifying the attention mask used by the model. This is an interesting result, as (except for two additions, which we elaborate on in Section 4) attention masks do not "add" any attention capabilities to the model. Instead, it seems that it is the removal of certain attention pairs that makes the difference. This suggests that vanilla Transformer is having a hard time suppressing non-compositional attention.

2 Background

This section overviews existing work on compositional generalization and then some background on the Transformer models used in this paper. Please see Section B in the appendix for detailed review.

Compositional Generalization. Compositional generalization can manifest in different ways (Hupkes et al., 2020) such as *systematicity* (recombination of known parts and rules) or *productivity* (extrapolation to longer sequences than those seen during training), among others. Early work focused on showing how different deep learning models do not generalize compositionally (Liška et al., 2018), and datasets such as SCAN (Lake and Baroni, 2018) or CFQ (Keysers et al., 2019) were proposed to show these effects.

Work toward improving compositional generalization has proposed ideas such as Syntactic attention (Russin et al., 2019), increased pretraining (Furrer et al., 2020), data augmentation (Andreas, 2019), or general purpose sequential models such as *Neural Turing Machines* or *Differ-*

ential Neural Computers (Graves et al., 2016).

ETC. For our experimental evaluation we use the ETC (Ainslie et al., 2020) Transformer model. ETC extends the standard Transformer model in 3 key ways: (1) it uses a global-local attention mechanism to scale to long inputs, (2) it uses relative attention (Shaw et al., 2018) and flexible masking and (3) it uses a new pre-training loss based on Contrastive Predictive Coding (CPC) (Oord et al., 2018). The last two extensions allow it to handle structured inputs containing, for example, hierarchical structure. In this work, we rely on (2) to annotate the structure of the input.

3 The CFQ Classification Dataset

The Compositional Freebase Questions (CFQ) dataset (Keysers et al., 2019) is an NLU dataset to measure the compositional capability of a learner. It is designed around the task of *translating* a natural language question into a SPARQL query. The dataset has been automatically generated by a grammar and contains 239,357 sentence/query pairs. An example is shown in Figure 3a.

As shown in the original work of Keysers et al. (2019) in order to properly measure the compositional generalization ability of a model, the train and test sets should be split with similar distributions of tokens (*atoms*), but different distributions of their compositions (the *compounds*). In the CFQ dataset, to ensure this, two divergences, namely *atom divergence* and *compound divergence*, between the train and dev/test set are measured while constructing the splits. As a result, carefully selected splits called *maximum compound divergence (MCD)* splits are hard for standard neural networks (they perform well in the train set, but poorly in the test set), while the random splits are easier.

We convert the CFQ dataset into a dataset with a binary classification task. In this new dataset, the input is a question and a SPARQL query, and the task is to determine whether these two sequences have the same meaning or not. Two considerations must be made to ensure the resulting dataset requires compositional generalization:

Negative Example Strategies: Positive instances of the binary classification task can be obtained directly from the original dataset, but to obtain negatives, we use either of two strategies:

- Random negatives: We pair each question with a randomly chosen query.
- Model negatives: Using baseline models (LSTM (Hochreiter and Schmidhuber, 1997), Transformer (Vaswani et al., 2017), and Universal Transformer (Dehghani et al., 2018)) trained on the original CFQ dataset, we get top-k query predictions for each question. After filtering syntactically invalid queries and duplicates, we can get hard examples for classification from their incorrect predictions.

Model negatives are important, as otherwise, the task becomes too easy and would likely not require compositional generalization. See Figure 1 for examples of random/model negative instances.

Compound Distribution of Negative Examples: To prevent data leakage (e.g., compounds from the test set of the original CFQ dataset leaking into the training set of the classification CFQ dataset), we carefully choose the sampling set for random negatives and the train and inference set for model negatives. We generate two splits of the original CFQ dataset. Each split contains three sets with 50% data on train, 25% on dev and 25% on test. The first is a *random split* of the data, and the second (*MCD split*), maximizes the compound divergence between train and dev/test using the same method as in the original CFQ work. Then, we process the examples in each of these sets generating positive and negative examples. For random negatives, we sample negative queries for each questions from the set which the original example belongs to (train/dev/test). For model negatives, to generate negatives for the training set, we divide it into two halves, train models in one, and generate negatives with the other half. For dev/test, we train on dev and generate negatives on test, and vice versa. Figure 2 illustrates this procedure, designed to ensure there is no leakage of compounds between train and dev/test.

For both strategies, we make 1 positive and 3 negatives per original CFQ example. Also, we set aside 5% of the train set as a hold-out set to check i.i.d. generalization.

4 Compositional Generalization via Structure Annotation

Our hypothesis is that part of the difficulty in compositional generalization is to parse the structure of the input. To test this, we evaluate the performance of models when we provide annotations for two structural elements of the inputs: parse

• **Question (CFQ input)**

```
Did M0 ' s writer , editor , director , and cinematographer found M1 and found M2
```

• **Positive query (CFQ output)**

```
SELECT count ( * ) WHERE {

Figure 1: Examples of the CFQ classification dataset. Each query pairs with the question to form an instance. Note the model negative resembles the positive, while the random negative query differs considerably.

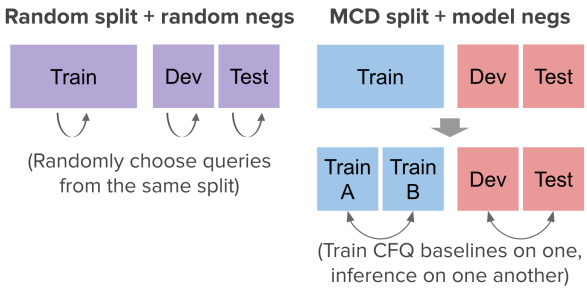

Figure 2: Negative example strategies. Different colors indicate different compound distributions.

trees of both the natural language sentences and SPARQL queries, and *entity cross links* (linking entity mentions from the natural language side to the corresponding mentions in the SPARQL query).

The parse trees of the questions are already given in the original CFQ dataset as constituency-based parse trees. Since the trees include intermediate nodes indicating syntactic structures, we append tokens representing them at the end of each question. We created a simple parser to generate dependency-based parse trees for the SPARQL queries. We join the roots of the two trees to make a single global tree with the `<CLS>` token as the root.

We represent the structure of the inputs by masking attention ("hard mask") or with relative attention (Shaw et al., 2018) labels ("soft mask").

- Hard mask: We customize the binary attention mask of the original Transformer to only allow attention between tokens connected by the edges of the parse tree.
- Soft mask: For every pair of input tokens, we assign relative attention labels based on which of the following edge relationships applies: parent-to-child, child-to-parent, itself, from-or-to-root, or entity-cross-link.

Additionally, we allow attention pairs in the masks connecting the entities appearing both in the question and the queries. We call these links *entity cross links*, and they are found by simple string match (e.g. "`M0`"). Notice that while relative attention labels and the additional tokens to represent the constituency parse tree of the natural language add capabilities to the model, the "hard mask" structure annotations described above (which result in the larger performance gains) do not *add* any attention capabilities to the model. Instead, they simply remove non-structure attention edges. Figure 3b shows the parse trees, and Figure 3c and 3d show the masks for an example.

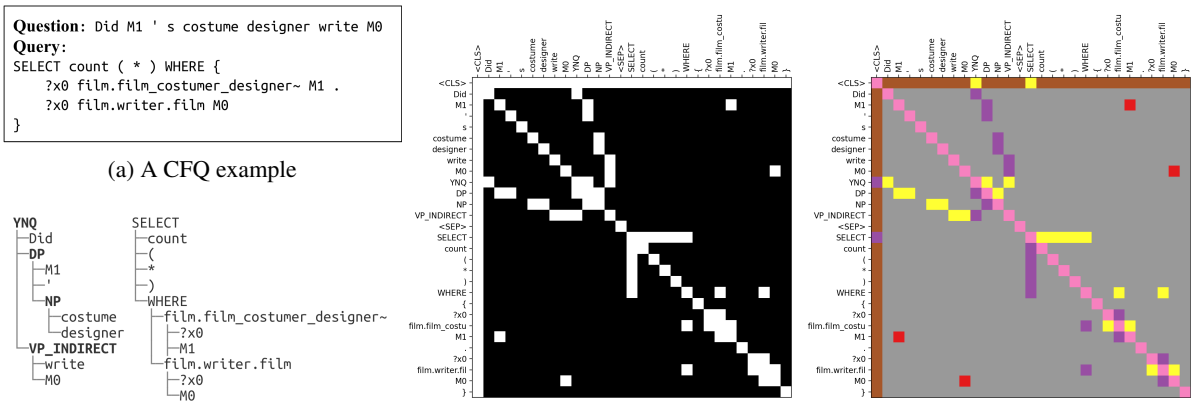
5 Results and Discussion

We used the ETC (Ainslie et al., 2020) Transformer model implementation as it allows us to provide the hard and soft masks described above in an easy way. In all experiments, we report AUC in the dev set as the evaluation metric (we did not evaluate on the test set). Please see Section A in the appendix for training details.

5.1 The CFQ Classification Dataset

We generate two classification datasets: "random split & random negatives" and "MCD split & model negatives", and evaluate LSTM and Transformer models. For both datasets, we evaluate AUC on the hold-out set (taken out of the training set as described above) to test i.i.d. generalization, and on the dev set to test compositional generalization.

As shown in Table 1, models easily generalize on the hold-out set (AUC $\geq$ 0.99). All baseline models also achieve almost 1.0 AUC in the dev set of the "random split & random negatives". However, in the "MCD split & model negatives" models cannot generalize well on the dev set, showing compositional generalization is required. Note that random guessing achieves 0.5 AUC score.



(a) A CFQ example

Transformer	-		0.9995	0.9931	0.8738
Transformer w/ structure annotations (ETC)	No	-	0.9994	0.9934	0.8868
	Hard	N	0.9999	0.9978	0.9061
		Y	1.0000	0.9992	0.9656
	Soft		0.9995	0.9936	0.8819
	Both		1.0000	0.9991	**0.9721**

Table 2: AUC on the CFQ classification dataset (*MCD Split & Model Neg*) with various structure annotations

5.2 Structure Annotation

Table 2 compares different ablations of our structure annotation approach compared to the baseline models. The first (no masks and no cross links) just shows that adding tokens to the input to represent the constituency parsing and moving to ETC only provide small gains (from 0.8738 to 0.8868 AUC). Adding a hard mask already helps the model (0.9061 AUC), and adding cross links on top of that achieves very significant gains (0.9656 AUC). Finally, soft masks by themselves do not seem to help, but a combination of soft and hard masks achieves our best result of 0.9721 AUC.

The interesting result here is that adding the hard mask with entity cross links *only removes* potential attention pairs, so it does not increase model capacity in any way. In other words, the underlying transformer model is in principle able to generalize compositionally to some extent but seems to struggle in suppressing non-compositional attention.

6 Conclusions

The main contribution of this paper is to show that providing structure annotations in the form of attention masks significantly helps Transformer models generalize compositionally. This is interesting for two main reasons: first, it shows that neural network models do have the innate ability to generalize compositionally to some extent, but need some guidance to do so (e.g., by providing attention masks as in our work). This reinforces previous work showing that LSTMs also can, in principle, generalize compositionally, but they just do so with very low probability (Liška et al., 2018). The second reason is that structure annotations, which we provided manually, could be generated by another model in future work. We also presented a procedure for generating classification datasets that require some degree of compositional generalization starting from sequence generation datasets.

A Full Experimental Results

In this section, we report the full results on the CFQ classification dataset and the structure annotation experiments. In all configurations, multiple evaluation metrics (accuracy, F1 score, and AUC) are computed by averaging the results of two randomly initialized experiments. We test each network using only the val set, not the test set, since the main purpose of the experiment is to compare the compositional generalization ability, not to select best hyper-parameter. Accuracy and F1 score are computed with the threshold 0.5 of the softmax output of label 1.

All the experiments of the CFQ classification datasets were run using the TensorFlow (Abadi et al., 2016) framework. As we explain in the Section 5, we use the ETC Transformer (Ainslie et al., 2020) code for relative position embeddings. For the Transformer implementation, we use the code provided in a Tensorflow tutorial. The training is run on the `n1-highmem-8` instance (52GB RAM, 8 virtual cpus) of Google Cloud Platform, extended with NVIDIA Tesla V100 GPUs.

Hyper-parameters used in the training of neural networks are listed in Table 3. One thing that we want to clarify is that training steps are required number of steps to converge and the training did not last longer than needed. Nevertheless, the experiments with structure annotations required more training steps than LSTM/Transformer, especially when the network is using hard mask. We conjecture that training with the hard mask of parse trees is slow since only a small part of the attention is not masked and hence propagating the gradient via supervision at the `<CLS>` position is slow.

A.1 The CFQ classification Dataset

Table 4 shows the classification results of various methods of generating classification datasets, including one additional configuration (*MCD Split & Random Negatives*). The dataset generated by this new configuration has the train and the dev/test set that have different compound distributions, because it is based on the MCD split. However, because of the method used in generating negative instances (random negatives), the binary classification of correspondence can be easily generalizable to the dev set.

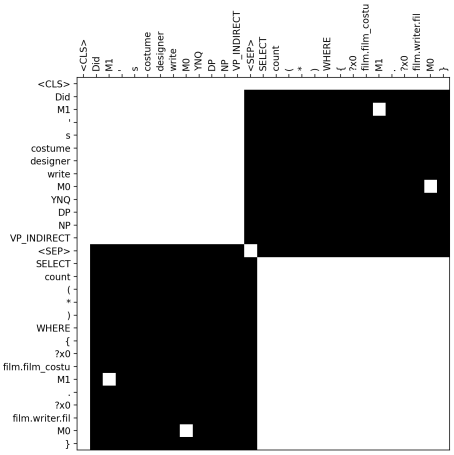

Figure 4: Block attention mask for the CFQ classification example of Figure 3. The dots at top-right and bottom-left are from entity cross links.

A.2 Structure Annotation

One possible annotation of the input structure is a mask to allow tokens of the question and SPARQL queries to only attend within their segment. We call this mask as *block attention* and test it as an alternative to the hierarchical attention structures (parse trees). This mask is denser than the attention mask from parse trees and sparser than "no mask". Figure 4 shows the block attention for the examples shown in the Figure 3.

Table 5 reports the full results of experiments on structure annotations. In all cases, entity cross links improve compositional generalization on the dev set, but provide a significant gain only when combined with the parse tree attention and the attention is guided by the "hard mask". As we can see in the "hard mask" experiments, block attention does not improve compositional generalization, which suggests a need for more detailed attention mask of input structure.

B Related Works on Compositional Generalization

In this section, we review prior works on improving compositional generalization in more detail.

Russin et al. (2019) proposed to split the attention mechanism into two separate parts, syntax and semantics. The semantic part encodes each token independent of the context (this is a pure embedding look-up table), and the syntactic part encodes each token by looking only at its context (without looking at the token itself). In this way, the syntactic part tries to capture the syntactic role a token

Table 3: Hyper-parameters used in training deep neural networks on the CFQ classification datasets

might play in a sequence. They show improved compositional generalization on the SCAN dataset using LSTMs, with respect to using standard attention. Compared to Russin et al. (2019) that uses LSTMs for the syntactic part, we use Transformer architecture to handle the hierarchical structure of the input.

In their follow up work on the CFQ dataset, Furrer et al. (2020) showed that an increased amount of pre-training helped Transformer models better generalize compositionally.

Another idea that has been proposed is to augment the training data, adding synthetic training examples to give the model a compositional learning bias (Andreas, 2019) .

Finally, work also exists on using general-purpose models like *Neural Turing Machines* or *Differential Neural Computers* (Graves et al., 2016) that are often trained via reinforcement learning to solve compositional generalization tasks. These models learn an "algorithm" that can solve the task at hand, rather than trying to learn a direct input/output mapping as the Transformer models used in most other works do.

C Examples of the CFQ classification dataset

In Figure 5, we present more examples of the CFQ classification datasets. In all cases, the random negative queries substantially differ from the positive queries, implying that a learner can easily perform the task. On the other hand, the model negative queries only differ by a token or a phrase, which demands a learner's higher ability.

Learning to Generate Task-Specific Adapters from Task Description

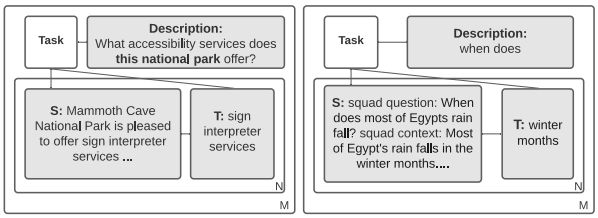
Qinyuan Ye **Xiang Ren**
University of Southern California
{qinyuany,xiangren}@usc.edu

Abstract

Pre-trained text-to-text transformers such as BART have achieved impressive performance across a range of NLP tasks. Recent study further shows that they can learn to generalize to novel tasks, by including task descriptions as part of the source sequence and training the model with (source, target) examples. At test time, these fine-tuned models can make inferences on new tasks using the new task descriptions as part of the input. However, this approach has potential limitations, as the model learns to solve individual (source, target) examples (*i.e.*, at the *instance* level), instead of learning to solve tasks by taking all examples within a task as a whole (*i.e.*, at the *task* level). To this end, we introduce HYPTER, a framework that improves text-to-text transformer's generalization ability to unseen tasks by training a hypernetwork to generate task-specific, light-weight adapters from task descriptions. Experiments on ZEST dataset and a synthetic SQuAD dataset demonstrate that HYPTER improves upon fine-tuning baselines. Notably, when using BART-Large as the main network, HYPTER brings 11.3% comparative improvement on ZEST dataset.[1]

1 Introduction

Pre-trained text-to-text models (Raffel et al., 2020; Lewis et al., 2020) provide a unified formulation and off-the-shelf weights for a variety of NLP tasks, such as question answering (Khashabi et al., 2020) and commonsense reasoning (Bosselut et al., 2019). In addition to their strong performance, text-to-text models naturally support generalizing to novel tasks, by incorporating task description as part of the source sequence and fine-tuning the model with (source, target) examples (Weller et al., 2020). At inference time, the model is required to perform unseen tasks with the source sequence containing new task descriptions.



(a) Zero-shot Learning from Task Description, ZEST dataset (Weller et al., 2020)

(b) Synthetic Version of SQuAD, (Rajpurkar et al., 2016)

Figure 1: Instead of learning from (source, target) examples, in this paper we study the problem of *learning from task descriptions* (Weller et al., 2020). The train set contains M tasks, and the i-th task contains N_i examples of (s, t) pairs in text format. During test time, the learned model is required to directly make inferences on a new task given a task description.

While this initial attempt shows positive results, there are two potential limitations for the direct fine-tuning approach. (1) Predictions can be sensitive to the task descriptions (or "prompts") that are heuristically designed (Jiang et al., 2020). Paraphrasing the task description may lead to performance downgrade. (2) The model still learns from individual (source, target) examples, instead of learning to solve tasks at a higher level, by explicitly taking multiple examples within a task as a whole (see Fig. 1). Meanwhile, applying existing zero-shot learning methods that supports task-level learning to text-to-text transformers is non-trivial. Methods designed specifically for classification problems, such as prototypical networks (Snell et al., 2017), cannot be directly applied to text-to-text models. Moreover, given the large size of text-to-text models, generating parameters for a whole model from the task description (Jin et al., 2020) is infeasible.

In this work, we follow the settings in (Weller et al., 2020) and aim to improve a model's generalization ability to unseen tasks by better incorporating task descriptions and using a task-level training procedure. We introduce HYPTER, a frame-

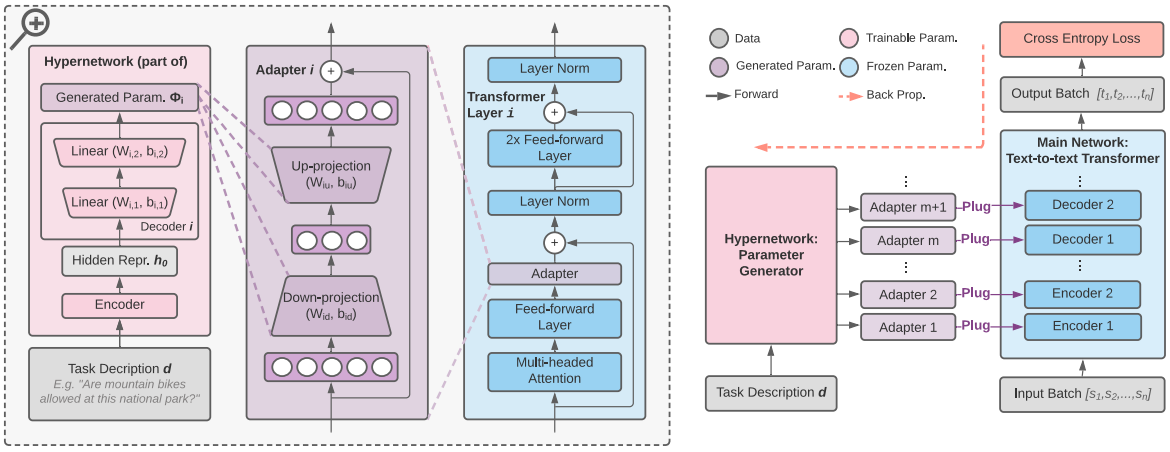

Figure 2: **Illustration of HYPTER Framework.** **Left:** A hypernetwork generates parameter ϕ_i for task-specific adapter i that is plugged to transformer layer i in the text-to-text model. **Right:** The adapted main network is evaluated on a task $(d, \mathcal{D})$. The final cross entropy loss is back-propagated to update the hypernetwork.

work that employs a hypernetwork (Ha et al., 2017) to dynamically generate task-specific parameters (*i.e.*, adapters) from task descriptions. Adapters (Houlsby et al., 2019) are light-weight modules that can be inserted into transformer layers for *parameter-efficient* adaptation. Such formulation also effectively enables learning at the *task* level, by learning to generate appropriate parameters for a task, and examine the model's competence on each task using multiple examples within that task. This is in contrast to learning at the *instance* level, by learning to generate the correct output for one specific input sequence.

We apply HYPTER to two datasets: ZEST (Weller et al., 2020) and a synthetic version of SQuAD (Rajpurkar et al., 2016). We demonstrate that HYPTER improves upon direct fine-tuning baselines. Notably, training with HYPTER achieves 0.45% absolute improvement (11.3% comparative improvement) in Competence@90 metric on ZEST, when BART-Large is used as the main network.

2 Problem Definition

We study the problem of *learning from task description* (Weller et al., 2020), and aim to improve models' competence on unseen tasks at the inference time. Formally, a task is denoted as a tuple of $(d, \mathcal{D})$, where d is the natural language description of the task, and $\mathcal{D} = \{(s_1, t_1), ..., (s_n, t_n)\}$ contains (source, target) examples of this task (See Fig. 1). In our text-to-text formulation, both s_i and t_i are text sequences. At train time, both d and $\mathcal{D}$ are available, while at test time, an unseen description d is given, and the model is expected to predict the correct t given input s without further training.

For instance, in the ZEST dataset (Weller et al., 2020), a train task description can be "*Are mountain bikes allowed at this national park?*", while $\mathcal{D}$ contains twenty paragraphs for different national parks and twenty corresponding answers. During test time, a novel task may be "*Are there fish in this national park that live in caves?*", and the model is asked to directly make inferences.

3 Background: Adapters

Our work is built on adapters (Houlsby et al., 2019), light-weight modules that can be placed into transformer layers for parameter-efficient transfer learning. In the original paper, the main model is frozen during training, while only layer norm and adapter parameters are learnable. In this paper, we adopt a simplified design compared to the original paper (see Fig. 2 (Left)) – In each transformer layer, exactly one adapter module will be added after the multi-headed attention. One adapter module contains two linear layers separated by an non-linearity activation layer. We use $(\mathbf{W}_{id}, \mathbf{b}_{id})$ to denote the down-projection parameters for the adapter in transformer layer i, and $(\mathbf{W}_{iu}, \mathbf{b}_{iu})$ for the up-projection parameters.

4 Method

Overview. Fig. 2 provides an illustration of our HYPTER framework. HYPTER has two major parts: (1) A main network, which is a pre-trained text-to-text model. We instantiate the main network with BART-Base/Large (Lewis et al., 2020). (2) A hyper-

network, which generates adapters to be plugged into the main network. Fig. 2 (Left) contains a detailed illustration of how adapter parameters are generated and how adapter layers are incorporated into one transformer layer.

Hypernetwork. The hypernetwork consists of an encoder and multiple decoders. The encoder maps the task description d to a latent representation $\mathbf{h}_0$, while the decoders use $\mathbf{h}_0$ to generate adapter parameters ϕ. In our work we instantiated the encoder with a RoBERTa-Base model (Liu et al., 2019), *i.e.*, $\mathbf{h}_0 = \text{RoBERTa}(d)$. For a text-to-text model with n transformer layers, the hypernetwork contains n decoders. Decoder i uses $\mathbf{h}_0$ as input, and outputs adapter parameters ϕ_i for transformer layer i, *i.e.*, $\mathbf{h}_{i,1} = \text{ReLU}(\mathbf{W}_{i,1}\mathbf{h_0} + \mathbf{b}_{i,1})$, $\phi_i = \mathbf{W}_{i,2}\mathbf{h}_{i,1} + \mathbf{b}_{i,2}$. Here $\mathbf{W}_{i,1}, \mathbf{b}_{i,1}, \mathbf{W}_{i,2}, \mathbf{b}_{i,2}$ are trainable parameters. The generated parameters ϕ_i are sliced and reshaped to become parameters $[\mathbf{W}_{id}, \mathbf{b}_{id}, \mathbf{W}_{iu}, \mathbf{b}_{iu}]$ used in the adapter i.

Model Training. We adopt a training schedule where we first train the main network, then train the hypernetwork while the main network is frozen. Conceptually, the first stage ensures that the main network captures the general ability across different tasks; the second stage allows the hypernetwork to learn to adapt the main network to a specific task. During the first stage the text-to-text model is fine-tuned with all $(\text{Concat}(d, s), t)$ examples in the training set. Here $\text{Concat}(d, s)$ means the concatenation of task description d and input s. The learned main network from this stage also serves as the baseline method.

During the second stage, we sample a task $(d, \mathcal{D})$ from the training set and sample a mini-batch of (s, t) examples from $\mathcal{D}$. Given a description d, the hypernetwork generates adapter parameters ϕ_i. We insert the resulting adapter layers into the main network, and compute the cross entropy loss L of generating t given input $\text{Concat}(d, s)$. The loss is end-to-end differentiable and is back-propagated to update the hypernetwork, while the main network is frozen. See Fig. 2 (Right) for illustration. This second stage of training effectively enables learning at the *task* level. The loss L characterizes the model's competence in the task $(d, \mathcal{D})$. Therefore, by optimizing L, the model is trained to *solve tasks*.

Model Inference. At test time the model is given an unseen task description d. The hypernetwork generates description-dependent adapter parameters, similar to the procedure during training. In this way, we obtain a model that is capable of making inferences for this new task.

5 Experiments

5.1 Experiment Setup

Datasets. We use two datasets that fit our setup. The first one is Zero-shot Learning from Task Descriptions dataset (ZEST, Weller et al. 2020), which formulates task descriptions as generalized questions, and provides multiple source-target examples for each question. The performance is evaluated with a novel metric: "Competence@K", along with mean F1 score. Competence@K is the percentage of all tasks for which the model achieves mean F1 score higher than K. For example, Competence@90=5 suggests that 5% of all tasks can be solved with mean F1 better than 90%. We report dev set performance, and hidden test set performance obtained from ZEST's official leaderboard.

We construct the second dataset from SQuAD v1 (Rajpurkar et al., 2016) to simulate the problem setting in this paper. We refer to this dataset as Synthetic SQuAD. Specifically, we construct tasks from the original SQuAD train set according to "question type", the bi-gram containing the central question word (*e.g.*, what, when). For example, "when does" questions are considered as a task, and "what country" questions are considered as another task. These bi-grams are used as "task descriptions". We select the 100 most frequent question types in SQuAD train set, and randomly subsample 64 examples from each type to formulate our dataset. We then randomly split the 100 types into 80/10/10 for train/dev/test. In addition, we select examples that fall into the 10 test question types from Natural Questions (Kwiatkowski et al., 2019) and NewsQA (Trischler et al., 2017), and use these as out-of-domain test examples. Performance is evaluated with mean F1. We include the list of question types and more details about this dataset in Appendix A.

Baseline. To demonstrate the efficacy of the HYPTER framework, we compare it to just its first half – the main text-to-text transformer model that we obtain after the first stage of training. This is identical to the fine-tuning baseline method in (Weller et al., 2020), and there are no other applicable baselines to the best of our knowledge.

Model	Mean-F1	C@75	C@90
Bart-Base	28.44 (±1.58)	5.76 (±2.10)	0.74 (±0.00)
+ HYPTER	**28.96** (±1.15)	**6.32** (±2.02)*	**1.08** (±0.62)
Bart-Large (reported)	40	13	8
Bart-Large	41.17 (±1.16)	15.74 (±2.16)	7.17 (±1.66)
+ HYPTER	**41.65** (±1.34)	**16.41** (±2.15)*	**7.62** (±1.66)*

Table 1: **Performance on ZEST Dev Set.** "C@75/90" refers to Competence@75/90 metric. We report mean and standard deviation over 7 runs. $*$ indicates statistical significance in a two-tailed paired t-test ($p < 0.05$).

Model	Mean-F1	C@75	C@90
Bart-Base	31.97	**7.03**	2.23
+ HYPTER	**32.32**	6.72	**2.53**
Bart-Large (reported)	37.93	11.19	3.96
Bart-Large	40.13	10.91	3.98
+ HYPTER	**40.41**	**11.35**	**4.43**

Table 2: **Performance on ZEST Test Set.** Performance obtained from ZEST official leaderboard[2].

Training Details. For each method, we train the model 7 times using different random seeds, and we report average and standard deviation. We discuss other training details, including hyperparameters, in Appendix B. Notably, we ensure all baseline models will not benefit from additional training, by tuning the number of epochs and using early stopping based on dev performance. This ensures the improvement brought by HYPTER is not due to additional training.

5.2 Results

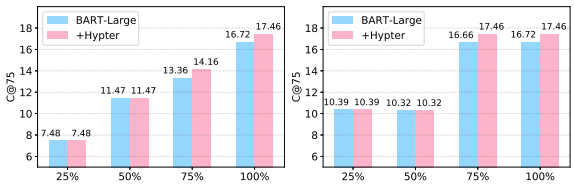
Main Results. We present the results for ZEST in Table 1-2 and results for Synthetic SQuAD in Table 3. On ZEST test set, we observe that the Competence@90 metric is improved from 3.98 to 4.43 when using BART-Large, yielding an 11.3% relative improvement. When BART-Base is used, C@90 is improved from 2.23 to 2.53. This demonstrates that by learning to solve tasks with HYPTER, the model's generalization ability to unseen tasks is improved. On Synthetic SQuAD dataset, we observe 0.74% improvement with BART-Base and 0.41% improvement with BART-Large. Additionally, models trained with HYPTER achieves comparable or better performance on out-of-domain test sets, suggesting the learned task-solving ability is generalizable to new test distribution.[3] It is a known issue that evaluating zero-shot performance can be tricky. We tried our best to reduce the randomness and instability by using different random seeds. In Table 1 and Table 3, we demonstrate that performance improvement is significant (p<0.05) in multiple settings, *e.g.*, on ZEST dev set when C@75 metric is used.

[2] https://leaderboard.allenai.org/zest/submissions/public

[3] Unexpectedly, in Table 3 we observe that performance of BART-Large on NewsQA is worse than that of BART-Base. We suspect that BART-Large may have overfit the SQuAD train set during the first stage of fine-tuning.

Model	SQuAD	NQ	NewsQA
Bart-Base	74.79 (±0.91)	49.78 (±0.95)	56.37 (±0.90)
+ HYPTER	**75.53** (±0.68)*	**50.39** (±1.01)*	**56.41** (±0.85)
Bart-Large	79.32 (±0.34)	59.21 (±0.89)	55.41 (±0.54)
+ HYPTER	**79.73** (±0.50)	**59.58** (±0.57)	**55.60** (±0.90)

Table 3: **Performance on Synthetic SQuAD dataset.** We report mean and standard deviation over 7 runs. NQ and NewsQA serve as out-of-domain test data.



(a) # Tasks (b) # Examples per Task

Figure 3: Competence@75 Performance on ZEST Dev when less training data is used.

Model Behavior Analysis on ZEST. ZEST dataset provides a comprehensive analysis protocol by splitting tasks into different generalization types (base, paraphrase, composition, semantic flips, and output structure) and defining four error types (recall, precision, partial, and other). Compared to the BART-Large fine-tuning baseline, our model achieves better performance in "base" and "paraphrase" categories in the ZEST official test set. We also manually inspected dev set predictions produced by the baseline and our model. We found the predictions corrected by our method span across the four error types. In particular, the proposed method flipped two "n/a" predictions into the correct answers in the task "Which royalty was this dog breed popular with?" ("base" category), reducing the recall errors and improving the competence metric. We do not observe more granular model behavioral patterns beyond this point.

Study of Data Efficiency. We study whether HYPTER is effective when trained with (1) fewer tasks, while the number of examples per task is unchanged; (2) fewer examples per task, while the number of total tasks is kept constant. We experiment with ZEST and BART-Large, and show the performance in Fig. 3. We observe that HYPTER is effective when trained with 75%/100% tasks, but does not improve performance with fewer tasks. This is reasonable since HYPTER learns at the *task*

level (taking one task as an "example"), and 50% of the tasks may be insufficient. We also observe performance improvement with 75%/100% examples per task, but not with fewer examples. This suggests sufficient number of examples per task is necessary for HYPTER to generate effective adapters.

6 Related Work

Zero-shot Learning with Transformers. Zero-shot learning (ZSL) has been explored for various NLP tasks, including text classification (Yin et al., 2019), entity linking (Logeswaran et al., 2019) and entity typing (Obeidat et al., 2019). Several works study cross-task transfer by unifying the input-output format, *e.g.*, relation extraction as machine reading comprehension (Levy et al., 2017), named entity recognition as machine reading comprehension (Li et al., 2020). Such formulation allows generalization to unseen relation or named entity types at test time. Learning from task descriptions (Weller et al., 2020) and instructions (Mishra et al., 2021) can be considered as a sub-category in zero-shot learning, with the goal of generalizing to unseen tasks during inference.

Adapters for Transformers. Houlsby et al. (2019) proposed adapter layers for parameter-efficient transfer learning in NLP. Adapter layers, which adopt a bottleneck architecture with two linear layers, are added after each multi-headed attention layer and each feed-foward layer in a pre-trained transformer. Adapters have been recently applied to multi-lingual settings, with successes in NER, QA and commonsense reasoning (Pfeiffer et al., 2020; Philip et al., 2020; Artetxe et al., 2020).

Hypernetworks and Contextual Parameter Generators. Hypernetwork (Ha et al., 2017) is a broad concept of "using one network to generate the weights for another network". This concept has been broadly applied to visual reasoning (Perez et al., 2018), zero-shot image classification (Jin et al., 2020), etc. Closely related to our work, UDapter (Üstün et al., 2020) studies multilingual dependency parsing by generating adapter parameters. Our work is more generalizable as we do not restrict task format (dependency parsing v.s. general text-to-text tasks) or relations between subtasks (cross-lingual tasks v.s. tasks with text-form descriptions).

7 Conclusion

In this paper, we introduced HYPTER, a framework to improve text-to-text transformer's generalization ability to unseen tasks. HYPTER enhances task-specific abilities by inserting adapters generated with a hypernetwork, meanwhile it maintains the model's general task-solving ability by freezing main model parameters. We demonstrated the effectiveness of HYPTER on two datasets. Future work may explore teaching models with compositional instructions using HYPTER, or propose robust fine-tuning methods that help the model generalize to unseen data. It is also necessary to construct a large dataset of diverse NLP tasks to facilitate future research in this direction.

A Dataset Details

ZEST. ZEST dataset is released at https://ai2-datasets.s3-us-west-2.amazonaws.com/zest/zest.zip. ZEST leaderboard is hosted at https://leaderboard.allenai.org/zest/submissions/public.

Synthetic SQuAD. We build our synthetic dataset from the processed version of SQuAD, Natural Questions and NewsQA in MRQA Shared Task 2019 (Fisch et al., 2019) (https://mrqa.github.io/2019/). We provide the script to reconstruct the data we use in our released code. We list the bigrams we use to formulate synthetic tasks and their train/dev/test partition in Listing 1.

Listing 1: Train/Dev/Test Partition in Synthetic SQuAD dataset.

B Training Details

We use transformers (Wolf et al., 2020) for all our experiments. All experiments are done with one single GPU. We use NVIDIA Quadro RTX 8000, NVIDIA Quadro RTX 6000, or NVIDIA GeForce RTX 2080 Ti, depending on availability.

For text-to-text model fine-tuning, we select learning rate from {1e-5, 3e-5, 5e-5}, and select the total number of epochs from {5, 10, 15, 20, 30} for ZEST and {10, 20, 30, 50, 100} for synthetic SQuAD. We use a fixed batch size of 32.

For hypernetwork training, we train up to 100 epochs (one epoch here refers to an iteration over all tasks). We update the hypernetwork every b tasks, and we call b as task batch size. When learning from one task, we sample b' examples within this task, and we call b' as the example batch size. We greedily and sequentially select adapter width d from {4,8,16,32}, learning rate α from {3e-6, 1e-5, 3e-5, 1e-4}, b from {4,8,16,32}, b' from {4,8,16,32}, based on dev set performance.

C Additional Baseline

Another reasonable baseline is to fine-tune a text-to-text model together with randomly initialized adapters plugged in it. We experiment with this method using BART-Large and list the performance in Table 4. We do not observe significant differences between the two methods (p=0.8840 for C@75, p=0.8118 for C@90 in two-tailed paired t-test).

Model	Mean-F1	C@75	C@90
Bart-Large	41.17 (±1.16)	15.74 (±2.16)	7.17 (±1.66)
Bart-Large with Adapters	39.76 (±1.26)	15.61 (±1.14)	6.96 (±1.15)

Table 4: Performance comparison when adapters are plugged / not plugged during fine-tuning.

D Dev Set Performance of Models Submitted to ZEST Leaderboard

In Table 5 we present the dev performance of models submitted to the leaderboard. The submitted models are the "first-runs" in the 7-run series, as we add the 7-run experiments and significance test later on, following a reviewer's suggestion.

Model	Mean-F1	C@75	C@90
Bart-Base	29.72	7.87	**4.05**
+ HYPTER	**29.81**	**8.67**	**4.05**
Bart-Large (reported)	40	13	8
Bart-Large	42.10	16.72	8.85
+ HYPTER	**43.50**	**17.46**	**9.64**

Table 5: Dev set performance of models submitted to ZEST leaderboard.

E Discussion

It is worth noting that the efficacy of HYPTER is at the cost of introducing new parameters in the hypernetwork. To generate adapter parameters, more parameters are introduced and trained in the hypernetwork. One may achieve better generalization ability to unseen tasks with larger pre-trained models with billions of parameters. In this case, we consider HYPTER as an alternative by augmenting a medium-sized pre-trained model with a hypernetwork. Meanwhile, we highlight our contribution to be the concept of generating task-specific adapters from descriptions and HYPTER's task-level training procedure.

QA-Driven Zero-shot Slot Filling with Weak Supervision Pretraining

Abstract

Slot-filling is an essential component for building task-oriented dialog systems. In this work, we focus on the zero-shot slot-filling problem, where the model needs to predict slots and their values, given utterances from new domains without training on the target domain. Prior methods directly encode slot descriptions to generalize to unseen slot types. However, raw slot descriptions are often ambiguous and do not encode enough semantic information, limiting the models' zero-shot capability. To address this problem, we introduce QA-driven slot filling (QASF), which extracts slot-filler spans from utterances with a span-based QA model. We use a linguistically motivated questioning strategy to turn descriptions into questions, allowing the model to generalize to unseen slot types. Moreover, our QASF model can benefit from weak supervision signals from QA pairs synthetically generated from *unlabeled* conversations. Our full system substantially outperforms baselines by over 5% on the SNIPS benchmark.

1 Introduction

Automatic slot filling, which extracts task-specific slot fillers (e.g. flight date, cuisine) from user utterances, is an essential component to spoken language understanding (Bapna et al., 2017). As shown in Figure 1, the model predicts the slot filler "Joe A. Pass" for the slot type "artist" given an input utterance. However, fully supervised slot filling models (Young, 2002; Goo et al., 2018) require labeled training data for each type of slot (Shah et al., 2019). It is even more of a problem for data-intensive models (Mesnil et al., 2014). This makes the development of new domains in these systems a challenging and resource-intensive task.

This has motivated studies in cross-domain zero-shot learning for the slot-filling task (ZSSF), where the goal is to achieve good slot-filling performance on new domains without requiring additional training data. Previous work (Bapna et al. (2017); Shah et al. (2019)) often uses a sequence tagging approach (similar to the upper image in Figure 1 in a high-level way). To achieve zero-shot domain transfer, they directly encode raw *slot descriptions or names*, such as "playlist", "music item", to enable models to generalize to slot types unseen at training time. However, slot descriptions are often ambiguous and typically do not encode enough semantic information by themselves.

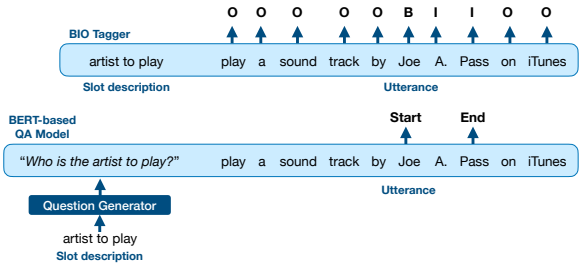

Figure 1: Comparison between two slot-filling frameworks: BIO tagging based model (upper) and our QA-based model (below).

Instead of directly encoding slot descriptions and examples, we introduce a QA-driven slot filling framework (QASF) (Figure 1). Inspired by the recent success of QA-driven approaches (McCann et al., 2018; Logeswaran et al., 2019; Gao et al., 2019; Li et al., 2020; Namazifar et al., 2020), we tackle the slot-filling problem as a reading comprehension task, where each slot type (e.g. "artist") is associated with a natural language question (e.g. "Who is the artist to play?"). A span-based reading comprehension model is then used to extract a slot filler span from the utterance by answering the question.[1] In this work, we use a linguisti-

*Work done during internship at Google Research.

cally motivated question generation strategy for converting slot descriptions and example values into natural questions, followed by a BERT-based QA model for extracting slot fillers by answering questions. As shown in our experiments, this QA-driven method is better at exploiting the semantic information encoded in the questions, therefore it generalizes better to new domains without any additional fine-tuning, as long as the questions are meaningful enough. To the best of our knowledge, we are the first to leverage weakly supervised synthetic QA pairs extracted from unlabeled conversations for a second-stage pretraining. Drawing insights from Mintz et al. (2009), we create a weakly supervised QA dataset from unlabeled conversations and an associated ontology. The synthetic QA pairs are constructed by matching unlabeled utterances against possible slot values in the ontology. This provides a general and cost-effective way to improve QA-based slot filling performance with easily obtainable data.

Experimental results show that (1) our QASF model significantly outperforms previous zero-shot systems on SNIPS (Coucke et al., 2018) and TOP (Gupta et al., 2018); (2) encoding natural questions help models better leverage weakly supervised signals in the pretraining phase, compared to encoding raw descriptions.

2 Task Definition

Given an input utterance u, a slot filling model extracts a set of (slot type, span) pairs $(s_i, a_i), i = 1, \ldots, k$ where s_i comes from a fixed set of slot types $\mathcal{S}$, and each $a_i = (j, k), 1 \leq j < k \leq |u|$ is a span in u. Each slot type is accompanied with a short textual description that describes its semantic meaning (Table 1). We also assume that a small amount of example slot values are given, following Shah et al. (2019).

Our goal is to build a slot filling model that performs well on a new target domain with unseen slot types. Our training data consists of utterances from N source domains $\mathcal{D}_1, \mathcal{D}_2, ..., \mathcal{D}_N$. Each domain $\mathcal{D}_i$ is associated with a set of predefined slot types S_i. At test time, utterances are drawn from a new domain $\mathcal{D}_{N+1}$. The new domain contains both seen and unseen slot types from the source domain. For example, in the SNIPS dataset (Coucke et al., 2018), domains "GetWeather" and "BookRestaurant" both have a slot type called "city", while "condition_temperature" only appears in the "GetWeather" domain.

predicate-argument structures are represented as QA pairs.

3 Methodology

In this section, we describe our framework for Question Answer-driven Slot Filling (QASF). The framework consists of (1) a *question generation strategy* that turns slot descriptions into natural language questions based on linguistic rules; (2) a generic span-extraction-based *question answering* model; (3) an intermediate pretraining stage with generated synthetic QA pairs from unlabeled conversations, which is before task-specific training.

3.1 Question Generation Strategy

To benefit from both language model pretraining and QA supervision, we design a question generation strategy to turn slot descriptions into natural questions. During this process, a considerable amount of knowledge and semantic information is encoded (Heilman, 2011). A generated question consists of a WH word and a normalized slot description following the template below:

`WH_word` is `slot_description` ?

Generating `WH_word` We draw insights from the literature on automatic question generation. Heilman and Smith (2010) propose to use linguistically motivated rules. In their more general case of question generation from the sentence, answer phrases can be noun phrases (`NP`), prepositional phrases (`PP`), or subordinate clauses (`SBAR`). Complicated rules are designed with help from superTagger (Ciaramita and Altun, 2006).

For our spoken language understanding (SLU) tasks, slot fillers are mostly noun phrases[2]. Therefore, we design a simpler set of conditions based on named entity types and part-of-speech (POS) tags. For each slot type, we sample 10 (utterance, slot value) examples from the validation set. Then we run a NER and a POS tagging model [3] to obtain entity types and POS tags for each of the sampled answer spans. Finally, we select `WH_word` based on a set of rules described in Table 6 in Appendix.

Generating `slot_description` Instead of directly adding a raw description phrase in the question template, we *normalize* the phrase with the

[2] around 90% cases in the SNIPS dataset.

[3] Provided by spaCy: `https://spacy.io/`

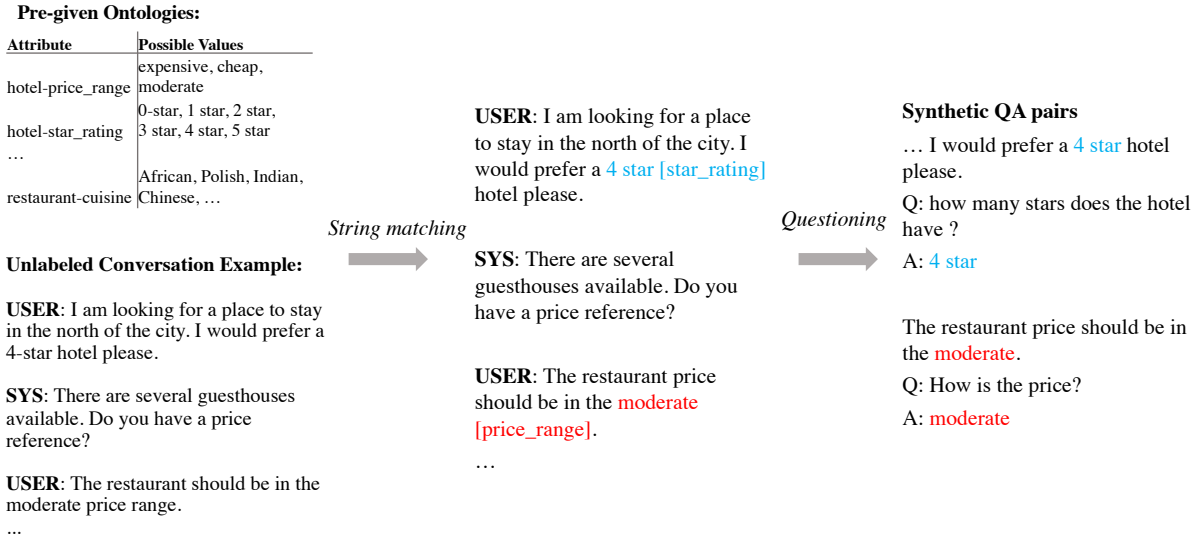

Figure 2: Obtaining weakly supervised synthetic QA pairs for pretraining. Given an ontology and unlabeled utterances, we generate synthetic QA pairs with weak supervision by matching values of slots against the utterances.

Slot	Raw Description	Our Question
playlist_owner	owner	who's the owner?
object_select	object select	which object to select?
best_rating	points in total	how many points in total?
num_book_people	number of people for booking	how many people for booking?

Table 1: Examples of generated questions.

following simple rule: *If the description is of the format "A of B", where both A and B are noun phrases (NP), we only keep B in the phrase if the WH_word is "How long" or "How many"*. Examples of generated questions for corresponding slots are presented in Table 1. Compared to slot descriptions, our questions are more precise and can encode more semantic information.

3.2 Question Answering Model

We use BERT (Devlin et al., 2019) as our base model for jointly encoding the question and utterance. Input sequences for the model share a standard BERT-style format: *[CLS] <question> [SEP] <utterance> [SEP]*, where [CLS] is BERT's special classification token and [SEP] is the special token to denote separation. Let $\mathbf{e}_{1:M}$ be the token-level output representation from the BERT encoder,

$$\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M = \texttt{BERT}(x_1, x_2, ..., x_M) \quad (1)$$

where $x_{1:M}$ are the input tokens.

Then the model predicts answer spans with two binary classifiers on top of the BERT outputs $\mathbf{e}_{1:M}$. The two classifiers are trained to predict whether each token is the start or the end of an answer span, respectively,

$$P_{\text{s}}(i \mid i \in 1 \dots M) = \texttt{softmax}(\mathbf{e}_i \mathbf{W}_{\text{s}})$$
$$P_{\text{e}}(i \mid i \in 1 \dots M) = \texttt{softmax}(\mathbf{e}_i \mathbf{W}_{\text{e}})$$

For negative examples, where a question has no answer spans in the utterance, we map the start and end token both to the [CLS] token. During training, we minimize the negative log-likelihood loss. All parameters are updated. During inference, predicting slot filler spans is more complex because there could be *several* or *no* spans to be extracted for each slot type. We first enumerate all possible spans and only keeping spans/answers satisfying certain constraints (Appendix Section B) as fillers.

3.3 Pretraining with Weak Supervision

Pretrained masked language models do not have the capability of question answering before being fine-tuned on task-specific data. We hypothesize that adding a pretraining step with synthetic QA pairs before fine-tuning can contribute to models' understanding of interactions between question and utterance. For example, improvements have been reported by QAMR (He et al., 2020) on SRL and textual entailment (TE). Previous researches (Wu et al., 2020; Gao et al., 2020) have used crowd-sourced QA pairs, but typically the improvement margin is not significant (Wu et al., 2020) when the task-specific data is in a different domain (SQuAD v.s. newswire). Therefore we introduce a method of collecting relevant and distantly supervised QA pairs and investigate their influences in pretraining. More specifically, we draw insights from

Mintz et al. (2009) for creating a weakly supervised dataset. Figure 2 illustrates the process. Given an *ontology or database* of slot types and all possible values for each slot type, we find all utterances containing those value strings in a large set of **unlabeled conversations**. For example, in Figure 2, for the "hotel_price_range" slot, there are three possible values "expensive", "cheap" and "moderate" in the ontology. We then form question-answer-utterance triples using the question generation strategy proposed in Section 3.1.

To obtain the pre-defined ontology and unlabeled conversations, we use MultiWOZ 2.2 (Zang et al., 2020), which is an improved version of MultiWOZ (Budzianowski et al., 2018). We do not use annotations in the dataset such as the (changes of) states in the conversations and we treat each utterance independently. We remove slot types that exist in the task-specific training/test data (i.e., SNIPS and TOP) from the ontology and end up with 67,370 QA examples for pretraining.

4 Experiments

4.1 Datasets and Baselines

SNIPS (Coucke et al., 2018) is an SLU dataset consisting of crowdsourced user utterances with 39 slots across 7 domains – "AddToPlaylist" (ATP), "BookRestaurant" (BR), "GetWeather" (GW), "PlayMusic" (PM), "RateBook" (RB), "SearchCreativeWork" (SCW), "FindScreeningEvent" (FSE). It has around 2000 training instances per domain. The slot types of each domain do not overlap with each other. Following previous work (Shah et al., 2019; Liu et al., 2020), we use this dataset to evaluate zero-shot cross-domain transfer learning – train on all training instances from domains other than D_i, and test exclusively on D_i, for $i = 1, \ldots, 7$.
TOP (Gupta et al., 2018) is a task-oriented utterance parsing dataset. It is based on a hierarchical annotation scheme for annotating utterances with nested intents and slots. Each slot type also comes with a description. In our setup, we train on all seven domains of SNIPS as well as varying amounts of training data from the TOP training set (0, 20, and 50 examples), and use the TOP test set as an out-of-distribution domain for evaluation. We report span-level F1 (micro-average).

We compare our method against a number of representative baselines. Concept Tagger (CT) (Bapna et al., 2017) is a slot-filling framework that directly uses *original* slot descriptions to generalize to unseen slot types. Robust Zero-shot Tagger (RZT) (Shah et al., 2019) is an extension of CT, which incorporates example values of slots to improve the robustness of the model's zero-shot capability. Coach (Liu et al., 2020) is a coarse-to-fine model for slot-filling. It also encodes raw slot descriptions. We also include a Zero-Shot BERT Tagger (ZSBT) based on BERT (Devlin et al., 2019) as an additional baseline. ZSBT directly encodes raw slot descriptions and utterances and predicts a tag (B, I, or O) for each token in the utterance.

4.2 Results and Analysis

We report F-1 of the baselines and our model on each target domain test set of **SNIPS** as well as average F-1 across domains. All models are trained on the other six domains for each target domain. As shown in Table 2, our QA-driven slot filling framework (QASF) significantly outperforms all baselines in five of the seven domains, with slightly lower performance on BookRestaurant than ZSBT, and lower performance on FindScreeningEvent than Coach. The average F-1 of QASF is around 7% higher than the prior published state-of-the-art Coach model, and about 2% higher than the Zero-shot BERT Tagger baseline. Adding the intermediate pre-training stage on weakly supervised data further improves performance on top of QASF in six of the seven domains except for AddToPlaylist. On average, adding pre-training improves over QASF by 2.9% F-1. The zero-shot performance of all models are relatively worse on PlayMusic, RateBook and FindScreeningEvent. A more detailed discussion is in Appendix Section C.

Table 3 summarizes **TOP test** results: (1) In both the zero-shot and few-shot settings, our QASF outperforms ZSBT, with a bigger improvement on the zero-shot setting. (2) Pretraining on the weakly supervised QA pairs helps more in the zero-shot setting than in the few-shot setting, with a 20% relative improvement. This shows that QASF (w/ pretraining) is more robust to the domain shift when there is no target domain training data.

Impact of QG strategy and pretraining To understand the influence of question generation and impact of pretraining with synthetic QA pairs, we perform ablation studies of both components on the SNIPS dataset. The table below shows ablation results (F-1). "w/o QG" refers to a model trained with *raw* slot descriptions and utterances.

Firstly, the question generation strategy consis-

	ATP	BR	GW	PM	RB	SCW	FSE	Average F-1
CT (Bapna et al., 2017)	38.82	27.54	46.45	32.86	14.54	39.79	13.83	30.55
RZT (Shah et al., 2019)	42.77	30.68	50.28	33.12	16.43	44.45	12.25	32.85
Coach (Liu et al., 2020)	50.90	34.01	50.47	32.01	22.06	46.65	25.63	37.39
ZSBT$^{\text{BERT}}$ (our baseline)	55.78	**49.34**	56.58	28.35	27.09	57.61	20.50	42.18
QASF$^{\text{BERT}}$ (ours)	**59.29**	43.13	59.02	33.62	33.34	59.90	22.83	44.45
w/ pre-training on WS	57.57	48.75	**61.27***	**38.54***	**36.51****	**60.82**	**27.72****	47.31

Table 2: Experimental results (F-1) on SNIPS dataset. * indicates statistical significance ($p < 0.05$), **: $p < 0.01$.

	Zero-shot	Few-shot (20)	Few-shot (50)
Random NE	1.34	-	-
ZSBT	8.82	37.60	42.73
QASF (ours)	10.27	36.86	46.49
w/ pre-training on WS	12.35	39.78	47.91

Table 3: Evaluation results on TOP test. Models trained on SNIPS, and varying amount of utterances of TOP train – zero-shot, 20-shot (1%), 50-shot (2.5%).

w/o pretraining			w/ pretraining		
QASF	w/o QG	Δ (F1)	QASF	w/o QG	Δ (F1)
44.45	41.97	+5.91%	47.31	43.09	+9.79%

Table 4: Ablation Study

tently helps, with a 2.48% F-1 gain in "w/o pretraining" and a 4.22% F-1 gain in "w/ pretraining". Secondly, the pretrained representations from additional weakly supervised data improve F-1 by 2.86% in "w/ QG" and 1.12% in "w/o QG". More interestingly, the gain from the questioning strategy is larger when combined with the pretraining (9.8% as compared to 5.9%). This demonstrates that synthetic QA pairs are also helping with getting better QA-aware representations before fine-tuning on the task-specific data for slot-filling.

4.3 Error Analysis

We further conduct manual error analysis on the models' predictions on SNIPS. We find that there are several sources where the errors are from:

The variance between the source and target domains. Sometimes even slot types of the same name refer to different kinds of objects in different domains. For example, slot type "object_type" in the "RateBook" domain refers to object types like textbook, essay and novel; while in the "FindScreeningEvent", it refers to event types like movie times/schedules. In the two domains, they have the same raw descriptions. In the table below, we show the performance of models on utterances with "object_type" and "object_name" spans (according to gold annotations). We can see that the performances on these special slots are significantly

	ZSBT	QASF	QASF (w/ pretraining)
Averaged F-1	17.43	22.26	24.29

lower than the general average on all the examples (40–50%). But still, the questioning strategy helps improve the transferring of semantic information.

Plus, the variance in semantic meaning between slot types in SNIPS and TOPS is even larger. For slots like "location_modifier", "road_condition", there are no semantic similar slots in SNIPS or pretraining dataset, which results in low performance. Having more specific/detailed slot descriptions and use them in the question generation would help further (Brown et al., 2020; Du and Cardie, 2020).

Annotation artifacts of SNIPS dataset and sparsity of vocabulary for certain slot types. Our QASF framework does not perform well on the target domain "BookRestaurant", thus we take a close look at it. We find that there are only 25 possible values in total for slot restaurant_type, over **51%** of them are of a single token "restaurant" (Table below). A very simple approach (assigning type "restaurant_type" to all tokens "restaurant" can obtain decent performance). This does not happen for

Slot Value	"restaurant"	"bar"	"pub"	"brasserie"
Proportion	51.81%	7.26%	6.60%	6.23%

other slot types in BookRestaurant (e.g., cuisine, restaurant_name). The possible values are more diverse and the distribution is more balanced.

5 Conclusion

We propose a QA-driven method with weakly supervised pretraining for zero-shot slot filling. Our experimental results and analyses demonstrate the benefits of QA-formulation, especially in the setting with synthetic QA pairs pretraining.

A Details of Question Generation

The part-of-speech tagset is based on the Universal Dependencies scheme [4]. The named entity labels are based on OntoNotes 5.0 (Weischedel et al., 2013). In Table 6, we describe the set of rules for the selection of `WH_word`.

B Inference Constraints

At inference time, predicting the slot filler spans is more complex – for each slot type, as there can be *several* or *no* spans to be extracted. After the output layer, we have the probability of each token x_i being the start ($P_{\text{s}}(i)$) and end ($P_{\text{e}}(i)$) of the span.

We harvest all the valid candidate spans for each slot type with the following heuristics:

1. Enumerate all possible combinations of start offset (start) and end offset (end) of the spans ($\frac{M(M-1)}{2}$ candidates in total);

2. Eliminate the spans not satisfying the constraints: (1) start and end token must be within the utterance; (2) the length of the span should be shorter than a maximum length constraint; (3) spans should have a larger probability than the probability of "no answer" (which is represented with [CLS] token), namely,

$$P_{\text{s}}(\text{start}) > P_{\text{s}}([\text{CLS}]), P_{\text{e}}(\text{end}) > P_{\text{e}}([\text{CLS}])$$

C Further Analysis and Discussions

We conduct further analysis to understand how and why the models are effective.

C.1 Impact of question generation strategy and pretraining

Table 7 shows full ablation results.

C.2 Analysis on Seen versus Unseen Slots

To understand the transferring capability of our models, we further split the SNIPS test for each target domain into "seen" and "unseen" slots. An example is categorized into "unseen" as long as there is an unseen slot (i.e., the slot does not exist in the remaining six source domains in its gold annotation.) Otherwise, it counts as "seen". A full list of unseen slots for each target domain can be found in the Appendix.

[4] universaldependencies.org/u/pos/

As is shown in Table 5, we can see that (1) both ZSBT baseline and our models perform better on the "seen" slots than the "unseen" ones – the numbers substantially drop on the "unseen" slots. This proves that transferring from the source domains to the unseen slots in the target domain is a hard problem. (2) On the portion of examples with "seen" slots, our best model outperforms ZSBT with around a 2% margin. (3) On the "unseen" portion of examples, the margin is larger – our QASF and pretraining step help improve the performance more (over 4%). The second and third observation together demonstrates that the questioning strategy help improve the model's capability of transferring between related but not exactly same slot types (e.g., "object_name" and "entity_name").

	Seen	Unseen
ZSBT	54.75	37.41
QASF	56.79	39.99
w/ pretraining	56.23	41.73

D Hyper-parameters and Training Details

We use the uncased version of the BERT-base (Devlin et al., 2019) model for QA finetuning and pretraining. The model is fine-tuned for 5 epochs with a starting learning rate of 3e-5 on the SNIPS dataset. The model is pretrained for 5 epochs with a starting learning rate of 5e-7 on the synthetic QA dataset. Our implementations are based on https://github.com/google-research/bert/blob/master/run_squad.py

WH_word	Conditions	Answer Examples
How long	The answer phrase is modified by a cardinal number (CARDINAL) or quantifier phrase (QUANTITY) whose object is a temporal unit, as is defined in (Pan et al., 2011), i.e., second/minute/hour/day/week/month/year/decade/century.	2 nights
How many	The answer phrase is modified by a cardinal number (CARDINAL) or quantifier phrase (QUANTITY) and the object is not a temporal unit.	2 stars, 3 tickets
How	adjective ADJ	moderate, expensive
When	The answer phrase's head word is tagged DATE or TIME	1:30 PM, 1999
Who	The answer phrase's head word is tagged PERSON or is a personal pronoun PRON (I, he, herself, them, etc.)	mother, Dr. Williams
Where	The answer phrase is a prepositional phrase whose object is tagged GPE or LOC, whose preposition is one of the following: on, in, at, over, to	amc theaters, fort point san francisco, east, west, ...
Which	The answer phrase is a determiner DT (this, that) or an ordinal ORDINAL	this, first, current, last
What	all other cases

Abstract

Language models like BERT and SpanBERT pretrained on open-domain data have obtained impressive gains on various NLP tasks. In this paper, we probe the effectiveness of domain-adaptive pretraining objectives on downstream tasks. In particular, three objectives, including a novel objective focusing on modeling predicate-argument relations, are evaluated on two challenging dialogue understanding tasks. Experimental results demonstrate that domain-adaptive pretraining with proper objectives can significantly improve the performance of a strong baseline on these tasks, achieving the new state-of-the-art performances.

1 Introduction

Recent advances in pretraining methods (Devlin et al., 2019; Joshi et al., 2020; Yang et al., 2019) have achieved promising results on various natural language processing (NLP) tasks, including natural language understanding, text generation and question anwsering (Liu et al., 2019; Song et al., 2019; Reddy et al., 2019). In order to acquire general linguistic and semantic knowledge, these pretraining methods are usually performed on open-domain corpus, like Wikipedia and BooksCorpus. In light of the success from open-domain pretraining, a further question is naturally raised: whether downstream tasks can also benefit from domain-adaptive pretraining?

To answer this question, later work (Baevski et al., 2019; Gururangan et al., 2020) has demonstrated that continued pretraining on the unlabeled data in the target domain can further contribute to the corresponding downstream task. However, these studies are dependent on additional data that can be unavailable in certain scenarios, and they only evaluated on easy downstream tasks. For instance, Gururangan et al. (2020) perform continued pretraining with masked language modeling loss on several relevant domains, and they obtain improvements on eight well-studied classification tasks, which are too simple to exhibit the strength of continued domain-adaptive pretraining. Besides, it is still unclear which pretraining objective is the most effective for each downstream task.

In this work, we give a deeper analysis on how various domain-adaptive pretraining methods can help downstream tasks. Specifically, we continuously pretrain a BERT model (Devlin et al., 2019) with three different kinds of unsupervised pretraining objectives on the domain-specific training set of each target task. Two of them are Masked Language Model (MLM) (Gururangan et al., 2020) and Span Boundary Objective (SBO) (Joshi et al., 2020), both objectives have been explored in previous work. In addition, a novel pretraining objective, namely Perturbation Masking Objective (PMO), is proposed to better learn the correlation between arguments and predicates. After domain-adaptive pretraining, the adapted BERT is then tested on dialogue understanding tasks to probe the effectiveness of different pretraining objectives.

We evaluate on two challenging tasks that focus on dialogue understanding, i.e. Conversational Semantic Role labeling (CSRL) and Spoken Language Understanding (SLU). CSRL (Xu et al., 2020, 2021) was recently proposed by extending standard semantic role labeling (SRL) (Palmer et al., 2010) with cross-utterance relations, which otherwise require coreference and anaphora resolution for being recognized. We follow previous work to consider this task as sequence labeling. On the other hand, SLU includes intent detection and slot filling. To facilitate domain-adaptive pretraining, we only use the training set of each downstream task. In this way, the usefulness of each pretraining objective can be more accurately examined, as no additional data is used.

Experimental results show that domain-adaptive

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 665–669
August 1–6, 2021. ©2021 Association for Computational Linguistics

pretraining significantly helps both tasks. Besides, our novel objective achieves better performances than the existing ones, shedding more lights for future work on pretraining.

2 Tasks

Conversational Semantic Role Labeling. Xu et al. (2021) first proposed the CSRL task, which extends standard SRL by explicitly annotating other cross-turn predicate-argument structures inside a conversation. Compared with newswire documents, human conversations tend to have more ellipsis and anaphora situations, causing more problems for standard NLU methods. Their motivation is that most dropped or referred components in the latest dialogue turn can actually be found in the dialogue history. As the result, CSRL allows arguments to be in different utterances as the predicate, while SRL can only work on each single utterance. Comparing with standard SRL, CSRL can be more challenging due to the long-range dependencies. Similar to SRL, we view CSRL as a sequence labeling problem, where the goal is to label each token with a semantic role.

Spoken Language Understanding. Proposed by Zhu et al. (2020), the SLU task consists of two key components, i.e., intent detection and slot filling. Given a dialogue utterance, the goal is to predict its intents and to detect pre-defined slots, respectively. We treat them as sentence-level classification and sequence labeling, respectively.

3 Domain-Adaptive Pretraining Objectives

While previous works have shown the benefit of continued pretraining on domain-specific unlabeled data (e.g., Lee et al. (2020); Gururangan et al. (2020)), these methods only adopt the Masked Language Model (MLM) objective to train an adaptive language model on a single domain. It is not clear how the benefit of continued pretraining may vary with factors like the objective function.

In this paper, we use the dialogue understanding task as a testbed to investigate the impact of three pre-training objectives to the overall performance. In particular, we explore the MLM (Devlin et al., 2019) and Span Boundary Objective (SBO) (Joshi et al., 2020) , and introduce a new objective, namely Perturbation Masking Objective (PMO), which is more fit for the dialogue NLU task.

3.1 Masked Language Model Objective

Masked Language Model (MLM) is the task of predicting missing tokens in a sequence from their placeholders. Specifically, given a sequence of tokens $X = (x_1, x_2, .., x_n)$, a subset of tokens $Y \subseteq X$ is sampled and substituted with a different set of tokens. In BERT's implementation, Y accounts for 15% of the tokens in X; of those, 80% are replaced with [MASK], 10% are replaced with a random token (according to the unigram distribution), and 10% are kept unchanged. Formally, the contextual vector of input tokens X is denoted as $\boldsymbol{H} = (\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_n)$. The task is to predict the original tokens in Y from the modified input and the objective function is:

$$\mathcal{L}_{MLM} = -\frac{1}{|Y|}\sum_{t=1}^{|Y|}\log p(x_t|\boldsymbol{h}_t;\boldsymbol{\theta})$$

where $|Y|$ is the number of masked tokens, and $\boldsymbol{\theta}$ represents the model parameters.

3.2 Span Boundary Objective

In many NLP tasks such as the dialogue understanding, it usually involves reasoning about relationships between two or more spans of text. Previous works (Joshi et al., 2020) have shown that SpanBERT is superior to BERT in learning span representations, which significantly improves the performance on those tasks. Conceptually, the differences between these two models are two folds.

Firstly, different with BERT that independently selects the masked token in Y, SpanBERT define Y by randomly selecting *contiguous spans*. In particular, SpanBERT first selects a subset $Y \subseteq X$ by iteratively sampling spans until masking 15% tokens[1]. Then, it randomly (uniformly) selects the starting point for the span to be masked.

Secondly, SpanBERT additionally introduces a span boundary objective that involves predicting each token of a masked span using only the representations of the observed tokens at the boundaries. For a masked span of tokens $(x_s, ..., x_e) \in Y$, where (s, e) are the start and end positions of the span, it represents each token in the span using the boundary vectors and the position embedding:

$$\boldsymbol{y_i} = f(\boldsymbol{h}_{s-1}, \boldsymbol{h}_{e+1}, \boldsymbol{p}_{i-s+1})$$

where p_i marks relative positions of span token x_i with respect to the left boundary token x_{s-1},

[1]The length of each span is sampled from the geometric distribution $l \sim Geo(p)$, with $p = 0.2$.

and $f(\cdot)$ is a 2-layer MLP with GeLU activations and layer normalization. SpanBERT sums the loss from both the regular MLM and the span boundary objectives for each token in the masked span:

$$\mathcal{L}_{SBO} = -\frac{1}{|Y|}\sum_{t=1}^{|Y|}\log p(x_t|\boldsymbol{y}_t;\boldsymbol{\theta})$$

3.3 Perturbation Masking Objective

In dialogue understanding tasks like CSRL, the major goal is to capture the semantic information such as the correlation between arguments and predicate. However, for the sake of generalization, existing pretraining models do not consider the semantic information of a word and also not assess the impact of predicate has on the prediction of arguments in their objectives. To address this, we propose to use the perturbation masking technique (Wu et al., 2020) to explicitly measure the correlation between arguments and predicate and further introduce that into our objective.

The perturbation masking is originally proposed to assess the impact one word has on the prediction of another in MLM. In particular, given a list of tokens X, we first use a pretrained language model $\mathbf{M}$ to map each x_i into a contextualized representation $H(X)_i$. Then, we use a two-stage approach to capture the impact word x_j has on the prediction of another word x_i. First, we replace x_i with the [MASK] token and feed the new sequence $X\backslash\{x_i\}$ into $\mathbf{M}$. We use $H(X\backslash\{x_i\})_i$ to denote the representation of x_i. To calculate the impact $x_j \in x\backslash\{x_i\}$ has on $H(X)_i$, we further mask out x_j to obtain the second corrupted sequence $X\backslash\{x_i, x_j\}$. Similarly, $H(X\backslash\{x_i, x_j\})_i$ denotes the new representation of token x_i. We define the the impact function as: $f(x_i, x_j) = d(H(X\backslash\{x_i\})_i, H(X\backslash\{x_i, x_j\})_i)$, where d is the distance metric that captures the difference between two vectors. In experiments, we use the Euclidean distance as the distance metric.

Since our goal is to better learn the correlation between arguments and predicate, we introduce a perturbation masking objective that maximizes the impact of predicate on the prediction of argument span:

$$\mathcal{L}_{PMO} = -\frac{1}{|Y|}\sum_{t=1}^{|Y|} -f(x_t, \{x_{p_0}, ..., x_{p_{m-1}}\})_i$$

where p_0,... p_{m-1} are m predicates that occur in the sentence. In practice, we first follow the SpanBERT to sample a subset of contiguous span texts and perform masking (i.e., span masking) on them. Then, we select verbs from X as predicates and perform perturbation masking on those predicates.

4 Experiments

We evaluate pretraining objectives on three datasets, DuConv, NewsDialog[2] and CrossWOZ. The former two datasets are annotated by Xu et al. (2021) for the CSRL task and the last one is provided by Zhu et al. (2020) for the SLU task.

Duconv is a Chinese knowledge-driven dialogue dataset, focusing on the domain of movies and stars. NewsDialog is a dataset collected in a way that follows the setting for constructing general open-domain dialogues: two participants engage in chitchat, and during the conversation, the topic is allowed to change naturally. Xu et al. (2021) annotates 3K dialogue sessions of DuConv to train their CSRL parser, and directly test on 200 annotated dialogue sessions of NewsDialog. CrossWOZ is a Chinese Wizard-of-Oz task-oriented dataset, including 6K dialogue sessions and 102K utterances on five domains.

Since the state-of-the-art models on these tasks are all developed based on BERT, we use the same model architectures but just replace the BERT base with our domain-adaptive pretrained BERT. Notice that, we also experiment with other pretrained language models such as RoBERTa and XLNet. We observed similar results but here we only report the results based on BERT due to the space limitation.

In particular, we perform the domain-adaptive pretraining on CSRL task using all dialogue sessions of training set in DuConv (Wu et al., 2019) and NewsDialog (Wang et al., 2021), which includes 26K and 20K sessions, respectively; on the SLU task, we use the whole CrossWOZ training dataset.

The hyper-parameters used in our model are listed as follows. The network parameters of our model are initialized using the pretrained language model. The batch size is set to 128. We use Adam (Kingma and Ba, 2015) with learning rate 5e-5 to update parameters.

Results and Discussion. On the CSRL task, we follow Xu et al. (2021) to use the micro-averaged F1 over the (*predicate*, *argument*, *label*) tuples. Specifically, we calculate F1 over all arguments

[2]We obtain the CSRL annotations on DuConv and NewsDialog directly from the author of Xu et al. (2021).

Pretraining Strategy	DuConv			NewsDialog			CrossWOZ

Table 1: Evaluation on the DuConv, NewsDialog and CrossWOZ. α is the ratio of sampling from noun phrases.

(referred as $F1_{all}$) and those in the same and different dialogue turns as predicates (referred as $F1_{intra}$ and $F1_{cross}$). On the SLU task, we report results on $F1_{intent}$, $F1_{slot}$ and $F1_{all}$. Table 1 summarizes the results. The first row shows the performance of existing state-of-the-art models without domain-adaptive pretraining on each dataset. We can see that on two tasks, existing models could benefit from the domain-adaptive pretraining, achieving new state-of-the-art performance on these datasets.

Let us first look at the CSRL task. Pretraining with MLM objective could slightly improve the performance by 0.4 and 0.12 in terms of $F1_{all}$ on DuConv and NewsDialog, respectively. By additionally considering the span boundary objective, the overall performance especially $F1_{cross}$ could be further improved by at least 0.75 and 2.6, respectively. These results are expected since arguments in the CSRL task are usually spans and SBO is better than MLM in learning the span representation. We can also see that our proposed perturbation masking objective boosts the performance by a larger margin than SBO, indicating that learning correlations between arguments and predicates is more crucial to the NLU task. By summing three objectives, the CSRL model could achieve the best performance, significantly improving the baseline that without domain-adaptive pretraining by 1.05 and 3.2 $F1_{all}$ score, respectively.

From Table 1, we can see that similar findings are also observed on the SLU task. First of all, domain-adaptive pretraining on CrossWOZ could also improve the performance. Secondly, adding either SBO or PMO, the F1 scores on intent and slot could be further improved. Thirdly, the best performance is achieved when all three objectives are considered. However, we do not observe similar substantial gains on the SLU task as on the CSRL task. We think this is because the state-of-the-art performance on CrossWOZ is relatively high, but it is still impressive to achieve absolute 0.81, 0.90 and 0.87 points improvement in terms of $F1_{intent}$, $F1_{slot}$ and $F1_{all}$.

We also investigate the impact of span masking scheme to the overall performance. Recall that, in the span masking, we randomly sample the span length and a start position of the span. Joshi et al. (2020) showed that no significant performance gains are observed by using more linguistically-informed span masking strategies such as masking *Named Entities* or *Noun Phrases*. Specifically, they use the spaCy's[3] named entity recognizer and constituency parser to extract named entities and noun phrases, respectively. In this paper, we revisit these span masking scheme. Since there is no available constituency parser designed for the dialogue, we use an unsupervised grammar induction method (Jin and Schuler, 2020) to extract grammars from the training data. **Noun phrases** from Viterbi parse trees from different grammars are tallied without labels, resulting in a posterior distributions of the spans, which are used in our span sampling. As shown in Table 1, we find the best choice is to combine random sampling and noun phrases sampling, i.e., sampling from the noun phrases at $\alpha\%$ of the time and from a geometric distribution for the other (1 - $\alpha\%$). The performance on all three datasets coherently increases when more noun phrases are used in the span sampling.

5 Conclusion

In this paper, we probe the effectiveness of domain-adaptive pretraining on dialogue understanding tasks. Specifically, we study three domain-adaptive pretraining objectives, including a novel objective: *perturbation masking objective* on three NLU datasets. Experimental results show that domain-adaptive pretraining with proper objectives is a sim-

Targeting the Benchmark: On Methodology in Current Natural Language Processing Research

David Schlangen
CoLabPotsdam / Computational Linguistics
Department of Linguistics, University of Potsdam, Germany
david.schlangen@uni-potsdam.de

Abstract

It has become a common pattern in our field: One group introduces a *language task*, exemplified by a *dataset*, which they argue is *challenging* enough to serve as a *benchmark*. They also provide a baseline *model* for it, which then soon is *improved* upon by other groups. Often, research efforts then move on, and the pattern repeats itself. What is typically left implicit is the argumentation for why this constitutes progress, and progress towards what. In this paper, I try to step back for a moment from this pattern and work out possible argumentations and their parts.

1 Introduction

The goal of any field of research is to make progress towards answering its foundational questions. To do so, a *methodology* is required that guides attempts at providing or improving answer proposals. In natural language processing, the object of study is human language, and any methodology for doing research in this field will need to have some contact with examples of this object. This contact has become more and more direct in the past decades, with samples of language becoming more directly the material from which proposals (in the form of statistical *models*) are derived. Recent years have seen an increase in the collection of samples specifically for the purpose of creating *benchmarks*, against which progress in devising models can be measured. It is this function of *benchmarking*, and its role in a progress-oriented methodology, that this paper aims to investigate.

Figure 1 illustrates the basic structure of a benchmarking methodology: A *language task* is devised that is a) restricted enough to be managable with current methods, and b) deemed challenging for the *capabilities* that it involves.[1] For this task, a *dataset* is collected, often via crowd sourcing, on which in turn models are trained and compared, using evaluation metrics defined together with the task. What can we learn by following such a methodology? Let's look at the components first and then at ways in which this methodology is, might, and perhaps should be used.

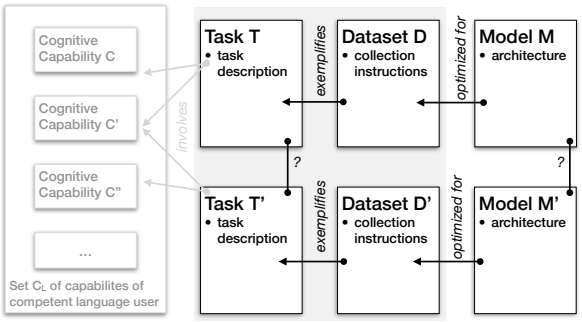

Figure 1: Relations between Research Objects in a Benchmark-Driven Methodology

2 What is a Language Benchmark?

2.1 What is a Benchmark?

In computing, a benchmark is *"a problem that has been designed to evaluate the performance of a system [which] is subjected to a known workload and the performance of the system against this workload is measured. Typically the purpose is to compare the measured performance with that of other systems that have been subject to the same benchmark test."* (Butterfield et al., 2016).

The use of this term in NLP is related: here, benchmark tasks are also specifically designed for evaluation; however, an important difference is that what is being evaluated is not a full system that has a separate main purpose, but rather an *algorithm* that is instantiated on the benchmark itself. I will discuss the consequences of this below.

This kind of evaluation of learning algorithm has a long tradition in the field of machine learning research.[2] In this field, a new algorithm would

[1] This figure is from (Schlangen, 2019), of which this is a shorter version developed in a somewhat different direction.

[2] For example, the UCI Machine Learning Repository has

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 670–674
August 1–6, 2021. ©2021 Association for Computational Linguistics

normally be tested on a large collection of datasets, possibly ranging from classifications of flowers to classification of credit records, with no assumption of any internal connection between the datasets. Again, NLP is different here, as all datasets represent facets of the same underlying phenomenon, language use.

I will argue that these two differences (life outside of benchmarking, and internal connection between tasks) are important, but understudied. But first we look at the notion of a *language task* in some more detail.

2.2 What is a Language Task?

A *language task* is a mapping between an *input space* and an *output* or *action space*, at least one of which contains natural language expressions. The mapping has to conform to a *task description*, which is typically given only informally, making reference to theoretical or pre-theoretical constructs external to the definition, such as "translation" or "is true of". I call this an *intensional description*. Typically, a task will also be specified *extensionally* through the provision of a *dataset* of examples of the mapping (that is, pairs of state and action). To collect such a dataset, the task description (e.g., "classification of entailment relations between sentence pairs") must be operationalised into a collection instruction ("please mark whether the situation that is well described by sentence A could normally also be described by sentence B").

3 How Can It be Evaluated?

3.1 Relation Task / Dataset

Given a task and a dataset, the first question to ask is how well the latter exemplifies the former. Investigating this is relatively straightforward. First, the dataset should be *verified*, which is to check whether the provided input/output pairs can indeed be judged correct relative to the task (in its intensional description). If the examples are collected specifically for the purpose of exemplifying the task, this is the process of controlling annotation, and standard methodologies exist (Artstein and Poesio, 2008; Pustejovsky and Stubbs, 2013). Care needs to be taken that the task is actually well-defined enough to pose an unambiguous challenge to capable language users.[3]

Validating a dataset is a less formalised process. It comprises arguing that the dataset indeed exemplifies the task intension well. For example, pairs only of images of giraffes and sentences describing them would arguably not exemplify the general task of *image description* very well (even if the descriptions are accurate), while perhaps exemplifying the task of *giraffe image description*.

Another way to evaluate a dataset is by trying to model it. If a model can "solve" the dataset even when deprived of information that for theoretical or pre-theoretical reasons is seen to be crucial, the dataset can be considered an unsatisfactory exemplification of the task. E.g., in a *visual (polar) question answering* setting (Antol et al., 2015), if in a dataset all and only the expressions that mention giraffes are true, a model could seize on this fact and perform well without needing the images, which would be evidence that the dataset is deficient relative to the task description.[4]

3.2 Relation Cognitive Capability / Task

While the dataset forms the visible surface of the task, it is the task itself that needs to provide value. We can categorise tasks by how they are embedded in further uses: a *product task* task is one that can be argued to have direct value to consumers (such as translation, or search); an *annotation task* is one where the task description is theoretically motivated and the output a linguistically motivated object (which may be consumed in a pipeline that itself is motivated as a product task); finally, a *benchmark task* – which is the type that concerns us here –is one which gets its value from how well it tests a particular ability (and nothing else) and how well it discriminates learners based on this ability.[5]

For a language benchmark task, the argument roughly goes as follows (even if typically only made implicitly): To be good at task T, an agent

been collecting and providing datasets for more than 20 years now (Dua and Graff, 2019).

[3] Pavlick and Kwiatkowski (2019), for example, show that the task of annotation textual entailments can lead to faultless annotator disagreements.

[4] The task of visual question answering provides an interesting example case of such a development. After Antol et al. (2015) introduced the first large scale dataset for this task, it quickly became clear that this dataset could be handled competitively by models that were deprived of visual input ("language bias", as noted e.g. by Jabri et al., 2016). This problem was then addressed by Goyal et al. (2017) with the construction of a less biased (and hence more valid) corpus for the same task.

[5] Martinez-Plumed and Hernandez-Orallo (2018), analysing AI benchmarks in general, distinguish between *difficulty* (which determines the ability level which must be reached to perform better than chance on a task) and *discrimination* (the slope of the graph plotting ability level vs. probability of correct response).

must possess a set C_T of capabilities (of representational or computational nature). If the $c \in C_T$ are capabilities that competent language users can be shown or argued to possess and make use of in using language—let's call the set of these capabilities of a competent language user C_L, so that $C_T \subseteq C_L$— then being able to model these capabilities (via modelling the task) results in progress towards the ultimate goal, which is to model competent language use. And hence, any task T that comes with an *interesting* set C_T is a good task.[6]

Under what conditions does this argument work? First of all, the assumed connection to the set of capabilities must indeed be there. We have already seen a way to challenge a claimed connection, through providing a model that can "solve" a given task (via a dataset) while not having access to information that, given our analysis of the task and interest in C_T, should be involved in the capability.[7] (Although this challenge in the first instance only targets the dataset and not the task itself.)

Secondly, following usual scientific methodology (Popper, 1934), we can rank the value of an instantiation of this argument by how precisely the capability is specified, from the trivially correct "task T involves the capability to do task T" to a statement that could be wrong, e.g. "task T involves the capability to compute the syntactic structure of a natural language sentence". Such a statement must make reference to theoretical constructs belonging to the analysis of cognitive capabilities.

Furthermore, we can rank the motivation given for a task by how explicit it is in delineating the set of capabilities it involves. For a given $c \in C_T$, is "c as required by T" fully *separable* from any other tasks involving c? Or is "c as required by T" perhaps all that there is to know about c, that is, is c *exhaustively* represented by T?

Finally, underlying the benchmarking methodology — where the benchmark is not just a measuring tool, but also a modelling target — there has to be the assumption that some sort of transferable knowledge is generated by modelling T, so that what the model (and not just the modeller!) has learned about (a sufficiently generally specified) c can be used in other tasks that involve c. (Let's call this *transferability*; which strictly speaking is a property of models, not of tasks.) More on this below.

To sum up, a benchmark task must point beyond itself and get its value from its connection to a particular facet of language, a particular capability of language users; this in turn seems to be difficult to specify without access to terms from theories of the domain, which allow us to name these capabilities.[8,9]

4 How are Language Benchmarks Used?

In the way that these tasks are set up, as single-step tasks that humans can quickly do ("describe this image", "is the elephant [in this image] sleeping?", "does sentence A follow from sentence B?"), it is tempting to see a similarity to tasks used in (human) intelligence testing (see e.g. Borsboom (2005) for an introduction). There is a crucial difference, however: Where intelligence testing works more in the way standard computing benchmarking works (subjecting the *otherwise functioning* learner to a standardised workload), in NLP, benchmarks are both the testing instrument as well as the training material.[10] The question then cannot be "to what extent does system Σ possess capability c", it has to be "to what extent can algorithm A learn c from dataset D?" — and what does that tell us?

4.1 Single-Task Models

Let's assume we have defined a task T that we are sufficiently convinced is well represented by

[6] To give some examples of informal versions of this argument, and choosing papers more or less randomly, here are some quotes:

From the paper that introduced the *visual question answering* task (Antol et al., 2015): "What makes for a compelling AI-complete task? [...] Open-ended questions require a potentially vast set of AI capabilities to answer – fine-grained recognition [...], object detection [...], activity recognition [...], knowledge based reasoning [...], and commonsense reasoning [...]."

Williams et al. (2018), on computing entailments: "The task of natural language inference (NLI) is well positioned to serve as a benchmark task for research on NLU. [...] In particular, a model must handle phenomena like lexical entailment, quantification, coreference, tense, belief, modality, and lexical and syntactic ambiguity."

[7] Such an attack challenges the claim of there being a *necessary* connection between handling T and possessing capability c. It might still very well be that humans can only perform this task if they possess capability c (and all the knowledge involved in it), because they wouldn't be able to pick up the statistical correlations that could be exploited.

[8] And one will indeed find that papers introducing such tasks make mention of terms like *syntax*, *semantics*, *compositionality*, *quantifiers*, etc.

[9] We can also note that with this focus on benchmarking normally comes a certain top-down approach, where the collected data is not investigated for how exactly the human participants went about solving their task. (But see (van Miltenburg, 2019) for a detailed study along those lines, for the task of image description.)

[10] For a recent paper also discussing the relation between AI benchmarking and intelligence testing, see (Chollet, 2019).

dataset D. We have trained a model M that performs well on this dataset. What have we learned? We have learned that a learning algorithm of the type of M can model D. Further, we have learned that the information to do task T (as exemplified in D), is contained in D, and M can pick it up.

Under what conditions can we now say that we have modelled T, rather than just D? If we have convinced ourselves that D represents T faithfully, then we might be willing to make this leap, and with it, claim that we have modelled C_T. We can get further support by collecting more data D' that also exemplifies T, but perhaps operationalises it differently. The prediction should be at least that the learning algorithm can also learn to model D'; but more significantly, we'd also want the model M learned from D to perform well on D'. Similarly, if we have another task T' of which we think that it involves similar capabilities, we should expect it to be amenable to being modelled with a learning algorithm of similar type to M.

What do we learn from a model M' (introducing architectural innovation κ over M) performing better on T (via D)? We can take this as indication that κ may be what is responsible for increasing performance, and hence what is leading to a more adequate model of C_T.

4.2 Multi-Task Models

With the advent of pre-training in NLP (Peters et al., 2018; Devlin et al., 2018), where a model is trained on (a typically large amount of) data under a specific task-regime (typically language modelling, i.e. the task of predicting the next word in a running text) and then becomes part of the model for a target task, it has become common to test on a collection of tasks (Wang et al., 2019b,a). What do we learn from such a setup? In our Figure 1, if we find a task on which we can pre-train a model M_P that becomes a part of models M and M', and which makes them more powerful than models that do not have access to the pre-trained model, then we can infer that whatever M_P models is a shared part of M and M' as well (and hence *involves* the hypothesised joint capability C'). This then provides an instrument to study the tasks: if the pre-trained model works well on some but not all, there must be something that those groups have in common. To make this intelligible, however, recourse to theoretical terms must again be taken. (E.g., assuming that these tasks involve the use of certain types of representation, or certain actions over representations.)

5 But Are We Making Progress?

Within the logic of this methodology, we are clearly making enormous progress at two links in the chain illustrated in Figure 1: For many of the established tasks, models have been and continue to be proposed that perform better, according to the metrics defined for the tasks. In addition, for many of the tasks, better datasets have been collected, avoiding exploitable biases. Where there is less activity is in systematically studying the implications of success at one task for success at others. The presentation above was largely idealised (or normative): In reality, there is very little explicitness about the assumed connection between tasks and capabilities, and no theory of how (or whether) language competence decomposes into capabilities that could be learned separately and then be assembled into a whole, and there is very little explicit knowledge about the vertical links in the Figure, from one task / model to the next.[11]

6 Conclusions

In this short paper, I have discussed the methodology of using *language tasks* to drive research on models of language competence. I have argued that the success of this approach hinges on how well progress on one task can be translated into progress on other tasks. While some steps have been taken in this direction, current work still appears to mostly focus on isolated tasks (or groups of tasks). Overcoming this, in my opinion, will require more explicit considerations about how tasks and capabilities are connected, and how the set of capabilities is structured—to ensure movement is not only uphill, but rather up the *right* hill (Bender and Koller, 2020), and it indeed is a single hill. For this, a (re-)connection with the fields that study the composition of language competence—linguistics and cognitive and developemental psychology—seems advisable (if only to disagree *explicitly*). As a positive proposal, I suggest that a focus should be put on assembling a *curriculum* of tasks, organised in a complexity and inclusion hierarchy, and that the benchmarking target should be the developmental trajectory on this. Working this out in detail I must leave for future work.

[11] In the neighbouring field of Computer Vision, there recently have been attempts to "disentangle task transfer learning" (Zamir et al., 2018).

X-FACT: A New Benchmark Dataset for Multilingual Fact Checking

Ashim Gupta, Vivek Srikumar
School of Computing,
University of Utah
{ashim,svivek}@cs.utah.edu

Abstract

In this work, we introduce X-FACT: the largest publicly available multilingual dataset for factual verification of naturally existing real-world claims. The dataset contains short statements in 25 languages and is labeled for veracity by expert fact-checkers. The dataset includes a multilingual evaluation benchmark that measures both out-of-domain generalization, and zero-shot capabilities of the multilingual models. Using state-of-the-art multilingual transformer-based models, we develop several automated fact-checking models that, along with textual claims, make use of additional metadata and evidence from news stories retrieved using a search engine. Empirically, our best model attains an F-score of around 40%, suggesting that our dataset is a challenging benchmark for evaluation of multilingual fact-checking models.

1 Introduction

Curbing the spread of fake news and misinformation on the web has become an important societal challenge. Several fact-checking initiatives, such as PolitiFact,[1] expend a significant amount of manual labor to investigate and determine the truthfulness of viral statements made by public figures, organizations, and social media users. Of course, since this process is time-consuming, often, a large number of falsified statements go unchecked.

With the aim of assisting fact-checkers, researchers in NLP have sought to develop computational approaches to fact-checking (Vlachos and Riedel, 2014; Wang, 2017; Pérez-Rosas et al., 2018). Many such works use the FEVER dataset, which contains claims extracted from Wikipedia documents (Thorne et al., 2018). Using real-world claims, Wang (2017) introduced LIAR, a dataset with 12,836 claims from PolitiFact. Recently, Augenstein et al. (2019) introduced MultiFC, an even larger corpus of 34,918 claims collected from 26 fact-checking websites.

Although misinformation transcends countries and languages (Bradshaw and Howard, 2019; Islam et al., 2020), much of the recent work focuses on claims and statements made in English. Developing Automated Fact Checking (AFC) systems in other languages is much more challenging, the primary reason being the absence of a manually annotated benchmark dataset for those languages. Moreover, there are fewer fact-checkers in these languages, and as a result, a non-English monolingual dataset will inevitably be small and less effective in developing fact-checking systems. As recent research points out, a possible solution in dealing with data scarcity is to train multilingual models (Aharoni et al., 2019; Wu and Dredze, 2019; Hu et al., 2020). Indeed, this finding motivates us to construct a large multilingual resource that the research community can use to further the development of fact-checking systems in languages other than English.

Recent efforts in the construction of a multilingual dataset are limited, both in scope and in size (Shahi and Nandini, 2020; Patwa et al., 2020). For instance, FakeCovid, a dataset introduced by Shahi and Nandini (2020) contains 3066 non-English claims about COVID-19. In comparison, X-FACT contains 31,189 general domain non-English claims from 25 languages. Moreover, FakeCovid contains only two labels, namely, *False*, and *Others*. We argue that this is undesirable, as fact checking is a fine-grained classification task. Due to subtle differences in language, most claims are neither entirely true nor entirely false (Rashkin et al., 2017). In contrast, our dataset contains seven labels—we make distinctions between *true*, *mostly true*, *half-true* etc. Table 1 shows two such

In summary, our contributions are:

1. We release a multilingual fact-checking benchmark X-FACT, which includes 31,189 short statements labeled for factual correctness and covers 25 typologically diverse languages across 11 language families. X-FACT is an order of magnitude larger than any other multilingual dataset available for fact checking.

2. Apart from the standard test set, we create two additional challenge sets to evaluate fact checking systems' generalization abilities across different domains and languages.

3. We report results for several modeling approaches and find that these models underperform on all three test sets in our benchmark, suggesting the need for more sophisticated and robust modeling methods.

The X-FACT dataset, and the code for our experiments, can be obtained at https://github.com/utahnlp/x-fact.

2 The X-FACT Dataset

X-FACT is constructed from several fact-checking sources. We briefly outline this process here.

Sources of Claims. We relied on a list of non-partisan fact-checkers compiled by International Fact-Checking Network (IFCN)[2], and Duke Reporter's Lab[3]. We removed all the websites that conduct fact-checks in English and are covered by previous work(Wang, 2017; Augenstein et al., 2019). As a starting point, we first queried Google's Fact Check Explorer (GFCE)[4] for all the fact-checks done by a particular website. Then we crawled the linked article on the website and additional metadata such as claimant, URL, date of the claim. For websites not linked through GFCE, we directly crawled all the available fact-checking articles from the fact-checker's website. We left out some fact-checkers because either the claims on their websites were not well specified or the fact-checker did not use any rating scale. We performed semi-automated text processing to remove duplicate claims and examples where the label appeared in the claim itself. This resulted in data from a total of 85 fact checkers for further processing. Refer to the appendix for more details on the this process.

Filtering the Dataset. There are two major challenges in using the crawled data directly: a) the labels are in different languages, and b) each fact checker uses a different rating scale for categorization. To deal with these issues, first, we manually translated all ratings to English, followed by semi-automatic merging of labels if they were found to be synonyms. Second, in consultation with Factly,[5] an IFCN signatory, we created a rating scale compatible with most fact-checkers. Our label set contains five labels with a decreasing level of truthfulness: *True*, *Mostly-True*, *Partly-True*, *Mostly-False*, and *False*. To encompass several other cases where assigning a label is difficult due to lack of evidence or subjective interpretations, we introduced *Unverifiable* as another label. A final label *Other* was used to denote cases that do not fall under the above-specified categories. Following the process described, we reviewed each fact-checker's rating system along with some examples and manually mapped these labels to our newly designed label scheme. See table 1 for examples. In our subsequent discussions, we refer to each fact-checking website as a *source*.

Data split	# claims	# languages
Train	19079	13
Development	2535	12
In-domain (α_1)	3826	12
Out-of-domain (α_2)	2368	4
Zero-Shot (α_3)	3381	12

Table 2: Dataset details. X-FACT contains three challenge sets, namely, In-domain Test (α_1), Out-of-domain Test (α_2), Zero-Shot Test (α_3).

We found that the data from several sources was dominated by a single label ($> 80\%$). Since it is difficult to train machine learning models on highly imbalanced datasets, we removed 54 such websites. We additionally removed fact-checking websites that contained fewer than 60 examples. In total, our dataset contains 31,189 fact-checks.

A Single Test Set is Not Sufficient. Recent advances in NLP have shown that multilingual models are effective for cross-lingual transfer (Kondratyuk and Straka, 2019; Wu and Dredze, 2019; Hu et al., 2020). A multilingual fact-checking system of similar transfer capabilities will certainly be an asset, especially in languages with no or few fact-checkers. From this perspective, we seek to provide a robust evaluation benchmark that can help us understand the generalization abilities of our fact-checking systems.

With this objective, we construct three test sets, namely α_1, α_2, and α_3.[6] The first test set (α_1) is distributionally similar to the training set. The α_1 set contains fact-checks from the same languages and sources as the training set.

Second, the *out-of-domain* test set (α_2), contains claims from the same languages as the training set but are from a different source. A model that performs well on both α_1 and α_2 can be presumed to generalize across different source distributions.

Third test set is the *zero-shot* set (α_3), which seeks to measure the cross-lingual transfer abilities of fact-checking systems. The α_3 set contains claims from languages not contained in the training set. Models that overfit language-specific artifacts will underperform on α_3.

Languages. For training and development, we choose the top twelve languages based on the number of labeled examples. The average number of examples per language is 1784, with Serbian being the smallest (835). We split the data into training (75%), development (10%), and α_1 test set (15%). This leaves us with 13 languages for our zero-shot test set (α_3). The remaining set of sources form our out-of-domain test set (α_2). See table 2 for the number of claims and langauges in each of these splits.

In total, X-FACT covers the following 25 languages (shown with their ISO 639-1 code for brevity): ar, az, bn, de, es, fa, fr, gu, hi, id, it, ka, mr, no, nl, pa, pl, pt, ro, ru, si, sr, sq, ta, tr. Please refer to the appendix for more details.

3 Experiments and Results

3.1 Experimental Setting

The goal of our experiments is to study how different modeling choices address the task of multilingual fact-checking. All our experiments use mBERT, the multilingual variant of BERT (Devlin et al., 2019) and use macro F1 score as the evaluation metric.[7] We report average F1 scores and standard deviations on four runs with different random seeds.

We implement the following multilingual models as baselines for future work:

1. **Claim Only Model (Claim-Only):** We provide textual claim as the only input to the model, in effect treating the problem as a simple sentence classification problem.

2. **Attention-based Evidence Aggregator (Attn-EA):** Typically, to determine the veracity of a claim, fact-checkers first gather relevant evidence by performing a web search and then aggregate this evidence to reach their final decision. We emulate this procedure by developing an attention-based evidence aggregation model that operates on evidence documents retrieved after performing web search with the claim using Google. For each claim, we obtain the top five results and use them as evidence. Using full text from web pages is not feasible, as the mBERT model has a restricted input sequence length of 512. Following previous work (Augenstein et al., 2019), we use snippets from search results as our evidence.

[6] The names for our test sets, and the idea of having multiple test sets without corresponding training sets, is inspired by Gupta et al. (2020).

[7] Although it is possible to develop partial scoring metrics, which we leave for future work to explore.

For a given claim and a collection of n evidence documents, we first encode the claim and evidences separately using mBERT by extracting the output of the `CLS` token, denoted as: $\mathbf{c}$, $[\mathbf{e_1}, \mathbf{e_2}, ..., \mathbf{e_n}]$. We first apply dot-product attention (Luong et al., 2015) to obtain the attention weights $[\alpha_1, \alpha_2, ..., \alpha_n]$, and then compute a linear combination using these attention coefficients: $\mathbf{e} = \sum_i \alpha_i \mathbf{e_i}$. This representation is then concatenated with $\mathbf{c}$ and fed to the classification layer. In all our experiments, we fix the number of evidence documents to five.

3. **Augmenting metadata (+Meta):** We concatenate additional key-value metadata with the claim text by representing it as a sequence of the form: `Key : Value` (Chen et al., 2019). This metadata includes the `language`, `website-name`, `claimant`, `claim-date`, and `review-date`. If a certain field is not available for a claim, we represent the value by `none`.

All the models are trained in a multilingual setting, i.e., a single model is trained for all languages. We could not use monolingual models as the trained monolingual models were unstable due to the small size of data for each language.

Model	α_1	α_2	α_3
Majority	6.9(–)	10.6(–)	7.6(–)
Claim-Only	38.2(0.9)	**16.2**(0.9)	14.7(0.6)
Claim-Only + Meta	39.4(0.9)	15.4(0.8)	**16.7**(1.1)
Attn-EA (Random)	37.5(0.8)	16.3(0.5)	14.9(1.2)
Attn-EA	38.9(0.2)	15.7(0.1)	16.5(0.7)
Attn-EA + Meta	**41.9**(1.2)	15.4(1.5)	16.0(0.3)

Table 3: Average F1 scores (and standard deviations) of the models studied in this work. Models in top rows are claim-only models while those in bottom are evidence-based. Attn-EA (Random) denotes the results of the evidence-based model when it is trained with random search snippets. (+ Meta) models denote those augmented with additional metadata.

3.2 Results

The results are shown in table 3. We will discuss results by answering a series of research questions. As an indicator of label distribution, we include a majority baseline with the most frequent label of the distribution (i.e. `false`).

Does the dataset exhibit claim-only bias? Before moving to more sophisticated systems, let us first examine if the model can predict a statement's veracity by only using the textual claim. Note that this setting is similar to that of hypothesis only models for the task of Natural Language Inference (NLI) (Poliak et al., 2018). From table 3, we see that a claim-only model outperforms a majority baseline by a large margin. We can draw two inferences: a) A significant number of examples in α_1 can be labeled by just relying on the textual claim, and b) the claim-only model has learned spurious correlations from the dataset.

Do search snippets improve fact-checking? First, results from table 3 show that augmenting models with metadata is helpful. Second, using search snippets as evidence with an attention-based model along with metadata improves performance by 2.5 percentage points on the in-domain test set (α_1). To further validate that snippets indeed help the evidence-based model, we perform another experiment in which we pair each claim with random search snippets of the same language. Since there is no relevant evidence, the performance is indeed similar to the claim-only model. This again confirms our finding that the dataset exhibits some claim-only bias.

While the Attn-EA model provides some performance improvement on the in-domain test set, surprisingly, the claim-only model outperforms the evidence-based model by a small margin on α_3. This might be due to the evidence-based over-fitting the in-domain data.

How informative are the search snippets? Note that we used snippets to summarize the retrieved search results. To gauge the relevance of these snippets, we manually examine 100 examples from α_1 test set for Hindi. Our preliminary analysis reveals that only 45% of snippets provide sufficient information to classify the claim, indicating why the performance increase with the evidence-based model is small. Our same analysis suggests that for 83% of the examples, using full text of the web pages provides sufficient evidence to determine veracity of the claim. Hypothetically, this means, were the models able to ingest large documents (web pages), their performance increase could have been much more significant.

Do the models generalize across sources and languages? We observe that performance on α_2

and α_3 is worse than on α_1, not only highlighting the difficulty of these challenge sets, but also showing that models overfit both source-specific patterns (α_2) and language-specific patterns (α_3).

Importantly, these results underscore the utility of our challenge sets in assessing model generalizability as well as diagnosing overfitting.

Model	α_1	α_2	α_3
X-FACT			
Claim-Only + Meta	39.4(0.9)	**15.4**(0.8)	**16.7**(1.1)
Attn-EA + Meta	**41.9**(1.2)	**15.4**(1.5)	16.0(0.3)
X-FACT + English			
Claim-Only + Meta	37.1(2.7)	14.5(0.5)	14.4(0.3)
Attn-EA + Meta	38.0(4.5)	14.7(2.6)	14.3(1.9)

Table 4: Performance comparison when augmenting the dataset with 12,311 English claims from PolitiFact. Average F1 scores (and standard deviations) of the models are reported over four random runs.

Can we improve performance by augmenting training data with English claims? Since X-FACT does not contain any examples from English, we answer this question by augmenting the training set with 12,311 claims from the PolitiFact subset of the MultiFC (Augenstein et al., 2019). Results are shown in table 4. Interestingly, we see that augmenting the models with English data hurts model performance. A possible cause is that the augmented data mostly contains political claims, while our dataset contains general claims.

4 Conclusion

We presented X-FACT, the currently largest multilingual dataset for fact-checking. Compared to the prior work, X-FACT is an order of magnitude larger, enabling the exploration of large transformer-based multilingual approaches to fact-checking. We presented results for several multilingual modeling methods and showed that the models find this new dataset challenging. We envision our dataset as an important benchmark in development and evaluation of multilingual approaches to fact-checking.

Acknowledgments

We would like to thank members of the Utah NLP group for their valuable insights, reviewers for their helpful feedback, and the team of Factly,[8] especially Mr. Shashi Kiran Deshetti, for discussions in developing a rating scale compatible with most fact-checkers. The authors acknowledge the support of NSF grants #1801446 (SATC) and #1822877 (Cyberlearning) and an award from Verisk Inc.

A Details on Dataset Construction

1. As mentioned in the paper, we omit several fact-checking websites from our data. A large number of these websites are not amenable to crawling and scraping the data. For instance, AFP[9] is a prominent fact-checker for many Indo-European Romance languages, but the template on its website does not lend itself to automatic data extraction tools. We can try to access this websites using GFCE, but case many times, the ratings assigned are sentences instead of a single label.

2. Another common reason is that on a number of these websites, the claim statements are not well-specified. Take for example Faktograf[10], a website performing fact-checking in Croatian. On this website , we can neither properly extract the claim statements nor do they clearly mention the rating assigned to the articles.

3. For a small percentage of the claim statements, Google search did not yield any results. We omitted all of these claims from our training, development, and test sets. These are only a very small percentage of claims, so we remove them from all models.

Because of these reasons, a large number of websites in a number of languages could not be crawled.

There are two ways we obtain our claims, labels, and other metadata. One is the Google's Fact Check Explorer (GFCE)[11], and the other is by crawling from the respective fact-checking website. In case, the links are available on GFCE, we download other metadata by visiting the website. Also, we will release the label mapping we created along with the dataset. Appendix A provides more details on the dataset we collected.

B Reproducibility

In this section, we provide details on our hyperparameter settings along with some comments on reproducibility.

X-FACT	Claim+Meta	1.5 hr
X-FACT	Attn-EA	2.3 hr
X-FACT	Attn-EA + Meta	2.3 hr
X-FACT + Eng	Claim+Meta	2.5 Hr
X-FACT + Eng	Attn-EA + Meta	4.1 Hr

Table 5: Average Training time of the models trained

B.1 Models and Code

As described in the main paper, we used multilingual BERT for performing our experiments. We implemented all our models in PyTorch using the transformers library (Wolf et al., 2019).

B.2 Computing Infrastructure Used

All of our experiments required access to GPU accelerators. We ran our experiments on three machines: Nvidia Tesla V100 (16 GB VRAM), Nvidia Tesla P100 (16 GB VRAM), Tesla A100 (40 GB VRAM). Our experiments for the claim-only model were run on V100, and P100 GPUs and evidence-based models required larger VRAM, so they were run on A100 GPUs.

B.3 Hyperparameters and Fine-tuning Details

1. We used the mBERT-*base* model for all of our experiments. This model has 12 layers each with hiddem size of 768 and number of attention heads equal to 12. Total number of parameters in this model is 125 million. We set all the hyper-parameters as suggested by Devlin et al. (2019), except the batch size which is fixed to 8.

2. All our models were run with four random seeds (seed $= [1, 2, 3, 4]$) and the numbers reported in paper are the means of these four runs. We fine-tuned all models for ten epochs and the model performing the best on development set across all epochs was chosen as the final model.

3. Due to constraints on the VRAM of the GPUs, we restricted the number of evidence documents to five.

Average Run times Average training times are presented in table 5.

nmT5 - Is parallel data still relevant for pre-training massively multilingual language models?

Mihir Kale* **Aditya Siddhant*** **Rami Al-Rfou**
Linting Xue **Noah Constant** **Melvin Johnson**
Google Research

Abstract

Recently, mT5 - a massively multilingual version of T5 - leveraged a unified text-to-text format to attain state-of-the-art results on a wide variety of multilingual NLP tasks. In this paper, we investigate the impact of incorporating parallel data into mT5 pre-training. We find that multi-tasking language modeling with objectives such as machine translation during pre-training is a straightforward way to improve performance on downstream multilingual and cross-lingual tasks. However, the gains start to diminish as the model capacity increases, suggesting that parallel data might not be as essential for larger models. At the same time, even at larger model sizes, we find that pre-training with parallel data still provides benefits in the limited labelled data regime.

1 Introduction

Recent works have shown that cross-lingual transfer learning in pre-trained multilingual models such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) could be improved further by using parallel data (Conneau and Lample, 2019; Hu et al., 2020a; Ouyang et al., 2020; Luo et al., 2020). In this paper, we continue this line of work by improving the recent mT5 model (Xue et al., 2020) by leveraging parallel corpora. We experiment with several text-to-text objectives that incorporate parallel data (spanning 198 language pairs) into mT5 pre-training. Our key findings are summarized below:

- In the regime of very small fine-tuning datasets, objectives with parallel data improve results significantly.
- The gain from using parallel data decreases as we scale up the size of the pre-trained model.
- Simple objectives based on neural machine translation (NMT) perform better than the traditionally employed "translation language modeling" (TLM) objective.

*Equal Contribution. Please direct correspondence to {mihirkale, adisid}@google.com

2 Method

We focus on the mT5-Large model, which is a 24 layer encoder-decoder transformer model and has shown strong performance on a variety of cross-lingual benchmarks (Xue et al., 2020). Instead of training a new model from scratch, we start from the publicly available mT5-Large checkpoint - which has been trained for over 1 trillion tokens - and do a second stage pre-training with a mix of monolingual and parallel data.

2.1 Objectives

The mT5 - multilingual version of T5 (Raffel et al., 2020) - series of models were pre-trained on a multilingual version of the C4 corpus with a masked language modeling "span-corruption" objective (Raffel et al., 2020), where the encoder is fed a chunk of text with random spans replaced with a mask token, and the decoder must reconstruct the masked-out tokens. One of their primary distinctions is the use of a unified "text-to-text" format for all text-based NLP problems.

In keeping with the text-to-text format, we experiment with the following objectives to incorporate parallel data into pre-training:

- **TLM** - A text-to-text version of translation language modeling, proposed by Conneau and Lample (2019) and subsequently used in several prior works for encoder only pre-training. We trivially extend it to the encoder-decoder setting.
- **NMT** - Standard machine translation. The input is the source text and the target is its

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 683–691

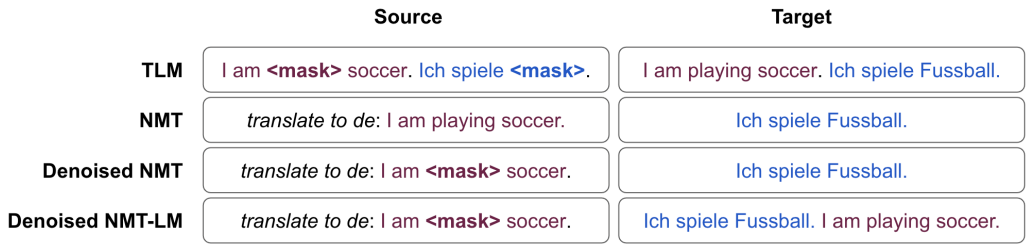

Figure 1: Example source and targets for different text-to-text style pre-training objectives incorporating parallel data. All objectives except TLM specify target language in the source sentence.

translation. A language code is prefixed to the input to inform the model of the target language (Johnson et al., 2017).

- **Denoised-NMT** - Similar to NMT, but we additionally mask spans in the source sentence. The model must now learn to implicitly perform language modeling of the source language while translating into the target language.
- **Denoised-NMT+LM** - Similar to Denoised-NMT, but instead of implicit language modeling, the model must explicitly predict the source text in addition to the translation. The target is a concatenation of the translation and source sentence, while the input is the masked source sentence.

We refer to the model trained with the standard NMT objective as nmT5.

3 Experiment Setup

Pre-training datasets For pre-training we use monolingual data from mC4 (Xue et al., 2020) and parallel data from OPUS-100 (Zhang et al., 2020). OPUS-100 is a dataset of 55M translations covering 100 languages (198 language pairs, either into or from English). The mC4 corpus consists of unlabeled web text covering 101 languages, of which 81 overlap with the OPUS-100 languages.

Fine-tuning datasets For downstream evaluation, we use the following four tasks:

- **TyDi QA** (Clark et al., 2020) - The GoldP subtask, which corresponds to extractive question answering. The input is a passage and a question, with the answer being a span from the passage.
- **MTOP** (Li et al., 2020) - Multilingual Task-Oriented Parsing. The task is one of structured prediction, where user queries must be parsed into a tree, capturing the domain, intent and slots.
- **WikiAnn NER** (Pan et al., 2019) - Named entity recognition task covering 40 languages featured in the XTREME benchmark (Hu et al., 2020b). There are 4 categories of entities - location, person, organization and miscellaneous.
- **WikiLingua** (Ladhak et al., 2020) - A recently introduced *cross-lingual* summarization dataset, where a document from an arbitrary language must be summarized in English. Since the dataset does not come with training and evaluation splits, we randomly create validation and test sets of 1000 examples each, and the rest of the data is used for training.

Dataset	Langs	Train size	Setting
TyDi QA	9	3.7K	zero-shot
MTOP	6	22K	zero-shot
WikiAnn NER	40	20K	zero-shot
WikiLingua	18	660K	multilingual

Table 1: Statistics of datasets used in the paper.

Table 1 lists further details of each dataset. Following Xue et al. (2020), all tasks are cast into the text-to-text format. The evaluation for TyDi QA, MTOP and NER is done in the zero-shot setting, where the model is trained on the English data and evaluated on all languages. Since zero-shot cross-lingual language generation is much harder, for WikiLingua we train the model in a multilingual setting, using available training data for all languages.

Hyperparameters Pre-training is done with a batch size of 1M tokens and fine-tuning with 131,072 tokens, with a constant learning rate of

Model (Metric)	TyDi QA (F1/EM)	MTOP (EM)	NER (F1)	WikiLingua (ROUGE-L)	Avg.
mT5	66.3 / 49.8	43.7	58.4	25.2	46.3
+MLM (additional 100K steps)	71.3 / 55.6	48.6	59.9	26.1	49.5
+MLM+TLM	71.1 / 54.6	48.6	61.4	26.1	49.7
+MLM+NMT	75.1 / 60.1	57.7	61.4	27.4	53.5
+MLM+denoised NMT	75.3 / 60.2	56.5	61.5	27.4	53.3
+MLM+denoised NMT-LM	75.0 / 59.4	56.0	62.4	26.9	53.1

Table 2: Results are averaged across all the languages in each dataset. We report F1/EM for QA, exact match accuracy (EM) for structured prediction, ROUGE-L (Lin, 2004) for summarization and F1 for NER. Each score is the median over five runs. The final columns lists the average of all the scores. Refer to Appendix A for scores on individual languages.

0.001. Starting from publicly available mT5-Large checkpoints, we further pre-train for 100K steps with a mix of monolingual and parallel objectives. The parallel data is mixed into monolingual data at a 10% ratio, which amounts to roughly 4 passes over the OPUS-100 corpus. Examples from each language pair are sampled using the same language sampling distribution as Xue et al. (2020), with alpha=0.3. For downstream tasks, we fine-tune for 10K steps for TyDiQA, MTOP, NER and 25K for WikiLingua, since it is a much larger dataset. Checkpoint selection is done based on the validation set.

Baselines Our first baseline is the publicly available mT5-Large model (1.3 billion parameters). For a fair comparison, we also experiment with an mT5 model further pre-trained for 100k steps with *only* monolingual data from mC4 (see row 2: mT5+MLM in Table 2). This lets us assess whether improvements stem from using parallel data or just pre-training for longer.

4 Results

We report results in table 2. Overall, adding parallel data through neural machine translation objectives improves scores for all 4 tasks, with the NMT objective performing the best.

Simply pre-training mT5 for longer with just monolingual data (MLM) leads to improved scores for all tasks. The TLM objective is not be able to effectively leverage the parallel data and performs on par with MLM. On the other hand, our three NMT-based objectives show gains over MLM across all tasks. Among these, NMT and Denoised-NMT are the best and perform similarly, while Denoised-NMT+LM fares slightly worse. Averaged across all tasks, NMT and Denoised-NMT outperform MLM by 4 points.

4.1 Model size

Xue et al. (2020) find that cross-lingual performance of language models increases monotonically with model size. To study the impact of model capacity, we also experiment with larger model sizes. Even at the XL size (3.7B params, 3× larger than mT5-Large), we observe gains for all tasks with nmT5 (Table 3). However, the magnitude of the gains is largely diminished, hinting that the need for parallel data reduces as model capacity increases. This finding is particularly promising for low-resource languages, where it is difficult to obtain high-quality parallel data.

At the same time, nmT5-Large substantially reduces the performance gap between mT5-Large and mT5-XL, covering 70% of the headroom. Since bigger models are expensive to train and even more expensive to deploy, this opens up avenues for effectively using parallel data to improve performance of smaller language models. Turc et al. (2019) found that pre-training student models before model distillation is helpful, and using parallel data to improve student pre-training is another interesting avenue of future work.

Model	TyDi QA	MTOP	NER	WikiLingua	Avg.
mT5-Large	66.3 / 49.8	43.7	58.4	25.2	46.3
nmT5-Large	75.1 / 60.1	57.7	61.4	27.4	53.5
Δ	8.8 / 10.3	14.0	3.0	2.2	7.2
mT5-XL	77.8 / 61.8	63.4	65.5	27.9	56.7
nmT5-XL	78.4 / 63.3	64.9	66.2	28.4	57.6
Δ	0.6 / 1.5	1.5	0.7	0.5	0.9

Table 3: Impact of model size on nmT5's performance.

Model	Few-Shot (100)	Low (3.7K)	High (80K)
mT5-Large	33.1 / 23.6	66.3 / 49.8	78.1 / 64.8
nmT5-Large	48.8 / 37.1	75.1 / 60.1	78.2 / 65.5
Δ	15.7 / 13.5	8.8 / 10.3	0.1 / 0.7
mT5-XL	45.0 / 31.7	77.8 / 61.8	78.7 / 65.8
nmT5-XL	57.2 / 44.4	78.4 / 63.3	79.7 / 67.0
Δ	12.2 / 12.7	0.6 / 1.5	1.0 / 1.2

Table 4: Performance on the TyDi QA eval set when fine-tuned in the *few-shot* (100 examples from TyDi QA English), *low* (full TyDi QA English with 3.7K examples) and *high* data regime (SQuAD English with 80K examples).

4.2 Limited labeled data

The TyDi QA dataset has only 3.7K English training examples. To study the impact of the size of fine-tuning data, we run experiments in two additional settings: a *few-shot* regime and a *high data* regime. Few-shot uses just 100 randomly sampled training examples, while for the latter we use the much larger SQuAD corpus (Rajpurkar et al., 2016), which consists of 80k examples.

When fine-tuned with SQuAD, nmT5 performs slightly better than mT5 for both Large and XL model sizes. However, in the few-shot setting, nmT5-Large improves over mT5-Large by 15 points. Even at the XL size, nmT5 is over 10 points higher than mT5. nmT5-Large even outperforms the much larger mT5-XL. Our experiments suggest that pre-training with parallel data is particularly useful in the limited labelled data setting.

4.3 Mixing ratio

So far, we have mixed parallel data into monolingual data at a 10% ratio. To assess how the mixing ratio impacts performance, we compare results with a 50% mix. With the 50% mix, average performance is slightly lower, validating our initial choice.

Mix	TyDi QA	MTOP	NER	WikiLingua	Avg.
10%	75.1 / 60.1	57.7	61.4	27.4	53.5
50%	76.5 / 60.1	53.9	62.0	26.5	52.7

Table 5: Impact of mixing ratio on nmT5.

4.4 Performance on unseen languages

We also test downstream performance on languages previously unseen by the models. We randomly pick 30 languages from the WikiAnn NER dataset that are not covered in either mC4 [1] or OPUS, and hence none of our models have seen them during pre-training. Table 6 shows nmT5 outperforms mT5 on this subset of languages as well, indicating that the representations of the nmT5 model are better suited for cross-lingual transfer.

Model	ckb	hsb	xmf	"Avg."
mT5-Large	66.5	64.8	58.4	54.9
nmT5-Large	72.2	69.8	62.2	57.4
Δ	5.7	5.0	3.8	2.5

Table 6: Performance on three randomly picked unseen languages. "Avg." is calculated by averaging performance across 30 unseen languages.

5 Related Work

Pre-trained multilingual models such as mBERT and XLM-R have shown to be effective at cross-lingual transfer learning (Devlin et al., 2019; Conneau et al., 2020). Subsequently, many attempts have leveraged parallel data to improve cross-lingual capability of these models. Conneau and Lample (2019) proposed translation language modeling (TLM), to encourage the model to align representations across languages. Alternating language modeling (Yang et al., 2020) and back-translation masked language modeling (Ouyang et al., 2020) used code-switched sentences and back-translation respectively to utilize parallel data. Other works using parallel data in this line of work include FILTER (Fang et al., 2020), AMBER (Hu et al., 2020a) and, MMTE (Siddhant et al., 2020). A key factor that differentiates this paper from these works is that our pre-trained models use a text-to-text architecture, having both an encoder and a decoder, while the aforementioned models only have the encoder. Other pretrained multilingual encoder-decoder models such as mT5 (Xue et al., 2020), mBART (Liu et al., 2020) and MASS (Song et al., 2019) do not make use of parallel data during pre-training.

6 Conclusion

In this work we attempted to improve mT5 pre-training by incorporating parallel data. We experimented with various text-to-text objectives and found that multi-tasking with the standard neural machine translation objective during pre-training

[1] Subject to precision of language ID models used for mC4.

leads to improved cross-lingual transfer. The improvements from parallel data are most pronounced in the limited labeled data scenario. Our experiments also indicate that smaller models, with the help of parallel data, can approach the performance of larger ones, while also suggesting that the need for parallel data is lesser as the model capacity increases.

Question Generation for Adaptive Education

Megha Srivastava

ngoodman@stanford.edu

Abstract

Intelligent and adaptive online education systems aim to make high-quality education available for a diverse range of students. However, existing systems usually depend on a pool of hand-made questions, limiting how fine-grained and open-ended they can be in adapting to individual students. We explore targeted question generation as a controllable sequence generation task. We first show how to fine-tune pre-trained language models for deep knowledge tracing (LM-KT). This model accurately predicts the probability of a student answering a question correctly, and generalizes to questions not seen in training. We then use LM-KT to specify the objective and data for training a model to generate questions conditioned on the student and target difficulty. Our results show we succeed at generating novel, well-calibrated language translation questions for second language learners from a real online education platform.

1 Introduction

Online education platforms can increase the accessibility of educational resources around the world. However, achieving equitable outcomes across diverse learning needs benefits from systems that are adaptive and individualized to each student (Doroudi and Brunskill, 2019). Traditionally, adaptive education methods involve planning over a pool of pre-made questions (Atkinson, 1972; Hunziker et al., 2018). These are naturally limited by the diversity and coverage of the pool, as well as the scaling capacity of curriculum planning algorithms. Recent approaches, such as procedural generation for personalized programming games (Valls-Vargas et al., 2017), are limited to well-specified small domains. We address these limitations by leveraging recent success in deep generative models, in particular language models (LMs).

Many educational activities involve sequential data, such as language translation, reading comprehension, algebra, and deductive logic. Meanwhile, pre-trained LMs can effectively handle sequences from a wide range of modalities (Madani et al., 2020; Polu and Sutskever, 2020). In this work, we focus on natural language sequences, where recent progress in language modeling has shown great success at capturing abstract properties of language (Hewitt and Manning, 2019; Liu et al., 2019). Specifically, we show how pre-trained LMs can be easily leveraged to adaptively generate questions for a given student and target difficulty in a *reverse translation task*, using difficulty at answering questions as a proxy for more complex future learning objectives.

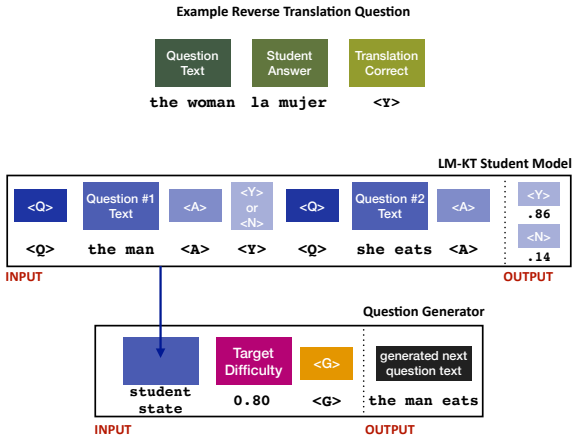

Figure 1: Example input and outputs for our LM-based knowledge tracing model (middle) and question generation model (bottom) for an online reverse language translation task (top). A question in this task consists of a target phrase for the student, in this case a Spanish learner, to translate (e.g. "the woman").

We introduce an LM-based knowledge tracing model (LM-KT) to predict students' difficulty on novel questions (e.g. target phrases to translate). We show that LM-KT is well-calibrated, allowing us to pose the learning problem for the question generator: given a student state, generate a question that will achieve a target difficulty, according

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 692–701
August 1–6, 2021. ©2021 Association for Computational Linguistics

to LM-KT. We evaluate both LM-KT and question generation models on real users and responses from Duolingo[1], a popular online second-language learning platform.

2 Background & Related Works

There exists a rich body of work on precisely modeling student "ability" and learning. For example, Item Response Theory (IRT) seeks to model individual student ability based on their responses to different questions, creating a strong factorization between students and test items (Lord, 1980; Hambelton and Jodoin, 2003). Meanwhile, Computer Adaptive Testing (CAT) techniques are used to determine a fixed student ability as quickly as possible by selecting test items based on information utility (Weiss and Kingsbury, 1984; Thissen and Mislevy, 2000; Settles et al., 2020). However, these methods, which have been used to develop efficient standardized tests, do not necessarily optimize a student's *learning* experience (Mu et al., 2018). We instead focus on tracking each student's evolving knowledge, choosing questions to target difficulty.

Knowledge Tracing (KT) seeks to model a student's knowledge state from their answer history in order to help individualize exercise sequences (Corbett and Anderson, 1995). This draws inspiration from traditional education curriculum practices, such as distributed spacing of vocabulary (Bloom and Shuell, 1981) and mixed review in mathematics (Rohrer, 2009). To address simplifying assumptions in earlier KT approaches, such as discrete knowledge representations, Piech et al. (2015) introduced Deep Knowledge Tracing (DKT), which uses RNNs to enable more complex knowledge representations for students. Recently, SAINT+ (Shin et al., 2020) showed state-of-the-art performance on the popular EdNet KT task using a Transformer model to capture temporal information across activities, motivating our use of Transformer LMs.

Controllable Text Generation aims to steer LMs towards desired attributes. Examples include using reinforcement learning to control quality metrics (Ranzato et al., 2016), adjusting sampling weights to control for poetry style (Ghazvininejad et al., 2017), and learning to condition on valence or domain-specific codes (Keskar et al., 2019; Peng et al., 2018). To the best of our knowledge, we are the first to use controllable generation in an education context with real student interaction data.

3 Method

Given any autoregressive language model (e.g. GPT-2 (Radford et al., 2019), we can fine-tune a **LM-KT model** ($p_{\theta_{KT}}$) to predict whether an individual student will correctly answer the next question. If this model has well-calibrated uncertainty, we can use its predicted probability of a correct answer as a proxy for the difficulty of a question to a student. We then train a **question generation model** ($p_{\theta_{QG}}$) to generate a new question conditioned on a student and desired target difficulty.

Question Representation Unlike standard DKT, which treats questions as IDs or simple handcrafted features, we represent questions fully in text (e.g. "she eats" in Figure 1). This is a key contribution of our work, required by our eventual goal of *generating* questions in text, and allows the model to leverage similarity across linguistic features. We thus represent a question q as a sequence of words, with prefix and suffix tokens:

$$q_i = \texttt{<Q>}\ w_1^i\ w_2^i\ w_3^i\ \ldots\ w_n^i\ \texttt{<A>}$$

Student State We represent a student as a temporally-evolving sequence of questions and their responses. As in much previous KT work, we represent the student response as simply correct/incorrect, with special tokens <Y> and <N>. A student's current state is thus represented as a sequence of all past question and response pairs:

$$s_j = q_1^j\ a_1^j\ q_2^j\ a_2^j\ \ldots\ q_m^j\ a_m^j\ , a_i \in \{\texttt{<Y>},\texttt{<N>}\}$$

LM-KT Given the sequential nature of student learning over time, we can easily frame knowledge tracing as an autoregressive language modeling task. Given a dataset D of students s_1, s_2, ..., $s_{|D|}$, we employ the standard training objective of finding the parameters θ_{KT} that minimizes

$$\mathscr{L}_{KT} = -\sum_{i=1}^{|D|}\sum_{t=1}^{|\mathbf{x}^{(i)}|} \log p_{\theta_{KT}}(x_t^{(i)}|x_{<t}^{(i)}) \quad (1)$$

where $\mathbf{x}^{(j)} = (x_1^{(j)}, ..., x_{|\mathbf{x}|}^{(j)})$ is the entire sequence tokens corresponding to student s_j, consisting of all their past questions and answers. Using the softmax output of the LM-KT model ($p_{\theta_{KT}}$), we estimate a student's (inverse) difficulty in answering a specific question as $d_{qs} = p_{\theta_{KT}}(\texttt{<Y>}|s, q)$. We find that $p_{\theta_{KT}}$ is well-calibrated (Section 4.2), yielding a good proxy for the true question difficulty.

Question Generation We frame question generation as finetuning a *new* autoregressive LM. Given random samples of students and questions from a held-out set not used to train LM-KT, we can construct a new dataset D' consisting of s_i d_i<G> q_i sequences, where <G> is a special generation token and $d_i = p_{\theta_{KT}}(\texttt{<Y>}|s_i, q_i)$ is the continuous difficulty value assigned by LM-KT. We learn a linear layer to map the continuous input difficulty into a *difficulty control vector* c_d of dimension matching the LM word-embeddings, which we append to the token embeddings. Unlike LM-KT, we train our question generation model $p_{\theta_{QG}}$ to minimize the loss only on the question text, which only appears *after* the<G> token. If t_g is the token index of <G>, then our modified loss is:

$$\mathscr{L}_{QG} = -\sum_{i=1}^{|D'|}\sum_{t=t_g+1}^{|\mathbf{x}^{(i)}|} \log p_{\theta_{QG}}(x_t^{(i)}|x_{<t}^{(i)}) \quad (2)$$

where sequence $\mathbf{x}^{(j)}$ contains the full s_j d_j<G>q_j sequence. At test time, we generate tokens $w_1 ... w_n$ conditioned on the s_j d_j <G> prefix.

4 Experiments

Our method generalizes to any education activity that can be represented with text sequences. Due to the availability of real student learning data, we focus on a *reverse language translation* task, where a student translates phrases from their native language (e.g. English, "she eats") to the second language they are learning (e.g. Spanish, "ella come").

4.1 Experimental Details

We use the 2018 Duolingo Shared Task on Second Language Acquisition Modeling (Settles et al., 2018) dataset, which contains questions and responses for Duolingo users over the first 30 days of learning a second language. While the original task's goal was to identify *token*-level mistakes, we collapse these errors into binary (correct / incorrect) per-question labels. We use the provided train/dev/test splits for users learning Spanish and French. We create separate held-out sets from the test set to evaluate the LM-KT and question generation models. For both models, we finetune separate GPT-2 (Radford et al., 2019) models. While we sample from a held-out set of student states and questions to train the question generation model, in principle questions can come from any source text domain. Further experiment details are in the Appendix, and source code can be found at: https://github.com/meghabyte/acl2021-education.

Model *(Spanish)*	**AUC (seen)**	**AUC (unseen)**
LM-KT	**0.75 ±.0001**	**0.76 ±.001**
Standard DKT	0.72 ±.0001	0.70 ±.001
Question Only	0.67 ±.0001	0.58 ±.002
Model *(French)*	**AUC (seen)**	**AUC (unseen)**
LM-KT	**0.73 ±.0002**	**0.71 ±.002**
Standard DKT	0.70 ±.0001	0.65 ±.002
Question Only	0.65 ±.0002	0.62 ±.001

Table 1: LM-KT improves AUC for both questions in the Duolingo test set that were seen during training (for other students) *and* novel questions, over Standard DKT with Question IDs and question-only baselines. Errors are 95% CIs.

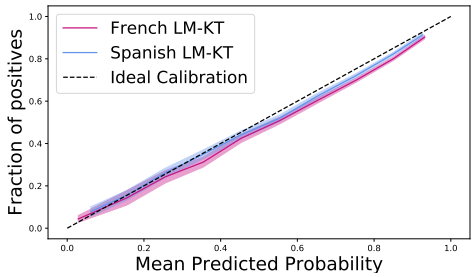

Figure 2: Both LM-KT models are well calibrated, but the French model is slightly more overconfident. Filled area shows bootstrap (n=1000) standard deviation.

4.2 Results: Student Modeling

We evaluate LM-KT two ways: first, its ability to predict if an individual student will answer a novel question correctly on a held-out test set of real Duolingo student responses. Second, how well-calibrated these predictions are, which is crucial to our later use of LM-KT for question generation.

Table 1 compares AUC-ROC on a held-out test set for our LM-KT model with standard DKT, which uses question IDs instead of text, and a baseline that ignores the student state, only using the question text representation. This question only baseline would perform well if the Duolingo dataset largely consisted of universally "easy" and "difficult" questions, independent of individual student. Our results show that incorporating the student state is crucial for accurately predicting Duolingo user responses, and including question text also leads to a significant improvement. LM-KT outperforms Standard DKT especially on novel questions—a necessary generalization ability for generation.

Finally, we measure the calibration of our LM-KT models for both Spanish and French (from En-

glish) learners, which is the crucial property for our downstream generation task. We bin our test data by predicted question difficulty, and plot the fraction of true correct answers in each bin. Figure 2 shows that LM-KT is well-calibrated, for both Spanish and French, meaning the predicted difficulty matches the empirically observed proportion of correct answers.

4.3 Results: Question Generation

We evaluate four different aspects of our question generation model: (i) successful control for difficulty, (ii) novelty, (iii) fluency, and (iv) latency.

Difficulty Control To explore whether our question generation model indeed depends on target difficulty and the individual student, we first measure the model's perplexity on a held-out test set of Duolingo questions, compared to permutation baselines. Table 2 (top) shows that perplexity is lower for true student / target difficulty inputs than when either or both of these are permuted. The target difficulty values in this analysis were defined by the LM-DKT model. We can remove this dependence by using the actual student responses from Duolingo: we set the target difficulty to 1 if the student was correct and 0 otherwise. Table 2 (bottom) shows our model prefers questions paired with these "true correctness" targets than paired with random ones.

To evaluate how well our generation model achieves target difficulties, we take 15 unseen students and generate 30 questions for each of 9 input difficulties (0.1-0.9). We then use LM-KT (a well-calibrated proxy for true difficulty) to measure the difficulty of these generated questions for each student. Figure 3 shows that we are able to achieve fine-grained control over target difficulty for both Spanish and French students, with an average Root-Mean Squared Error (RMSE) of **.052** across all students and target difficulties. Adding a sampling penalty (Keskar et al., 2019) increases the variance in difficulty (RMSE .062) in exchange for more novel and diverse questions, as discussed next.

Novelty and Fluency By leveraging a pre-trained language model's ability to manipulate structure, we can generate novel questions not present in the entire Duolingo question set (See Table 3). Across 4,050 questions generated for Spanish learners, we found that with a repetition penalty (Keskar et al., 2019), around 43% of all questions, and 66% of high difficulty ($d = 0.1$) questions, were novel [2]. For French learners, 48% of all and 55% of high difficulty ($d = 0.1$) questions were novel. However, around 3% of generated sentences were judged to be non-fluent [3], although most were still able to be translated (e.g."if i eat some baguettes it breaks."). Without a sampling penalty, the proportion of novel questions drops to about 11 % of questions for French learners (6 % for Spanish learners), yet with far fewer non-fluent examples. Further details and examples of novel and non-fluent generated questions for both Spanish and French learners, are in the Appendix.

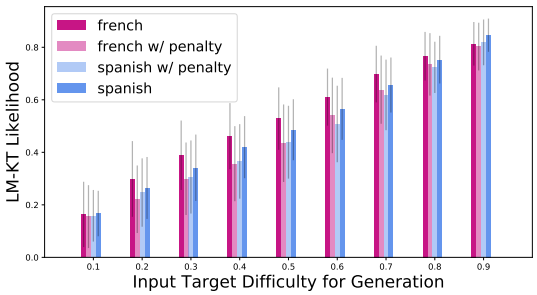

Figure 3: For a random selection of 15 students, our question generator successfully controls for difficulty across a range of 9 target values, evaluated by the LM-KT model. Error bars show standard deviation.

Ablation Type	ppl Spanish	ppl French
LM-DKT Likelihood (0 - 1)		
Ground Truth	**4.33 ±0.20**	**3.86 ±0.09**
Permute Student	6.73 ±0.24	5.11 ±0.41
Permute Difficulty	12.5 ±1.01	7.66 ±0.33
Permute Both	13.1 ±0.43	7.87 ±0.26
Real Student Answers (0 or 1)		
Ground Truth	**17.7 ±1.3**	**9.49 ±.20**
Permute Student	19.75 ±0.43	10.56 ±.60
Permute Difficulty	30.6 ±2.17	13.5 ±0.60
Permute Both	31.3 ±1.49	13.8 ±0.43

Table 2: Perplexity of the question generation model over a held-out evaluation set with ablations.

Latency Positive student experience in online education requires low latency. In about four seconds, our model can generate 30 questions close to a target difficulty. An alternative to question generation is to rank questions from a preexisting pool, according to a target difficulty objective. We compare the quality (RMSE in achieving target difficulty) of the top 30 questions in a pool against the run-time

[2]The CTRL penalty discounts the scores of previously generated tokens, with the HuggingFace Transformers library (Wolf et al., 2020) implementation including tokens provided as part of the prompt. In our setting, this effectively penalizes for generating questions already seen by the student.

[3]We use the language-check Python tool to verify grammar https://pypi.org/project/language-check/.

Difficulty: 0.1 (very hard)	**0.9 (very easy)**
you write letters.	*spoon or tea*
i know about that book.	socks
she reads your letters.	good morning!
those ducks drink water.	a horse
he mixes coffee with water.	*oil against salt*
Difficulty: 0.3 (hard)	**0.7 (easy)**
you drink juice or water	*what dream?*
you drink water	saturday and sunday
accordingly he does it	until tomorrow
can we as a band?	*yes, it is possible!*
during the night	me too

Table 3: Example questions generated by our model for a Spanish learner. *Italic questions* are novel, and do not exist in the Duolingo dataset.

required to rank all questions in the pool, varying its size (Figure 4). On one NVIDIA Titan XP GPU, we find that, averaged across all target difficulties, our question generation model takes half the time to achieve the same quality as pool selection. The gap increases when trying to sample harder questions (d <0.5) – even a pool size of 1000 does not have sufficient difficult questions, likely due to a skew in the Duolingo question set. Additional controls, such as for style or topic, can easily be combined with our generation method, but would make pool selection exponentially more complex.

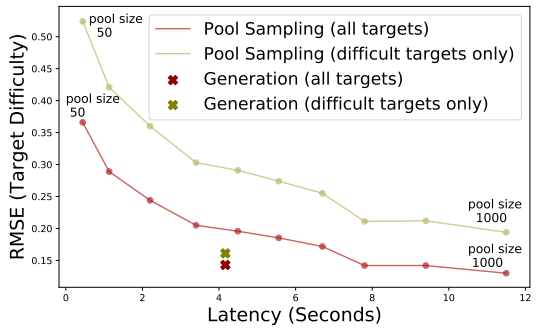

Figure 4: Pool selection (for one student) suffers worse question quality vs. latency trade-off than question generation, especially for sampling difficult questions.

5 Conclusion

Our work is a first step toward showing that sequence-based models combined with domain knowledge, such as pre-trained LMs, can be leveraged for adaptive learning tasks. We show how to use modern LMs to generate novel reverse-translation questions that achieve a target difficulty, allowing adaptive education methods to expand beyond limited question pools.

Limitations of our approach include the compute constraints of large LMs and training data availability. More detailed student data will be crucial to future model development. For instance, while most publicly available education datasets do not include the full student responses (e.g. full translation response in Duolingo), such information could significantly improve the performance of our LM-KT model. Other future directions include exploring non-language domains, such as math or logic exercises, and controlling for auxiliary objectives such as question topic.

Finally, designing appropriate user studies to evaluate our method is a complex yet critical next step to determine its suitability in a real-world education setting. Our techniques allows control for individual student difficulty, but it leaves open the question of optimal curriculum design using difficulty-directed question generation.

6 Broader Impact

Online education platforms can increase the accessibility of high quality educational resources for students around the world. Adaptive techniques that allow for more individualized learning strategies can help such technologies be more inclusive for students who make less-common mistakes or have different prior backgrounds (Lee and Brunskill, 2012). However, our method is subject to biases found in the training data, and careful consideration of using safe and appropriate data is crucial in an education context. Moreover, our specific use of pre-trained LMs relies on the significant progress of NLP tools for English language – further research and development of these tools for other languages can help ensure our method benefits a larger population of students.

A APPENDIX

A.1 Dataset Details

The 2018 Duolingo Shared Task on Second Language Acquisition Modeling (Settles et al., 2018) dataset contains questions and responses for Duolingo users over the first 30 days of learning a second language. The dataset contains three different question types: reverse translate (free response translation of a given prompt in the language they are learning), reverse tap (a selection-based equivalent of reverse translate), and listen, where students listen to a vocal utterance. We focus on the reverse translate question type for English-speaking students learning French and Spanish. The dataset size for French learners (1.2k users) is roughly half the size of that for Spanish learners (2.6k users).

Because the original dataset was intended for per-token error prediction, each question has per-token information that includes whether the student translated the token correctly, as well as Universal Dependencies tags such as part of speech and morphology labels. We use the full question text, rather than individual tokens, for our task, and combine the labels such that if a Duolingo user incorrectly translated one or more tokens in a question, the entire question is marked incorrect. We do not use any additional features.

We use the publicly provided train/dev/test splits from the Shared Task, which are temporally ordered in sequence. We therefore construct student states by tracking user IDs throughout the datasets and appending each new question and response to the current student state. When evaluating our LM-KT model, we use the true responses of preceding questions in the test set to form the student state for a given question. Overall, we find that the dataset is severely imbalanced (as in the original task) - about 30% of questions are answered incorrectly across students studying both French and Spanish.

Finally, we create a held-out set of Duolingo questions for both French and Spanish learners to create the training data for our question generation model. From a set of random student states, we select questions from this set and use a trained LM-KT model to assign the difficulty score. In practice, this held-out set can come from any source, not just Duolingo data.

A.2 Model Training Details

To train both our LM-KT knowledge tracing model and our question generation model, we use the pre-trained OpenAI GPT-2 model from the HuggingFace Transformers library (Wolf et al., 2020). For question generation, we modify the library to add a linear layer and the modified loss function for question generation from Section 3.

We use 1 NVIDIA TitanXP GPU with 12GB of memory available. Because the maximum input sequence length of the GPT-2 model we use is 1024 tokens, we resize all inputs to the last 1024 tokens before training. We report results for an LM-KT model trained for 13k steps with the default batch size of 2 and learning rate of 5e-5, and a Question Generation model trained for 25k steps with the same batch size and learning rate. The total compute time to train both models was 2.5 hours for each language learning task.

A.3 Question Generation Details

For both French and Spanish question generation models, we select 15 students unseen during training and generate 30 questions across 9 difficulties from 0.1 to 0.9, using nucleus sampling (Holtzman et al., 2020) ($p = 0.99$) with a maximum output length of 20 tokens. We also vary a repetition penalty (Keskar et al., 2019) that penalizes for previous tokens (including those in the student state). Lastly, we resize all prompts (student state and target difficulty) to fit into the GPT-2 Model by taking the most recent 1024 tokens, as in training. This is a limitation of our work, as the full student history is not able to be considered for students who have answered a large set of questions.

A.4 Additional Question Generation Outputs

Our question generation model demonstrates the ability to generate novel questions that do not exist in the entire Duolingo question dataset, especially when a sampling penalty is applied to encourage more diverse outputs. However, this comes at a cost to fluency. Below we include a set of outputs generated by our model for 1 Spanish student and 1 French student from the Duolingo dataset, with a target difficulty of $d = 0.1$, and both with and without a repetition penalty. We observe that while applying a penalty results in a far more novel questions generated, several of these are also non-fluent, using a combination of manual judgement and the Python language-check package (https://pypi.org/project/language-check/).

Table 4: Random selection of generated questions for one Spanish learner with for a a target difficulty of $d = 0.1$. *Italic questions* are novel, **bold questions** are judged to be non-fluent.

Spanish (w/ Penalty)	**Spanish (No Penalty)**
accordingly he does it.	*he mixes coffee with milk.*
clean your room or close!	*the cuts are not big.*
clean your room!	*the gallery is enormous.*
he mixes coffee with water.	*the horses are not natural.*
how many elephants eat cheese or fish?	*the men drink a beer.*
i know about that book.	***they probably do not think me.***
october finds him maximum distance from here today!	*we can desk a book.*
please clean your room!	from september to december
please open your bottle or newspaper?	according to you, it is yellow.
she blames us!	clean the mirror.
she reads us lunchtime newspapers.	i do not know it.
she reads your letters.	i read the newspaper.
those ducks drink water.	i want a sandwich without cheese.
we can abandon him.	june starts tomorrow.
what book have they Chosen me so far?	she reads the calendar.
you can control her water.	the plates are not big.
you can establish two properties.	we are following the clue.

Abstract

This paper presents a simple recipe to train state-of-the-art multilingual Grammatical Error Correction (GEC) models. We achieve this by first proposing a language-agnostic method to generate a large number of synthetic examples. The second ingredient is to use large-scale multilingual language models (up to 11B parameters). Once fine-tuned on language-specific supervised sets we surpass the previous state-of-the-art results on GEC benchmarks in four languages: English, Czech, German and Russian. Having established a new set of baselines for GEC, we make our results easily reproducible and accessible by releasing a CLANG-8 dataset.[1] It is produced by using our best model, which we call gT5, to clean the targets of a widely used yet noisy LANG-8 dataset. CLANG-8 greatly simplifies typical GEC training pipelines composed of multiple fine-tuning stages – we demonstrate that performing a single fine-tuning step on CLANG-8 with the off-the-shelf language models yields further accuracy improvements over an already top-performing gT5 model for English.

1 Introduction

Grammatical Error Correction (GEC) is the task of correcting grammatical and other related errors in text. It has been the subject of several modeling efforts in recent years due to its ability to improve grammaticality and readability of user generated texts. This is of particular importance to non-native speakers, children, and individuals with language impairments, who may be more prone to producing texts with grammatical errors.

Modern approaches often view the GEC task as monolingual text-to-text rewriting (Náplava and Straka, 2019; Katsumata and Komachi, 2020; Grundkiewicz et al., 2019) and employ encoder-decoder neural architectures (Sutskever et al., 2014; Bahdanau et al., 2015). These methods typically require large training sets to work well (Malmi et al., 2019) which are scarce especially for languages other than English. One of the largest and most widely used datasets for GEC is the LANG-8 Learner Corpus, which covers 80 languages and has been created by language learners correcting each other's texts.[2] However, the distribution of languages is very skewed, with Japanese and English being the most prevalent languages with over a million ungrammatical-grammatical sentence pairs each, while only ten languages have more than 10,000 sentence pairs each. Additionally, given the uncontrolled nature of the data collection, many of the examples contain unnecessary paraphrasing and erroneous or incomplete corrections.

Limited amounts of suitable training data has led to multiple approaches that propose to generate synthetic training data for GEC (Madnani et al., 2012; Grundkiewicz and Junczys-Dowmunt, 2014; Grundkiewicz et al., 2019; Lichtarge et al., 2019; Awasthi et al., 2019). Although using synthetic data as the first fine-tuning step has been shown to improve model accuracy, it introduces practical challenges that make the development and fair comparison of GEC models challenging: (i) the synthetic methods often require language-specific tuning (e.g. language-specific hyperparameters and spelling dictionaries (Náplava and Straka, 2019)), and; (ii) due to the inability of synthetic data to capture the complete error distribution of the target eval sets, the final model is obtained by following a multi-stage fine-tuning process (Lichtarge et al., 2019, 2020; Omelianchuk et al., 2020). Because of this, carefully picking the learning rates and number of training steps for each of the fine-tuning

stages is required, making it difficult to replicate and build on top of previous best reported models.

The ideas of leveraging self-supervised pre-training and increasing the model size have yielded significant improvements on numerous seq2seq tasks in recent years (Raffel et al., 2019; Xue et al., 2020; Lewis et al., 2020; Song et al., 2019; Chan et al., 2019; Rothe et al., 2020), but these approaches have been applied to GEC to only a limited extent.

In this paper we adopt the mT5 (Xue et al., 2020) as our base model which has already been pre-trained on a corpus covering 101 languages. To adapt the model to the GEC task, we design a fully unsupervised language-agnostic pre-training objective that mimics corrections typically contained in labeled data. We generate synthetic training data by automatically corrupting grammatical sentences, but in contrast to the previous state-of-the-art by Náplava and Straka (2019) for low-resources languages, we use our synthetic pre-training to train a single model on all 101 languages, employing no language-specific priors to remain fully language-agnostic. After pre-training we further fine-tune our model on supervised GEC data for available languages (with data conditions ranging from millions to tens of thousands). Additionally, we explore the effect of scaling up the model size from 60M to 11B parameters. We surpass the previous state-of-the-art results on four evaluated languages: English, Czech, German and Russian.

Fine-tuning and running inference with our largest and most accurate models require multi-GPU/TPU infrastructure. To make the results of our research widely accessible we release a CLANG-8 dataset obtained by using our largest gT5 model to clean up the targets of the frequently used yet noisy LANG-8 dataset. We show that off-the-shelf variants of T5 (Raffel et al., 2019) when fine-tuned only on CLANG-8, outperform those models trained on the original LANG-8 data with and w/o additional fine-tuning data, thus simplifying the complex multi-stage process of training GEC models. Thus CLANG-8 not only allows others to easily train highly competitive GEC models, but it also greatly simplifies GEC training pipeline, basically reducing a multi-step fine-tuning processs to a single fine-tuning step.

Our contributions in this paper are three-fold: (1) We show that a simple language-agnostic pre-training objective can achieve state-of-the-art GEC results when models are scaled up in size; (2) We show the effect model size has on GEC, and; (3) We release a large multilingual GEC dataset based on Lang-8, which allows for state-of-the-art results without additional fine-tuning steps, thus significantly simplifying the training setup.

2 Model

Our model builds on top of mT5 (Xue et al., 2020) a multilingual version of T5 (Raffel et al., 2019) – a Transformer encoder-decoder model which has been shown to achieve state-of-the-art results on a wide range of NLG tasks. mT5 comes in different sizes, however for this work we use *base* (600M parameters) and *xxl* (13B parameters).

2.1 mT5 Pre-training

mT5 has been pre-trained on mC4 corpus, a subset of Common Crawl, covering 101 languages and composed of about 50 billion documents. For details on mC4, we refer the reader to the original paper (Xue et al., 2020). The pre-training objective is based on a span-prediction task, an adaptation of masked-language objective for autoregressive seq2seq models. An example of span prediction:

Input: `A Simple` [x] `Multilingual Grammatical Error` [y]
Target: [x] `Recipe for` [y] `Correction`

All mT5 models were trained for 1M steps on batches of 1024 input sequences with a maximum sequence length of 1024, corresponding to roughly 1T seen tokens. For all of our experiments we use the publicly available mT5 and T5 checkpoints (Section 4 only).

2.2 GEC Pre-training

The span-prediction objective of mT5 does not enable the model to perform GEC without further fine-tuning, as the span-prediction task uses special tokens to indicate where text should be inserted. Another limiting constraint is that mT5 has been trained on paragraphs, not sentences. We therefore split all paragraphs in mC4 corpus into sentences. We corrupt each sentence using a combination of the following operations: a) drop spans of tokens b) swap tokens c) drop spans of characters d) swap characters e) insert characters[3] f) lower-case a word g) upper-case the first

[3]We insert characters from the same passage, thus avoiding to insert character from a different alphabet.

character of a word. An example pair of an original sentence and its corrupted version looks as follows:

Input: `Simple recipe for Multingual Grammatical Correction Error`
Target: `A Simple Recipe for Multilingual Grammatical Error Correction`

We leave about 2% of examples uncorrupted, so the model learns that inputs can also be grammatical. We refrain from using more sophisticated text corruption methods, as these methods would be hard to apply to all 101 languages. For example, Náplava and Straka (2019) perform word substitutions with the entries from ASpell[4] which in turn makes the generation of synthetic data language-specific. Pre-training with this unsupervised objective is done on all languages in the mC4 corpus and not limited to the languages evaluated in this paper.

3 gT5: Large Multilingual GEC Model

Fine-tuning datasets. For English, we fine-tune our pre-trained models on the FCE (Yannakoudakis et al., 2011) and W&I (Bryant et al., 2019a) corpora. For Czech, German, and Russian, we use the AKCES-GEC (Náplava and Straka, 2019), Falko-MERLIN (Boyd, 2018), and RULEC-GEC (Rozovskaya and Roth, 2019) datasets, respectively. Table 1 reports statistics of datasets available for different languages.

lang	Corpus	Train	Dev	Test
EN	FCE, W&I	59,941		
EN	CoNLL-13/-14		1,379	1,312
EN	BEA			4,477
CS	AKCES-GEC	42,210	2,485	2,676
DE	Falko-MERLIN	19,237	2,503	2,337
RU	RULEC-GEC	4,980	2,500	5,000

Table 1: The size of the datasets used to fine-tune gT5.

Training Regime. We experimented with several training setups. All of them build on the mT5 pre-trained models (Section 2.1). We experimented with a) mixing GEC pre-training data (Section 2.2) with fine-tuning data (Section 3), b) mixing pre-training and finetuning examples but annotating them with different prefixes, and c) first using GEC pre-training until convergence and then fine-tuning. While c) is the most computationally expensive approach, it also gave us the best results. GEC pre-training as well as finetuning uses a constant learning rate of 0.001. Pre-training is done until convergence and fine-tuning until exact match accuracy on the development set degrades, which happens after 200 steps or 800k seen examples or 7 epochs.

Models	CoNLL-14	BEA test	Czech	German	Russian
Omelianchuk et al.*	66.5	**73.6**	-	-	-
Lichtarge et al.*	**66.8**	73.0	-	-	-
Náplava and Straka	63.40	69.00	80.17	73.71	50.20
Katsumata and Komachi*	63.00	66.10	73.52	68.86	44.36
gT5 base	54.10	60.2	71.88	69.21	26.24
gT5 xxl	65.65	69.83	**83.15**	**75.96**	**51.62**

Table 2: $F_{0.5}$ Scores. Models denoted with * are ensemble models. We used the M^2 scorer for CoNLL-14, Russian, Czech and German, and the ERRANT scorer (Bryant et al., 2019b) for BEA test.

Results. For English, we evaluate on standard benchmarks from CoNLL-14 and the BEA test (Bryant et al., 2019a), while we use CoNLL-13 as the development set (Table 1). For other languages we use the test and development sets associated with their training data. Table 2 shows the results for all languages. We first see that the base model size is inferior to the current state-of-the-art models. This is expected as the model capacity is not enough to cover all 101 languages. We therefore use a larger xxl (11B) model, which produces new state-of-the-art results on all languages except for English. When looking at the development set performance for English, we observed that it had a high variance and the training was over-fitting very quickly. This suggests that train and dev/test set domains are not well aligned for English. In the following Section 4 we further refine our approach, also achieving state-of-the-art results for English.

4 cLang-8: Cleaned Lang-8 Corpus

To be able to distill the knowledge learned by gT5 xxl into smaller, more practical models, we create and release cLang-8, a cleaned version of the popular Lang-8 corpus. As discussed earlier, Lang-8 is a large corpus of texts written by language learners and user-annotated corrections to these texts. However, corrected texts frequently contain unnecessary paraphrasing and erroneous or incomplete corrections – phenomena that hurt the performance of a GEC model trained on this data. For instance, the following source–target pair

	LR	WER	Sub	Del	Ins
LANG-8	98%	15.46	8.85	2.41	4.19
CLANG-8	98%	10.11	5.85	1.35	2.92
CLANG-8-S	99%	01.22	0.64	0.00	0.58

Table 3: Dataset statistics of English LANG-8 and CLANG-8, including sequence **L**ength **R**atio between the source and the target, **W**ord **E**rror **R**ate, which is comprised of **Sub**stitutions, **Del**etions, and **Ins**ertions.

is taken from LANG-8: *"It is cloudy or rainy recently ."* → *"It is It 's been cloudy or and rainy recently ."*

We experiment with two approaches for cleaning the data. First, to create CLANG-8, we generate new targets for LANG-8, disregarding the original targets. We tried using both the unsupervised model, which was trained using the GEC pretraining objective (Section 2.2) and the supervised model (gT5 xxl) (Section 3), but the former did not yield comparable results, so all reported numbers use the supervised model. Second, to create CLANG-8-S, we used the unsupervised and the supervised models to score the original targets, disregarding the lowest scoring 20%, 50%, 70%, or 90% targets. Disregarding 50% was the best performing setup and there was not a significant difference between the supervised and unsupervised model. We therefore report numbers using the unsupervised model disregarding the worst 50% of the targets. Table 3 shows that CLANG-8 moderately reduces the Word Error Rate (WER) between the source and target, with deletions receiving the largest relative reduction, which may suggest that less information from the source sentence is removed. In contrast CLANG-8-S has a significantly lower WER, indicating that the unsupervised model has only kept corrections which are close to the source sentence.

Experiments. To evaluate the effect cleaning LANG-8 has for English, we train two distinct models on this data: T5 (Raffel et al., 2019), a monolingual sequence-to-sequence model, and FELIX (Mallinson et al., 2020), a non-auto-regressive text-editing model.[5] We also tried fine-tuning these models on BEA (i.e. FCE and W&I) after fine-tuning them on CLANG-8, but this did not further improve the scores but slightly decreased them, e.g. 0.43 absolute decrease for BEA test when using T5 base. This can be explained by the fact that the model used to clean the target texts has already been trained on BEA. This suggests that the typical GEC training pipeline where a model is first fine-tuned on LANG-8 and then on BEA can be both simplified and made more accurate by only fine-tuning on CLANG-8.

Finally, we train mT5 models on the German and Russian portions of the CLANG-8 dataset and evaluate these models on the test sets from Table 1.

[5]The FELIXINSERT variant which we use does not employ re-ordering.

Model	#params	Training Data	CoNLL-14	BEA test
SOTA			66.8	73.6
gT5 xxl			65.65	69.83
FELIX	220M	LANG-8	41.63	30.54
FELIX	220M	LANG-8 + BEA	48.75	48.80
FELIX	220M	CLANG-8	**58.21**	**59.05**
T5 base	220M	LANG-8	52.77	59.14
T5 base	220M	LANG-8 + BEA	60.61	67.12
T5 base	220M	CLANG-8	**65.13**	**69.38**
T5 base	220M	CLANG-8-S	58.70	59.95
T5 small	60M	CLANG-8	60.70	65.01

DET	63.84	77.31	79.04	**83.88**
PREP	57.09	72.54	74.67	**79.79**
ORTH	72.77	**76.86**	69.23	71.39
SPELL	74.38	84.64	85.83	**88.29**

Table 5: BEA test scores for the top five error types. Bold scores represent the best score for each error type.

Results & Analysis. The results for CoNLL-14 and BEA test benchmarks can be seen in Table 4. For both models and both test datasets, CLANG-8 improves the $F_{0.5}$ score compared to using the original LANG-8 corpus. While CLANG-8-S performs significantly worse than CLANG-8, it still improves over LANG-8. In terms of model size, larger models are consistently better then their smaller siblings. This is even true when comparing xl and xxl, suggesting that there might still be headroom by using models larger than xxl.

In Table 5 we compare error types made on BEA

Model	#params	Training Data	German	Russian
SOTA			73.71	50.20
gT5 xxl			**75.96**	**51.62**
mT5 small	300M	CLANG-8	61.78	17.80
mT5 base	580M	CLANG-8	67.19	25.20
mT5 large	1.2B	CLANG-8	70.14	27.55
mT5 xl	3.7B	CLANG-8	72.59	39.44
mT5 xxl	13B	CLANG-8	74.83	43.52

Table 6: $F_{0.5}$ scores on German and Russian.

test for T5 base and T5 xxl, trained on either LANG-8 or CLANG-8. We see that for both data conditions increasing the model size leads to an increase in performance. Comparing CLANG-8 and LANG-8, shows that CLANG-8 improves on all error types apart from orthographic (ORTH) and punctuation (PUNCT).

In Table 6, we evaluate mT5 trained on the German and Russian portions of the CLANG-8 dataset, which contain 114K and 45K training examples, respectively. We see that for both languages performance increases with the model size, with no indication of slowing, suggesting further headroom for improvement. For German, the xxl model achieves a better score than the previous state-of-the-art, however, it is worse than gT5 xxl. Whereas for Russian, mT5 trained on CLANG-8 does not match state-of-the-art performance. We believe this is in part due to the small size of CLANG-8 in Russian. Additionally, the training data for Russian and German comes from the same dataset as the test data which is not the case for English, making the training data of significantly greater relevance. For German and Russian GEC tasks, where in-domain training data is unavailable, CLANG-8 could have a greater impact.

We release the re-labeled CLANG-8 dataset, which contains 2.4M training examples for English, 114k examples for German, and 45k examples for Russian. The Czech portion of Lang-8 would have resulted in only 2k examples, and as such is excluded.

5 Conclusion

In this paper we report new state-of-the-art results on GEC benchmarks in four languages we studied. Our simple setup relies on a language-agnostic approach to pretrain large multi-lingual language models. To enable the distillation of our largest model into smaller, more efficient models, we released a cleaned version of the LANG-8 dataset, enabling easier and even more accurate training of GEC models.

Acknowledgements

We would like to thank Costanza Conforti, Shankar Kumar, Felix Stahlberg and Samer Hassan for useful discussions as well as their help with training and evaluating the models.

Abstract

Pathology imaging is broadly used for identifying the causes and effects of diseases or injuries. Given a pathology image, being able to answer questions about the clinical findings contained in the image is very important for medical decision making. In this paper, we aim to develop a pathological visual question answering framework to analyze pathology images and answer medical questions related to these images. To build such a framework, we create PathVQA, a pathology VQA dataset with 32,795 questions asked from 4,998 pathology images. We also propose a three-level optimization framework which performs self-supervised pretraining and VQA finetuning end-to-end to learn powerful visual and textual representations jointly and automatically identifies and excludes noisy self-supervised examples from pretraining. We perform experiments on our created PathVQA dataset and the results demonstrate the effectiveness of our proposed methods. The datasets and code are available at https://github.com/UCSD-AI4H/PathVQA

1 Introduction

Pathology (Levison et al., 2012) studies the causes and effects of diseases or injuries. It underpins every aspect of patient care, such as diagnostic testing, providing treatment advice, preventing diseases using cutting-edge genetic technologies, to name a few. Given a pathology image, being able to answer questions about the clinical findings contained in the image is very important for medical decision-makings.

In this paper, we aim to develop a pathological visual question answering framework to analyze pathology images and answer medical questions related to these images. We first need to collect a dataset containing questions about pathology imaging. One possible way to create a pathology VQA dataset is crowdsourcing, which is used successfully for creating general domain VQA datasets (Malinowski and Fritz, 2014; Antol et al., 2015; Ren et al., 2015a; Johnson et al., 2017; Goyal et al., 2017). However, it is much more challenging to build medical VQA datasets than general domain VQA datasets via crowdsourcing. First, medical images such as pathology images are highly domain-specific, which can only be interpreted by well-educated medical professionals. It is rather difficult and expensive to hire medical professionals to help create medical VQA datasets. Second, to create a VQA dataset, one first needs to collect an image dataset. While images in the general domain are pervasive, medical images are very difficult to obtain due to privacy concerns.

To address these challenges, we resort to pathology textbooks, especially those that are freely accessible online, as well as online digital libraries. We extract images and captions from the textbooks and online digital libraries. Given these images, question-answer pairs are created based on image captions. These QA pairs are verified by medical professionals to ensure clinical meaningfulness and correctness. In the end, we created a pathology VQA dataset called PathVQA, which contains 32,795 questions asked from 4,998 pathology images. To our best knowledge, this is the first dataset for pathology VQA.

Given the pathology VQA dataset, the next step is to develop a pathology VQA system, which is also very challenging, due to the following reason. The medical concepts involved in PathVQA are very diverse while the number of question-answer pairs available for training is limited. Learning effective representations of these diverse medical concepts using limited data is technically difficult. Poorly learned representations lead to infe-

rior VQA performance. To address this challenge, we propose a three-level optimization framework which performs cross-modal self-supervised pretraining (Tan and Bansal, 2019) and VQA finetuning of a pathology image encoder and a question encoder end-to-end to learn powerful visual and textual representations jointly and automatically identifies and excludes noisy self-supervised examples from pretraining. Experiments on our developed PathVQA dataset demonstrates the effectiveness of our proposed methods.

The major contributions of this paper are as follows:

- We create a pathology visual question answering dataset – PathVQA, to foster the research of medical VQA. To our best knowledge, this is the first dataset for pathology VQA.
- We propose a three-level optimization framework which performs cross-modal self-supervised pretraining and VQA finetuning of a pathology image encoder and a question encoder end-to-end to learn powerful visual and textual representations jointly and automatically identifies and excludes noisy self-supervised examples from pretraining.
- On our PathVQA dataset, we demonstrate the effectiveness of our proposed method.

2 Related Work

2.1 Medical VQA Datasets

To our best knowledge, there are two existing datasets for medical visual question answering. The VQA-Med (Abacha et al., 2019) dataset is created on 4,200 radiology images and has 15,292 question-answer pairs. Most of the questions are in multiple-choice (MC) style and can be answered by multi-way classifiers. This makes the difficulty of this dataset significantly lower. VQA-RAD (Lau et al., 2018) is a manually-crafted dataset where questions and answers are given by clinicians on radiology images. It has 3515 questions of 11 types. Our dataset differs from VQA-Med and VQA-RAD in two-fold. First, ours is about pathology while VQA-Med and VQA-RAD (Lau et al., 2018) are both about radiology. Second, our dataset is a truly challenging QA dataset where most of the questions are open-ended while in VQA-Med and VQA-RAD the majority of questions have a fixed number of candidate answers and can be answered by multi-way classification. Besides, the number of questions in our dataset is much larger than that in VQA-Med and VQA-RAD.

2.2 Cross-modal Self-supervised Learning

Cross-modal self-supervised learning learns representations for data with multiple modalities by solving cross-modal auxiliary tasks. VisualBERT (Li et al., 2019) learns representations for images and texts by implicitly aligning elements of a text and regions in an associated image with self-attention. CVLP (Shi et al., 2020) proposes an unbiased contrastive visual-linguistic pretraining approach, which constructs a self-supervised loss based on contrastive learning. ViLBERT (Lu et al., 2019) proposes to pretrain a vision-and-language BERT model through masked multi-modal modeling and alignment tasks, and then transfer the model to visual question answering tasks.

2.3 Data Selection and Data Reweighting

A number of approaches have been proposed for data selection. Ren et al. (2018) proposes a meta learning method to learn the weights of training examples by performing a meta gradient descent step on the weights of the current mini-batch of examples. Shu et al. (2019) propose a method which can adaptively learn an explicit weighting function directly from data.

3 The PathVQA Dataset

The PathVQA dataset consists of 32,795 question-answer pairs generated from 1,670 pathology images collected from two pathology textbooks: "Textbook of Pathology" (Muir et al., 1941) and

Table 1: Frequency of questions in different categories

Question type	Total number and percentage
Yes/No	16,329 (49.8%)
What	13,401 (40.9%)
Where	2,157 (6.6%)
How	595 (1.8%)
How much/many	139 (0.4%)
Why	114 (0.3%)
When	51 (0.2%)
Whose	9 (0.1%)

"Basic Pathology" (Robbins et al., 1981), and 3,328 pathology images collected from the PEIR[1] digital library. The question-answer pairs are generated using a semi-automated pipeline with linguistic rules. Figure 1 shows some examples.

On average, each image has 6.6 questions. The maximum and minimum number of questions for a single image is 14 and 1 respectively. The average number of words per question and per answer is 9.5 and 2.5 respectively. There are eight different categories of questions: what, where, when, whose, how, why, how much/how many, and yes/no. Table 1 shows the number of questions and percentage in each category. The questions in the first 7 categories are open-ended: 16,466 in total and accounting for 50.2% of all questions. The rest are close-ended "yes/no" questions. The questions cover various aspects of visual contents, including color, location, appearance, shape, etc. Such clinical diversity poses great challenges for AI models to solve this pathology VQA problem.

4 Method

We propose a three-level optimization based framework to perform VQA on PathVQA. In our framework, there are three learning stages, which are performed end-to-end jointly. In the first stage, self-supervised learning (He et al., 2019; Tan and Bansal, 2019) is performed to pretrain the image encoder and text encoder. In the second stage, we finetune the image encoder and text encoder on the PathVQA dataset. In the third stage, the trained model is validated on the validation set. In the first stage, we perform cross-modal self-supervised learning (Tan and Bansal, 2019) of an image encoder W and a text encoder T. The image encoder is used to extract visual features of pathology images. The text encoder is used to extract semantic features of questions and answers. Self-supervised learning (He et al., 2019) is an unsupervised representation learning approach where pretext tasks are defined solely based on the input data, and representations are learned by solving these pretext tasks.

There are many ways to construct pretext tasks. In our work, following (Tan and Bansal, 2019), we define a simple yet effective pretext task: in the PathVQA dataset, given a pathology image and a question, judge whether this question is about this image. From the PathVAQ training set D, we create another dataset $D' = \{(x_i, y_i, t_i)\}_{i=1}^{M}$ to perform the SSL task. There are M tuples, each containing a pathology image x from D and a question y from D. t_i is a binary variable where $t_i = 1$ if x and y are from the same training example in D and $t_i = 0$ if otherwise. Given D', we develop a model to map (x_i, y_i) to t_i. In this model, an image encoder is used to encode x_i and a text encoder is used to encode y_i; the concatenation of these two encodings is fed into a linear layer to predict whether the image matches with the question.

In self-supervised learning (He et al., 2019), the labels are typically constructed automatically without human supervision. As a result, they contain a lot of noises. For example, in D', t is determined simply based on whether x and y are from the training example in D. It is totally possible that a question y asked about an image x' is appropriate to be a question for another image x as well if x and x' are pathologically similar. In this case, the correct label t for (x, y) should be 1. However, it is set to 0 in D'. Training the encoders using these noisy and incorrect labels may confuse the encoders and result in poor-quality representations.

To address this problem, we aim to develop a method to automatically identify incorrectly auto-labeled examples in the training data of the SSL task. For each example (x, y, t) in D', we associate a selection variable $a \in [0, 1]$ with it. If a is close to 1, it means this example is correctly labeled; if a is close to 0, it means this example is incorrectly labeled. Let $l(f(x, y; W, T), t)$ denote the SSL loss defined on (x, y, t), where $f(x, y; W, T)$ is the predicted probability that $t = 1$ and $l(\cdot)$ is the cross-entropy loss. We multiply a with $l(f(x, y; W, T), t)$ so that if (x, y, t) is incorrectly

[1] http://peir.path.uab.edu/library/index.php?/category/2

labeled, its loss will be down-weighted to 0 and effectively (x, y, t) is excluded from the SSL pretraining process. In the end, only correctly-labeled examples are used for pretraining the encoders. To this end, in the first stage, we solve the following optimization problem:

$$W^*(A), T^*(A) = \underset{W,T}{\text{argmin}} \sum_{i=1}^{M} a_i l(f(x_i, y_i; W, T), t_i).$$

In this problem, the selection variables $A = \{a_i\}_{i=1}^M$ are fixed (we will discuss how to learn A later on). $\{a_i\}_{i=1}^M$ are used to weigh the losses of individual examples in D. W and T are trained by minimizing the sum of weighted losses. Note that the optimal solutions $W^*(A)$ and $T^*(A)$ are functions of A since $W^*(A)$ and $T^*(A)$ are functions of the loss function, which is a function of A.

In the second stage, we finetune the image encoder and text encoder in the VQA task defined on the PathVQA dataset D. Let V, U, R denote the network weights of the image encoder, text encoder, and QA network respectively. We train V, U, R by minimizing the VQA loss: $\sum_{i=1}^{N^{(\text{tr})}} L(d_i^{(\text{tr})}, V, U, R)$ where $d_i^{(\text{tr})}$ is a training example in D, consisting of an input pathology image, an input question, and an output answer. When training V and U, we encourage them to be close to the optimally trained network weights $W^*(A)$ and $T^*(A)$ of the image and text encoder in the first stage, to transfer the representations learned in the SSL task to the VQA task. The second stage amounts to solving the following optimization problem:

$$\begin{aligned} &V^*(W^*(A)), U^*(T^*(A)), R^* = \\ &\underset{V,U,R}{\text{argmin}} \sum_{i=1}^{N^{(\text{tr})}} L(d_i^{(\text{tr})}, V, U, R) + \\ &\gamma_1 \left\|V - W^*(A)\right\|_2^2 + \gamma_2 \left\|U - T^*(A)\right\|_2^2. \end{aligned} \quad (1)$$

where the L2 losses encourage V and U to be close to $W^*(A)$ and $T^*(A)$. γ_1 and γ_2 are tradeoff parameters. Note that $V^*(W^*(A))$ is a function of $W^*(A)$ since $V^*(W^*(A))$ is a function of $\|V - W^*(A)\|_2^2$ which is a function of $W^*(A)$. Similarly, $U^*(T^*(A))$ is a function of $T^*(A)$.

In the third stage, we apply the optimally trained VQA model including $V^*(W^*(A))$, $U^*(T^*(A))$, and R^* to make predictions on the validation dataset. Then we learn the selection variables A by minimizing the validation loss $\sum_{i=1}^{N^{(\text{val})}} L(d_i^{(\text{val})}, V^*(W^*(A)), U^*(T^*(A)), R^*)$.

Putting all these pieces together, we have the following three-level optimization framework:

$$\begin{aligned} &\min_A \sum_{i=1}^{N^{(\text{val})}} L(d_i^{(\text{val})}, V^*(W^*(A)), U^*(T^*(A)), R^*) \\ &s.t. \quad V^*(W^*(A)), U^*(T^*(A)), R^* = \\ &\quad \text{argmin}_{V,U,R} \sum_{i=1}^{N^{(\text{tr})}} L(d_i^{(\text{tr})}, V, U, R) \\ &\quad\quad +\gamma_1 \left\|V - W^*(A)\right\|_2^2 + \gamma_2 \left\|U - T^*(A)\right\|_2^2 \\ &\quad W^*(A), T^*(A) = \text{argmin}_{W,T} \sum_{i=1}^{M} a_i l(f(x_i, y_i; W, T), t_i) \end{aligned}$$

4.1 VQA Models

Our proposed method can be applied to any VQA method. In this work, we choose two well-established and state-of-the-art VQA methods to perform the study while noting that other VQA methods are applicable as well.

- **Method 1**: In (Tan and Bansal, 2019), a large-scale Transformer (Vaswani et al., 2017) model is built that consists of three encoders: an object relationship encoder, a language encoder, and a cross-modal encoder. The three encoders are built mostly based on two kinds of attention layers — self-attention layers and cross-attention layers. The object relationship encoder and the language encoder are both single-modality encoders. A cross-modal encoder is proposed to learn the connections between vision and language.

- **Method 2**: The method proposed in (Kim et al., 2018) uses a Gated Recurrent Unit (GRU) (Cho et al., 2014) recurrent network and a Faster R-CNN (Ren et al., 2015b) network to embed the question and the image. It extends the idea of co-attention to bilinear attention which considers every pair of multimodal channels.

5 Experiment

5.1 Experimental Settings

Data split We partition the images in the PathVQA dataset along with the associated questions into a training set, validation set, and testing set with a ratio of about 3:1:1. In the PathVQA dataset, the frequencies of question categories are imbalanced. Because of this, during the partition process, we perform sampling to ensure the frequencies of these categories in each set to be consistent. In the end, there are 19,755 question-answer pairs in the training set, 6,279 in the validation set, and 6,761 in the testing set.

Table 2: Accuracy (%), BLEU-n (%), and F1 (%) achieved by different methods. We denote cross-modal SSL on image-question pairs and image-answer pairs as CMSSL-IQ and CMSSL-IA.

Method	Accuracy	BLEU-1	BLEU-2	BLEU-3	F1
Method 1 without image	49.2	50.2	2.8	1.2	9.5
Method 1	57.6	57.4	3.1	1.3	9.9
Method 1 with CMSSL-IQ	58.7	59.0	3.5	2.1	11.0
Method 1 with CMSSL-IQ + three-level optimization framework	**63.4**	**63.7**	**4.1**	**2.5**	**12.2**
Method 1 with CMSSL-IA	58.6	58.9	3.4	2.0	10.3
Method 1 with CMSSL-IA + three-level optimization framework	62.4	62.2	3.6	2.3	12.0
Method 2 without image	46.2	46.5	1.0	0.0	0.8
Method 2	55.1	56.2	3.2	1.2	8.4
Method 2 with CMSSL-IQ	55.9	57.1	3.4	1.4	9.2
Method 2 with CMSSL-IQ + three-level optimization framework	**58.9**	**59.1**	3.8	**1.6**	9.2
Method 2 with CMSSL-IA	55.9	57.1	3.5	1.5	9.2
Method 2 with CMSSL-IA + three-level optimization framework	58.8	**59.1**	**4.0**	**1.6**	**9.4**

Evaluation metrics We perform evaluation using three metrics: 1) accuracy (Malinowski and Fritz, 2014) which measures the percentage of inferred answers that match exactly with the ground-truth using string matching; only exact matches are considered as correct; 2) macro-averaged F1 (Goutte and Gaussier, 2005), which measures the average overlap between the predicted answers and ground-truth, where the answers are treated as bag of tokens; 3) BLEU (Papineni et al., 2002), which measures the similarity of predicted answers and ground-truth by matching n-grams.

5.2 Results

Table 2 shows the VQA performance achieved by different methods. From this table, we make the following observations. **First**, for both Method 1 and Method 2, applying our three-level optimization based framework improves the performance. Our framework learns to identify and remove noisy and erroneous SSL training examples, which can avoid the model to be distorted by such bad-quality examples. **Second**, for both Method 1 and 2, applying cross-modal SSL (CMSSL) methods including CMSSL-IQ and CMSSL-IA improves the performance, which demonstrates the effectiveness of CMSSL. CMSSL uses auxiliary tasks, including judging whether an image matches with a question and judging whether an image matches with an answer, to learn semantic correspondence between image regions and words in questions/answers, which can improve the effectiveness of visual and textual representations for accurate VQA. It also learns image and text encoders by encourages the image and text encoders to solve auxiliary tasks, which reduces the risk of overfitting to the data-deficient VQA task on the small-sized training data.

One may suspect how much information in images is used during the inference of the answers? Could it be possible that the models simply learn the correlations between questions and answers and ignore the images? In light of these concerns, we perform studies where the images are not fed into VQA models and only questions are used as inputs for inferring answers. Table 2 shows the results of not using images ("Method 1/2 without image"). As can be seen, for both Method 1 and 2, ignoring images leads to substantial degradation of performance. This shows that images in our dataset provide valuable information for VQA and PathVQA is a meaningful VQA dataset. The models trained on our datasets are not degenerated to simply capturing the correlation between questions and answers.

6 Conclusion

In this paper, we build a pathology VQA dataset – PathVQA – that contains 32,795 question-answer pairs of 8 categories, generated from 4,998 images. Majority of questions in our dataset are open-ended, posing great challenges for the medical VQA research. Our dataset is publicly available. To address the challenges that the self-supervised training data may contain errors and the effective representations of pathology images and questions are difficult to learn on limited data, we propose a three-level optimization framework to automatically identify and remove problematic SSL training examples and learn sample-efficient visual and textual representations. Experiments on the PathVQA dataset demonstrate the effectiveness of our method.

# QA pairs	19,755	6,279	6,761

Appendix

A Experimental setup

Table 3 shows dataset split statistics. We implement the methods using PyTorch and perform training on four GTX 1080Ti GPUs.

We basically follow the original model configurations used in (Tan and Bansal, 2019), (Kim et al., 2018), and (Yang et al., 2016). Data augmentation is applied to images, including shifting, scaling, and shearing. From questions and answers in the PathVQA dataset, we create a vocabulary of 4,631 words that have the highest frequencies.

In Method 1, we use the default hyperparameter settings in (Tan and Bansal, 2019). For the text encoder, the hidden size was set to 768. The image features were extracted from the outputs of the Faster-RCNN network, which is pretrained on BCCD[2] – a medical dataset containing blood cells photos, as well as on Visual Genome (Krishna et al., 2017). The initial learning rate was set to 5e-5 with the Adam (Kingma and Ba, 2014a) optimizer used. The batch size was set to 256. The model was trained for 200 epochs. In the SSL pretraining task on Method 1, we train a linear classifier with a dimension of 1,280 to judge whether an image matches with a question. In Method 2, words in questions and answers are represented using GloVe (Pennington et al., 2014) vectors pretrained on general-domain corpora such as Wikipedia, Twitter, etc. The image features are extracted from the outputs of the Faster-RCNN network pretrained on BCCD and Visual Genome. Given an image and a question, the model outputs an answer from a predefined set of answers. The dropout (Srivastava et al., 2014) rate for the linear mapping was set to 0.2 while for the classifier it was set to 0.5. The initial learning rate was set to 0.005 with the Adamax optimizer (Kingma and Ba, 2014b) used. The batch size was set to 512. The model was trained for 200 epochs. In the SSL pretraining task on Method 2, similar to that on Method 1, we train a linear classifier with a dimension of 1,280 to predict whether an image matches with a question. We optimize the selection variables using the Adam optimizer, with an initial learning rate of 0.01. We set γ_1 and γ_2 to 0.3 and 0.7 respectively.

B Dataset Creation

We develop a semi-automated pipeline to generate a pathology VQA dataset from pathology textbooks and online digital libraries. We manually check the automatically-generated question-answer pairs to fix grammar errors. The automated pipeline consists of two steps: (1) extracting pathology images and their captions from electronic pathology textbooks and the Pathology Education Informational Resource (PEIR) Digital Library[3] website; (2) generating questions-answer pairs from captions.

B.1 Extracting Pathology Images and Captions

Given a pathology textbook that is in the PDF format and available online publicly, we use two third-party tools PyPDF2[4] and PDFMiner[5] to extract images and the associated captions therefrom. PyPDF2 provides APIs to access the "Resources" object in each PDF page where the "XObject" gives information about images. PDFMiner allows one to obtain text along with its exact location in a page. To extract image captions from text in each page, we use regular expressions to search for snippets with prefixes of "Fig." or "Figure" followed by figure numbers and caption texts. For a page containing multiple images, we order them based on their locations; the same for the captions. Images and locations are matched based on their order. Given an online pathology digital library such as PEIR, we use two third-party tools Requests[6] and Beautiful Soup[7] to crawl images and the associated captions. Requests is an HTTP library built using Python and provides APIs to send HTTP/1.1 requests. Beautiful Soup generates the 'http.parser' and can access the urls and tags of the images on the website pages. Given a set of urls, we use Requests to read website pages and use Beautiful Soup to find images under the targeted HTML tags including the Content Division element $\langle div \rangle$, the unordered list element $\langle ul \rangle$, and the $\langle li \rangle$ element.

Table 4: Number of questions in different categories in each set

Dataset	Question types					
	What	Where	How	How much/many	Why	Yes/No
Training set	8083	1316	366	62	71	9804
Validation set	2565	409	108	21	21	3135
Testing set	2753	432	121	18	22	3390

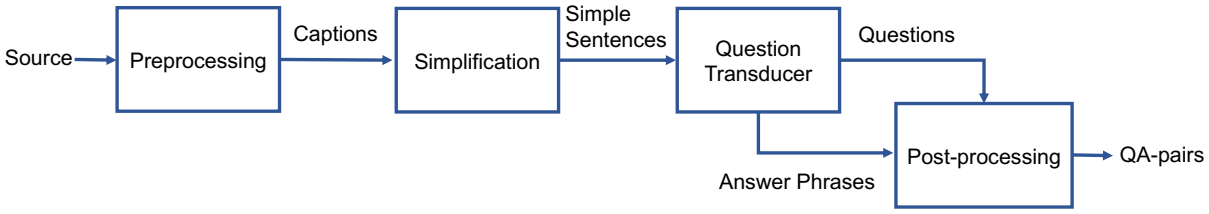

Figure 2: The framework of generating questions from captions

Then we can download images with Requests and write their captions directly to local files. Given the extracted image-caption pairs, we perform post-processing including (1) removing images that are not pathology images, such as flow charts and portraits; (2) correcting erroneous matching between images and captions.

B.2 Question Generation

In this section, we discuss how to semi-automatically generate questions from captions. Figure 2 shows the overall framework. We perform natural language processing of the captions using the Stanford CoreNLP (Klein and Manning, 2003) toolkit, including sentence split, tokenization, part-of-speech (POS) tagging, named entity recognition (NER), constituent parsing, and dependency parsing. Many sentences are long, with complicated syntactic structures. We perform sentence simplification to break a long sentence into several short ones. Given the subjects, verbs, clauses, etc. labeled by POS tagging and syntactic parsing, we rearrange them using the rules proposed in (Toutanova et al., 2007; Dorr et al., 2003) to achieve simplification. Figure 3 shows an example.

Given the POS tags and named entities of the simplified sentences, we generate questions for them: including "when"-type of questions for date and time entities and phrases such as "in/during ... stage/period", "before ...", and "after ..."; "how much/how many"-type of questions for words tagged as numbers; "whose" questions for possessive pronouns (e.g., "its", "their"); "where" questions for location entities and prepositional

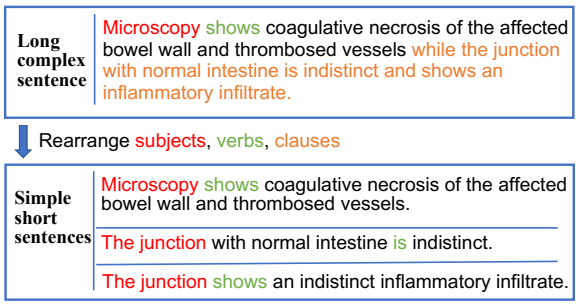

Figure 3: Sentence simplification

phrases starting with "inner", "within", "on the right/left of"; "how" questions for adjective words and phrases starting with "using", "via", "with", and "through", and "what" questions for the remaining noun phrases. Table 5 shows an example for each type of questions.

We use Tregex from Stanford CoreNLP tools (Manning et al., 2014), a tree query language including various relational operators based on the primitive relations of immediate dominance and immediate precedence, to implement the rules (Heilman and Smith, 2009) for transforming declarative sentences (captions) into questions.

To reduce grammatical errors, we avoid generating questions on sentences with adverbial clauses such as "chronic inflammation in the lung, showing all three characteristic histologic features". The question transducer mainly contains three steps. First, we perform the main verb decomposition based on the tense of the verb. For instance, we decompose "shows" to "does show". It is worth noting that for passive sentences with a structure of

Type	Original sentence	Question
What	**The end of the long bone** is expanded in the region of epiphysis.	What is expanded in the region of epiphysis?
Where	The left ventricle is **on the lower right** in this apical four-chamber view of the heart.	Where is the left ventricle in this apical four-chamber view of the heart?
When	**After 1 year of abstinence**, most scars are gone.	When are most scars gone?
How much/How many	**Two** multi-faceted gallstones are present in the lumen.	How many multi-faceted gallstones are present in the lumen?
Whose	The tumor cells and **their** nuclei are fairly uniform, giving a monotonous appearance.	The tumor cells and whose nuclei are fairly uniform, giving a monotonous appearance?
How	The trabecular bone forming the marrow space shows trabeculae **with osteoclastic activity at the margins**.	How does the trabecular bone forming the marrow space show trabeculae?

Table 5: Examples of generated questions for different types

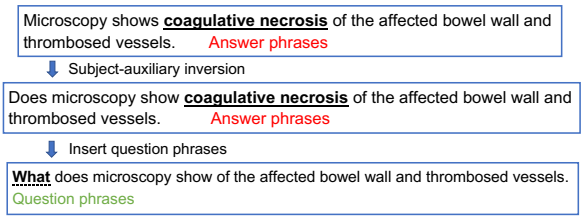

Figure 4: Syntactic transformation

"be+shown/presented/demonstrated", we keep their original forms rather than performing the verb decomposition. Second, we perform subject-auxiliary inversion. We invert the subject and the auxiliary verb in the declarative sentences to form the interrogative sentence. After the inversion, the binary "yes/no" questions are generated. For instance, as shown in Figure 4, the sentence "microscopy shows coagulative necrosis of the affected bowel wall and thrombosed vessels" is inverted to "does microscopy show coagulative necrosis of the affected bowel wall and thrombosed vessels?". To generate questions whose answers are "no", we randomly select a phrase with the same POS tagging from other captions to replace the head words in the original question. For example, we replace "coagulative necrosis" in the sentence "does microscopy show coagulative necrosis of the affected bowel wall and thrombosed vessels" with other noun phrases. Third, we remove the target answer phrases and insert the question phrase obtained previously to generate open-ended questions belonging to types of "what", "where", "when", "whose", "how", and "how much/how many" as shown in Table 5. For instance, we transduce "microscopy shows coagulative necrosis of the affected bowel wall and thrombosed vessels" to "what of the affected bowel wall and thrombosed vessels does microscopy show?" as shown in Figure 4. Given the automatically generated questions which may contain syntactic and semantic errors, we perform post-processing to fix those issues. We manually proofread all questions to correct misspellings, syntactic errors, and semantic inconsistencies. The questions and answers are further cleaned by removing extra spaces and irrelevant symbols. Questions that are too short or vague are removed. Articles appearing at the beginning of answers are stripped.

C Additional Related Works

C.1 VQA datasets

A number of visual question answering datasets have been developed in the general domain. DAQUAR (Malinowski and Fritz, 2014) is built on top of the NYU-Depth V2 dataset (Silberman et al., 2012) which contains RGBD images of indoor scenes. DAQUAR consists of (1) synthetic question-answer pairs that are automatically generated based on textual templates and (2) human-created question-answer pairs produced by five annotators. The VQA dataset (Antol et al., 2015) is developed on real images in MS COCO (Lin et al., 2014) and abstract scene images in (Antol et al., 2014; Zitnick and Parikh, 2013). The question-answer pairs are created by human annotators who are encouraged to ask "interesting" and "diverse" questions. VQA v2 (Goyal et al., 2017) is extended from the VQA (Antol et al., 2015) dataset to achieve more balance between visual and textual information, by collecting complementary images in a way that each question is associated with a pair of similar images with different answers. In the COCO-QA (Ren et al., 2015a) dataset, the question-answer pairs are automatically generated from image captions based on syntactic parsing and linguistic rules. CLEVR (Johnson et al., 2017; Kembhavi et al., 2017) is a dataset developed on rendered images of spatially related objects (including cube, sphere, and cylinder) with different sizes, materials, and colors. The locations and attributes of objects are annotated for each image. The questions are automatically generated from the annotations.

Table 6: Comparison of VQA datasets

	Domain	# images	# QA pairs	Answer type
DAQUAR	General	1,449	12,468	Open
VQA	General	204K	614K	Open/MC
VQA v2	General	204K	1.1M	Open/MC
COCO-QA	General	123K	118K	Open/MC
CLEVR	General	100K	999K	Open
VQA-Med	Medical	4,200	15,292	Open/MC
VQA-RAD	Medical	315	3,515	Open/MC
Ours	Medical	4,998	32,795	Open

The comparison of existing VQA datasets is shown in Table 6. The first five datasets are in the general domain while the last three are in the medical domain. Not surprisingly, the size of general-domain datasets (including the number of images and question-answer pairs) is much larger than that of medical datasets since general-domain images are much more available publicly and there are many qualified human annotators to generate QA pairs on general images. Our dataset is larger than the two medical datasets: VQA-Med and VQA-RAD, and majority of questions in our dataset are open-ended while majority of questions in VQA-Med and VQA-RAD are in multiple-choices style.

C.2 Automatic Construction of Question-Answer Pairs

Existing datasets have used automated methods for constructing question-answer pairs. In DAQUAR, questions are generated with templates, such as "How many {object} are in {image_id}?". These templates are instantiated with ground-truth facts from the database. In COCO-QA, the authors develop a question generation algorithm based on the Stanford syntactic parser (Klein and Manning, 2003), and they form four types of questions—"object", "number", "color", and "location" using hand-crafted rules. In CLEVR, the locations and attributes of objects in each image are fully annotated, based on which the questions are generated by an automated algorithm. Their algorithm cannot be applied to natural images where detailed annotation of objects and scenes are very difficult to obtain. In (Fan et al., 2018), the authors develop a conditional auto-encoder (Kingma and Welling, 2013) model to automatically generate questions from images. To train such a model, image-question pairs are needed, which incurs a chicken-and-egg problem: the goal is to generate questions, but realizing this goal needs generated questions. In VQA-Med, the authors collect medical images along with associated side information (e.g., captions, modalities) from the MedPix[8] database and generate question-answer pairs based on manually-defined patterns in (Lau et al., 2018).

D Number of questions in different categories for training, validation, and test set

For our data split, the number of questions in different categories in each set is shown in Table 4.

Abstract

Text-based games (TBGs) have emerged as useful benchmarks for evaluating progress at the intersection of grounded language understanding and reinforcement learning (RL). Recent work has proposed the use of external knowledge to improve the efficiency of RL agents for TBGs. In this paper, we posit that to act efficiently in TBGs, an agent must be able to track the state of the game while retrieving and using relevant commonsense knowledge. Thus, we propose an agent for TBGs that induces a graph representation of the game state and jointly grounds it with a graph of commonsense knowledge from ConceptNet. This combination is achieved through *bidirectional knowledge graph attention* between the two symbolic representations. We show that agents that incorporate commonsense into the game state graph outperform baseline agents.

1 Introduction

Text-based games (TBGs) are simulation environments in which an agent interacts with the world purely in the modality of text. TBGs have emerged as key benchmarks for studying how reinforcement learning agents can tackle the challenges of language understanding, partial observability, and action generation in combinatorially large action spaces. One particular text-based gaming environment, TextWorld (Côté et al., 2018), has received significant attention in recent years.

Recent work has shown the need for additional knowledge to tackle the challenges in TBGs. Ammanabrolu and Riedl (2019) proposed handcrafted rules to represent the current state of the game using a state knowledge graph (much like a map of the game). Our own prior work (Murugesan et al., 2021) proposed an extension of TextWorld, called TextWorld Commonsense (TWC), to test agents' ability to use commonsense knowledge while interacting with the world. The hypothesis behind TWC

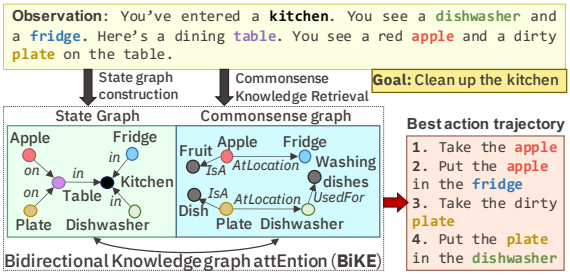

Figure 1: An illustration of a TBG that requires both the state representation of the game as well as the external commonsense knowledge for efficient exploration and learning the best action trajectory. The observation text feeds into the state and commonsense graphs; and the best action trajectory is computed based on information from both graphs.

is that commonsense knowledge allows the agent to understand how current actions might affect future world states; and enable look-ahead planning (Juba, 2016), thus leading to sample-efficient selection of actions at each step and driving the agent closer to optimal performance.

In this paper, we posit that to efficiently act in such text-based gaming environments, an agent must be able to effectively track the state of the game, and use that to jointly retrieve and leverage the relevant commonsense knowledge. For example, commonsense knowledge such as `apple should be placed in the refrigerator` would help the agent to act closer to the optimal behavior; whereas state information like `apple is on the table` would help the agent plan more efficiently. Thus, we propose a technique to: (a) track the state of the game in the form of a symbolic graph that represents the agent's current belief of the state of the world (Ammanabrolu and Hausknecht, 2020a; Adhikari et al., 2020); (b) retrieve the relevant commonsense knowledge from ConceptNet (Speer et al., 2017), and (c) jointly leverage the state graph and the

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 719–725
August 1–6, 2021. ©2021 Association for Computational Linguistics

retrieved commonsense graph. This combined information is then used to select the optimal action. Finally, we demonstrate the performance of our agent against state of the art baseline agents on the TWC Environment.

2 Related Work

Text-based reinforcement learning Text-based games have recently emerged as a promising framework to drive advances in RL research. Prior work has explored text-based RL to learn strategies based on an external text corpus (Branavan et al., 2012) or from textual observations (Narasimhan et al., 2015). In both cases, the text is analyzed and control strategies are learned jointly using feedback from the gaming environment. Zahavy et al. (2018) proposed the Action-Elimination Deep Q-Network (AE-DQN), which learns to classify invalid actions to reduce the action space. The use of the commonsense and state graph in our work has the same goal of down-weighting implausible actions by jointly reasoning over the state of the game and prior knowledge. Recently, Côté et al. (2018) introduced `TextWorld` and Murugesan et al. (2021) proposed *TextWorld Commonsense* (TWC), a text-based gaming environment which requires agents to leverage prior knowledge in order to solve the games. In this work, we build on the agents of Murugesan et al. (2021) and show that prior knowledge and state information are complementary and should be learned jointly.

KG-based state representations A recent line of work in TBGs aims at enhancing generalization performance by using symbolic representations of the agent's belief. Notably, Ammanabrolu and Riedl (2019) proposed *KG-DQN* and Ammanabrolu and Hausknecht (2020b) proposed *KG-A2C*. The idea behind both approaches is to represent the game state as a belief graph. Recently, Adhikari et al. (2020) proposed the graph-aided transformer agent (*GATA*), an approach to construct and update a latent belief graph during planning. Our work integrates these graph-based state representations with a prior commonsense graph that allows the agent to better model the state of the game using prior knowledge.

Sample-efficient reinforcement learning A key challenge for current RL research is low sample efficiency (Kaelbling et al., 1998). To address this problem, there have been few attempts on adding prior or external knowledge to RL approaches. Notably, Murugesan et al. (2020) proposed to use prior knowledge extracted from ConceptNet. Garnelo et al. (2016) proposed *Deep Symbolic RL*, which relies on techniques from symbolic AI as a way to introduce commonsense priors. There has also been work on *policy transfer* (Bianchi et al., 2015) which aims at reusing knowledge gained in different environments. Moreover, *Experience replay* (Wang et al., 2016; Lin, 1992, 1993) provides a framework for how previous experiences can be stored and later reused. In this paper, following Murugesan et al. (2020), we use external KGs as a source of prior knowledge and we combine this knowledge representation with graph-based state modeling in order to allow the agents to act more efficiently.

3 Model & Architecture

TBGs can be framed as partially observable Markov decision processes (POMDPs) (Spaan, 2012) denoted $\langle S, A, O, T, E, r \rangle$, where: S denotes the set of states, A denotes the action space, O denotes the observation space, T denotes the state transition probabilities, E denotes the conditional observation emission probabilities, and $r : S \times A \rightarrow \mathbb{R}$ is the reward function. The observation o_t at time step t depends on the current state. Both observations and actions are rendered in text. The agent receives a reward at every time step t: $r_t = r(o_t, a_t)$, and the agent's goal is to maximize the expected discounted sum of rewards: $\mathbb{E}[\sum_t \gamma^t r_t]$, where $\gamma \in [0, 1]$ is a discount factor.

The high-level architecture of our model contains three major components: (a) the input encoder; (b) a graph-based knowledge extractor; and (c) the action prediction module. The input encoding layers are used to encode the observation o_t at time step t and the list of admissible actions using GRUs (Ammanabrolu and Hausknecht, 2020a). The graph-based knowledge extractor collects relevant knowledge from complementary knowledge sources: the game state, and external commonsense knowledge. We allow information from each knowledge source to guide and direct better representation learning for the other.

Recent efforts have demonstrated the use of primarily two different types of knowledge sources for TextWorld RL Agents. A **State Graph** (SG) captures state information (Ammanabrolu and Riedl, 2019) about the environment represented via a language-based semantic graph. The example in Figure 2 shows that information such as `Apple` →

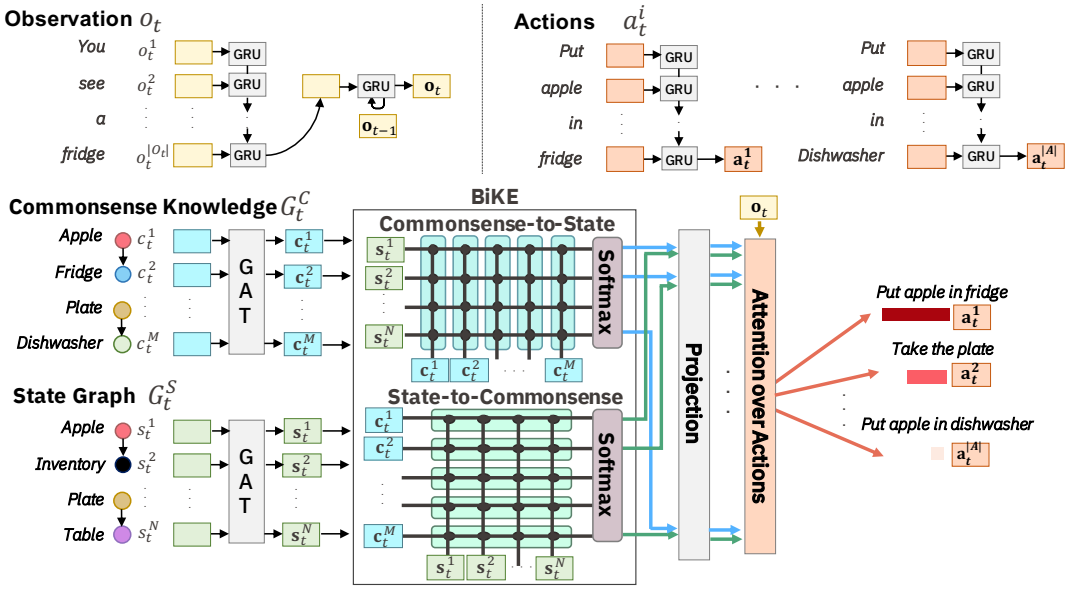

Figure 2: Visualization of our overall approach with BiKE

on → Table is extracted from the textual observations from the environment. Specifically, Ammanabrolu and Riedl (2019) create such knowledge graphs by extracting information using OpenIE (Angeli et al., 2015) and some manual heuristics. A **Commonsense Graph** (CG) captures external commonsense knowledge (Murugesan et al., 2021) between entities (from commonsense knowledge sources such as ConceptNet). We posit that RL agents can make use of information from both these graphs during different sub-tasks, enabling efficient learning. The SG provides the agent with a symbolic way of representing its current perception of the game state, including its understanding of the surroundings. On the other hand, the CG provides the agent with complementary human-like knowledge about what actions make sense in a given state, thus enabling more efficient exploration of the very large natural language based action space.

We combine the state information with commonsense knowledge using a **Bi**directional **K**nowledge-graph attEntion (**BiKE**) mechanism, which re-contextualizes the *state* and *commonsense* graphs based on each other for optimal action trajectories. Figure 2 provides a compact visualization.

4 Knowledge Integration using BiKE

The aforementioned graph-based knowledge extractor produces M entities $(c_t^1, c_t^2, \cdots, c_t^M)$ for the commonsense graph (CG); and N entities $(s_t^1, s_t^2, \cdots, s_t^N)$ for the state graph (SG). Note that the entities extracted for the CG are based on the vocabulary used in ConceptNet, and may not necessarily have the same set of entities as the SG (Figure 1). We embed the extracted entities in both graphs using *Numberbatch* (Liu and Singh, 2004). We then encode these graph representations using a Graph Attention Network (GAT) (Veličković et al., 2018). GAT allows the node entities s_t and c_t within the graphs G_t^S and G_t^C respectively to share information among each other by message passing.

We then integrate sub-graphs extracted from the previous steps to improve the agent's exploration strategy. Inspired from bidirectional attention mechanism in QA (Seo et al., 2016), we use BiKE attention mechanism between G_t^S and G_t^C to fuse the knowledge from these two graphs. The information flow across the graphs allows the model to learn commonsense-aware state graph representations, and state-aware commonsense knowledge graph representations.

To implement this, we compute a graph similarity matrix $\mathtt{S} \in \mathbb{R}^{N \times M}$ across the graph entities to learn a state-to-commonsense graph attention function and a commonsense-to-state graph attention function. $\mathtt{S}_{ij} = f(s_t^i, c_t^j)$ captures how each node s_t^i in the graph G_t^S is linked to a node c_t^j in the other graph G_t^C, and vice versa. Here f is a learnable function that maps s_t^i and c_t^j to a similarity score. This allows us to measure the similarity between (for instance) Apple observed in the state graph and Apple observed in the commonsense graph. We compute the state-to-commonsense graph attention values A by taking a softmax along the rows

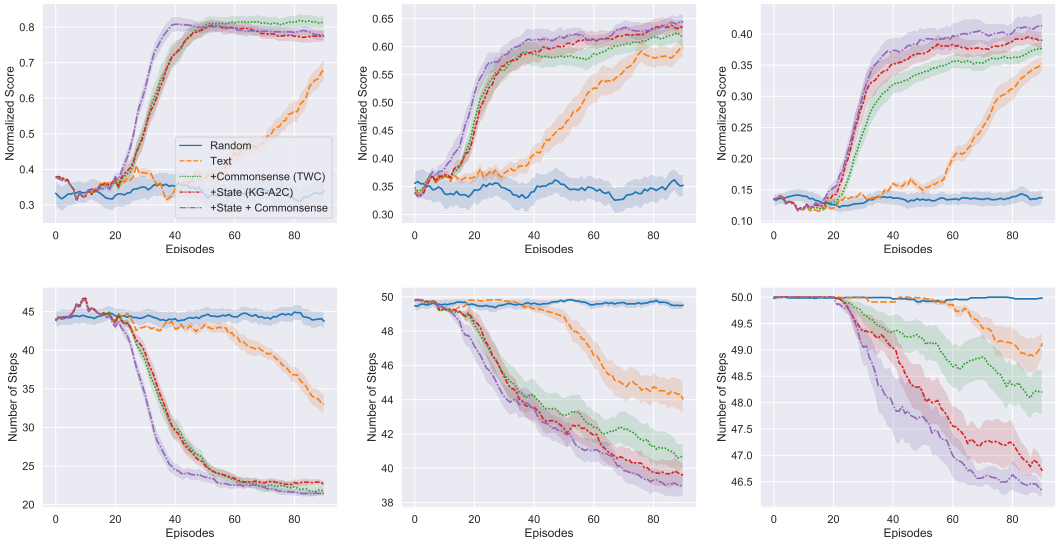

Figure 3: Performance evaluation (showing mean and standard deviation averaged over 3 runs) for the three difficulty levels: Easy (left), Medium (middle), Hard (right) using normalized score and the number of steps taken.

of S: this signifies the attention bestowed by each state graph node on the nodes of the commonsense graph. Similarly, we compute the commonsense-to-state graph attention values $\bar{A}$ by taking a softmax along the columns of S. We capture the relevant knowledge in the commonsense graph G_C^t by updating the state representations $\bar{s}_t^i$. We compute the updated state representation as: $s_{t+1}^i = g(s_t^i, \tilde{s}_t^i, \bar{s}_t^i)$; where $\tilde{s}_t^i = \sum_j A^{ij} c_t^j$, $\bar{s}_t^i = \sum_j A^{ij} \sum_{i'} \bar{A}^{ji'} s_t^{i'}$, and g is a learnable function that maps the concatenated s_t^i, $\tilde{s}_t^i$, and $\bar{s}_t^i$ to an updated state representation. Finally, we use the general attention between the o_t and the state graph entities s_{t+1} to get the state graph representation $\mathbf{g}_{t+1}^S$ (Luong et al., 2015). We perform a similar process for the commonsense-to-state graph attention and obtain the commonsense graph representation: $\mathbf{g}_{t+1}^C$. We select the relevant action by computing an attention over the actions: $h(o_t, a_t^i, \mathbf{g}_{t+1}^S, \mathbf{g}_{t+1}^C)$; where h is a learnable function that projects the concatenation $\langle\, o_t, a_t^i, \mathbf{g}_{t+1}^S, \mathbf{g}_{t+1}^C \,\rangle$ to the attention score for the i^{th} action.

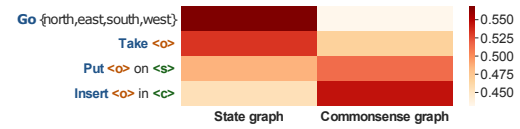
5 Experiments

We generate a set of games with 3 difficulty levels using the TWC (Murugesan et al., 2021) framework: (i) *easy* level, which has 1 room containing 1 to 3 objects; (ii) *medium* level, which has 1 or 2 rooms with 4 or 5 objects; and (iii) *hard* level, a mix of games with a high number of objects (6 or 7 objects in 1 or 2 rooms) or high number of rooms (3 or 4 rooms containing 4 or 5 objects).

We compare 5 text-based RL agents: (a) a text-only agent (**Text**), which selects the best action based only on the encoding of the history of observations; (b) **DRRN** (He et al., 2016; Narasimhan et al., 2015), which relies on the relevance between the observation and action spaces; (c) an agent enhanced with access to an external commonsense knowledge graph (**+Commonsense**) (Murugesan et al., 2021); (d) an agent that, following Ammanabrolu and Hausknecht (2020a), models the state of the world as a symbolic graph (**+State**); and (e) the agent (BiKE) described in Section 3, which relies on both state and commonsense graph representations. The agents are trained over 100 episodes with a 50-step maximum. All policies are learned using Actor-Critic (Mnih et al., 2016).

5.1 Improving Performance with State and Commonsense Knowledge

Figure 3 shows the learning curves for the text-only agent and the agents equipped with state and/or commonsense graph representations at training time. For reference, we also report the performance of an agent that selects a random action at each time step (**Random**). We notice that, overall, agents equipped with either state or commonsense graph representations perform better than their text-only counterparts, both in terms of the number of steps taken and the normalized score. In particular, the BiKE agent outperforms all other agents in all difficulty levels, showing that symbolic state representations and prior commonsense knowledge can be jointly used for better sample efficiency and results. Table 1 shows the performance of the agents on the test set. Following Murugesan et al. (2021), we



(a) Average relevance of the main action templates to the state and commonsense graphs across the *hard* games.

Timestep	t	$\rightarrow t+1$	$\rightarrow t+2$
Room	*Living Room*	→ *Living Room*	→ *Bedroom*
Action Taken	take checkered jumper	→ go west	→ insert checkered jumper into wardrobe
Most relevant graph	*State graph*	*State graph*	*Commonsense graph*
Most relevant nodes	checkered jumper	checkered jumper, exit to west	wardrobe

(b) Example of most relevant graphs and nodes (by action taken) for one example game excerpted from the *hard* difficulty level.

Figure 4: Relevance given to the: (a) state and commonsense graphs; and to (b) their nodes (by action taken).

Table 1: Test-set performance results for within distribution (*IN*) and out-of-distribution (*OUT*) games.

compared our agents on two test sets: (**IN**) uses the same entities as the training set, and (**OUT**) uses entities that were not included in the training set. The experimental results show that the BiKE agent generalizes better than all the baselines across the 3 difficulty levels.

5.2 Qualitative Analysis

From Figure 3 and Table 1, we notice that the **+Commonsense** agent performs better on the *easy* level, whereas the **+State** agent performs better on the *medium* and *hard* levels. This suggests that the state representation can be leveraged to drive exploration and interaction with objects in environments with multiple rooms; whereas prior commonsense knowledge allows the agent to act more efficiently by selecting the appropriate commonsensical locations of different objects. In order to investigate this hypothesis, we computed the average importance given by the agent to the state graph and the commonsense graph when selecting the different action templates shown in Figure 4a. For each action template, the figure shows the normalized attention weight given to the two graphs, averaged across 5 runs of all games in the *hard* difficulty level. Actions requiring information about the goal of the game, like `put` and `insert`, benefit more from attending to the commonsense graph; whereas actions aimed at exploring the environment and collecting objects, like `go` and `take`, benefit more from the state representation.

As further qualitative analysis, we report an example of the most attended nodes and graphs from an excerpt of a game belonging to the *hard* difficulty level in Figure 4b. As noted above, the `take` and `go` actions rely more on the state graph, whereas the `insert` action relies on the commonsense graph. Among the nodes in these graphs, the entities that are finally mentioned in the action receive the highest attention score. This shows how our agent is able to transfer the bidirectional attention over graphs into specific game instances.

6 Conclusion

In this paper, we showed that in order to be sample-efficient in TBGs, agents must be able to jointly track the state of the game and relevant commonsense knowledge. We proposed a technique that models both forms of knowledge as graphs, and combines them using Bidirectional Knowledge-graph attEntion (BiKE). The resulting agent was found to be more sample-efficient than approaches that considered neither or only one of these graphs.

Broader Impact and Discussion of Ethics

While our model is not tuned for any specific real-world application, our method could be used in sensitive contexts such as legal or health-care settings; and it is essential that any work that builds on our approach undertake extensive quality-assurance and robustness testing before using it in their setting. The dataset used in our work does not contain sensitive information to the best of our knowledge.

MTVR: Multilingual Moment Retrieval in Videos

Jie Lei **Tamara L. Berg** **Mohit Bansal**
Department of Computer Science
University of North Carolina at Chapel Hill
{jielei, tlberg, mbansal}@cs.unc.edu

Abstract

We introduce MTVR, a large-scale multilingual video moment retrieval dataset, containing 218K English and Chinese queries from 21.8K TV show video clips. The dataset is collected by extending the popular TVR dataset (in English) with paired Chinese queries and subtitles. Compared to existing moment retrieval datasets, MTVR is multilingual, larger, and comes with diverse annotations. We further propose mXML, a multilingual moment retrieval model that learns and operates on data from both languages, via encoder parameter sharing and language neighborhood constraints. We demonstrate the effectiveness of mXML on the newly collected MTVR dataset, where mXML outperforms strong monolingual baselines while using fewer parameters. In addition, we also provide detailed dataset analyses and model ablations. Data and code are publicly available at https://github.com/jayleicn/mTVRetrieval

1 Introduction

The number of videos available online is growing at an unprecedented speed. Recent work (Escorcia et al., 2019; Lei et al., 2020) introduced the Video Corpus Moment Retrieval (VCMR) task: given a natural language query, a system needs to retrieve a short moment from a large video corpus. Figure 1 shows a VCMR example. Compared to the standard text-to-video retrieval task (Xu et al., 2016; Yu et al., 2018), it allows more fine-grained moment-level retrieval, as it requires the system to not only retrieve the most relevant videos, but also localize the most relevant moments inside these videos. Various datasets (Krishna et al., 2017; Hendricks et al., 2017; Gao et al., 2017; Lei et al., 2020) have been proposed or adapted for the task. However, they are all created for a single language (English), though the application could be useful for users speaking other languages as well. Besides, it is also unclear whether the progress and findings in one language generalizes to another language (Bender, 2009). While there are multiple existing multilingual image datasets (Gao et al., 2015; Elliott et al., 2016; Shimizu et al., 2018; Pappas et al., 2016; Lan et al., 2017; Li et al., 2019), the availability of multilingual video datasets (Wang et al., 2019a; Chen and Dolan, 2011) is still limited.

Figure 1: A MTVR example in the Video Corpus Moment Retrieval (VCMR) task. Ground truth moment is shown in *green* box. Colors in the query text indicate whether the words are more related to video (orchid) or subtitle (salmon) or both (orange). The query and the subtitle text are presented in both English and Chinese. The video corpus typically contains thousands of videos, for brevity, we only show 3 videos here.

Therefore, we introduce MTVR, a large-scale, multilingual moment retrieval dataset, with 218K human-annotated natural language queries in two

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 726–734

languages, English and Chinese. MTVR extends the TVR (Lei et al., 2020) dataset by collecting paired Chinese queries and Chinese subtitle text (see Figure 1). We choose TVR over other moment retrieval datasets (Krishna et al., 2017; Hendricks et al., 2017; Gao et al., 2017) because TVR is the largest moment retrieval dataset, and also has the advantage of having dialogues (in the form of subtitle text) as additional context for retrieval, in contrast to pure video context in the other datasets. We further propose mXML, a compact, multilingual model that learns jointly from both English and Chinese data for moment retrieval. Specifically, on top of the state-of-the-art monolingual moment retrieval model XML (Lei et al., 2020), we enforce encoder parameter sharing (Sachan and Neubig, 2018; Dong et al., 2015) where the queries and subtitles from the two languages are encoded using shared encoders. We also incorporate a language neighborhood constraint (Wang et al., 2018; Kim et al., 2020) to the output query and subtitle embeddings. It encourages sentences of the same meaning in different languages to lie close to each other in the embedding space. Compared to separately trained monolingual models, mXML substantially reduces the total model size while improving retrieval performance (over monolingual models) as we show in Section 4. Detailed dataset analyses and model ablations are provided.

2 Dataset

The TVR (Lei et al., 2020) dataset contains 108,965 high-quality English queries from 21,793 videos from 6 long-running TV shows (provided by TVQA (Lei et al., 2018)). The videos are associated with English dialogues in the form of subtitle text. MTVR extends this dataset with translated dialogues and queries in Chinese to support multilingual multimodal research.

2.1 Data Collection

Dialogue Subtitles. We crawl fan translated Chinese subtitles from subtitle sites.[1] All subtitles are manually checked by the authors to ensure they are of good quality and are aligned with the videos. The original English subtitles come with speaker names from transcripts that we map to the Chinese subtitles, to ensure that the Chinese subtitles have the same amount of information as the English version.

[1] https://subhd.tv, http://zimuku.la

QType (%)	Query Examples (in English and Chinese)
video-only (74.2)	Howard places his plate onto the coffee table. 霍华德将盘子放在咖啡桌子上。
sub-only (9.1)	Alexis and Castle talk about the timeline of the murder. 亚历克西斯和卡塞尔谈论谋杀的时间顺序。
video+sub (16.6)	Joey waives his hand when he asks for his food. 乔伊催餐时摆了摆手。

Table 1: MTVR English and Chinese query examples in different query types. The percentage of the queries in each query type is shown in brackets.

Query. To obtain Chinese queries, we hire human translators from Amazon Mechanical Turk (AMT). Each AMT worker is asked to write a Chinese translation of a given English query. Languages are ambiguous, hence we also present the original videos to the workers at the time of translation to help clarify query meaning via spatio-temporal visual grounding. The Chinese translations are required to have the exact same meaning as the original English queries and the translation should be made based on the aligned video content. To facilitate the translation process, we provide machine translated Chinese queries from Google Cloud Translation[2] as references, similar to (Wang et al., 2019b). To find qualified bilingual workers in AMT, we created a qualification test with 5 multiple-choice questions designed to evaluate workers' Chinese language proficiency and their ability to perform our translation task. We only allow workers that correctly answer all 5 questions to participate our annotation task. In total, 99 workers finished the test and 44 passed, earning our qualification. To further ensure data quality, we also manually inspect the submitted results during the annotation process and disqualify workers with poor annotations. We pay workers $0.24 every three sentences, this results in an average hourly pay of $8.70. The whole annotation process took about 3 months and cost approximately $12,000.00.

2.2 Data Analysis

In Table 2, we compare the average sentence lengths and the number of unique words under different part-of-speech (POS) tags, between the two languages, English and Chinese, and between query and subtitle text. For both languages, dialogue subtitles are linguistically more diverse than queries, i.e., they have more unique words in all

[2] https://cloud.google.com/translate

Data	Avg Len	#unique words by POS tags				
		all	verb	noun	adj.	adv.
English						
Q	13.45	15,201	3,015	7,143	2,290	763
Sub	10.78	49,325	6,441	19,223	7,504	1,740
Q+Sub	11.27	52,545	7,151	20,689	8,021	1,976
Chinese						
Q	12.55	34,752	12,773	18,706	1,415	1,669
Sub	9.04	101,018	36,810	53736	4,958	5,568
Q+Sub	9.67	117,448	42,284	62,611	5,505	6,185

Table 2: Comparison of English and Chinese data in MTVR. We show average sentence length, and number of unique tokens by POS tags, for Query (*Q*) and or Subtitle (*Sub*).

categories. This is potentially because the language used in subtitles are unconstrained human dialogues while the queries are collected as declarative sentences referring to specific moments in videos (Lei et al., 2020). Comparing the two languages, the Chinese data is typically more diverse than the English data.[3] In Table 1, we show English and their translated Chinese query examples in Table 1, by query type. In the appendix, we compare MTVR with existing video and language datasets.

3 Method

Our multilingual moment retrieval model mXML is built on top of the Cross-model Moment Localization (XML) (Lei et al., 2020) model, which performs efficient video-level retrieval at its shallow layers and accurate moment-level retrieval at its deep layers. To adapt the monolingual XML model into the multilingual setting in MTVR and improve its efficiency and effectiveness, we apply encoder parameter sharing and neighborhood constraints (Wang et al., 2018; Kim et al., 2020) which encourages the model to better utilize multilingual data to improve monolingual task performance while maintaining smaller model size.

Query and Context Representations. We represent videos using ResNet-152 (He et al., 2016) and I3D (Carreira and Zisserman, 2017) features extracted every 1.5 seconds. We extract language features using pre-trained, then finetuned (on our queries and subtitles) RoBERTa-base (Liu et al., 2019), for English (Liu et al., 2019) and Chinese (Cui et al., 2020), respectively. For queries, we use token-level features. For subtitles, we max-pool the token-level features every 1.5 seconds to align with the video features. We then project the extracted features into a low-dimensional space via a linear layer, and add learned positional encoding (Devlin et al., 2018) after the projection. We denote the resulting video features as $E^v \in \mathbb{R}^{l\times d}$, subtitle features as $E^s_{en} \in \mathbb{R}^{l\times d}$, $E^s_{zh} \in \mathbb{R}^{l\times d}$, and query features as $E^q_{en} \in \mathbb{R}^{l_q\times d}$, $E^q_{zh} \in \mathbb{R}^{l_q\times d}$. l is video length, l_q is query length, and d is hidden size. The subscripts en and zh denote English and Chinese text features, respectively.

[3] The differences might be due to the different morphemes in the languages. E.g., the Chinese word 长发 ('long hair') is labeled as a single noun, but as an adjective ('long') and a noun ('hair') in English (Wang et al., 2019b).

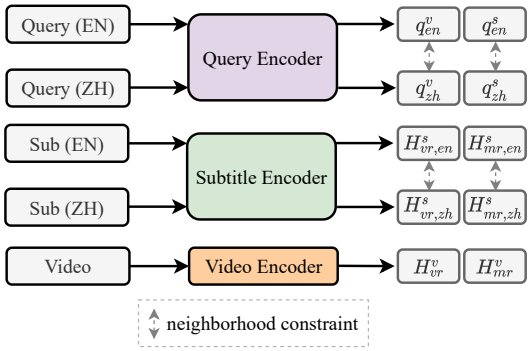

Figure 2: Illustration of mXML's encoding process. Compared to monolingual models, mXML learns from the two languages simultaneously, and allows them to benefit each other via *encoder parameter sharing* and *neighborhood constraints*. We show the detailed encoding process of the model in the appendix (Figure 3).

Encoders and Parameter Sharing. We follow Lei et al. (2020) to use *Self-Encoder* as our main component for query and context encoding. A Self-Encoder consists of a self-attention (Vaswani et al., 2017) layer, a linear layer, and a residual (He et al., 2016) connection followed by layer normalization (Ba et al., 2016). We use a Self-Encoder followed by a modular attention (Lei et al., 2020) to encode each query into two modularized query vectors $\boldsymbol{q}^v_{lang}, \boldsymbol{q}^s_{lang} \in \mathbb{R}^d$ $(lang \in \{en, zh\})$ for video and subtitle retrieval, respectively. For videos, we apply two Self-Encoders instead of a Self-Encoder and a Cross-Encoder as in XML, because we found this modification simplifies the implementation while maintains the performance. We use the outputs from the first and the second Self-Encoder $H^v_{vr,lang}, H^v_{mr,lang} \in \mathbb{R}^{l\times d}$ for video retrieval and moment retrieval. Similarly, we have $H^s_{vr,lang}, H^s_{mr,lang} \in \mathbb{R}^{l\times d}$ for subtitles. All the Self-Encoders are shared across languages, e.g., we use the same Self-Encoder to encode both English and Chinese queries, as illustrated in Figure 2. This parameter sharing strategy greatly reduces the

model size while maintaining or even improving model performance, as we show in Section 4.

Language Neighborhood Constraint. To facilitate stronger multilingual learning, we add neighborhood constraints (Wang et al., 2018; Kim et al., 2020; Burns et al., 2020) to the model. This encourages sentences that express the same or similar meanings to lie close to each other in the embedding space, via a triplet loss. Given paired sentence embeddings $\boldsymbol{e}^i_{en} \in \mathbb{R}^d$ and $\boldsymbol{e}^i_{zh} \in \mathbb{R}^d$, we sample negative sentence embeddings $\boldsymbol{e}^j_{en} \in \mathbb{R}^d$ and $\boldsymbol{e}^k_{zh} \in \mathbb{R}^d$ from the same mini-batch, where $i \neq j, i \neq k$. We use cosine similarity function $\mathcal{S}$ to measure the similarity between embeddings. Our language neighborhood constraint can be formulated as:

$$\mathcal{L}_{nc}=\frac{1}{n}\sum_i[\max(0,\mathcal{S}(\boldsymbol{e}^i_{en},\boldsymbol{e}^k_{zh})-\mathcal{S}(\boldsymbol{e}^i_{en},\boldsymbol{e}^i_{zh})+\Delta) + \max(0,\mathcal{S}(\boldsymbol{e}^j_{en},\boldsymbol{e}^i_{zh})-\mathcal{S}(\boldsymbol{e}^i_{en},\boldsymbol{e}^i_{zh})+\Delta)], \quad (1)$$

where Δ=0.2 is the margin. We apply this constraint on both query and subtitle embeddings, across the two languages, as illustrated in Figure 2. For queries, we directly apply it on the query vectors $\boldsymbol{q}^v_{lang}, \boldsymbol{q}^s_{lang}$. For the subtitle embeddings, we apply it on the embeddings $H^s_{vr,lang}, H^s_{mr,lang}$, after max-pooling them in the temporal dimension.

Training and Inference. During training, we optimize video retrieval scores with a triplet loss, and moment scores with a cross-entropy loss. At inference, these two scores are aggregated together as the final score for video corpus moment retrieval. See appendix for details.

4 Experiments and Results

We evaluate our proposed mXML model on the newly collected MTVR dataset, and compare it with several existing monolingual baselines. We also provide ablation studies evaluating our model design and the importance of each input modality (videos and subtitles).

Data Splits and Evaluation Metrics. We follow TVR (Lei et al., 2020) to split the data into 80% *train*, 10% *val*, 5% *test-public* and 5% *test-private*. We report average recall (R@1) on the Video Corpus Moment Retrieval (VCMR) task. A predicted moment is correct if it has high Intersection-over-Union (IoU) with the ground-truth.

Baseline Comparison. In Table 3, we compare mXML with multiple baseline approaches. Given a natural language query, the goal of video corpus moment retrieval is to retrieve relevant moments from a large video corpus. The methods for this task can be grouped into two categories, (*i*) proposal based approaches (MCN (Hendricks et al., 2017) and CAL (Escorcia et al., 2019)), where they perform video retrieval on the pre-segmented moments from the videos; (*ii*) retrieval+re-ranking methods (MEE (Miech et al., 2018)+MCN, MEE+CAL, MEE+ExCL (Ghosh et al., 2019) and XML (Lei et al., 2020)), where one approach is first used to retrieve a set of videos, then another approach is used to re-rank the moments inside these retrieved videos to get the final moments. Our method mXML also belongs to the retrieval+re-ranking category. Across all metrics and both languages, we notice retrieval+re-ranking approaches achieve better performance than proposal based approaches, indicating that retrieval+re-ranking is potentially better suited for the VCMR task. Meanwhile, our mXML outperforms the strong baseline XML significantly[4] while using few parameters. XML is a monolingual model, where a separate model is trained for each language. In contrast, mXML is multilingual, trained on both languages simultaneously, with parameter sharing and language neighborhood constraints to encourage multilingual learning. mXML prediction examples are provided in the appendix.

Method	#param	English R@1		Chinese R@1	
		IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
Chance	-	0.00	0.00	0.00	0.00
Proposal based					
MCN	6.4M	0.02	0.00	0.13	0.02
CAL	6.4M	0.09	0.04	0.11	0.04
Retrieval + Re-ranking					
MEE+MCN	10.4M	0.92	0.42	1.43	0.64
MEE+CAL	10.4M	0.97	0.39	1.51	0.62
MEE+ExCL	10.0M	0.92	0.33	1.43	0.72
XML	6.4M	7.25	3.25	5.91	2.57
mXML	**4.5M**	**8.30**	**3.82**	**6.76**	**3.20**

Table 3: Baseline comparison on MTVR *test-public* split. mXML achieves better retrieval performance on both languages while using fewer parameters.

Ablations on Model Design. In Table 4, we present our ablation study on mXML. We use '*Baseline*' to denote the mXML model without parameter sharing and neighborhood constraint. Shar-

[4]Statistically significant with p<0.01. We use bootstrap test (Efron and Tibshirani, 1994; Noreen, 1989).

Method	#param	English R@1		Chinese R@1	
		IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
Baseline	6.4M	5.77	2.63	4.7	2.38
+ Share Enc.	**4.5M**	6.09	2.85	4.72	2.25
+ NC (mXML)	**4.5M**	**6.22**	**2.96**	**5.17**	**2.41**

Table 4: mXML ablation study on MTVR *val* split. *Share Enc.* = encoder parameter sharing, *NC* = Neighborhood Constraint. Each row adds an extra component to the row above it.

Model Type	English R@1		Chinese R@1	
	IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
Query type: video				
Baseline	5.46	2.53	4.78	2.47
mXML	5.77	2.67	5.14	2.32
Query type: subtitle				
Baseline	4.15	1.97	3.11	1.14
mXML	6.12	3.32	4.05	1.87
Query type: video+subtitle				
baseline	8.02	3.38	5.18	2.62
mXML	8.29	4.09	5.89	3.11

Table 5: Comparison of mXML and the baseline on MTVR *val* set, with breakdown on query types. Both models are trained with video and subtitle as inputs.

ing encoder parameter across languages greatly reduces #parameters while maintaining (Chinese) or even improving (English) model performance. Adding neighborhood constraint does not introduce any new parameters but brings a notable ($p<0.06$) performance gain to both languages. We hypothesize that this is because the learned information in the embeddings of the two languages are complementary (though the sentences in the two languages express the same meaning, their language encoders (Liu et al., 2019; Cui et al., 2020)) are pre-trained differently, which may lead to different meanings at the embedding level. In Table 5, we show a detailed comparison between mXML and its baseline version, by query types. Overall, we notice the mXML perform similarly with *Baseline* in '*video*' queries, but shows a significant performance gain in '*subtitle*' queries, suggesting the parameter sharing and neighborhood constraint are more useful for queries that need more language understanding.

Ablations on Input Modalities. In Table 6, we compare mXML variants with different context inputs, i.e., video or subtitle or both. We report their performance under the three annotated query types, *video*, *sub* and *video+sub*. Overall, the model with both video and subtitle as inputs perform the best. The video model performs much better on the *video* queries than on the *sub* queries, while the subtitle model achieves higher scores on the *sub* queries than the *video* queries.

QType (percentage)	English R@1		Chinese R@1	
	IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
Model input: video				
video (74.32%)	4.12	1.89	3.73	1.86
sub (8.85%)	1.97	1.24	1.35	1.04
video+sub (16.83%)	2.67	1.2	2.45	1.15
Model input: subtitle				
video	1.35	0.62	1.11	0.51
sub	6.33	2.9	4.15	1.97
video+sub	6.22	2.62	4.2	2.13

video	5.77	2.67	5.14	2.32
sub	6.12	3.32	4.05	1.87
video+sub	8.29	4.09	5.89	3.11

Table 6: mXML performance breakdown on MTVR *val* set by query types, with different inputs.

In the appendix, we also present results on '*generalization to unseen TV shows*' setup.

5 Conclusion

In this work, we collect MTVR, a new large-scale, multilingual moment retrieval dataset. It contains 218K queries in English and in Chinese from 21.8K video clips from 6 TV shows. We also propose a multilingual moment retrieval model mXML as a strong baseline for the MTVR dataset. We show in experiments that mXML outperforms monolingual models while using fewer parameters.

A Appendix

Data Analysis. In Table 8 we show a comparison of MTVR with existing moment retrieval datasets and related video and language datasets. Compared to other moment retrieval datasets, MTVR is significantly larger in scale, and comes with query type annotations that allows in-depth analyses for the models trained on it. Besides, it is also the only moment retrieval dataset with multilingual annotations, which is vital in studying the moment retrieval problem under the multilingual context. Compared to the existing multilingual video and language datasets, MTVR is unique as it has a more diverse set of context and annotations, i.e., dialogue, query type, and timestamps.

Training and Inference Details. In Figure 3 we show an overview of the mXML model. We compute video retrieval score as:

$$s^{vr} = \frac{1}{2} \sum_{m \in \{v,s\}} \max\left(\frac{H^m_{vr}}{\|H^m_{vr}\|} \frac{\boldsymbol{q}^m}{\|\boldsymbol{q}^m\|}\right). \quad (2)$$

	English R@1		Chinese R@1	
Setting	IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
unseen	1.68	0.79	1	0.54
seen	4.82	2.79	4.18	2.32

Table 7: mXML performance on the MTVR val split *Friends* examples, in both *unseen* and *seen* settings.

The subscript $lang \in \{en, zh\}$ is omitted for simplicity. It is optimized using a triplet loss similar to main text Equation (1). For moment retrieval, we first compute the query-clip similarity scores $S^{q,c} \in \mathbb{R}^l$ as:

$$S^{q,c} = \frac{1}{2}(H^s_{mr}\boldsymbol{q}^s + H^v_{mr}\boldsymbol{q}^v). \quad (3)$$

Next, we apply Convolutional Start-End Detector (ConvSE module) (Lei et al., 2020) to obtain start, end probabilities $P_{st}, P_{ed} \in \mathbb{R}^l$. These scores are optimized using a cross-entropy loss. The single video moment retrieval score for moment $[t_{st}, t_{ed}]$ is computed as:

$$s^{mr}(t_{st}, t_{ed}) = P_{st}(t_{st})P_{ed}(t_{ed}),\ t_{st} \leq t_{ed}. \quad (4)$$

Given a query q_i, the retrieval score for moment [t_{st}:t_{ed}] in video v_j is computed following the aggregation function as in (Lei et al., 2020):

$$s^{vcmr}(v_j, t_{st}, t_{ed}|q_i) = s^{mr}(t_{st}, t_{ed})\exp(\alpha s^{vr}(v_j|q_i)), \quad (5)$$

where α=20 is used to assign higher weight to the video retrieval scores. The overall loss is a simple summation of video and moment retrieval loss across the two languages, and the language neighborhood constraint loss.

Implementation Details. mXML is implemented in PyTorch (Paszke et al., 2017). We use Adam (Kingma and Ba, 2014) with initial learning rate 1e-4, β_1=0.9, β_2=0.999, L2 weight decay 0.01, learning rate warm-up over the first 5 epochs. We train mXML for at most 100 epochs at batch size 128, with early stop based on the sum of R@1 (IoU=0.7) scores for English and Chinese. The experiments are conducted on a NVIDIA RTX 2080Ti GPU. Each run takes around 7 hours.

Generalization to Unseen TV shows. To investigate whether the learned model can be transferred to other TV shows, we conduct an experiment by using the TV show '*Friends*' as an '*unseen*' TV

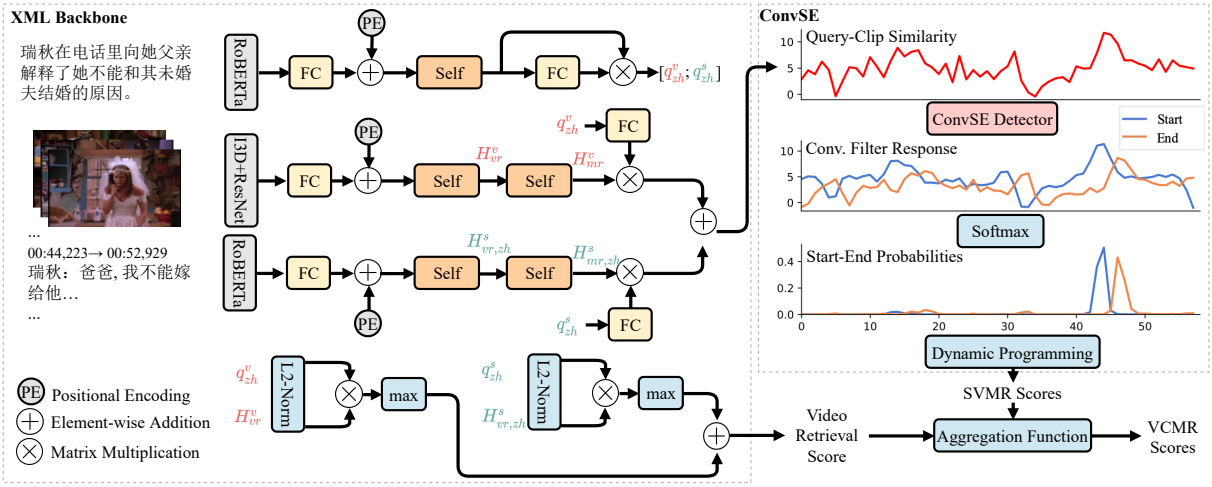

Figure 3: mXML overview. For brevity, we only show the modeling process for a single language (Chinese). The cross-language modifications, i.e., parameter sharing and neighborhood constraint are illustrated in Figure 2. This figure is edited from the Figure 4 in (Lei et al., 2020).

show for testing, and train the model on all the other 5 TV shows. For comparison, we also include a model trained on '*seen*' setting, where we use all the 6 TV shows including *Friends* for training. To ensure the models on these two settings are trained on the same number of examples, we downsample the examples in the *seen* setting to match the *unseen* setting. The results are shown in Table 7. We notice our mXML achieves a reasonable performance even though it does see a single example from the TV show *Friends*. Meanwhile, the gap between *unseen* and *seen* settings are still large, we encourage future work to further explore this direction.

Prediction Examples We show mXML prediction examples in Figure 4. We show both Chinese (*top*) and English (*bottom*) prediction examples, and correct (*left*) and incorrect (*right*) examples.

Explicitly Capturing Relations between Entity Mentions via Graph Neural Networks for Domain-specific Named Entity Recognition

Abstract

Named entity recognition (NER) is well studied for the general domain, and recent systems have achieved human-level performance for identifying common entity types. However, the NER performance is still moderate for specialized domains that tend to feature complicated contexts and jargonistic entity types. To address these challenges, we propose explicitly connecting entity mentions based on both global coreference relations and local dependency relations for building better entity mention representations. In our experiments, we incorporate entity mention relations by Graph Neural Networks and show that our system noticeably improves the NER performance on two datasets from different domains. We further show that the proposed lightweight system can effectively elevate the NER performance to a higher level even when only a tiny amount of labeled data is available, which is desirable for domain-specific NER.[1]

1 Introduction

Named entity recognition (NER) has been well studied for the general domain, and recent systems have achieved close to human-level performance for identifying a small number of common NER types, such as *Person* and *Organization*, mainly benefiting from the use of Neural Network models (Ma and Hovy, 2016; Yang and Zhang, 2018) and pretrained Language Models (LMs) (Akbik et al., 2018; Devlin et al., 2019). However, the performance is still moderate for specialized domains that tend to feature diverse and complicated contexts as well as a richer set of semantically related entity types (e.g., *Cell*, *Tissue*, *Organ* etc. for the biomedical domain). With these challenges in view, we hypothesize that being aware of the re-occurrences of the same entity as well as semantically related entities will lead to better NER performance for specific domains.

Therefore, we propose to explicitly connect entity mentions in a document that are coreferential or in a tight semantic relation to better learn entity mention representations. Precisely, as shown in Figure 1, we first connect repeated mentions of the same entity even if they are sentences away. For example, the named entity "tumor vasculature" appears both in the *Title* and sentence *S6* but in quite different contexts. Connecting the repeated mentions in a document enables the integration of contextual cues as well as enables consistent predictions of their entity types.

Second, we also connect entity mentions based on sentence-level dependency relations to effectively identify semantically related entities. For example, the two entities in sentence *S3*, "bone marrow" of the type *Multi-tissue Structure* and "endothelial progenitors" of the type *Cell*, are the subject and object of the predicate "contains" respectively in the dependency tree. If the system can reliably predict the type of one entity, we can infer the type of the other entity more easily, knowing that they are closely related on the dependency tree.

We incorporate both relations by using Graph Neural Networks (GNNs), specifically, we use the Graph Attention Networks (GATs) (Velickovic et al., 2018) that have been shown effective for a range of tasks (Sui et al., 2019; Linmei et al., 2019). Empirical results show that our lightweight method can learn better word representations for sequence tagging models and further improve the NER performance over strong LMs-based baselines on two datasets, the AnatEM (Pyysalo and Ananiadou, 2014) dataset from the biomedical domain and the Mars (Wagstaff et al., 2018) dataset from the planetary science domain. In addition, considering the lack of annotations challenge for

[1]The code for the system is available here: https://github.com/brickee/EnRel-G

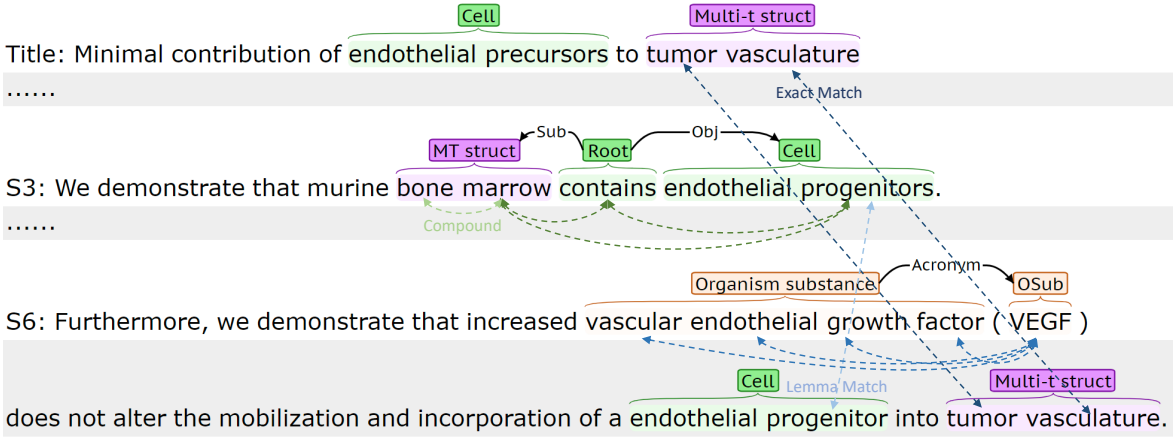

Figure 1: An example of NER with both discourse-level and sentence-level entity relations.

domain-specific NER, we plot learning curves and show that leveraging relations between entity mentions can effectively and consistently improve the NER performance when limited annotations are available.

2 Related Work

NER research has a long history and recent approaches (Yang and Zhang, 2018; Jiang et al., 2019; Jie and Lu, 2019; Li et al., 2020) using Neural Network models like BiLSTM-CNN-CRF (Ma and Hovy, 2016) and contextual embeddings such as BERT (Devlin et al., 2019) and FLAIR (Akbik et al., 2018) have improved the NER performance in the general domain to the human-level. However, the NER performance for specific domains is still moderate due to the challenges of limited annotations and dealing with complicated domain-specific contexts.

We aim to further improve NER performance by considering coreference relations and semantic relations between entity mentions. This is in contrast to the usual way of thinking about NER as an up-stream task conducted before coreference resolution or entity relation extraction. The idea aligns with recent works that conduct joint inferences among multiple information extraction tasks (Miwa and Bansal, 2016; Li et al., 2017; Bekoulis et al., 2018; Luan et al., 2019; Sui et al., 2020; Yuan et al., 2020), including NER, coreference resolution and relation extraction, by mining dependencies among the extractions. However, joint inference approaches require annotations for all the target tasks and aim to improve performance for all the tasks as well, while our lightweight approach aims to improve the performance of the basic NER task requiring no additional annotations (usually unavailable for specific domains).

Our approach is also related to several recent neural approaches for NER that encourage label dependencies among entity mentions. The Pooled FLAIR model (Akbik et al., 2019) proposed a global pooling mechanism to learn word representations. Dai et al. (2019) used a coreference layer with a regularizer to harmonize word representations. Closely related to our work, Qian et al. (2019) used graph neural nets to capture repetitions of the same word as well, but in a denser graph that includes edges between adjacent words and is meant to completely overlay the lower encoding layers. Memory networks (Gui et al., 2020; Luo et al., 2020) were also used to store and refine predictions of a base model by considering repetitions or co-occurrences of words. In addition, dependency relations have been commonly used to connect entities for relation extraction (Zhang et al., 2018; Bunescu and Mooney, 2005), but we aim to better infer the type of an entity by associating it with other closely related entities in a sentence.

3 Model Architecture

Our system with Entity Relation Graphs (EnRelG) mainly contains 5 layers as in Figure 2: an embedding layer, an encoding layer, a GNNs layer, a fusion layer, and a decoding layer.

3.1 Embedding Layer

We choose the BERT-base LM as our embedding layer. For domain-specific datasets, we use BioBERT (Lee et al., 2020) for the biomedical domain and SciBERT (Beltagy et al., 2019) for the planetary science domain. Specifically, for an input

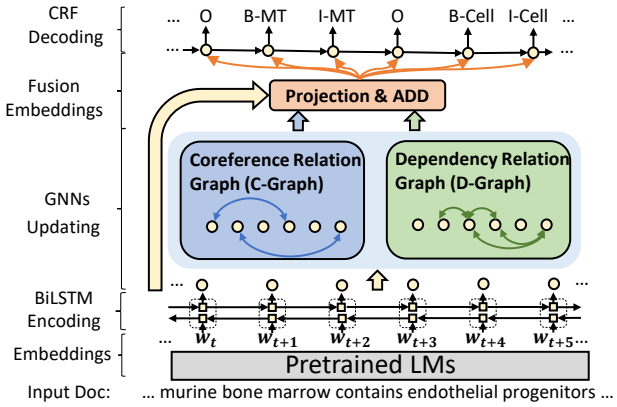

Figure 2: Overall Architecture of the EnRel-G system

document $D = [w_1, w_2, ..., w_n]$ with n words, the BERT model will output a contextual word embeddings matrix $\boldsymbol{E} = [\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_n] \in \mathbb{R}^{n \times d_1}$ with a d_1 dimension vector for each word.

3.2 Encoding Layer

To capture the sequential context information, we use a BiLSTM layer to encode the word embeddings from the BERT model. We concatenate the forward and backward LSTM hidden states as the encoded representations and then obtain embedding matrix $\boldsymbol{E}^{lstm} = BiLSTM(\boldsymbol{E}) \in \mathbb{R}^{n \times d_2}$ with a d_2 dimension vector for each word.

3.3 Graph Neural Networks Layer

For the GNNs layer, we first introduce how to build Entity Relation Graphs using global coreference relations (coreference graph, C-graph) and local dependency relations (dependency graph, D-graph) between entities, and then describe how the GNNs model incorporates them into the word representations.

Coreference Relation Graph For each document, we build a graph $G^C = (\mathcal{V}, \mathcal{A}^C)$ based on coreference relations, in which $\mathcal{V}$ is a set of nodes denoting all the words in a document and $\mathcal{A}^C$ is the adjacency matrix. Specifically, we approximate the entity coreference relations using 3 syntactic coreference clues as in Figure 1: (1) *Exact Match*, two nouns are connected if they are the same, e.g., "tumor vasculature" in both the *Title* and *S6*; (2) *Lemma Match*, two nouns are linked together if they have the same lemma, e.g., "progenitors" and "progenitor" in the *S3* and *S6*; (3) *Acronym Match*, the acronym word is connected to all full expression words, e.g., "VEGF" and "vascular endothelial growth factor" in the *S6*. For each connected node pair (i, j), we set $\mathcal{A}^C_{i,j} = 1$. We also add a self-connection to each node ($\mathcal{A}^C_{i,i} = 1$) to maintain the words' original semantic information.

Dependency Relation Graph We build a Dependency Relation Graphs $G^D = (\mathcal{V}, \mathcal{A}^D)$ for each document based on sentence-level dependency relations. We first parse each sentence using the scispaCy[2] tool and then connect the following word pairs in the dependency tree: (1) *subject head word & object head word & their predicate*, we connect them to enhance the interactions between the entities from the subject and object. e.g., "marrow" and "progenitors" with the predicate "contains" in the *S3*; (2) *compound & head word*, we connect the compounds with their head words because they often both exist in an entity. e.g., the "bone" and "marrow" in the *S3*. Same as before, We set $\mathcal{A}^D_{i,j} = 1$ for each connect pair (i, j), and also add self-connection ($\mathcal{A}^D_{i,i} = 1$) for each node.

Then we update the encoded word embeddings with the entity relations graphs based on GNNs, particularly the GATs. Since nodes represent the words in a document, we initialize the node representations in the graphs from the encoding layer as $\boldsymbol{E}^{lstm} = [\boldsymbol{w}^{lstm}_1, \boldsymbol{w}^{lstm}_2, ..., \boldsymbol{w}^{lstm}_n]$. The graph attention mechanism updates the initial representation of node $\boldsymbol{w}^{lstm}_i$ to $\boldsymbol{w}^{gnn}_i$ by aggregating its neighbors' representations with their corresponding normalized attention scores.

$$\boldsymbol{w}^{gnn}_i = \Big\Vert_{k=1}^{K} \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha^k_{ij} W^k \boldsymbol{w}^{lstm}_j\right) \tag{1}$$

As in equation (1), and we have K attention heads and concatenate ($\|$) them as the final representation. For head k, we weighted all the adjacent nodes ($\mathcal{N}_i$, obtained from the adjacent matrix $\mathcal{A}$) by W^k and and then aggregate them with the attention score α^k_{ij}. σ is the activation function LeakyReLU. The attention score α^k_{ij} is obtained as followed ($\boldsymbol{a}^T$ is a weight vector):

$$\alpha^k_{ij} = \frac{\exp\left(\sigma\left(\boldsymbol{a}^T\left(W^k \boldsymbol{w}^{lstm}_i \| W^k \boldsymbol{w}^{lstm}_j\right)\right)\right)}{\sum_{z \in \mathcal{N}_i} \exp\left(\sigma\left(\boldsymbol{a}^T\left(W^k \boldsymbol{w}^{lstm}_i \| W^k \boldsymbol{w}^{lstm}_z\right)\right)\right)} \tag{2}$$

For each of the two relation graphs, we use an independent graph attention layer. The output word representations from the two GATs are denoted as: $\boldsymbol{G}^C = [\boldsymbol{w}^{gnn(C)}_1, \boldsymbol{w}^{gnn(C)}_2, ..., \boldsymbol{w}^{gnn(C)}_n] \in \mathbb{R}^{n \times d_3}$ and $\boldsymbol{G}^D = [\boldsymbol{w}^{gnn(D)}_1, \boldsymbol{w}^{gnn(D)}_2, ..., \boldsymbol{w}^{gnn(D)}_n] \in \mathbb{R}^{n \times d_3}$, with d_3 dimension for each word.

Table 1: Test results of baselines and our system (Average Precision/Recall/F1 Scores±standard deviation,%)[3]

3.4 Fusion Layer

Similar to Sui et al. (2019), we also use a fusion layer to blend the encoded word embeddings and the GNNs updated word embeddings. We first project these embeddings into the same hidden space using liner transformation and then add them, as in $\boldsymbol{F} = W_N \boldsymbol{E}^{lstm} + W_C \boldsymbol{G}^C + W_D \boldsymbol{G}^D$, where W_N, W_C, W_D are trainable weights. Then we will have a feature matrix $\mathbf{F} \in \mathbb{R}^{n \times d_4}$ for the n words blended with both the sequential context information and global entity relations.

3.5 Decoding Layer

Finally, a Conditional Random Field (CRF) (Lafferty et al., 2001) layer is used to decode the enriched embeddings $\boldsymbol{F} = [\boldsymbol{f}_1, \boldsymbol{f}_2, ..., \boldsymbol{f}_n]$ into a sequence of labels $y = \{y_1, y_2, ..., y_n\}$. In the training phrase, we optimize the whole model by minimizing the negative log-likelihood loss with respect to gold labels.

4 Experiments[4]

We test our model on two domain-specific datasets: the AnatEM (Pyysalo and Ananiadou, 2014) from the biomedical domain and the Mars (Wagstaff et al., 2018) from the planetary science domain. The AnatEM has annotated 12 types of entities in 1,212 documents with 13,701 entity mentions; the Mars has 117 longer documents with 4,458 entity mentions containing 3 types.

4.1 Baselines

NCRF++ (Yang and Zhang, 2018) is an open-source Neural Sequence Labelling Toolkit. We use the BiLSTM-CNN-CRF structrue as a baseline.

FLAIR (Akbik et al., 2018) is a character-level pretrained LM based on BiLSTM, which has been used in many NER systems (Jiang et al., 2019; Wang et al., 2019). We use the embeddings from it with a BiLSTM-CRF architecture as a baseline.

Pooled FLAIR (Akbik et al., 2019) is an extended version of the FLAIR model with global memory and pooling mechanism for the same word, which helps consistent predictions of coreferential entity mentions. We also use the embeddings from it with a BiLSTM-CRF architecture as a baseline.

Tuning Bio/SciBERT We also use Bio/SciBERT with a BiLSTM-CRF architecture as baselines for the AnatEM/Mars datasets, which do not have the GNNs layer or Fusion layer as compared with our system.

4.2 Results

To alleviate random turbulence, we train all the systems five times using different random seeds and evaluate their average performance on the test sets using the same script[5], as in the Table 1.

We can see that our system with both the global entity coreference and local dependency relations performs the best among all the systems. It improves the average F1 score by 0.88 points (84.41% vs. 83.53%) compared to BioBERT on the AnatEM, and 0.62 points (90.57% vs. 89.95%) compared to SciBERT on the Mars. Further, both the coreference and dependency relations help to improve the NER performance. Specifically, our model with either the coreference or dependency relation graph improves the F1 scores by 0.64 point or 0.7 point on the AnatEM dataset, and by 0.32 point or 0.34 point on the Mars dataset.

[3]Previous systems on the AnatEM dataset either evaluate the NER performance by head match or only evaluate the performance on span identification; therefore, so we do not include their results here.

[4]More details about the datasets, data preprocessing, and model settings can be found in the appendices.

Table 2: Edge Selection in the Dependency Graph (Average Precision/Recall/F1 Scores±standard deviation,%)

4.3 Learning Curves

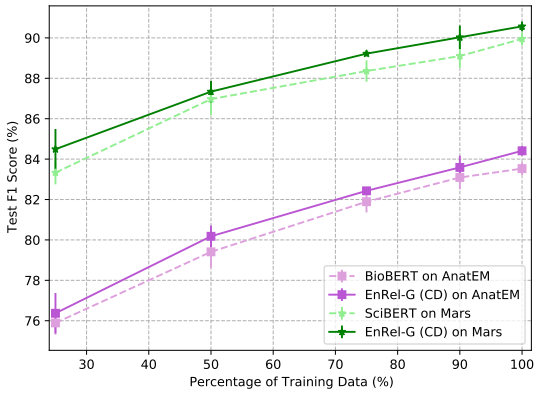

Figure 3: Learning Curves, each point shows the average performance of 5 system runs.

One main limitation of domain-specific NER systems is the lack of annotations, therefore, it is vital to make the best use of labeled data. The learning curves (Figure 3) shows that leveraging the relations between entity mentions can effectively elevate the NER performance to a higher level even when only a tiny amount of labeled data (a quarter of training data) is available, and this is true on both the AnatEM dataset and the Mars dataset.

4.4 Analysis of Computation Cost

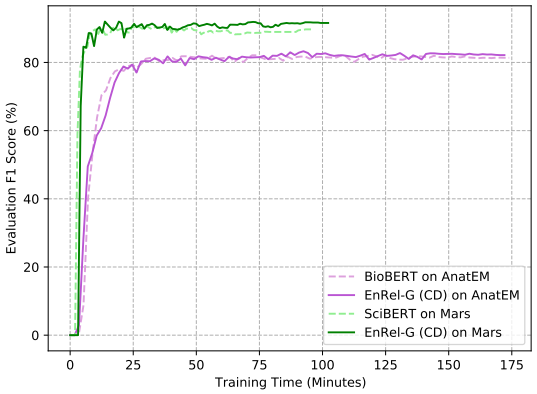

Figure 4: Comparison of Training Time

Although fine-tuning pretrained LMs has improved the performance of many NLP tasks, one limitation is the increase of training time. Therefore, it is important to build computing efficient models based on pretrained LMs. As shown in Figure 4, our model with the GNNs layer does not increase the time cost for fine-tuning the BERT models. The training time of methods with or without the GNNs layer is similar.

4.5 Edge selection in the Dependency Graph

To build the sentence-level dependency graph, we selected only two types of dependency relations: between the subject, object and their predicate (*Key Edges*) and between a compound modifier and its head word. As shown in the Table 2, we also tried to connect all the modifiers with their head word and found that this yields slightly worse performance, and the reason may be that many modifiers other than compounds are not entities themselves. In addition, including all the dependency edges also yields worse performance than using the two selected types of dependency relations, probably for the same reason that many of the nodes in a dependency tree are not parts of entity mentions and many dependency relations do not directly contribute to capturing relations between entities.

5 Conclusion

In this work, we explicitly capture the global coreference and local dependency relations between entity mentions, and use graph neural nets to incorporate the relations to improve domain-specific NER tasks. Experimental results on two datasets show the effectiveness of this lightweight approach. We also find that the selection of entity relations is important to the system performance. Future work may consider about using GNNs to incorporate external knowledge for performance improvement.

Appendices

Appendix A: Dataset Details

The AnatEM (Pyysalo and Ananiadou, 2014) dataset is an extended Anatomical Entity Mention corpus combining both the Anatomical Entity Mention (AnEM) (Ohta et al., 2012) dataset and Multi-level Event Extraction (MLEE) (Pyysalo et al., 2012) corpus. All the documents are selected from PubMed[6] abstracts or full-text papers. AnatEM is manually annotated by biological experts and it has 12 types of entities annotated, namely *Anatomical System, Cancer, Cell, Cellular Component, Developing Anatomical Structure, Immaterial Anatomical Entity, Multi-tissue Structure, Organ, Organism Subdivision, Organism Substance, Pathological Formation, Tissue*. In total, this dataset consists of 1,212 documents and 13,701 entities annotated.

[6] https://pubmed.ncbi.nlm.nih.gov/

Datasets		#Doc	#Words	#Entities	#Words/Doc
AnatEM	Train	606	153,823	6,946	254
	Dev	202	58,785	2,139	291
	Test	404	99,976	4,616	247
	Total	1,212	312,584	13,701	258
Mars	Train	62	99,952	2,431	1,612
	Dev	20	33,743	906	1,687
	Test	35	58,392	1,121	1,668
	Total	117	192,087	4,458	1,642

Table 3: Statistics of the AnatEM and Mars datasets.[7]

Mars is from the scientific literature domain, and it is about planetary science. All documents come from the Lunar and Planetary Science Conference (LPSC)[8], and the entity mentions are annotated manually. It has 3 types of entities: *Element*, *Mineral*, *Target*. The corpus consists of 117 documents. 62 of them are from LPSC 2015 and they are for training and 55 of them are from LPSC 2016 for evaluation. Same as previous work, we divide the 2016 documents into a validation set with 20 documents and a testing set with 35 documents.

Appendix B: Data Preprocessing

We want our model to take advantage of the document-level information, but some of the documents are extremely too long. Moreover, the BERT model also has a limitation of 512 subtokens for input texts. So we need to split the long documents. Besides, the BERT language model needs a big enough batch size (e.g., 16 or 32) to be well fine-tuned, which is also a burden for the GPU memory consumption. In consideration of these restrictions, we limit the max subtoken count of a split document to 128 in the data preprocessing. Future work with more computing resources may try longer input documents.

Moreover, we also add the POS and Dependency Tree information into the data using scispaCy for constructing the Coreference Graph and the Dependency Graph in our model.

Appendix C: Model Settings

For the **NCRF++** baseline, we use one layer of BiLSTM for word sequence representation with 300-dim Glove (Pennington et al., 2014) embeddings, four layers of CNN for character sequence representation with 50-dim random initialized character embeddings, and a CRF layer for inference.

Methods	Optimizer	Learning Rate	Batch Size
NCRF++	SGD	1e-2	10
(pooled) FLAIR	Adam	2e-3	8
Tuning Bio/SciBERT	Adam	5e-5	32
EnRel-G	Adam	5e-5	32

Table 4: Model Settings

For the **FLAIR** and **Pooled FLAIR** baselines, we use the PubMed version (pretrained on the biomedical corpus) for the AnatEM dataset and the general English version (pretrained on the English news articles) for the Mars dataset. Particularly, for the Pooled FLAIR model, we set the *mean* pooling mechanism to calculate the average of embeddings for multiple occurrences of a word, and then use it as the representation for the word.

For the **Tuning BERT** baselines, we use *BioBERT-Base v1.1* for the AnatEM dataset and *SciBERT-scivocab-uncased* for the Mars dataset.

For our **EnRel-G** system, we keep the embeddings layer the same as the Tuning BERT baselines. As for the GNNs layer, we use one layer of the graph attention mechanism with 4 heads, and each head has a hidden dimension of 128.

For the optimization related parameters, as in the Table 4, we mainly use the recommended settings for the baseline models. For our EnRel-G system, we keep the same parameters as in the Tuning BERT baseline for fair comparison.

We train all the systems on a single Nvidia GEFORCE GTX 2080Ti GPU. We set the maximum epoch as 100 and use the best-performed model on the development set to evaluate the test data.

[7] We remove the redundantly annotated entities in the Mars.

Improving Lexically Constrained Neural Machine Translation with Source-Conditioned Masked Span Prediction

Gyubok Lee* **Seongjun Yang*** **Edward Choi**

Abstract

Accurate terminology translation is crucial for ensuring the practicality and reliability of neural machine translation (NMT) systems. To address this, lexically constrained NMT explores various methods to ensure pre-specified words and phrases appear in the translation output. However, in many cases, those methods are studied on general domain corpora, where the terms are mostly uni- and bi-grams (>98%). In this paper, we instead tackle a more challenging setup consisting of domain-specific corpora with much longer n-gram and highly specialized terms. Inspired by the recent success of masked span prediction models, we propose a simple and effective training strategy that achieves consistent improvements on both terminology and sentence-level translation for three domain-specific corpora in two language pairs.

1 Introduction

Despite its recent success in neural machine translation (NMT) (Wu et al., 2016; Johnson et al., 2017; Barrault et al., 2020), delivering correct terms in the translation output is still a vital component for high-quality translation. This concern becomes more salient in domain-specific scenarios, such as in legal documents, where generating correct and consistent terminology is key to ensuring the practicality and reliability of machine translation (MT) systems (Chu and Wang, 2018; Exel et al., 2020).

To address this, lexically constrained NMT works have proposed various methods to preserve terminology in translations as lexical constraints with or without the help of a term dictionary at test time. In most lexically constrained NMT setups, datasets and terms used for training and evaluating the methods are extracted from WMT news corpora (Dinu et al., 2019; Susanto et al., 2020; Chen et al., 2020). Since the terms, regardless of their source, can only be utilized as long as they exist in the corpus, the term coverage solely depends on the choice of the corpus. By analyzing the previous setups carefully, we discover that the terms found in WMT are mostly uni- or bi-grams (see Figure 1) and highly colloquial (see Table 1 for the top 10 most frequent terms). These leave the question of whether the previous methods are effective in domain-specific scenarios where accurate terminology translation is truly vital.

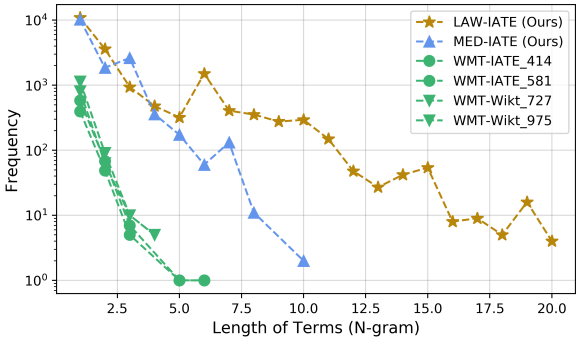

Figure 1: The frequency of terms sorted by n-gram between Dinu et al. (2019)'s and our test splits. While the terms in WMT De-En are mostly uni- or bi-grams, our setup contains heavy-tailed n-gram distributions with more quantity and diversity in terminology.

In this paper, inspired by the recent masked span prediction models, which have demonstrated improved representation learning capability of contiguous words (Song et al., 2019b; Joshi et al., 2019; Lewis et al., 2020; Raffel et al., 2020), we propose a simple yet effective training scheme to improve terminology translation in highly specialized domains. We specifically select two highly specialized domains (*i.e.*, law and medicine) which contain domain-specific terminologies to address more challenging and realistic setups, in addition to applying it to both typologically similar and dissimilar pairs of languages (German-English (De→En) and Korean-English (Ko→En)). Thanks to its sim-

* equal contributions

plicity, the proposed method is compatible with any autoregressive Transformer-based model, including ones capable of utilizing term dictionaries at training or test time. In domain-specific setups where longer n-gram terms are pervasive, our method demonstrates improved performance over the standard maximum likelihood estimation (MLE) approach in terms of terminology and sentence-level translation quality. Our code and datasets are available at https://github.com/wns823/NMT_SSP.

2 Background

Lexically constrained NMT We could group lexically constrained NMT methods into two streams: *hard* and *soft*. The hard approaches aim to force all terminology constraints to appear in the generated output. The methods include replacing constraints (Crego et al., 2016), constrained decoding (Hokamp and Liu, 2017; Chatterjee et al., 2017; Post and Vilar, 2018; Hasler et al., 2018), and additional attention heads for external supervision (Song et al., 2020). Although those approaches are reliable and widely used in practice, they typically require a pre-specified term dictionary and an extra candidate selection module if there are multiple matching candidates for a single term (see caption in Table 2).

Several soft methods address this problem without the help of a term dictionary, one of which is training on both constraint pseudo-labeled (with statistical MT) and unlabeled data (Song et al., 2019a). More recently, Susanto et al. (2020) and Chen et al. (2020) proposed methods that do not assume any word alignment or dictionary supervision at training time to handle unseen terms at test time. For their flexibility, we choose them as our baselines. As discussed in Section 1, most previous methods are trained and evaluated on general domain corpora. In this work, we instead tackle highly specialized domain-specific corpora such as law and medicine, where the terms are much longer and often rare.

Domain-specific NMT Another line of research related to our problem is domain-specific NMT, where difficulties arise from both a limited amount of parallel data and specialized lexicons. Similar to the hard approaches in lexically constrained NMT, several works rely on domain-specific dictionaries (Zhang and Zong, 2016a; Hu et al., 2019; Thompson et al., 2019; Peng et al., 2020) when generating translations, but they are also prone to the same issues. Other domain-specific NMT methods include unsupervised lexicon adaptation (Hu et al., 2019), synthetic parallel data generation with monolingual data (Sennrich et al., 2016a), and multi-task learning that combines language modeling and translation objectives (Gulcehre et al., 2015; Zhang and Zong, 2016b; Domhan and Hieber, 2017). Our method is a form of multi-task learning by utilizing both the source and target language text for an additional task, while the previous works mostly use only the target language text.

Table 1: Top 10 most frequent terms in Dinu et al. (2019)'s and our test splits. Numbers in parenthesis indicate the frequency of terms in each data. As shown in the two tables, all top 10 terms in the WMT corpus are unigrams, while there are longer terms (up to 6-grams) in the domain-specific corpora. Furthermore, compared to WMT, the terms in the domain-specific corpora are more specialized for their corresponding domains.

Span-based Masking Span-based masking is to predict the spans of masked tokens, as opposed to individual token predictions in BERT (Devlin et al., 2019). With this training objective, the model showed improved performance on span-level tasks including question answering and coreference resolution (Joshi et al., 2019). Concurrently, autoregressive sequence-to-sequence pre-trained models also utilized span-based masking as their objectives and demonstrated its effectiveness in many downstream tasks (Song et al., 2019b; Lewis et al., 2020; Raffel et al., 2020). Similar to theirs, our training scheme takes advantage of autoregressive

span-based prediction but we condition on both the source language and the previous non-masked target language tokens.

3 Approach

3.1 Source-Conditioned Masked Span Prediction

We posit that adopting auxiliary span-level supervision in generation can benefit both short and long terminology and sentence-level translation. We, therefore, propose an extra span-level prediction task in translation—namely, source-conditioned masked span prediction (SSP). Different from the recent sequence-to-sequence pre-trained models (Song et al., 2019b; Lewis et al., 2020; Raffel et al., 2020), our approach applies span masking only on the target side. By conditioning on the full context of the source language and the previous non-masked target language tokens (due to autoregressive decoding), the model is forced to predict the spans of missing tokens given fully referenced information in the encoder and partially in the decoder.

Span masking We follow the masking procedure proposed in SpanBERT (Joshi et al., 2019), where we first sample the length of spans from a clamped geometric distribution (p=0.2, max=10) and then corrupt 80% of masked tokens with [MASK], 10% with random tokens, and 10% unchanged. We set the corruption ratio to 50%.

Multi-task Learning As our training scheme consists of two objectives (*i.e.* translation and masked span prediction), we define the total training objective as follows. Let θ be the model parameter and $\mathbb{C}$ be the term-matched corpus where each sentence contains at least one or more terms. The first objective, translation, is to maximize the likelihood of the conditional probability of y:

$$p_\theta(y|x) = \prod_{t=1}^{T+1} p_\theta(y_t|y_{0:t-1}, x), \qquad (1)$$

where $y = (y_1, \ldots, y_T)$ is the target ground-truth (GT) sentence with length T and $x = (x_1, \ldots, x_S)$ is the source sentence with length S. For the SSP objective, we first corrupt random spans of y until the corruption ratio, resulting in $\tilde{y}$. Then we autoregressively predict the masked tokens $\bar{y}$ while conditioned on both $\tilde{y}$ and x:

$$p_\theta(\bar{y}|\tilde{y}, x) = \prod_{t=1}^{T+1} m_t p_\theta(y_t|\tilde{y}_{0:t-1}, x), \qquad (2)$$

where $m_t = 1$ means y_t is masked.

Finally, we simultaneously optimize the joint loss:

$$\mathcal{L}_{total} = -\frac{1}{|\mathbb{C}|} \sum_{\substack{(x,y)\sim\mathbb{C}, \\ \tilde{y}\sim C(y)}} \log p_\theta(y|x) + \gamma \log p_\theta(\bar{y}|\tilde{y}, x), \qquad (3)$$

where C is a span-level corrupter and γ is a task coefficient that weights the relative contribution of SSP.

		# Sent.	Avg. words per sent.	# Terms	Avg. terms per sent.	# Unique terms
Law (De→En)	SRC	447,410 (441K/3K/3K)	27.46	1,677,852	2.33	25,460
	TRG		30.77			27,755
Medical (De→En)	SRC	494,316 (488K/3K/3K)	19.01	1,494,269	1.34	8,633

Law (Ko→En)	SRC	93,240 (87K/3K/3K)	16.52	353,894	3.52	2,354
	TRG		34.56			2,733

Table 2: Statistics of the filtered corpus and matched terms. Note that *# unique terms* in the source (SRC) and target (TRG) languages are not the same. For instance, "Arzneimittel" can translate into multiple forms—"pharmaceutical products", "drug", "medicinal product", etc.— depending on the context.

4 Experiments

4.1 Setup

Data We use De-En legal and medical domain corpora from OPUS[1] (Tiedemann, 2012) and the De-En bilingual term dictionary from IATE[2]. Terms in different languages are aligned via term IDs. For the typologically distant pair of languages, we use the Ko-En legal domain corpus available on AI Hub[3], and the manually processed bilingual term dictionary downloaded from the Korea Legislation Research Institute (KLRI) website[4]. In cases where

Table 3: (*Without dictionary*) Results on legal domain corpora (De→En and Ko→En) without terminology guidance at test time. VASWANI17 combined with our training objective (Eq.(3)) outperforms other methods in most cases. Note that GU19 is a non-autoregressive model, therefore not applicable to our proposed method. Higher Term% and LSM-3 mean better performance.

Table 4: (*With dictionary*) Results on legal domain corpora when the GT terms are provided at test time. +SSP consistently shows improvements over its MLE counterparts. Contrary to the previous findings (Susanto et al., 2020; Chen et al., 2020), the models do not show improved BLEU scores compared to those in Table 3. We argue that providing terms at test time is indeed helpful for terminology generation, but it can often hinder the generation of fluent text. This becomes more apparent in our non-autoregressive setup.

one term translates into multiple terms, we consider all possible pairs to maximize the number of sentence and term matches.

To avoid trivial matches between the parallel sentences and terms, we filtered out terms that are less than four characters long and longer than 20 grams. Sentences that do not contain any term are also removed. The statistics of the datasets are reported in Table 2. More details about the preprocessing steps are in Appendix A.1.

For data splitting, we developed a new data splitting algorithm that considers the same distribution of n-grams across each data split. We use 3,000 sentences for valid and test sets in case of high redundancy in certain corpora, while previous works that utilize OPUS use only 2,000 (Koehn and Knowles, 2017; Müller et al., 2020). It is important to note that all the sentences in our data splits are matched with domain-specific terms (i.e. at least one or more terms exist in each sentence) following the style of Dinu et al. (2019). The pseudo-code for the terminology-aware data split algorithm is in Appendix B.

Baselines We compare our method on two recent lexically constrained NMT models of different natures: autoregressive (Chen et al., 2020) and non-autoregressive (Susanto et al., 2020), but both can operate with or without a term dictionary at test time. We refer to them as CHEN20 and SUSANTO20, respectively. +SSP indicates models trained with our proposed training scheme, while no indication is the standard MLE method. A base Transformer (Vaswani et al., 2017), denoted as VASWANI17, and a Levenshtein Transformer (Gu et al., 2019), denoted as GU19, are also reported to compare the relative performance between models. SUSANTO20 without a dictionary is equivalent to GU19.

Evaluation We use SacreBLEU[5] (Post, 2018) for measuring translation quality. For terminology translation, we use *term usage rate* for both short (≤2-grams) and long (>2-grams) terms. Term usage rate (Term%) is the number of generated terms divided by the total number of terms (Dinu et al., 2019; Susanto et al., 2020). Specifically for evaluating long terms, we report both the macro and micro averages due to the heavy-tailed nature of n-grams. In addition, although exact term translation is the primary objective for terminology translation, due to its harshness, evaluating models only with Term% may not fully describe the models'

behavior. Therefore, we also evaluate each model in terms of partial n-gram matches, which is explained in the next paragraph. All evaluations are conducted with a beam size of 5.

Partial N-gram Match Inspired by the longest common substring problem (Gusfield, 1997), we devised a partial n-gram match score for evaluating long terminology—*longest sub n-gram match* (LSM) score. Formally, let the generated target sentence be $\hat{y} = (\hat{y}_1, ..., \hat{y}_T)$ and the matched terms for the target ground truth (GT) sentence y be $y' = \bigcup_{i=1}^{N}(y'_{i1}, ..., y'_{il})$, where N is the number of GT terms in y and l is an arbitrary n-gram length for i-th term. Then, LSM is defined as the ratio of the longest n-gram overlap divided by l. As too many overlaps can occur at the uni and bi-gram levels, we only calculate LSM for long terminology, which means the least overlap has to be greater than or equal to 3 grams, all else being zero, therefore denoted as LSM-3.

4.2 Results and Analysis

For the legal domain, where many terms are exceptionally long compared to most other domains, our training scheme shows consistent improvements over the standard MLE counterparts, as shown in Table 3 and Table 4. Even with the extreme setting of law Ko→En, low-resourced and typologically divergent, our method is still effective in most metrics we use. Compared to the autoregressive models, GU19 and SUSANTO20 did not achieve competitive BLEU scores in our domain-specific setup. We suspect that this is due to both its complex decoding nature and the small amount of training data (originally WMT). Sampled translation results are reported in Table 9.

For the medical domain, the behaviors of two baselines, VASWANI17 and CHEN20, are not clearly shown compared to the legal domain. However, our training scheme shows consistent improvements in BLEU and Term% at 2>micro which reflects the global performance of long terminology generation. Similar to the legal De→En results, SUSANTO20 shows better performance on several metrics on long terminology translation, but the BLEU score is decreased by about 8 points, compared to no dictionary use.

5 Conclusion

We propose a simple and effective training scheme for improving lexically constrained NMT by introducing the masked span prediction task on the decoder side. Our method shows its effectiveness in terms of terminology and sentence-level translation over the standard MLE training in highly specialized domains in two language pairs. As we publicly release our code and datasets, we hope that more people can join this area of research without much burden. In the future, we plan to further investigate applying our method to non-autoregressive methods.

Acknowledgments

We want to thank Minjoon Seo for his constructive comments on our research direction and Wooju Kim for his help in starting this topic. We also thank anonymous reviewers for their effort and valuable feedback. This work was supported by Institute of Information & Communications Technology Planning & Evaluation (IITP) grant (No.2019-0-00075, Artificial Intelligence Graduate School Program (KAIST)), and National Research Foundation of Korea (NRF) grant (NRF-2020H1D3A2A03100945), funded by the Korea government (MSIT).

A Preprocessing and Training

A.1 Preprocessing

For De→En, we applied Moses tokenization (Koehn et al., 2007) and joint source-target byte pair encoding (BPE) (Sennrich et al., 2016b) with 20,000 split operations. For En→Ko, English was tokenized using spaCy[6] and Korean using KoNLPy's MeCab-ko[7] (Park and Cho, 2014), followed by BPE with 20,000 operations. We apply sentence filtering up to 80 tokens.

A.2 Training

Model We follow the base Transformer architecture and fix the same hyperparameter configurations for all baselines. For the exact implementation of each baseline, we followed the authors' official code on github (CHEN20[8] and SUSANTO20[9]). We implemented our code using FAIRSEQ[10] (Ott et al., 2019), trained on Nvidia GeForce RTX 3090 and RTX 2080 Ti GPUs.

Hyperparameter Detailed hyperparameter settings of baselines are reported below. Span masking and task coefficient only apply to our proposed training scheme.

Transformer	
Embedding dim.	512
Transformer FFN dim.	2048
Enc/Decoder layers	6
Attention heads	8
Share all embedding	True
Dropout	0.3
Label smoothing	0.1
Optimizer	Adam
Learning rate	0.0005
Warmup updates	4000
Maximum token per batch	4096
Maximum token lengths	80
Span Masking	
Span length	Geometric (p=0.2)
Maximum span length	10
Minimum span length	1
Corruption ratio	0.5
Task Coefficient	
Task coefficient (γ)	0.5

B Terminology-Aware Data Split Algorithm

Algorithm 1: Terminology-Aware Data Split Algorithm

Data: Dictionary $\mathbb{D}$, Corpus $\mathbb{C}$, Held-out Size R
Result: Sent=(Sent$_{train}$, Sent$_{valid}$, Sent$_{test}$)
Term=(Term$_{train}$, Term$_{valid}$, Term$_{test}$)

1: Sort $\mathbb{D}$ in a descending order
2: N = dict()
3: T' = dict()
4: S = ($|\mathbb{C}| - 2 * R, R, R$)
5: Sent$_{train}$ = [], Sent$_{valid}$ = [], Sent$_{test}$ = []
6: Term$_{train}$ = [], Term$_{valid}$ = [], Term$_{test}$ = []
7: **for** i in {1,2, ..., $|\mathbb{C}|$} **do**
8: x, y = $\mathbb{C}[i]$
9: *ngramlist* = []
10: T'' = []
11: **for** (x', y') in $\mathbb{D}$ **do**
12: **if** y' in y and x' in x **then**
13: *ngramlist*.append(ngram(y'))
14: y = y.replace(y', "", 1)
15: x = x.replace(x', "", 1)
16: T''.append((x', y'))
17: **end if**
18: **end for**
19: n = Max(*ngramlist*)
20: **if** n is not in N.keys() **then**
21: $N[n]$ = []
22: **end if**
23: $N[n]$.append(i)
24: $T'[i] = T''$
25: **end for**
26: K = Sort the keys in N in a descending order.
27: **for** k in K **do**
28: i_{dk} , i_{uk} = DuplicateCheck($N[k]$)
29: (Sent, Term) += Distributor_Dup(i_{dk}, $N[k]$, T', S)
30: (Sent, Term) += Distributor_Uni(i_{uk}, $N[k]$, T', S)
31: **end for**

Line 1 : Sort $\mathbb{D}$ w.r.t. target language terms.

Line 2 : Initialize a dictionary for storing paired sentences. The keys are the longest n-gram lengths for each sentence w.r.t. the target language.

Line 3 : Initialize a dictionary for storing matched terms. The keys are the indices of a corresponding sentence.

Line 13 : ngram() returns the token length of a term. In our case, it is used for calculating the length of a target language token y'.

Line 14 : Replace y' with "" in y to avoid unwanted substring duplication (e.g., In case of having "public officer" and "officer" in a sentence, we would like to first match "public officer" instead of "office" when we have "public officer" in the dictionary. See Line 1).

Line 19 : Calculate the maximum length of n-grams in y.

Line 23 : Store the sentence index w.r.t. its longest length of n-grams.

Line 24 : Store the list of terms w.r.t. its sentence index.

Line 28 : DuplicateCheck() checks for duplication in the corpus and returns duplicate and non-duplicate indices. Note

that i_{dk} is a list of duplicate sentence indices, and S_{uk} is a list of unique sentence indices.

Line 29 : Distributor_Dup() first calculates the number of sentences and phrases to be distributed across train, valid, and test sets following the ratio in *S*, and then distributes sentences accordingly.

Line 30 : Distributor_Uni() distributes unique sentences and phrases alternatively between train, valid, and test sets.

C Removing duplicates

As the OPUS datasets contain duplicate sentences (Aharoni and Goldberg, 2020), we further evaluate each model with unseen, unique test samples only. Similar to Tables 7 and 8, our training scheme outperforms its MLE counterparts. The Ko-En law corpus does not contain any duplicate sentence, and therefore the results are equivalent to those in Tables 3 and 4.

Abstract

To help individuals express themselves better, quotation recommendation is receiving growing attention. Nevertheless, most prior efforts focus on modeling quotations and queries separately and ignore the relationship between the quotations and the queries. In this work, we introduce a transformation matrix that directly maps the query representations to quotation representations. To better learn the mapping relationship, we employ a mapping loss that minimizes the distance of two semantic spaces (one for quotation and another for mapped-query). Furthermore, we explore using the words in history queries to interpret the figurative language of quotations, where quotation-aware attention is applied on top of history queries to highlight the indicator words. Experiments on two datasets in English and Chinese show that our model outperforms previous state-of-the-art models.

1 Introduction

Quotations are essential for successful persuasion and explanation in interpersonal communication. However, it is a daunting task for many individuals to write down a suitable quotation in a short time. This results in a pressing need to develop a quotation recommendation tool to meet such a demand.

To that end, extensive efforts have been made to **quotation recommendation**, which aims to recommend an ongoing conversation with a quotation whose sense continues with the existing context (Wang et al., 2020). As quotations are concise phrases or sentences to spread wisdom, which are always in figurative language and difficult to understand, they are assumed written in a different pseudo-language (Liu et al., 2019a). Intuitively, we can infer the meanings of quotations by their neighborhood contexts, especially by the *query* turn (the last turn of conversation that needs recommendation).

$[t_1]$: Save your money. Scuf is the biggest ripoff in gaming. $[t_2]$: What would you suggest instead? $[t_3]$: Just use a normal controller. $[t_4]$: Oooooh, I get it now...you're just dumb. $[t_5]$: The dumb ones are the people spending over $100 for a controller. [*A fool and his money are soon parted.*]
$[h_1]$: Anyone that spends that much money just to get different writing on a box..... [*A fool ... parted.*] $[h_2]$: And that's probably why you'll never have a billion dollars. [*A fool ... parted.*] $[h_3]$: Seriously. Why do people not do market research before buying something!?! [*A fool ... parted.*]

Figure 1: A Reddit conversation snippet (upper part) with three history queries (lower part). Quotations to be recommended are in square brackets. Indicative words are on wavy-underline.

To illustrate our motivation, Figure 1 shows a Reddit conversation with some history queries associated with quotation Q, "*A fool and his money are soon parted*". From the queries (t_5 and h_1 to h_3), we can infer the meaning of quotation Q is "A foolish person spends money carelessly and won't have a lot of money." based on the contexts. From h_3, we can also know the implication behind the words, which is "Do a marketing research before buying". Humans can establish such a relationship between quotations and queries and then decide what to quote in their writings, so can machines (neural network). Therefore, we introduce a transformation matrix, in which machines can learn the direct mapping from queries to quotations. The matrix is worked on the outputs of two encoders, conversation encoder and quotation encoder, encoding conversation context and quotations respectively.

Furthermore, we can use the words in the queries to interpret quotations. h_1 to h_3 in Figure 1 are

The code is available at https://github.com/Lingzhi-WANG/Quotation-Recommendation

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 754–758
August 1–6, 2021. ©2021 Association for Computational Linguistics

denoted as *history queries*, and the words on wavy-underline are denoted as indicators to quotations. It can be seen that we can interpret quotations by highlighting the words in the queries. Therefore, we compute quotation-aware attention over all the history queries (after the same transformation as we mentioned before) and then display indicators we learned, which also reflects the effectiveness of the transformation.

In summary, we introduce a transformation between the query semantic space and quotation semantic space. To minimize the distance of their semantic space after transformation mapping, an auxiliary mapping loss is employed. Besides, we propose a way to interpret quotations with indicative words in the corresponding queries.

The remainder of this paper is organized as follows. The related work is surveyed in Section 2. Section 3 presents the proposed approach. And Section 4 and 5 present the experimental setup and results respectively. Finally, conclusions are drawn in Section 6.

2 Related Work

Quotation Recommendation. In previous works on quotation recommendation, some efforts are made for online conversations (Wang et al., 2020; Lee et al., 2016) and some for normal writing (Liu et al., 2019a; Tan et al., 2015, 2016). Our work focuses on the former. For methodology, the methods they applied can be divided into generation-based framework (Wang et al., 2020; Liu et al., 2019a) and ranking framework (Lee et al., 2016; Tan et al., 2015, 2016). Different from previous works which mainly focus on separate modeling of quotation and query and pay little attention to the relationship between them, our model directly learns the relationship between quotations and query turns based on a mapping mechanism. The relationship mapping is jointly trained with the quotation recommendation task, which improves the performance of our model.

3 Our model

This section describes our quotation recommendation model, whose overall structure is shown in Figure 2. The input of the model mainly contains the observed conversation c and the quotation list q. The conversation c is formalized as a sequence of turns (e.g., posts or comments) $\{t_1, t_2, ..., t_{n_c}\}$ where n_c represents the length of the conversation

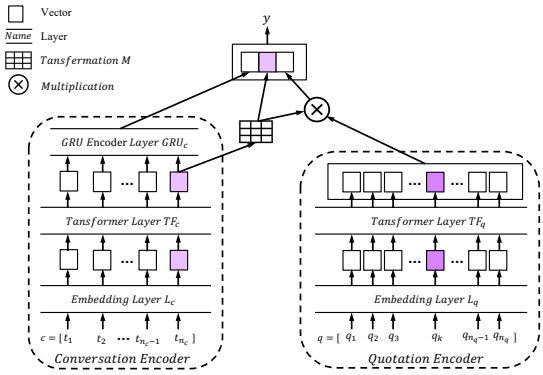

Figure 2: Our model for quotation recommendation.

(number of turns) and t_{n_c} is the query turn. t_i represents the i-th turn of the conversation and contains words $\boldsymbol{w}_i$. The quotation list q is $\{q_1, q_2, ..., q_{n_q}\}$, where n_q is the number of quotations and q_k is the k-th quotation in list q, containing words $\boldsymbol{w}'_k$. Our model will output a label $y \in \{1, 2, ..., n_q\}$, to indicate which quotation to recommend.

3.1 Conversation Modeling

Our model encodes the observed conversation c with a hierarchical structure, which is divided into three parts. The first part is an embedding layer mapping the words $\boldsymbol{w}_i$ in each turn t_i into vectors. We then apply transformer (Vaswani et al., 2017) to learn the representation for each turn. Similar to BERT (Devlin et al., 2018), we only use the encoder of transformer, which is stacked of several self-attention and feed-forward layers. We add a token [CLS] at the beginning of each turn. The hidden representation of [CLS] after transformer encoder is defined as the turn representation $\boldsymbol{r}_i^t$ of turn t_i. The procedures for the first two parts are summarized as follows:

$$\boldsymbol{h}_i^T = \mathrm{FFN}(\mathrm{Self\_Attention}(\mathrm{Embed}([w_0; \boldsymbol{w}_i]))) \quad (1)$$

where w_0 represents the [CLS] token, and $[;]$ indicates concatenation. Therefore $\boldsymbol{r}_i^t = \boldsymbol{h}_{i,0}^T$.

Next, we use a Bi-GRU (Cho et al., 2014) layer to model the whole conversation structure. With the turn representations $\{\boldsymbol{r}_1^t, \boldsymbol{r}_2^t, ..., \boldsymbol{r}_{n_c}^t\}$ ($\boldsymbol{r}_{n_c}^t$ is the representation for the query turn) of conversation c derived from previous procedure, the hidden states are updated as follows:

$$\overrightarrow{\boldsymbol{h}}_i^G = \overrightarrow{\mathrm{GRU}}(\overrightarrow{\boldsymbol{h}}_{i-1}^G, \boldsymbol{r}_i^t), \ \overleftarrow{\boldsymbol{h}}_i^G = \overleftarrow{\mathrm{GRU}}(\overrightarrow{\boldsymbol{h}}_{i+1}^G, \boldsymbol{r}_i^t) \quad (2)$$

Finally, we define the conversation representation as the concatenation of the final hidden states from two directions: $\boldsymbol{h}^c = [\overrightarrow{\boldsymbol{h}}_{n_c}^G; \overleftarrow{\boldsymbol{h}}_1^G]$.

3.2 Quotation Modeling

For each quotation q_k in list q, we extract quotation representation $\boldsymbol{r}_k^q$ with similar operation as turn representations (see Eq. 1). As Liu et al. (2019b) points out, the language used in quotations is usually different from our daily conversations, which results in two different semantic spaces. Therefore, we do not share the parameters of the embedding layer and transformer layers for quotations and conversation turns. We concatenate all the quotation representations and get a combined quotation matrix $\boldsymbol{Q}$, which includes n_q rows and each row represents one quotation.

3.3 Recommendation Based on Transformation

To perform a reasonable recommendation, we consider the observed conversation c, the query turn t_{n_c} as well as the quotation list q. Since they are in different semantic spaces (Section 3.2), we first map the query turns into the space of quotations with a transformation matrix $\boldsymbol{M}$. We assume with such transformation, the space gap can be resolved. Thus, we can calculate the distance between queries and quotations. We use $\boldsymbol{z}^c$ to represents the distances between $\boldsymbol{r}_{n_c}$ and the quotations, and it is defined with the following equation:

$$\boldsymbol{z}^c = \boldsymbol{Q} \times (\boldsymbol{M}\boldsymbol{r}_{n_c}) \tag{3}$$

Finally, the output layer is defined as:

$$\boldsymbol{y} = \boldsymbol{W}[\boldsymbol{z}^c; \boldsymbol{h}^c; \boldsymbol{M}\boldsymbol{r}_{n_c}] + \boldsymbol{b} \tag{4}$$

where $\boldsymbol{W}$ and $\boldsymbol{b}$ are learnable parameters. We recommend the quotations with the top n highest probabilities, which are derived with a softmax function:

$$p(\hat{q} = i) = \frac{\exp(y_i)}{\sum_{k=1}^{n_q} \exp(y_k)} \tag{5}$$

3.4 Training Procedure

We define our training objective as two parts. The first part is called recommendation loss, which is the cross entropy over the whole training corpus $\mathbb{C}$:

$$\mathcal{L}_{rec} = -\sum_{c \in \mathbb{C}} \log\, p(\hat{q} = q^c | c, q) \tag{6}$$

where q^c is the ground-truth quotation for conversation c in training corpus. The second part is to help on the learning of transformation matrix $\boldsymbol{M}$, where we minimize the distance between the transformed query turn representation and the corresponding ground-truth quotation:

$$\mathcal{L}_{map} = \sum_{c \in \mathbb{C}} ||\boldsymbol{M}\boldsymbol{r}_{n_c} - \boldsymbol{r}_{q^c}^q||_2^2 \tag{7}$$

To train our model, the final objective is to minimize $\mathcal{L}$, the combination of the two losses:

$$\mathcal{L} = \mathcal{L}_{rec} + \lambda \cdot \mathcal{L}_{map} \tag{8}$$

where λ are the coefficient determining the contribution of the latter loss.

4 Experimental Setup

Datasets. We conduct experiments based on datasets from two different platforms, Weibo and Reddit, released by Wang et al. (2020). To make our experimental results comparable to Wang et al. (2020), we utilize their preprocessed data directly.

Parameter Setting. We first initialize the embedding layer with 200-dimensional Glove embedding (Pennington et al., 2014) for Reddit and Chinese words embedding (Song et al., 2018) for Weibo. For transformer layers, we choose the number of layers and heads as (2, 3) for Reddit and (4, 4) for Weibo. For the hidden dimension of transformer layers and BiGRU layers (each direction), we set it to 200. We employ Adam optimizer (Kingma and Ba, 2015) with initial learning rate with 1e-4 and early stop adoption (Caruana et al., 2001) in training. The batch size is set to 32. Dropout strategy (Srivastava et al., 2014) and L_2 regularization are used to alleviate overfitting. And the tradeoff parameter λ is chosen from {1e-4, 1e-3}. All the hyper-parameters above are tuned on the validation set by grid search.

Evaluation and Comparisons. Our model returns a quotation list arranged in descending order of likelihood of recommendation for each conversation. Therefore, we adopt MAP (Mean Average Precision), P@1 (Precison@1), P@3 (Precison@3), and nDCG@5 (normalized Discounted Cumulative Gain@5) for evaluation.

For comparison, we compare with previous works that focus on quotation recommendation. Below shows the details:

1) LTR (Learning to Rank). We first collect features (e.g., frequency, Word2Vec, etc.) mentioned in Tan et al. (2015) and then use the learning to rank tool RankLib [1] to do the recommendation.

[1] https://github.com/danyaljj/rankLib1

Models	Weibo				Reddit			
	MAP	P@1	P@3	NG@5	MAP	P@1	P@3	NG@5
Baselines								
LTR	9.3	3.6	8.5	8.1	7.1	1.7	6.4	6.2

BERT	31.4	27.9	34.0	32.3	26.4	18.0	30.2	28.5
OUR MODEL	**34.9**	**30.3**	**36.1**	**34.9**	**31.8**	**23.3**	**35.0**	**32.1**

Table 1: Main comparison results on Weibo and Reddit datasets (in %). NG@5 refers to NDCG@5. The best results in each column are in **bold**. Our model yields significantly better scores than all other comparisons for all metrics ($p < 0.01$, paired t-test).

2) CNN-LSTM. We implement the model proposed in Lee et al. (2016), which adopts CNN to learn the semantic representation of each turn and then uses LSTM to encode the conversation.
3) NCIR. It formulates quotation recommendation as a context-to-quote machine translation problem by using the encoder–decoder framework with attention mechanism (Liu et al., 2019b).
4) CTIQ. The SOTA model (Wang et al., 2020), which employs an encoder-decoder framework enhanced by Neural Topic Model to continue the context with a quotation via language generation.
5) BERT. We encode the conversation by BiLSTM on the BERT representations for the turns, followed by a prediction layer.

5 Experimental Results

5.1 Quotation Recommendation

Table 1 displays the recommendation results comparing our model with the baselines on Weibo and Reddit datasets. Our model achieves the best performance, exceeding the baselines by a large margin, especially on Reddit dataset. The fact that better performance comes from BERT and our model indicates the importance of learning efficient content representations. Our model further considers the mapping between different semantic spaces, resulting in the best performance.

Ablation Study. We conduct an ablation study to examine the contributions of different modules in our model. We replace the transformer layers with Bi-GRU (W/O Transformer) to examine the effects of different turn encoders. We also compare the models by removing transformation matrix M (W/O M) or mapping loss $\mathcal{L}_{map}$ (W/O $\mathcal{L}_{map}$). The results are shown in Table 2. As can be seen, each module in our model plays a role in improving performance. The largest improvement comes from applying transformers as our encoders. The performance drop due to removing transformation and mapping loss justifies our assumption of different semantic spaces between quotations and queries.

Models	Weibo			Reddit		
	MAP	P@1	NDCG@5	MAP	P@1	NDCG@5

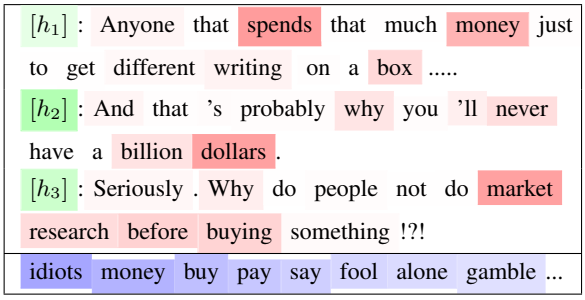

Figure 3: Upper part: example queries associated with the quotation "A fool and his money are soon parted.". Lower part: top 8 indicative words with the highest weighted summed self-attention scores. Darker colors represent higher weights.

5.2 Quotation Interpretation

We also explore how to interpret the figurative language of quotations with our model. We first extract the queries that are related to one certain quotation as history queries, then compute quotation-aware attention over all history queries. Specifically, for quotation q_k, with its relative history queries $\{h_1, h_2, ..., h_{m_k}\}$ from the corpus (m_k is the history number), we can compute their quotation-aware attention (query-level) with their representations derived from our model :

$$a_{k,i} = \frac{\exp(\boldsymbol{r}_k^q \cdot \boldsymbol{r}_{h_i})}{\sum_{j=1}^{m_k} \exp(\boldsymbol{r}_k^q \cdot \boldsymbol{r}_{h_j})} \quad (9)$$

On the other hand, we can extract the scores for the words in each history query with their self-attention weights (word-level) in transformer. Finally, the indicative words of one quotation are those with the highest scores after the multiplication of query-level and word-level attention scores.

Figure 3 shows an interpretation example. We display three example queries mentioned in Figure 1, with both their query-level attention (green) and

word-level attention (red). We can find that words like "spends", "money" and "dollars" are assigned higher scores since they are more related to the quotation topics . We also present the most indicative words derived from all history queries (the lower part of Figure 3). We can easily infer the meaning of the quotation with the help of indicative words like "idiots" and "buy".

6 Conclusion

In this paper, we propose a transformation from queries to quotations to enhance a quotation recommendation model for conversations. Experiments on Weibo and Reddit datasets show the effectiveness of our model with transformation. We further explore using indicative words in history queries to interpret quotations, which shows rationality of our method.

Abstract

Topic models extract groups of words from documents, whose interpretation as a topic hopefully allows for a better understanding of the data. However, the resulting word groups are often not *coherent*, making them harder to interpret. Recently, neural topic models have shown improvements in overall coherence. Concurrently, contextual embeddings have advanced the state of the art of neural models in general. In this paper, we combine contextualized representations with neural topic models. We find that our approach produces more meaningful and coherent topics than traditional bag-of-words topic models and recent neural models. Our results indicate that future improvements in language models will translate into better topic models.

1 Introduction

One of the crucial issues with topic models is the quality of the topics they discover. *Coherent* topics are easier to interpret and are considered more meaningful. E.g., a topic represented by the words "apple, pear, lemon, banana, kiwi" would be considered a meaningful topic on *FRUIT* and is more coherent than one defined by "apple, knife, lemon, banana, spoon." Coherence can be measured in numerous ways, from human evaluation via intrusion tests (Chang et al., 2009) to approximated scores (Lau et al., 2014; Röder et al., 2015).

However, most topic models still use Bag-of-Words (BoW) document representations as input. These representations, though, disregard the syntactic and semantic relationships among the words in a document, the two main linguistic avenues to coherent text. I.e., BoW models represent the input in an inherently incoherent manner.

Meanwhile, pre-trained language models are becoming ubiquitous in Natural Language Processing (NLP), precisely for their ability to capture and maintain sentential coherence. Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019), the most prominent architecture in this category, allows us to extract pre-trained word and sentence representations. Their use as input has advanced state-of-the-art performance across many tasks. Consequently, BERT representations are used in a diverse set of NLP applications (Rogers et al., 2020; Nozza et al., 2020).

Various extensions of topic models incorporate several types of information (Xun et al., 2017; Zhao et al., 2017; Terragni et al., 2020a), use word relationships derived from external knowledge bases (Chen et al., 2013; Yang et al., 2015; Terragni et al., 2020b), or pre-trained word embeddings (Das et al., 2015; Dieng et al., 2020; Nguyen et al., 2015; Zhao et al., 2017). Even for neural topic models, there exists work on incorporating external knowledge, e.g., via word embeddings (Gupta et al., 2019, 2020; Dieng et al., 2020).

In this paper, we show that adding contextual information to neural topic models provides a **significant** increase in topic coherence. This effect is even more remarkable given that we cannot embed long documents due to the sentence length limit in recent pre-trained language models architectures.

Concretely, we extend Neural ProdLDA (Product-of-Experts LDA) (Srivastava and Sutton, 2017), a state-of-the-art topic model that implements black-box variational inference (Ranganath et al., 2014), to include contextualized representations. Our approach leads to consistent and significant improvements in two standard metrics on topic coherence and produces competitive topic diversity results.

Contributions We propose a straightforward and easily implementable method that allows neural topic models to create coherent topics. We show

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 759–766
August 1–6, 2021. ©2021 Association for Computational Linguistics

that the use of contextualized document embeddings in neural topic models produces significantly more coherent topics. Our results suggest that topic models benefit from latent contextual information, which is missing in BoW representations. The resulting model addresses one of the most central issues in topic modeling. We release our implementation as a Python library, available at the following link: https://github.com/MilaNLProc/contextualized-topic-models.

2 Neural Topic Models with Language Model Pre-training

We introduce a Combined Topic Model (CombinedTM) to investigate the incorporation of contextualized representations in topic models. Our model is built around two main components: (i) the neural topic model ProdLDA (Srivastava and Sutton, 2017) and (ii) the SBERT embedded representations (Reimers and Gurevych, 2019). Let us notice that our method is indeed agnostic about the choice of the topic model and the pre-trained representations, as long as the topic model extends an autoencoder and the pre-trained representations embed the documents.

ProdLDA is a neural topic modeling approach based on the Variational AutoEncoder (VAE). The neural variational framework trains a neural inference network to directly map the BoW document representation into a continuous latent representation. Then, a decoder network reconstructs the BoW by generating its words from the latent document representation[1]. The framework explicitly approximates the Dirichlet prior using Gaussian distributions, instead of using a Gaussian prior like Neural Variational Document Models (Miao et al., 2016). Moreover, ProdLDA replaces the multinomial distribution over individual words in LDA with a product of experts (Hinton, 2002).

We extend this model with contextualized document embeddings from SBERT (Reimers and Gurevych, 2019),[2] a recent extension of BERT that allows the quick generation of sentence embeddings. This approach has one limitation. If a document is longer than SBERT's sentence-length limit, the rest of the document will be lost. The document representations are projected through a hidden layer with the same dimensionality as the vocabulary size, concatenated with the BoW representation. Figure 1 briefly sketches the architecture of our model. The hidden layer size could be tuned, but an extensive evaluation of different architectures is out of the scope of this paper.

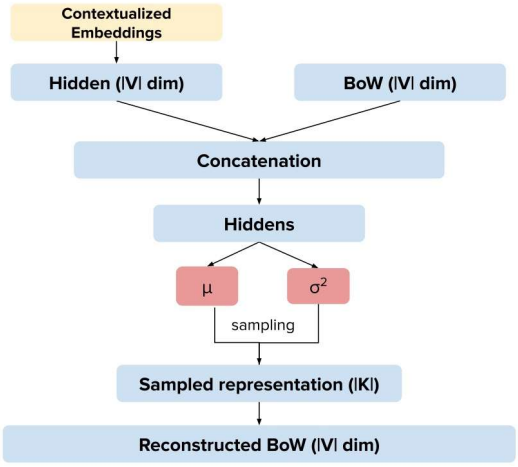

Figure 1: High-level sketch of CombinedTM. Refer to (Srivastava and Sutton, 2017) for more details on the architecture we extend.

Dataset	Docs	Vocabulary
20Newsgroups	18,173	2,000
Wiki20K	20,000	2,000

3 Experimental Setting

We provide detailed explanations of the experiments (e.g., runtimes) in the supplementary materials. To reach full replicability, we use open-source implementations of the algorithms.

3.1 Datasets

We evaluate the models on five datasets: 20NewsGroups[3], Wiki20K (a collection of 20,000 English Wikipedia abstracts from Bianchi et al. (2021)), Tweets2011[4], Google News (Qiang et al., 2019), and the StackOverflow dataset (Qiang et al., 2019). The latter three are already pre-processed. We use a similar pipeline for 20NewsGroups and Wiki20K: removing digits, punctuation, stopwords, and infrequent words. We derive SBERT document representations from unpreprocessed text for Wiki20k

and 20NewsGroups. For the others, we use the pre-processed text;[5] See Table 1 for dataset statistics. The sentence encoding model used is the pre-trained RoBERTa model fine-tuned on SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), and the STSb (Cer et al., 2017) dataset.[6]

3.2 Metrics

We evaluate each model on three different metrics: two for topic coherence (normalized pointwise mutual information and a word-embedding based measure) and one metric to quantify the diversity of the topic solutions.

Normalized Pointwise Mutual Information (τ) (Lau et al., 2014) measures how related the top-10 words of a topic are to each other, considering the words' empirical frequency in the original corpus. τ is a symbolic metric and relies on co-occurrence. As Ding et al. (2018) pointed out, though, topic coherence computed on the original data is inherently limited. Coherence computed on an external corpus, on the other hand, correlates much more to human judgment, but it may be expensive to estimate.

External word embeddings topic coherence (α) provides an additional measure of how similar the words in a topic are. We follow Ding et al. (2018) and first compute the average pairwise cosine similarity of the word embeddings of the top-10 words in a topic, using Mikolov et al. (2013) embeddings. Then, we compute the overall average of those values for all the topics. We can consider this measure as an external topic coherence, but it is more efficient to compute than Normalized Pointwise Mutual Information on an external corpus.

Inversed Rank-Biased Overlap (ρ) evaluates how diverse the topics generated by a single model are. We define ρ as the reciprocal of the standard RBO (Webber et al., 2010; Terragni et al., 2021b). RBO compares the 10-top words of two topics. It allows disjointedness between the lists of topics (i.e., two topics can have different words in them) and uses weighted ranking. I.e., two lists that share some of the same words, albeit at different rankings, are penalized less than two lists that share the same words at the highest ranks. ρ is 0 for identical topics and 1 for completely different topics.

3.3 Models

Our main objective is to show that contextual information increases coherence. To show this, we compare our approach to ProdLDA (Srivastava and Sutton, 2017, the model we extend)[7], and the

[5] This can be sub-optimal, but many datasets in the literature are already pre-processed.

[6] stsb-roberta-large

[7] We use the implementation of Carrow (2018).

following models: (ii) Neural Variational Document Model (NVDM) (Miao et al., 2016); (iii) the very recent ETM (Dieng et al., 2020), MetaLDA (MLDA) (Zhao et al., 2017) and (iv) LDA (Blei et al., 2003).

3.4 Configurations

To maximize comparability, we train all models with similar hyper-parameter configurations. The inference network for both our method and ProdLDA consists of one hidden layer and 100-dimension of softplus units, which converts the input into embeddings. This final representation is again passed through a hidden layer before the variational inference process. We follow (Srivastava and Sutton, 2017) for the choice of the parameters. The priors over the topic and document distributions are learnable parameters. For LDA, the Dirichlet priors are estimated via Expectation-Maximization. See the Supplementary Materials for additional details on the configurations.

4 Results

We divide our results into two parts: we first describe the results for our quantitative evaluation, and we then explore the effect on the performance when we use two different contextualized representations.

4.1 Quantitative Evaluation

We compute all the metrics for 25, 50, 75, 100, and 150 topics. We average results for each metric over 30 runs of each model (see Table 2).

As a general remark, our model provides the most coherent topics across all corpora and topic settings, even maintaining a competitive diversity of the topics. This result suggests that the incorporation of contextualized representations can improve a topic model's performance.

LDA and NVDM obtain low coherence. This result has also also been confirmed by Srivastava and Sutton (2017). ETM shows good external coherence (α), especially in 20NewsGroups and StackOverflow. However, it fails at obtaining a good τ coherence for short texts. Moreover, ρ shows that the topics are very similar to one another. A manual inspection of the topics confirmed this problem. MetaLDA is the most competitive of the models we used for comparison. This may be due to the incorporation of pre-trained word embeddings into MetaLDA. Our model provides very competitive results, and the second strongest model appears to be MetaLDA. For this reason, we provide a detailed comparison of τ in Table 3, where we show the average coherence for each number of topics; we show that on 4 datasets over 5 our model provides the best results, but still keeping a very competitive score on 20NG, where MetaLDA is best.

Readers can see examples of the top words for each model in the Supplementary Materials. These descriptors illustrate the increased coherence of topics obtained with SBERT embeddings.

4.2 Using Different Contextualized Representations

Contextualized representations can be generated from different models and some representations might be better than others. Indeed, one question left to answer is the impact of the specific contextualized model on the topic modeling task. To answer to this question we rerun all the experiments with CombinedTM but we used different contextualized sentence embedding methods as input to the model.

We compare the performance of CombinedTM using two different models for embedding the contextualized representations found in the SBERT repository:[8] *stsb-roberta-large* (Ours-R), as employed in the previous experimental setting, and using *bert-base-nli-means* (Ours-B). The latter is derived from a BERT model fine-tuned on NLI

data. Table 4 shows the coherence of the two approaches on all the datasets (we averaged all results). In these experiments, RoBERTa fine-tuned on the STSb dataset has a strong impact on the increase of the coherence. This result suggests that including novel and better contextualized embeddings can further improve a topic model's performance.

5 Related Work

In recent years, neural topic models have gained increasing success and interest (Zhao et al., 2021; Terragni et al., 2021a), due to their flexibility and scalability. Several topic models use neural networks (Larochelle and Lauly, 2012; Salakhutdinov and Hinton, 2009; Gupta et al., 2020) or neural variational inference (Miao et al., 2016; Mnih and Gregor, 2014; Srivastava and Sutton, 2017; Miao et al., 2017; Ding et al., 2018). Miao et al. (2016) propose NVDM, an unsupervised generative model based on VAEs, assuming a Gaussian distribution over topics. Building upon NVDM, Dieng et al. (2020) represent words and topics in the same embedding space. Srivastava and Sutton (2017) propose a neural variational framework that explicitly approximates the Dirichlet prior using a Gaussian distribution. Our approach builds on this work but includes a crucial component, i.e., the representations from a pre-trained transformer that can benefit from both general language knowledge and corpus-dependent information. Similarly, Bianchi et al. (2021) replace the BOW document representation with pre-trained contextualized representations to tackle a problem of cross-lingual zero-shot topic modeling. This approach was extended by Mueller and Dredze (2021) that also considered fine-tuning the representations. A very recent approach (Hoyle et al., 2020) which follows a similar direction uses knowledge distillation (Hinton et al., 2015) to combine neural topic models and pre-trained transformers.

6 Conclusions

We propose a straightforward and simple method to incorporate contextualized embeddings into topic models. The proposed model significantly improves the quality of the discovered topics. Our results show that context information is a significant element to consider also for topic modeling.

Ethical Statement

In this research work, we used datasets from the recent literature, and we do not use or infer any sensible information. The risk of possible abuse of our models is low.

A Datasets

We pre-processed 20NewsGroup and Wiki20K. We removed punctuation, digits, and nltk's English stop-words. Following other researchers, we selected 2,000 as the maximum number of words for the BoW, and thus we kept only the 2,000 most frequent words in the documents. The other datasets come already pre-processed (reference links are in the paper) and thus we take them as is.

B Models and Baselines

B.1 ProdLDA

We use the implementation made available by Carrow (2018) since it is the most recent and with the most updated packages (e.g., one of the latest versions of PyTorch). We run 100 epochs of the model. We use ADAM optimizer. The inference network is composed of a single hidden layer and 100-dimension of softplus units. The priors over

the topic and document distributions are learnable parameters. Momentum is set to 0.99, the learning rate is set to 0.002, and we apply 20% of drop-out to the hidden document representation. The batch size is equal to 200. More details related to the architecture can be found in the original work (Srivastava and Sutton, 2017).

B.2 Combined TM

The model and the hyper-parameters are the same used for ProdLDA with the difference that we also use SBERT features in combination with the BoW: we take the SBERT English embeddings, apply a (learnable) function/dense layer $R^{1024} \rightarrow R^{|V|}$ and concatenate the representation to the BoW. We run 100 epochs of the model. We use ADAM optimizer.

B.3 LDA

We use Gensim's[9] implementation of this model. The hyper-parameters α and β, controlling the document-topic and word-topic distribution respectively, are estimated from the data during training.

B.4 ETM

We use the implementation available at https://github.com/adjidieng/ETM with default hyperparameters.

B.5 Meta-LDA

We use the authors' implementation available at https://github.com/ethanhezhao/MetaLDA. As suggested, we use the Glove embeddings to initialize the models. We used the 50-dimensional embeddings from https://nlp.stanford.edu/projects/glove/. The parameters α and β have been set to 0.1 and 0.01 respectively.

B.6 Neural Variational Document Model (NVDM)

We use the implementation available at https://github.com/ysmiao/nvdm with default hyperparameters, but using two alternating epochs for encoder and decoder.

C Computing Infrastructure

We ran the experiments on two common laptops, equipped with a GeForce GTX 1050: models can be easily run with basic infrastructure (having a GPU is better than just using CPU, but the experiment can also be replicated with CPU). Both laptops have 16GB of RAM. CUDA version for the experiments was 10.0.

C.1 Runtime

What influences the computational time the most is the number of words in the vocabulary. Table 5 shows the runtime for one epoch of both our Combined TM (CTM) and ProdLDA (PDLDA) for 25 and 50 topics on Google News and 20Newsgroups datasets with the GeForce GTX 1050. ProdLDA is faster than our Combined TM. This is due to the added representation. However, we believe that these numbers are quite similar and make our model easy to use, even with common hardware.

	GNEWS		20NG	
	50 topics	100 topics	50 topics	100 topics
CTM	2.1s	2.2s	1.2s	1.2s
PLDA	1.5s	1.5s	0.8s	0.9s

Table 5: Time to complete one epoch on Google News and 20Newsgroups datasets with 25 and 50 topics.

Abstract

Neural semantic parsers have obtained acceptable results in the context of parsing DRSs (Discourse Representation Structures). In particular models with character sequences as input showed remarkable performance for English. But how does this approach perform on languages with a different writing system, like Chinese, a language with a large vocabulary of characters? Does rule-based tokenisation of the input help, and which granularity is preferred: characters, or words? The results are promising. Even with DRSs based on English, good results for Chinese are obtained. Tokenisation offers a small advantage for English, but not for Chinese. Overall, characters are preferred as input, both for English and Chinese.

1 Introduction

Recently, sequence-to-sequence models have achieved remarkable performance in various natural language processing tasks, including semantic parsing (Dong and Lapata, 2016; Jia and Liang, 2016; Konstas et al., 2017; Dong and Lapata, 2018), the task of mapping natural language to formal meaning representations (Figure 1). In this short paper we focus on parsing Discourse Representation Structures (DRSs): the meaning representations proposed in Discourse Representation Theory (DRT, Kamp and Reyle, 1993), covering a large variety of linguistic phenomena including coreference, thematic roles, presuppositions, scope, quantification, tense, and discourse relations.

Several data-driven methods based on neural networks have been proposed for DRS parsing (van Noord et al., 2018b, 2019; Liu et al., 2019a; Evang, 2019; Fancellu et al., 2019; Fu et al., 2020; van Noord et al., 2020). These approaches frame semantic parsing as a sequence transformation problem and map the target meaning representation to string format. These models learn the meaning of a series of semantic phenomena by taking sentences

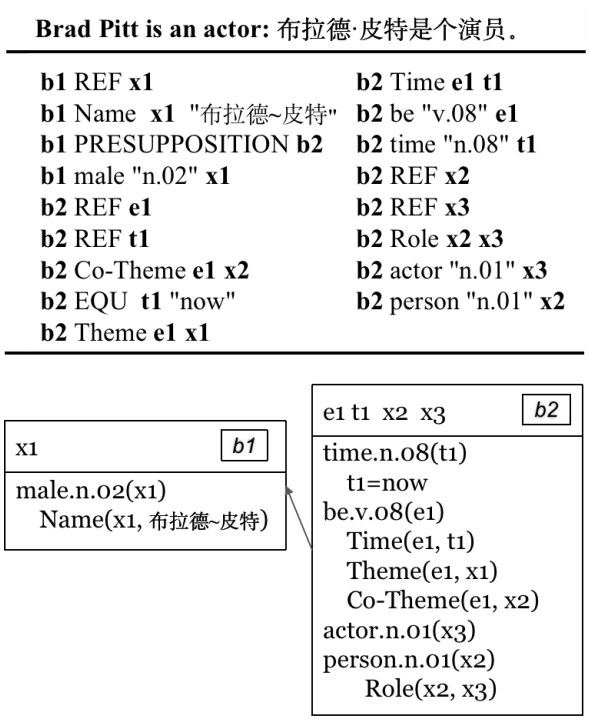

Figure 1: Example DRS for Chinese in both clause and box representation.

as input and directly outputting the corresponding DRSs, without the aid of any extra linguistic information (such as part-of-speech or syntactic structure). These previous studies have achieved good results, but have mostly focused on English or other languages that use the Latin alphabet.

Our objective is to investigate whether the same method is applicable to Mandarin Chinese, an extremely analytic language which makes deep parsing challenging (Levy and Manning, 2003; Yu et al., 2011; Tse and Curran, 2012; Min et al., 2019). But Chinese is not only different on the level of syntax; its writing system also shows large differences with English, as there are no explicit word separators in written Chinese, and there is no distinction between

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 767–775
August 1–6, 2021. ©2021 Association for Computational Linguistics

lower- and upper case characters. Unlike English, Chinese words comprise few characters, but the number of different characters is about two orders of magnitude higher than that of English.

These orthographic differences are interesting in the context of previous work, as van Noord et al. (2018b) use character-level input and word-level input to compare the impact of different input representations on DRSs parsing for English, finding that the character-level representation obtained better performance. In this paper we want to investigate how Chinese fits in this picture. To the best of our knowledge, we are the first to explore methods for Chinese DRS parsing. We aim to answer the following questions:

1. Can existing DRS parsing models achieve good results for Chinese? (RQ1)
2. Given the different writing systems used for English and Chinese, which input granularity is best for either language? (RQ2)
3. Is rule-based word segmentation (tokenization) beneficial for Chinese DRS parsing? (RQ3)

This paper is organised as follows. First we provide a short background on the formal meaning representations that we use, the difference between the writing systems of English and Chinese, and the issues that arise around characters and words. Then we will introduce our approach, the data set that we use, and how we conduct our experiments. In the final section we show that we can achieve good results for Chinese DRS parsing, with characters as the preferred representation.

2 Background

Representing Meaning DRT proposes DRSs to represent the meaning of sentences and short texts. An impressive repertoire of semantic phenomena is covered by DRT, including quantification, negation, reference resolution, comparatives, discourse relations, and presupposition. We use the DRS version as employed in the Parallel Meaning Bank (Abzianidze et al., 2017), where concepts (triggered by nouns, verbs, adjectives and adverbs) are represented by WordNet synsets (Fellbaum, 1998), and semantic relations by Verbnet roles (Kipper et al., 2008). DRSs can be represented in box format or clause format (see Figure 1), where x, e, s, and t are discourse referents denoting individuals, events, states, and time, respectively, and b is used for variables denoting DRSs. Named entities are preserved from the original language used in the input, so names in Chinese are literally transferred in the DRS interpretation (see Figure 1). This means that the only difference between English and Chinese DRSs is the way names are represented: English orthography is used for proper names in English DRSs; Chinese characters are used for names in the corresponding Chinese DRSs.

The box format has become a common representation of DRSs because of its convenient reading and intuitive understanding. The clause format is a flat version of the standard box notation, which represents DRSs as a set of clauses. Due to its simple and flat structure it is more suitable for machine learning purposes. At the same time, however, the structure of DRSs poses a challenge to sequence-to-sequence models, because they need to be able to generate the well-formed recursive semantic structures.

Chinese Word Segmentation Differently from English, Chinese words are not separated by white spaces, as shown in Table 1. The first step of a typical Chinese NLP task is usually to use separators to mark boundaries at appropriate positions to identify words in a sentence. These words define the basic semantic units of Chinese. This process, i.e., Chinese word segmentation (Lafferty et al., 2001; Xue, 2003; Zheng et al., 2013; Cai and Zhao, 2016; Min et al., 2019), is a fundamental step for many Chinese NLP applications, which directly affects downstream performance (Foo and Li, 2004; Xu et al., 2004). Despite the large body of existing research, the quality of Chinese word segmentation remains far from perfect, because many characters are highly ambiguous.

Input Formats for Neural Methods Character-level representations have proved useful for neural network models in many NLP tasks such as POS-tagging (Santos and Zadrozny, 2014; Plank et al., 2016), dependency parsing (Ballesteros et al., 2015) and neural machine translation (Chung et al., 2016). However, only a few studies have used character-level representations as input representations for Chinese NLP tasks (Yu et al., 2017; Li et al., 2018, 2019; Min et al., 2019). For Chinese semantic parsing, previous studies mostly used word-based representations as well (Che et al., 2016; Wang et al., 2018). For English DRS parsing, how-

Type	English input representation	Chinese input representation
Char (raw)	^ b r a d | ^ p i t t | i s | a n | a c t o r .	布 拉 德 · 皮 特 是 个 演 员 。
Char (continuous)	^ b r a d ^ p i t t i s a n a c t o r .	
Char (tokenized)	^ b r a d | ^ p i t t | i s | a n | a c t o r | .	布 拉 德 | · | 皮 特 | 是 | 个 | 演 员 | 。
Word	brad pitt is an actor .	布拉德 · 皮特 是 个 演员 。
BPE (5k)	^ b@ ra@ d ^ p@ it@ t is an ac@ tor@ .	布 拉 德 · 皮 特 是个 演 员。

Table 1: Input representations for the English sentence *Brad Pitt is an actor* and its Chinese translation (布拉德.皮特是个演员). Note that raw and continuous character representations are identical in Chinese. Char (tokenized) adds explicit word boundaries after tokenizing the text. The symbol | represents a word boundary, while the symbol ^ represents a shift to uppercase.

ever, van Noord et al. (2018b) showed that a bi-LSTM sequence-to-sequence model with character-level representations outperformed word-based representations, as well as a combination of words and characters. This will be the starting point of our exploration of Chinese DRS parsing.

3 Methodology

Annotated Data We use data from the Parallel Meaning Bank (PMB 3.0.0, Abzianidze et al., 2017). The documents in this PMB release are sourced from seven different corpora from a wide range of genres. For one of these corpora, Tatoeba, Chinese translations already exist, and we added them to the PMB data. For the remaining texts that had no Chinese translation, we translated the English documents into Chinese using the Baidu API, manually verified the results and, when needed, corrected the translations. Only a few translations needed major corrections. About a hundred translated sentences lacked past or future tense or used uncommon Chinese expressions. Special care was given to the translation of named entities, ambiguous words, and proverbs, and required about a thousand changes. For economical reasons the silver part of the data was only checked on grammatical fluency. Table 2 shows the difference in word- and character-level vocabulary size between English and Chinese. The full translated data set is publicly available.[1]

Language	Chars	Tokens	Words	Tokens
English	139	5,149,912	32,447	1,088,252
Chinese	3,832	1,514,181	39,705	950,310

Table 2: Vocabulary sizes and number of tokens. The number of tokens is calculated after tokenizing the text with either Moses or Jieba.

[1] https://github.com/wangchunliu/Chinese-DRS-data

Chinese Meaning Representations We start from the English–Chinese sentence pairs with the DRSs originally annotated for English. Interestingly, the DRSs in the PMB can be conceived as language-neutral. Even though the English WordNet synsets present in the DRS are reminiscent of English, they really represent concepts, not words. Similarly, the VerbNet roles have English names, but are universal thematic roles. An exception is formed by named entities, that are grounded by the orthography used in the source language. In sum, we assume that the translations are, by and large, meaning preserving, and project English to Chinese DRSs by changing all English named entities to Chinese ones as they appeared in the Chinese input (see Figure 1). This semantic annotation projection method bears strong similarities and is inspired by Damonte et al. (2017) and Min et al. (2019).

Input Representation Types We consider five types of input representations, outlined in Table 1: (i) raw characters, (ii) continuous characters (i.e., without spaces), (iii) tokenised characters, (iv) tokenised words, and (v) byte-pair encoded text (BPE, Sennrich et al., 2016). Note that for Chinese, the first two options amount to the same kind of input. For BPE, we experiment with the number of merges (1k, 5k and 10k) and found in preliminary experiments that it was preferable to not add the indicator "@" for Chinese. For English character input we use an explicit "shift" symbol (^) to indicate uppercased characters, to keep the vocabulary size low. Moreover, the | symbol represents an explicit word boundary. For tokenisation we use the Moses tokenizer (Koehn et al., 2007) for English, while we use the default mode of the Jieba tokenizer[2] to segment the Chinese sentences. To fairly compare these different input representations, we do not employ pretrained embeddings.

[2] https://github.com/fxsjy/jieba

Output Representation Appendix B shows how DRSs are represented for the purpose of training neural models, following van Noord et al. (2018b). Variables are replaced by indices, and the DRSs are coded in either a linearised character-level or word-level clause format. For Chinese, we experimented with both representations and found that the output representation had little effect on parsing performance. To follow previous work (van Noord et al., 2018b) and to allow a fair comparison between the languages, we therefore use the character-level DRS representation for both languages.

Data Splits We distinguish between *gold* (manually corrected meaning representations) and *silver* (automatically generated and partially corrected meaning representations) data. There are a total of 8,403 English–Chinese documents with gold data, of which 885 are used as development set and 898 as test set. The silver data (97,597 documents) is only used to augment the training data, following van Noord et al. (2018b). We use a fine-tuning approach to effectively use high-quality data in our experiments: first training the system with silver and gold data, then restarting the training to fine-tune on only the gold data.

Neural Architecture We use a recurrent sequence-to-sequence neural network with two bi-directional LSTM layers (Hochreiter and Schmidhuber, 1997) as implemented by Marian (Junczys-Dowmunt et al., 2018), similar to van Noord et al. (2019).[3] Specific hyper-parameters are shown in Appendix A. We also experimented with the Transformer model (Vaswani et al., 2017), as implemented in the same framework. However, similar to van Noord et al. (2020), none of our experiments reached the performance of the bi-LSTM model. We will therefore only show results of the bi-LSTM model in this paper.

Evaluation DRS output is evaluated by using Counter (van Noord et al., 2018a), a tool that calculates the micro precision and recall of matching DRS clauses. Counter has been widely used in the evaluation of DRS parsers (Abzianidze et al., 2019). The generated DRSs have to be syntactically as well as semantically well-formed, as checked by the Referee tool (van Noord et al., 2018b), and are otherwise penalised with an F-score of 0.[4]

[3]Code to reproduce our experiments is available at: https://github.com/wangchunliu/Chinese-DRS-parsing

[4]For all our models, this only happened <1% of the time.

	English		Chinese	
Input type	**Dev**	**Test**	**Dev**	**Test**
Char (raw)	87.9	87.6	78.8	76.2
Char (continuous)	86.1	86.9		
Char (tokenised)	88.0	88.1	79.5	76.2
BPE (1k)	86.8	87.0	78.5	76.2
BPE (5k)	87.4	87.1	75.1	71.8
BPE (10k)	82.5	82.3	68.5	65.2
Word	84.5	83.2	74.7	71.6

Table 3: F-scores for DRS parsing with different input representations, averaged over 5 training runs. For BPE, the number of merges is given.

4 Results and Discussion

Table 3 shows the average of five runs for each input representation type. Generally, performance on English is significantly better than on Chinese, which is not surprising as the DRSs are based on English input using English WordNet synsets as concepts (see Figure 1). Given the situation, it is remarkable that Chinese reaches high scores given the differences between the languages in how they convey meaning (Levy and Manning, 2003).

In general, F-scores start to decrease when sentences get longer (Figure 2), though there is no clear difference between the character and word-level models. This is in line with the findings of van Noord et al. (2018b). For English, the input types based on characters outperform those based on words. BPE approaches character-level performance for small amounts of merges (1k), but never surpasses it. This too is in line with van Noord et al. (2018b), but also with previous work on NMT for Chinese (Li et al., 2019). There is a small benefit (0.5) for tokenizing the input text before converting the input to character-level format, though the continuous character representation also works surprisingly well. For Chinese, character-based input shows the best performance too, though for a very small amount of merges BPE obtains a similar score. As opposed to English, tokenizing the Chinese input is not beneficial when using a character-level representation, though it also does not hurt performance. In general, character-level models seem the most promising for Chinese DRS parsing. Similar results were obtained by Min et al. (2019) for Chinese SQL parsing.

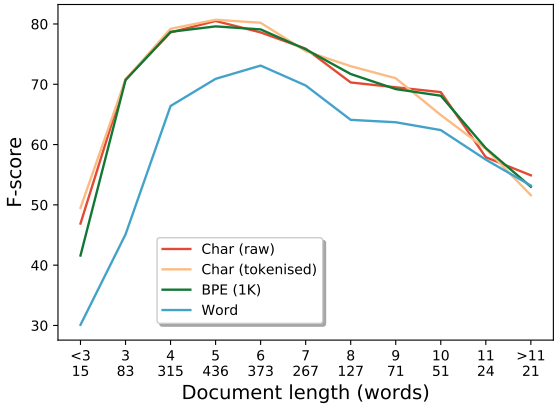

Figure 2: F-scores over Chinese document length on the combined dev and test set, averaged over 5 runs. The x-axis shows the document length in words (top) and the number of documents for that length (bottom).

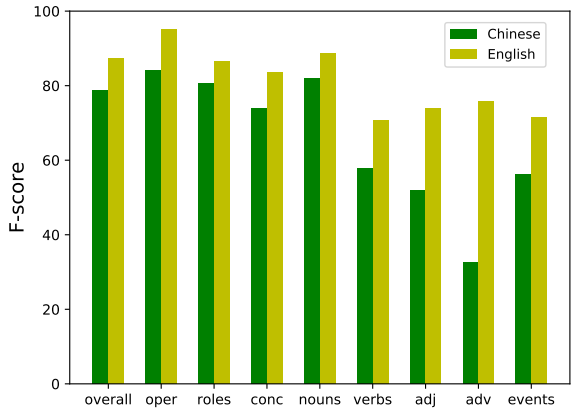

Figure 3: F-scores per clause type (DRS operators, VerbNet roles and WordNet concepts) and concept type (nouns, verbs, adjectives, adverbs and events) as introduced by van Noord et al. (2018b). Reported scores are on the Chinese and English dev set for the raw character-level models, averaged over 5 runs.

Figure 3 shows detailed scores for the character-based (raw) model on the Chinese and English dev set, categorizing operators (e.g., negation, presupposition or modalities), VerbNet roles (e.g., Agent, Theme), predicates, and senses. Modifiers, especially adverbs, get a systematic lower score in Chinese compared to English. This is interesting, and examination of the data reveals that English adverbs are regularly translated as Chinese noun phrases (e.g., *slightly* → *a little*). This will lower the F-score even though the meaning is preserved, only expressed in a semantically different way.

5 Conclusion and Future Work

DRS parsing for Chinese based on projecting meaning representations from English translations gives remarkable performance (**RQ1**), though Chinese adverbs remain challenging. English results outperform those of Chinese, but it is likely that this is due to the general bias of the meaning representations towards English. Similar as for English, we find that characters are the preferred input representation for Chinese (**RQ2**). Surprisingly, for English, good results are even obtained by using characters without spaces as input. Tokenisation (segmenting the text into words) of the input offers a small advantage for English, but not for Chinese (**RQ3**), though it will be interesting to experiment with higher quality word segmentation systems (Higashiyama et al., 2019; Tian et al., 2020).

There are many research directions one could take next. One is to include pre-trained models. For instance, we could use recently proposed pre-trained models such as BART (Lewis et al., 2020) or mBART (Liu et al., 2020) to improve parsing performance. Another interesting idea is, rather than assuming the English WordNet as a background ontology for concepts in the DRS, using concepts based on Chinese WordNet or multilingual wordnets (Wang and Bond, 2013; Bond and Foster, 2013). Both possibilities will likely further improve performance of semantic parsing for Chinese and inspire research for developing semantic parsing models for languages other than English.

A Hyperparameters

Table 4 gives an overview of the hyperparameters we experimented with in the tuning stage. The hyperparameters of the bi-LSTM model are mostly taken from van Noord et al. (2018b), but tuned on the Chinese development set. The hyperparameters of the Transformer model were randomly selected, and then also tuned on the Chinese development set. We also experimented with the hyperparameter selection of Liu et al. (2019b) for the Transformer model, but did not get the desired results.

Fine-tuning We first train the models on gold + silver data for 15 epochs, then we restart the training process from that checkpoint to fine-tune on only the gold data for 30 epochs.

bi-LSTM					
Parameter	**value**	**Parameter**	**value**	**Parameter**	**value**
dim-emb	300	dim-rnn	300	enc-cell	lstm
dec-cell	lstm	enc-depth	2	dec-depth	2

Code Generation from Natural Language with Less Prior and More Monolingual Data

Sajad Norouzi* **Keyi Tang** **Yanshuai Cao**
Borealis AI
sajadn@cs.toronto.edu,{keyi.tang,yanshuai.cao}@borealisai.com

Abstract

Training datasets for semantic parsing are typically small due to the higher expertise required for annotation than most other NLP tasks. As a result, models for this application usually need additional prior knowledge to be built into the architecture or algorithm. The increased dependency on human experts hinders automation and raises the development and maintenance costs in practice. This work investigates whether a generic transformer-based seq2seq model can achieve competitive performance with minimal code-generation-specific inductive bias design. By exploiting a relatively sizeable monolingual corpus of the target programming language, which is cheap to mine from the web, we achieved 81.03% exact match accuracy on Django and 32.57 BLEU score on CoNaLa. Both are SOTA to the best of our knowledge. This positive evidence highlights a potentially easier path toward building accurate semantic parsers in practice. †

1 Introduction

For a machine to act upon users' natural language inputs, a model needs to convert the natural language utterances to machine-understandable meaning representation, i.e. semantic parsing (SP). The output meaning representation is beyond shallow identification of topic, intention, entity or relation, but complex structured objects expressed as logical forms, query language or general-purpose programs. Therefore, annotating parallel corpus for semantic parsing requires more costly expertise.

SP shares some resemblance with machine translation (MT). However, SP datasets are typically smaller, with only a few thousand to at most tens of thousands of examples, even smaller than most low resource MT problems. Simultaneously, because the predicted outputs generally need to be exactly correct to execute and produce the right answer, the accuracy requirement is generally higher than MT. As a result, inductive bias design in architecture and algorithm has been prevalent in the SP literature (Dong and Lapata, 2016; Yin and Neubig, 2017, 2018; Dong and Lapata, 2018; Guo et al., 2019; Wang et al., 2019; Yin and Neubig, 2019).

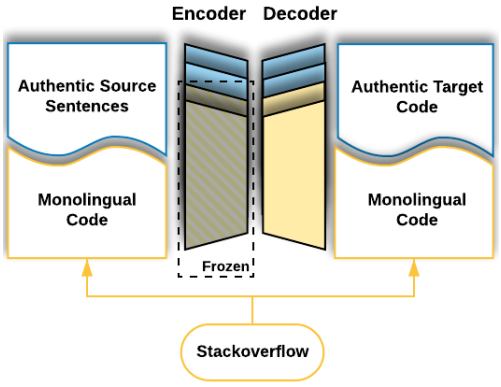

Figure 1: TAE: the monolingual corpus is used both as source and target. The encoder is frozen in the computation branch on the monolingual data.

While their progress is remarkable, excessive task-specific expert design makes the models complicated, hard to transfer to new domains, and challenging to deploy in real-world applications. In this work, we look at the opposite end of the spectrum and try to answer the following question: *with little inductive bias in the model, and no additional labelled data, is it still possible to achieve competitive performance?* This is an important question, as the answer could point to a much shorter road to practical SP without breaking the bank.

This paper shows that the answer is encouragingly affirmative. By exploiting a relatively large monolingual corpus of the programming language, a transformer-based Seq2Seq model (Vaswani et al., 2017) with little SP specific prior could potentially attain results superior to or competitive with the

state-of-the-art models specially designed for semantic parsing. Our contributions are three-fold:

- We provide evidence that transformer-based seq2seq models can reach a competitive or superior performance with models specifically designed for semantic parsing. This suggests an alternative route for future progress other than inductive bias design;
- We do empirical analysis over previously proposed approaches for incorporating monolingual data and show the effectiveness of our modified technique on a range of datasets;
- We set the new state-of-the-art on Django (Oda et al., 2015) reaching 81.03% exact match accuracy and on CoNaLa (Yin et al., 2018) with a BLEU score of 32.57.

2 Previous Work on Semantic Parsing

Different sources of prior knowledge about the SP problem structure could be exploited.

Input structure: Wang et al. (2019) adapts the transformer relative position encoding (Shaw et al., 2018) to express relations among the database schema elements as well as with the input text spans. Herzig and Berant (2020) proposed a span-based neural parser with compositional inductive bias built-in. Herzig and Berant (2020) also leverages a CKY-style (Cocke, 1969; Kasami, 1966; Younger, 1967) inference to link input features to output codes.

Output structure: The implicit tree or graph-like structures in the programs can also be exploited. Dong and Lapata (2016) proposed parent-feeding LSTM following the tree structure. Dong and Lapata (2018) proposed a coarse-to-fine decoding approach. Guo et al. (2019) crafted an intermediate meaning representation to bridge the large gap between input utterance and the output SQL queries. Yin and Neubig (2017, 2018) proposed TranX, a more general-purpose transition-based system, to ensure grammaticality of predictions. Using TranX, the neural model predicts the linear sequence of AST-tree constructing actions instead of the program tokens. However, a human expert needs to craft the grammar, and the design quality impacts the learning and generalization for the neural nets.

Sequential models with less SP specific priors have been investigated (Dong and Lapata, 2016; Ling et al., 2016b; Zeng et al., 2020), However, they generally fell short in accuracy comparing to the best of structure-exploiting ones listed above.

The most closely related to ours is the work by Xu et al. (2020) for incorporating external knowledge from extra datasets, which used a noisy parallel dataset from Stackoverflow to pre-train the SP and fine-tuned it on the primary dataset. Their approach's main limitation is still the need for (noisy) parallel data, albeit cheaper than the primary labelled set. Nonetheless, as we shall see in the experiment section later, our approach achieves better results when using the same amount of data mined from the same source despite ignoring the source sentence.

3 Background and Methodology

BERT (Devlin et al., 2018) class of pre-trained models can make up for the lack of inductive bias on the input side to some degree. On the output side, we hope to learn the necessary prior knowledge about the target meaning representation from unlabelled monolingual data.

Using monolingual data to improve seq2seq models is not new and has been extensively studied in MT before. Notable methods include *fusion* (Gulcehre et al., 2015; Ramachandran et al., 2016; Sriram et al., 2018; Stahlberg et al., 2018), *back-translation (BT)* (Sennrich et al., 2015; Edunov et al., 2018; Hoang et al., 2018), (Currey et al., 2017; Burlot and Yvon, 2018, 2019), and *BT with copied monolingual data* (Currey et al., 2017; Burlot and Yvon, 2019). However, due to more structured outputs, less training data, and different evaluation metrics of exact match correctness instead of BLEU, it is unclear if these lessons transfer from MT to SP. So SP-specific investigation is needed.

3.1 Target Autoencoding with Frozen Encoder

We assume a parallel corpus of natural language utterances and their corresponding programs, $\mathcal{B} = \{\boldsymbol{x}_i, \boldsymbol{y}_i\}$. The goal is to train a translator model (TM) to maximize the conditional log probability of $\boldsymbol{y}_i$ given $\boldsymbol{x}_i$, $T_{\boldsymbol{\theta}}(\boldsymbol{y}_i|\boldsymbol{x}_i)$, over the training set: $\mathcal{L}_{\text{sup}} = \sum_{\mathcal{B}} T_{\boldsymbol{\theta}}(\boldsymbol{y}_i \mid \boldsymbol{x}_i)$ where $\boldsymbol{\theta}$ is the vector of TM model parameters. Let $\mathcal{M} = \{\boldsymbol{y}'_i\}$ denote the monolingual dataset in the target language.

Currey et al. (2017); Burlot and Yvon (2019) demonstrated that in low resource MT, auto-encoding the monolingual data besides the main supervised training is helpful. Following the same path, we add an auto-encoding objective term on monolingual data: $\mathcal{L}_{\text{full}} = \mathcal{L}_{\text{sup}} + \sum_{\mathcal{M}} T_{\boldsymbol{\theta}}(\boldsymbol{y}'_i \mid \boldsymbol{y}'_i)$.

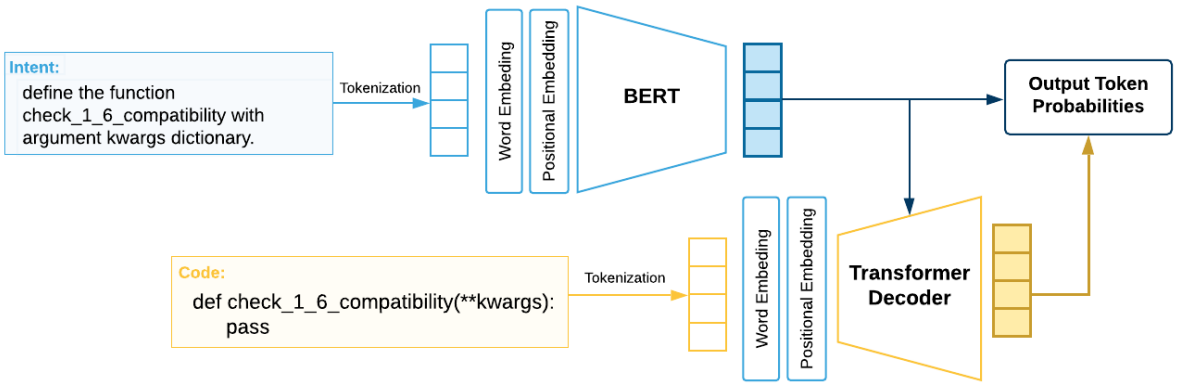

Figure 2: Model overview during training: we use a standard transformer-based encoder-decoder model where the positional and word embeddings are shared between encoder and decoder. The modules related to the encoder are represented in blue and the decoder ones are in yellow. Standard teacher forcing and transformer masking is applied during training.

The target $\boldsymbol{y}_i'$'s are reconstructed using the shared encoder-decoder model.

We conjecture that monolingual data auto-encoding mainly helps the decoder, so we propose to freeze the encoder parameters for monolingual data. Writing the encoder and decoder parameters separately with $\boldsymbol{\theta} = [\boldsymbol{\theta}_e, \boldsymbol{\theta}_d]$, then $\boldsymbol{\theta}_e$ is updated using the gradient of the supervised objective $\mathcal{L}_{\text{sup}}$, whereas the decoder gradient comes from $\mathcal{L}_{\text{full}}$. We verify this hypothesis in section 4.1.

In terms of model architecture, our TM is a standard transformer-based seq2seq model with copy attention (Gu et al., 2016) (illustrated in Fig. 2 of C). We fine-tune BERT as the encoder and use a 4-layer transformer decoder. There is little SP-specific inductive bias in the architecture. The only special structure is the copy attention, which is not a strong inductive bias designed for SP as copy attention is widely used in other tasks as well.

We refer to the method of using copied monolingual data and freezing the encoder over them as *target autoencoding* (TAE). Unless otherwise specified in the ablation studies, the encoder is always frozen.

4 Experiments

For our primary experiments we considered two python datasets namely Django and CoNaLa. The former is based on Django web framework and the latter is annotated code snippets from stackoverflow answers. Additionally, we experiment on the SQL version of GeoQuery and ATIS from Finegan-Dollak et al. (2018) (with query split), WikiSQL (Zhong et al., 2017), and Magic (Java) (Ling et al., 2016b).

Python Monolingual Corpora: CoNaLa comes with $600K$ mined questions from Stackoverflow. We ignored the noisy source intents/sentences and just use the python snippets. To be comparable with Xu et al. (2020), we also select a corresponding $100K$ subset version for comparison. See Appendix A for details on the SQL and Java monolingual corpora.

Experimental Setup: In all experiments, we use label smoothing with a parameter of 0.1 and Polyak averaging (Polyak and Juditsky, 1992) of parameters with a momentum of 0.999 except for GeoQuery which we use 0.995. We use Adam (Kingma and Ba, 2014) and early stopping based on the dataset specific evaluation metric on dev set. The learning rate for the encoder is 1×10^{-5} over all datasets. We used the learning rate of 7.5×10^{-5} on all datasets except GeoQuery and ATIS which we use $1 \times 10 - 4$. The architecture overview is shows in Fig. 2. At the inference time we use beam search with beam size of 10 and a length normalization based on (Wu et al., 2016). We run each experiment with 5 different random seeds and report the average and standard deviation. WordPiece tokenization is used for both natural language utterances and programming code.

4.1 Empirical Analysis

First, we considered a scenario where the monolingual corpus comes from the same distribution as the bitext. We simulate this setup by using 10% of Django training data as labeled data while using all the python examples from Django as the mono-

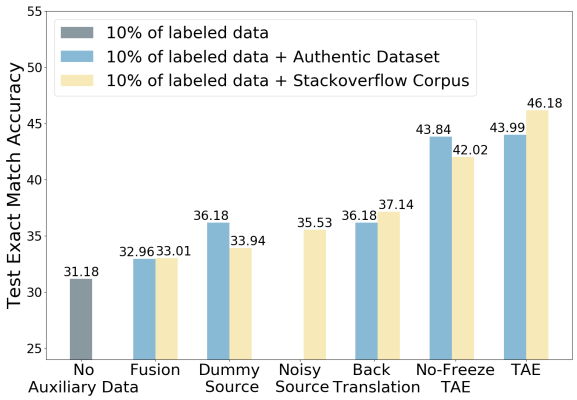

Figure 3: Analysis using only 10% Django train bitext.

lingual dataset of 10 times bigger. Results with "Authentic Dataset" in Fig. 3 shows the effectiveness of TAE vs other approaches.

Next, we used the monolingual dataset prepared for python (StackOverflow Corpus) which is from a different distribution. Fig. 3 shows even more considerable improvement, thanks to the larger monolingual set. We considered noisy intents provided in CoNaLa monolingual corpus and dummy source sentences where each monolingual sample is paired along with a random length array containing zeros. We also compared against other well-known approaches like fusion and back-translation, see experiments details in Appendix D. TAE outperforms all those approaches by a large margin.

Now one important question is, what part of the model benefits from monolingual data most? In Sec. 3.1, we conjectured that auto-encoding of monolingual data should mostly help the decoder, not the encoder. To verify this, we perform an ablation by comparing freezing encoder parameters versus not freezing over the monolingual set. Fig. 3 shows that without freezing the encoder, performance drops slightly for TAE on authentic Django while dropping significantly when copying on Stackoverflow data. This confirms that the performance gain is due to its effect on the decoder, while the copied monolingual data might even hurts the encoder.

4.2 Main Results on Full Data

Table 2-3 showcase our SOTA results on Django and CoNaLa. While our simple base seq2seq model does not outperform previous works, with TAE on the monolingual data, our performance improves and outperforms all the previous works.

The most direct comparison is with Xu et al. (2020) that also leverage the same extra data mined from StackOverflow (*EK* in Table 3). As mentioned in Sec. 2, they used the noisy parallel corpus for pre-training, whereas we only leverage the monolingual set. However, we obtain both larger relative improvements over our baseline (32.29 from 30.98) compared to Xu et al. (2020) (28.14 from 27.20), as well as better absolute results in the best case. In fact, with only the $100K$ StackOverflow monolingual data, our result is on par with the best one from Xu et al. (2020) that uses the additional python API bitext data. Finally, note that part of our superior performance is due to using BERT as an encoder.

Finally, TAE also yields improvements on other programming languages, as shown for GeoQuery (SQL), ATIS (SQL) and Magic (Java) in Table 4. We observe no improvement on WikiSQL. But it is not surprising given its large dataset size and the simplicity of its targets. As observed by previous works (Finegan-Dollak et al., 2018), more than half of queries follow simple pattern of "`SELECT col FROM table WHERE col = value`".

The main results in terms of improvement over previous best methods are statistically significant in Table 2-3. On Django, our result is better than Reranker (Yin and Neubig, 2019) (best previous method in Table 2) with a P-value < 0.05, under one-tailed two-sample t-test for mean equality. Since the previous state of the art on CoNaLa (EK + 100k + API in Table 3) did not provide the standard deviation, we cannot conduct a two-sample t-test against it. Instead, we performed a one-tailed two-sample t-test against the TranX+BERT baseline and observed that our improvement is statistically significant with P-value < 0.05. In Table 4,

Model	Django
YN17 (Yin and Neubig, 2017)	71.6
TRANX (Yin and Neubig, 2018)	73.7
Coarse2Fine (Dong and Lapata, 2018)	74.1
TRANX2 (Yin and Neubig, 2019)	77.3 ± 0.4
TRANX2 + BERT	79.7 ± 0.42
Reranker (Yin and Neubig, 2019)*	80.2 ± 0.4
Our baseline	77.05 ± 0.6
Our baseline + TAE	$\mathbf{81.03 \pm 0.14}$

Table 2: Exact match accuracy for Django test set. Yin and Neubig (2019)* trained a separate model on top of SP to rank beam search outputs.

Model	CoNaLa
Reranker (Yin and Neubig, 2019)*	30.11
TRANX (Yin and Neubig, 2019) + BERT	30.47 ± 0.7
EK (baseline) (Xu et al., 2020)	27.20
EK + 100k (Xu et al., 2020)	28.14
EK + 100k + API (Xu et al., 2020)*†	32.26
Our baseline	30.98 ± 0.1
Our baseline + TAE on 100k	32.29 ± 0.4
Our baseline + TAE on 600k	$\mathbf{32.57 \pm 0.3}$

Table 3: CoNaLa test BLEU. Methods with * trained a separate model on top of SP to rerank beam search outputs. Xu et al. (2020)† used an additional bitext corpus mined from python API documentation.

Dataset	Baseline (%)	Baseline + TAE (%)
GeoQuery	47.69 ± 0.05	51.87 ± 0.02
ATIS	38.04 ± 0.77	40.56 ± 0.57
Magic	41.61 ± 2.07	42.34 ± 0.52
WikiSQL	85.36 ± 0.06	85.30 ± 0.07

Table 4: Additional dataset results: test set exact match accuracy on all dataset.

improvements on GeoQuery and ATIS are statistically significant with P-value < 0.05, while it is not the case for Magic and WikiSQL.

4.3 Discussion

Thus far, we have verified that the decoder benefits from TAE and the encoder does not. For a better understanding of what TAE improves in the decoder, we propose two metrics namely *copy accuracy* and *generation accuracy*. Copy accuracy only considers tokens appearing in the source sentence. If the model produces all of the tokens that need to be copied from the source sentence, and in the right order, then the score is one otherwise zero for the example. Generation-accuracy ignores tokens appearing in the source intent and computes the exact match accuracy of the prediction. We show how to compute these metrics for the following example:
Question: define the function timesince with d, now defaulting to none, reversed defaulting to false as arguments.
Ground Truth:
"`def timesince(d, now=none, reversed=false): pass`"

We iterate over the ground truth script tokens one by one and remove those that can be copied from the source, leading to this code:
Generation Ground Truth:
"`def (=none=):pass`", and the removed tokens will be considered for copy ground truth.
Copy Ground Truth: "`timesince d , now , reversed false`".

We would then use the copy and generation ground truth strings to compute each metric. Note that the order of tokens are still important and exact equality is required.

As shown in Table 5 both metrics are improved. Table 1 illustrates one example from each type and with more samples in the Appendix E. Copy accuracy is important for producing the right variable names mentioned, and it is improved as expected. It is also encouraging to see quantitatively and qualitatively that grammar mistakes are reduced, meaning that the lack of prior knowledge of target language structure is compensated by learning from monolingual data.

Model	Copy	Generation
10% basline	34.18	55.73
10% baseline + TAE	58.89	66.31
Full baseline	80.11	81.27
Full baseline + TAE	84.59	82.65

Table 5: Copy and generation accuracies on Django test set

5 Conclusion

This work has shown the possibility to achieve a competitive or even SOTA performance on semantic parsing with little or no inductive bias design. Besides the usual large-scale pre-trained encoders, the key is to exploit relatively large monolingual corpora of the meaning representation. The modified copied monolingual data approach from machine translation literature works well in this extremely low-resource setting. Our results point to a promising alternative direction for future progress.

A Datasets

We used 6 datasets in total. Django includes programs from Django web framework and CoNaLa contains diverse set of intents annotated on python snippets gathered from Stackoverflow. WikiSQL, GeoQuery, and ATIS include natural language questions and their corresponding SQL queries. WikiSQL includes single table queries while GeogQuery and ATIS requires queries on more than one table. Finally, Magic has Java class implementation of game cards with different methods used during the game. Table 6 summarises all the parallel datasets. For GoeQuery we used query split provided by (Finegan-Dollak et al., 2018).

Monolingual Corpus: CoNaLa comes with $600K$ mined questions from Stackoverflow. We ignored the noisy source intents/sentences and just use the python snippets. To be comparable with Xu et al. (2020), we also select a corresponding $100K$ subset version for comparison. For SQL, Yao et al. (2018) automatically parsed StackOverflow questions related to SQL and provided a set containing $120K$ SQL examples. We automatically parsed the SQL codes and removed samples with grammatical mistakes. We also filtered samples not starting with SELECT special token. Allamanis and Sutton (2013) downloaded full repositories of individual projects that were forked at least once; duplicate projects were removed. We randomly sampled 100K Java examples from more than 14K projects and use that as monolingual set. Table 7 summarises all the monolingual datasets.

Parallel Corpus	Language	Train	Dev	Test
Django (Oda et al., 2015) (link)	Python	16000	1000	1805
CoNaLa (Yin et al., 2018) (link)	Python	2,179	200	500
WikiSQL (Zhong et al., 2017) (link)	SQL	56,355	8421	15878
ATIS (Finegan-Dollak et al., 2018) (link)	SQL	4812	121	347
GeoQuery (Finegan-Dollak et al., 2018) (link)	SQL	536	159	182
Magic (Ling et al., 2016a) (link)	Java	8,457	446	483

Table 6: Parallel dataset sizes. We filtered out Magic data with java code longer than 350 tokens in order to fit in GPU memory.

Monolingual Corpus	Source	Size
Python (Yin et al., 2018) (link)	Stackoverflow	100K
SQL (Yao et al., 2018) (link)	Stackoverflow	52K
Java (Allamanis and Sutton, 2013) (link)	Github	100k

Table 7: Monolingual dataset sizes.

B Dev Set Results

Dataset	Baseline (%)	Baseline + TAE (%)
CoNaLa	32.43 ± 0.21	34.81 ± 0.36
ATIS	5.79 ± 0.29	7.23 ± 0.45
GeoQuery	53.33 ± 1.47	52.58 ± 0.70
Django	75.52 ± 0.21	78.56 ± 0.39
Magic	42.26 ± 1.42	44.17 ± 0.99
WikiSQL	85.92 ± 0.09	85.83 ± 0.07

Table 8: Dev set exact match accuracy on all datasets except CoNaLa which uses BLEU. We followed (Yin and Neubig, 2018) implementation of BLEU score which can be found here.

C Architecture and Experiment Details

We selected the decoder learning rate based on linear search over $[1 \times 10^{-3} - 2.5 \times 10^{-5}]$. Number of decoder layers has been decided based on search over {2, 3, 4, 5, 6} layers and 4 layer decoder shows superior performance (we used a single run for hyperparameter selection). Each model has 150M parameters optimized using a single GTX 1080 Ti GPU. With batch size of 16 each step takes 1.7s on GeoQuery dataset (other datasets have very similar runtime). On Django and CoNaLa, we followed (Yin and Neubig, 2018; Xu et al., 2020) on replacing quoted values with a "str#" where # is a unique id. On Magic dataset, we replaced all newline "\n" tokens with "#"; following (Ling et al., 2016a), we splitted Camel-Case words (e.g., class TirionFordring → class Tirion Fordring) and all punctuation characters. We filtered out Magic data with java code longer than 350 tokens in order to fit in GPU memory.

D Back-Translation and Fusion details

For fusion we follow equation 1 where TM stands for translation model and LM stands for language model. τ limits the confidence of the language model and λ controls the balance between TM and LM. figure 4 shows the performance of a base TM trained on 10% of Django training data with test exact match accuracy of 31.80 over different values of λ and τ. The LM is trained over full Django training set.

$$\log p(y_i^t) = \log p_{TM}(y_i^t) + \lambda \log p_{LM}(y_i^t) = \log p_{TM}(y_i^t) + \lambda \log \frac{e^{l_i^t}/\tau}{\sum_i e^{l_i^t}/\tau} \tag{1}$$

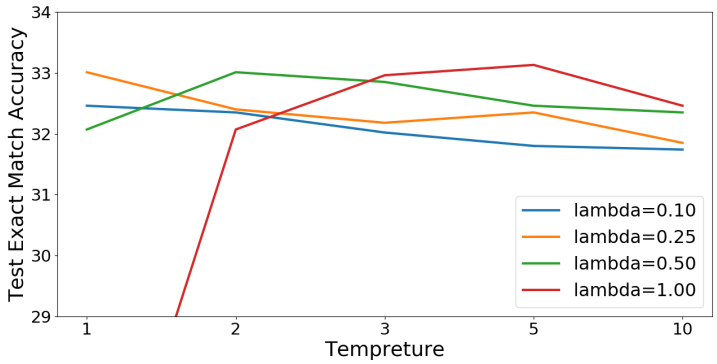

Figure 4: Test exact match accuracy of TM leverage fusion with different parameters

For back-translation we first trained the model using the same architecture explained above in the backward direction. We used BLEU score as a evaluation metric and use early stopping based on that. Using greedy search we generate the corresponding source intent for each code snippet. In the end, the synthetic data is merged with the bitext and trained a forward model.

E Additional Qualitative Examples

Source:	call the function lazy with 2 arguments : _string_concat and six.text_type [six . text_type] , substitute the result for string_concat .
Gold:	`string_concat = lazy(_string_concat, six.text_type )`
Baseline:	`string_concat = lazy (_concat_concat , six. text_type )`
TAE:	`string_concat = lazy ( _string_concat , six. text_type )`
Note:	wrong var

Source:	get translation_function attribute of the object t , call the result with an argument eol_message , substitute the result for result .
Gold:	`result = getattr(t, translation_function)( eol_message)`
Baseline:	`result = getattr ( t , translation_message ) ( eol_message )`
TAE:	`result = getattr ( t , translation_function ) ( eol_message )`
Note:	wrong var

Source:	convert whitespace character to unicode and substitute the result for space .
Gold:	`space = unicode(' ')`
Baseline:	`space = unicode ( character )`
TAE:	`space = unicode ( ' ' )`
Note:	wrongly copied variable name

Source:	assign integer 2 to parts if third element of version equals to zero , otherwise assign it integer 3 .
Gold:	`parts = 2 if version[2] == 0 else 3`
Baseline:	`parts [ 2 ] = 2`
TAE:	`parts = 2 if version [ 2 ] == 0 else 3`
Note:	baseline failed to copy a few source tokens, and instead formed a grammatically correct but semantically incorrect output

Copy mistake examples

Source:	define the function timesince with d , now defaulting to none , reversed defaulting to false as arguments .
Gold:	`def timesince(d, now=none, reversed=false): pass`
Baseline:	`def timesince ( d = none, reversed ( d = false ) : pass`
TAE:	`def timesince ( d, now = none, reversed = false ) : pass`
Note:	unbalanced paranthesis and multiple semantic mistakes.

Source:	define the function exec with 3 arguments : _code_ , _globs_ set to none and _locs_ set to none .
Gold:	`def exec_(_code_, _globs_=none, _locs_=none): pass`
Baseline:	`def exec ( _code_ , _globs= none , _locs_ set ( ) ) : pass`
TAE:	`def exec ( _code_ , _globs_ = none , _locs_ = none ) : pass`
Note:	wrong variable name and grammar mistake

Source:	return an instance of escapebytes , created with an argument , reuslt of the call to the function bytes with an argument s .
Gold:	`return escapebytes(bytes(s))`
Baseline:	`return escapebytes ( bytes ( s ) . re ( s )`
TAE:	`return escapebytes ( bytes ( s ) )`
Note:	extra semantically incorrect predictions and unbalanced paratheses

Source:	call the function blankout with 2 arguments : p and str0 , write the result to out .
Gold:	`out.write(blankout(p, 'str0'))`
Baseline:	`out .write ( blankout ( p , 'str0' )`
TAE:	`out .write ( blankout ( p , 'str0' ) )`
Note:	unbalanced paratheses

Grammar or semantic mistake examples

Abstract

The general format of natural language inference (NLI) makes it tempting to be used for zero-shot text classification by casting any target label into a sentence of hypothesis and verifying whether or not it could be entailed by the input, aiming at generic classification applicable on any specified label space. In this opinion piece, we point out a few overlooked issues that are yet to be discussed in this line of work. We observe huge variance across different classification datasets amongst standard BERT-based NLI models and surprisingly find that pre-trained BERT without any fine-tuning can yield competitive performance against BERT fine-tuned for NLI. With the concern that these models heavily rely on spurious lexical patterns for prediction, we also experiment with preliminary approaches for more robust NLI, but the results are in general negative. Our observations reveal implicit but challenging difficulties in entailment-based zero-shot text classification.

1 Introduction

Natural language inference (NLI, Bowman et al., 2015), also known as recognizing *textual entailment* (RTE, Condoravdi et al., 2003; Dagan et al., 2005), is normally formatted as the task of determining whether or not a **premise** sentence semantically entails a **hypothesis** sentence. The generality of the task format has aroused some recent studies to apply NLI models for various downstream applications (Poliak et al., 2018), and more recently text classification (Yin et al., 2019, 2020), making them generally-applicable solutions along with all those similar attempts to build a universal framework for various NLP tasks (Kumar et al., 2016; Raffel et al., 2020, *inter alia*). Text classification is then reduced to textual entailment by setting the input sentence as the premise and simultaneously casting the candidate label into a hypothesis sentence using pre-defined templates or lexical definitions from WordNet. Once we have any pre-trained NLI models at hand, *zero-shot text classification* under any specified label space is enabled for free without the need to collect annotated data. With contextualized representation based on pre-trained language models such as BERT (Devlin et al., 2019), NLI performance has been drastically improved. Promising empirical results have been shown on various text classification benchmarks that vary across topic classification, emotion classification, and situation classification, outperforming earlier standard approaches (Chang et al., 2008) or simple scoring schemes derived from distributional similarity (Mikolov et al., 2013).

However, such generality is conceptually contradictory with the specificity of text classification in many practical scenarios. In this opinion piece, we conduct extended analysis on the recent attempts (Yin et al., 2019) and point out some implicit issues under entailment-based zero-shot text classification that are overlooked in this line of work. We experiment with additional classification datasets and observe huge variance across them amongst standard BERT-based NLI models. More surprisingly, we find that raw BERT models without fine-tuning can sometimes yield more competitive results. We also experiment with preliminary approaches for improving the robustness of NLI models, but only to find negative results in general. Our observations reveal implicit but massive difficulties in building a successful general-purpose zero-shot text classifier based on text entailment models.

2 Our Investigation and Implied Issues

We attempt at re-examining the earlier study (Yin et al., 2019) with extended analysis to help estab-

*Work during internship at Microsoft Research Asia.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 786–796

lish a better understanding of zero-shot text classification based on textual entailment. Our focus is to check **how well the models pre-trained for NLI could generalize to the prediction of unseen categories**, which is the major target of zero-shot classification. We did not study the setting that test set also include labels seen in training, commonly phrased as *generalized zero-shot learning* (Xian et al., 2018) and referred to as the *label-partially-unseen* setting by Yin et al. (2019). That setting strongly assumes that a bunch of in-domain data for a number of classes are available already. [1]

2.1 Basic setup

2.1.1 Text classification datasets

As an attempt to study zero-shot text classification in conceptually different and diverse aspects, Yin et al. (2019) experimented with three instances:

Topic classification : The Yahoo! Answers dataset from Zhang et al. (2015) with 10 categories.

Emotion classification : The Unify Emotion dataset (Bostan and Klinger, 2018) with 9 emotion types and a `none` label if no emotion applies.

Situation classification : The Situation Typing dataset (Mayhew et al., 2019) with 11 situation types and instances and an extra type `none`.

Additionally, we extend our experiments with the test sets from the following datasets:

Snips : A popular dataset[2] for *intent detection* collected from the Snips personal voice assistant (Coucke et al., 2018), with seven intent labels.

AG's news : To further study the models on *topic classification* in a different genre, we additionally use the English news data from (Zhang et al., 2015) that consists of four types of articles: `World`, `Sports`, `Business`, `Sci/Tech`.

SST-2 : The Stanford Sentiment Treebank dataset[3] processed by Socher et al. (2013) for *sentiment polarity classification* with binary labels (`positive` and `negative`).

[1] Another reason for not studying on this setting is that the split of development set and test set in (Yin et al., 2019) contain the same label space, which is flawed to be used for any claim on the performance of "unseen labels".

[2] https://github.com/snipsco/snips-nlu

[3] For SST-2 we follow Zhang et al. (2021) and Gao et al. (2021) to use the development set from GLUE for testing.

2.1.2 Experimented systems

To study entailment-based approaches, we use the models released by Yin et al. (2019) which are `bert-base-uncased` models pretrained on GLUE RTE (Dagan et al., 2005; Wang et al., 2019b), MNLI (Williams et al., 2018), and FEVER (Thorne et al., 2018), respectively. We reuse the same scheme for mapping labels into hypotheses using templates and WordNet definition for all datasets[4], as well as the same mechanism for producing final predictions. We leave more implementation details to the Appendix.

We keep reporting results from these baselines following Yin et al. (2019) for reference:

- **Majority**: Output the most frequent label.
- **Word2Vec**: Using the average word embeddings to vectorize input and labels, output label with maximum cosine similarity.
- **ESA**: Representing the text and label in the Wikipedia concept vector space. Using the implementation[5] from Chang et al. (2008).

Moreover, due to the obvious variance in performance for models trained on different NLI datasets, we are also tempted to check how much the performance might degrade when given no NLI data at all for fine-tuning. This corresponds to naively using a raw BERT model which has been pre-trained for *next sentence prediction* (NSP). For consistency, we use the same premises and hypotheses as the delegate for label names and templates to formulate the sentence pair classification. Since NSP is not predicting for a directional semantic entailment, we also try a variant with all pairs reversed, i.e., setting all hypothesis sentences ahead of premises as input, denoted as NSP(Reverse).

2.2 Results and further analysis

The results from all systems on different datasets are displayed in Table 1, including an additional group for MNLI results as we found an even better run overall in our experiments. There are some interesting observations emerge from our extended experiments and analysis.

[4] For newly introduced datasets we follow the similar strategy to prepare for the hypothesis templates.

[5] https://github.com/CogComp/cogcomp-nlp/tree/master/dataless-classifier

	Topic (Yahoo)	Emotion	Situation	AG's News	SST-2	Snips
Majority	10.0	5.9	11.0	25.0	50.9	17.7
ESA	28.6	8.0	26.0	73.3	55.5	63.4
Word2Vec	35.7	6.9	15.6	44.1	53.7	63.6
RTE (Yin et al., 2019)	43.8	12.6	**37.2**	56.7	52.5	56.4
FEVER (Yin et al., 2019)	40.1	**24.7**	21.0	**78.3**	71.7	69.4
MNLI (Yin et al., 2019)	37.9	22.3	15.4	72.4	67.5	77.6
MNLI (our best overall run)	49.1	19.9	14.5	77.7	67.5	77.6
NSP (Reverse)	**53.1**	16.1	19.9	**78.3**	**79.7**	**81.3**
NSP	50.6	16.5	25.8	72.1	73.9	73.4

Table 1: Text classification results. We report label-wise weighted F1 for emotion and situtation datasets, and accuracy for the others. Reported results from (Yin et al., 2019) have been reproduced from their released models.

2.2.1 How much have NLI data contributed?

The big difference from various NLI datasets drives us to try a raw BERT without fine-tuning on any NLI data, i.e., merely relying on NSP pre-training for sentence pair classification. The results are shown at the bottom two rows in Table 1, which turn out to be surprisingly strong, especially on topic classification, intent classification, and binary sentiment classification.

We conjecture that the raw BERT model has already acquired certain ability of topic distinction and sentiment polarity due to the construction of positive and negative sentence pairs in NSP pre-training to detect pairwise coherence. In this way, NSP could serve as a non-trivial, strong alternative baseline for zero-shot text classification scenarios where the target labels are semantically more concrete (e.g., topics) or more frequently appeared (e.g., words expressing sentiment). In such scenarios, fine-tuning on limited NLI data could weaken the semantic coherence acquired from the raw BERT pre-trained on generic-domain corpora, especially now that fine-tuned models have utilized many spurious lexical cooccurrence features as shown in many similar sentence pair classification models (Feng et al., 2019; Niven and Kao, 2019), possibly due to the inherent lexical bias from the current NLI datasets collected from crowd workers. [6] Readers who are curious about more details on this problem can refer to our qualitative analysis in the Appendix which could hopefully help establish a slightly better sense on the behavioral difference introduced by NLI fine-tuning.

On the other hand, fine-tuning on NLI data might seem to be marginally helpful for more abstract cases such as emotion and situation typing, but the performance metrics are in fact pathetically disappointing across all systems.

2.2.2 How stable are these NLI models?

Apart from the obvious difference caused by different training data, there underlies a more serious concern: the *discrepancy* between the training task (NLI) and the target usage (classification). The gap in task formatting (and henceforth data distribution) naturally raises a question: *do NLI models with similar in-domain performance generalize similarly for text classification?*

We train NLI models on the largest MNLI dataset with varied hyperparameter settings and random seeds, and keep models achieving similarly strong in-domain generalization performance as measured by the early-stopping dev set performance. Results are listed in Table 2, where the absolute differences between the worst and the best are large, especially on classifying topic or intent. We observe even worse trends on other smaller NLI datasets (see Appendix). These results are consistent with recent studies within the scope of NLI reporting that BERT instances which achieve similar performance metrics on standard NLI datasets could have huge variance in out-of-distribution generalization or linguistic stress testing (McCoy et al., 2020; Zhou et al., 2020; Geiger et al., 2020), while providing another instance of the underspecification problem in modern machine learning (D'Amour et al., 2020).

As a verification, we also try to tune the models for different development sets that better characterize the generalization behavior for zero-shot

[6] Some readers might guess that other NLI datasets collected via a more careful process (Jiang and de Marneffe, 2019; Eisenschlos et al., 2021) might partially mitigate the bias appearing from crowdsourced annotation, but this does not mean that such better intended datasets can be free from statistically biased lexical distributions with coincidental cooccurrences that could be utilized by our strong data-fitting models during fine-tuning (Geirhos et al., 2020; Du et al., 2021). Our additional results described in the Appendix do not seem to be promising on this direction towards better NLI data.

Dataset	Average	Std	Min	Max
MNLI dev set	90.5	0.3	90.0	90.8
Yahoo	39.0	10.5	26.9	50.2
Emotion	18.1	2.0	15.7	20.5
Situation	16.2	1.5	14.5	18.7
AGNews	63.7	11.0	50.0	77.7
SST-2	68.6	2.0	66.1	70.9
Snips	74.1	3.9	68.4	77.6

Table 2: Results of five runs of BERT fine-tuned on MNLI and tested on classification datasets

classification. We reorganize the splitted development set and the test set of the topic classification datasets (Yahoo and AG's News) to make sure they do not have overlapped classes.[7] The new results are shown in Table 3, where we can clearly see more stable generalization performance. This observation necessitates that a certain amount of annotated data for targeted classification already existed, making NLI models difficult to apply in practice. Results in this part reveals that text classification via NLI is asking for out-of-distribution generalization, a property that current NLI models rarely have, henceforth susceptible to huge *instability*.

Dataset	Average	Std	Min	Max
Yahoo-dev	52.7	2.6	49.1	56.2
Yahoo-test	48.1	2.7	44.2	51.7
AGNews-dev	79.0	6.9	72.1	89.1
AGNews-test	73.8	3.8	69.6	77.4

Table 3: Results of five runs for training BERT on MNLI with model selection via target domain dev set

2.2.3 Is more robust NLI helpful?

Previous studies have raised concerns on that the current NLI models heavily rely on spurious lexical overlap patterns (Sanchez et al., 2018; Naik et al., 2018; McCoy et al., 2019, *inter alia*). For analytical purposes, we randomly permute the tokens of each input instance to see how much the predictions might change. Results shown in Table 4 suggest that shuffling the input tokens does not affect the model performance by much, which is consistent with similar recent findings (Gupta et al., 2021; Sinha et al., 2021). This reveals a concern that all these models might just predict with shallow lexical patterns that may not be robust for more semantically abstractive input instances.

There have been a few recent attempts trying to remove the shallow overlap bias for NLI model

[7]Details are described in the Appendix.

Model	Yahoo	AGNews	SST-2
NSP(Reverse)	-5.1 / 67.2	+0.4 / 82.7	-13.5 / 75.9
RTE	-2.0 / 77.5	+0.3 / 90.0	+0.6 / 94.5
FEVER	-7.2 / 64.6	+0.5 / 90.6	-9.5 / 82.3
MNLI	+1.6 / 54.8	+2.7 / 84.9	-6.4 / 84.4
Random	- / 10.0	- / 25.0	- / 50.0

Table 4: Results of shuffling perturbation. In each cell: the change of accuracy after input shuffling, followed by the percentage of examples where the predictions do not change. All these results are reported as the average score of five different random shuffles.

training. We experiment with three schemes on the MNLI data to see whether they could lead to better generalization of zero-shot classification: (1) *Data augmentation* with syntactic transformations (Min et al., 2020)[8], denoted as *DA*, (2) *Instance reweighting* following Clark et al. (2019) that reweights each example with one minus the probability a bias-only model assigns the correct label, denoted as *RW*, and (3) The *bias product* method (Clark et al., 2019) that ensembles a bias-only model via a product of experts, denoted as *BP*, which is essentially the same as its concurrent work via fitting the residual of the biased models (He et al., 2019). There exist additional solutions with richer details such as multi-task learning (Tu et al., 2020) where proper auxiliary tasks could be identified to improve robustness. We plan to explore more in this line in our more extensive future study.

The results are shown in Table 5 . All the three debiasing methods improve the NLI performance on the HANS dataset (McCoy et al., 2019) for robustness testing, indicating that the debiased models overcome the word overlap heuristics to some extend. In general, we do not observe any real improvement other than the neglectable gains on emotion and situation datasets where the original performance is pathetically low.

	HANS	Yahoo	Emo.	Situ.	AG	SST	Snips
MNLI	53.0	**49.1**	19.9	14.5	**77.7**	67.5	**77.6**
w/ DA	**67.3**	47.3	18.0	16.3	74.3	**73.1**	76.6
w/ RW	64.5	43.4	21.8	**23.5**	71.7	68.6	71.6
w/ BP	65.4	48.5	**23.0**	22.3	75.6	69.8	72.7

3 Conclusion and Discussion

We investigate entailment-based zero-shot text classification further with extended analysis, uncovering the following overlooked issues:

- Raw BERT models trained for next sentence prediction are surprisingly strong baselines and NLI fine-tuning does not bring performance gain on many classification datasets.
- Large variance on different classification scenarios and instability to different runs, still requiring annotated data (at least used for validation) to stablize generalization performance.
- NLI models usually rely heavily on shallow lexical patterns, which hampers generalization as required by text classification, and currently more robust NLI methods might not help.

Our observations reveal *implicit but massive difficulties in building a usable zero-shot text classifier based on text entailment models*. Given the difficulty of NLI data collection that aims at out-of-domain generalization or transfer learning (Bowman et al., 2020), we question the feasibility of this setup in the current progress of language technology. Before significant progress in language understanding and reasoning, it seems more promising to consider alternative schemes built on explicit external knowledge (Zellers and Choi, 2017; Rios and Kavuluru, 2018; Zhang et al., 2019) or more crafted usage of pre-trained models that hopefully have captured more comprehensive semantic coverage and better compositionality from large corpora or grounded texts (Meng et al., 2020; Brown et al., 2020; Radford et al., 2021).

This study also implies *the huge difficulty for benchmarking zero-shot text classification without any further restriction on the task setting*. The three datasets used by Yin et al. (2019) were originally intended for diverse coverage but are not sufficient to draw consistent conclusions as we have shown. We suggest future studies on zero-shot text classification either conduct experiments over even more diverse classification scenarios to verify any claimed generality, or directly focus on more specific task settings and verify claims within a smaller but clearer scope such as zero-shot intent classification or zero-shot situation typing for more reliable results with less instability, and perhaps based on more carefully curated data (Rogers, 2021).

Acknowledgments

We thank all the anonymous reviewers for their helpful comments on our submitted draft. The empirical studies conducted in this work were mostly based on the open-source repositories on GitHub from other papers as described earlier. We thank their original authors for sharing their implementation and we also publicly release our experimental scripts on GitHub[9].

A Appendix

A.1 Additional Experimental Details

Templates for generating hypothesis For Yahoo, Emotion, and Situation datasets, we followed Yin et al. (2019) and just explored the label names and WordNet definition accompanied with a template[10] to convert labels to hypotheses for entailment-based models. When applying NSP, we only used label names to generate hypotheses as we did not observe real improvement from using WordNet definitions in our preliminary experiments. For AGNews, SST-2, and Snips, we simply used the label names to fill the templates. The templates we used are given in Table A.1.

Other implementation details For all experiments, we train BERT models by using *bert-base-uncased* version and code from the HuggingFace library (Wolf et al., 2019). We used the same prediction strategy as Yin et al. (2019): we pick the label with the maximal probability in single-label scenarios while choosing all the labels with "next sentence" decision in multi-label cases for both NSP and NSP(Reverse) baselines.

Label spaces of classification The labels of each dataset we used are listed in Table A.2.

[10] https://github.com/yinwenpeng/BenchmarkingZeroShot

Dataset	Template	Label to words mapping
Yahoo	It is related with [LABEL] .	[Sports]: sports, [Society & Culture]: society or culture, etc.
Emotion	This person feels [LABEL] .	[sadness]: sad, [anger]: angry, [guilt]: guilty, etc.
Situation	The people there need [LABLE] .	[shelter]: shelter, [utilities]: utilities, etc.
AGNews	It is related with [LABEL] .	[Sci/Tec]: technology, [Business]: business, etc.
SST-2	The movie is [LABEL] .	[positive]: great , [negative]: terrible
Snips	I want to [LABEL] .	[RateBook] : rate a book, [SearchCreativeWork]: search creative work, etc.

Table A.1: Templates used for each dataset. For Topic Emotion and Situation dataset, we also use the WordNet definitions following Yin et al. (2019)

Dataset	Labels
Yahoo	Society & Culture, Science & Mathematics, Health, Education & Reference, Computers & Internet, Sports, Business & Finance, Entertainment & Music, Family & Relationships, Politics & Government
Emotion	sadness, joy, anger, disgust, fear, surprise, shame, guilt, love, none
Situation	search, evacuate, infrastructure, utilities, water, shelter, medical assistance, food, crimeviolence, terrorism, regime change, none
AGNews	World, Sports, Business, Sci/Tech.
SST-2	Positive, Negative
Snips	RateBook, SearchScreeningEvent, PlayMusic, GetWeather, SearchCreativeWork, AddToPlaylist, BookRestaurant,

Table A.2: The label names of the evaluation datasets.

Additional results on CommitmentBank We finetune BERT on the CommitmentBank dataset (de Marneffe et al., 2019; Wang et al., 2019a) converted into the NLI format (Jiang and de Marneffe, 2019), denoted as CB. Following Wang et al. (2019a), we also try to pretrain BERT on MNLI dataset before finetuning on CommitmentBank, called MNLI+CB. In our experiments, we found both two models trained on CB did not show a better performance compared to model trained on other NLI datasets, especially on Yahoo and AGNews (19.9% accuracy on Yahoo for CB and 17.8% accuracy on Yahoo for MNLI+CB). This indicates that the finetuned BERT models may still focus on features that are beneficial for NLI performance, while losing the topic discriminability.

A.2 Qualitative Analysis

Table 1 shows that NSP(reverse) achieves better performance than NSP on several datasets. This could be related to the templates we used for generating previous or next sentences. For example, for the input *"play the god that failed on vimeo"* with label "PlayMusic", NSP(Reverse) predicts "PlayMusic" while NSP predicts "AddToPlaylist". It is a more natural expression for *"I want to play music. play the god that failed on vimeo"* than *"play the god that failed on vimeo. I want to play music"*. Among the entailment models, We find the RTE-based model performs best on situation dataset. The main class of situation dataset is the "none" label. As shown in Figure A.1, we find RTE-based model performs best on "none" label. Actually, if we calculate the average number of prediction labels each instance, we find NSP, NSP(Reverse), and FEVER's average prediction label number per instance is about 6.2 to 8.3, while RTE and MNLI's average number is about 1, which is closer to the average number of gold labels per instance. The implies NSP is not good at identifying the "none" label since the condition of predicting "entailment" (a premise entails its hypothesis) is more strict than predicting a "next sentence" label. For SST-2, we observe that all three entailment models tend to mislabel sentences with "negative" label as "positive". This may be attributed to the label word distribution in NLI datasets. We find the keyword "great" for positive label is much more frequently occurred than the keyword "terrible" for negative label in all the three NLI datasets.

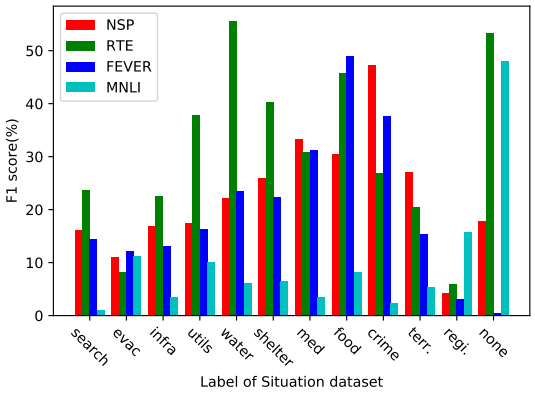

Figure A.1: F1 score of each label in Situation dataset

Case study To get a better understanding of NLI models' behavior, we carry out a case study on

SNIPS. We use Integrated Gradient (Sundararajan et al., 2017) method to attribute the entailment class's output score of BERT model to per input token [11]. Several examples are shown in Table A.3.

We found the NLI models sometimes rely on spurious patterns to do prediction. In the first example, the model finetuned on FEVER assigns a high negative attribution score to the word "*zero*" and makes a wrong prediction. However, if we replace "*zero*" with other numbers, the model changes its prediction and can correctly predicts the "RateBook" label. These examples reflect model trained on FEVER dataset learns the spurious correlations between "not entailment" label and the occurrence of word "*zero*"[12]. These superficial patterns may not be the models' main behaviour for prediction, it still leaks the model's fragility and could be an important factor to the model's failure in zero-shot scenario.

The other two groups of cases show another problem: current NLI models only predict "*entailment*" label when the premise *entails* its hypothesis, this problem definition is just different from the zero-shot test tasks. For example, in the last group, model trained on MNLI outputs a low probability for entailment since "*restaurant*" can not be directly inferred from premise sentence. If we change "*restaurant*" into "*place*", the model confidently predicts "*entailment*" .

Error cases We also show some additional examples in Table A.4, from which we might naturally conjecture that the entailment models could rely on spurious lexical features for prediction.

Impact of template choice How to properly choose templates is another issue when utlizing NLI for zero-shot classification. As shown in Table A.5, different templates that seem meaningful to human might have large performance variance on SST-2.

A.3 Details for Stability Experiments

Details for training settings For MNLI dataset, we merge the *neutral* and *contradiction* labels into *not-entailment* label following Yin et al. (2019). We choose hyperparameters randomly for different runs: we choose learning rate from $\{2e^{-5}, 3e^{-5}, 5e^{-5}\}$, training epochs from $\{3, 4, 5\}$ and randomly set the random seed.

Results for training on RTE As shown in Table A.6, the performance of different runs has large variance on both RTE dev and text classification datasets due to its small size.

Reorganize dev and test sets for Yahoo and AGNews We reorganize the Yahoo development set provided by Yin et al. (2019) and divide test set as follows: For the dev set, the instances with label in set {"Society & Culture", "Health", "Computers & Internet", "Business & Finance", "Family & Relationships"} are preserved, we call this new dev set as **Yahoo-dev** . For the original test set, we only select instances with the label which doesn't appear in the dev set as our new test set, denoted as **Yahoo-test**. During the NLI model training, we select the checkpoint by the performance on Yahoo-dev, and we report the variance of five different runs trained on MNLI. We also conduct experiments on AGNews in the same way. We use {"World", "Sports"} as seen labels and select 1800 instances per seen label randomly in train data as our new development set. In the same way, we get dev set : **AGNews-dev** and our test set **AGNews-test**.

A.4 Details of Robust NLI models

Details for training settings For all the models, we use the same set of hyperparameters: We train all the models with batch size of 64, the Adam optimizer with the initial learning rate of $2e^{-5}$ and finetune the BERT model for 3 epochs. The maximum sequence length is limited to 128.

For DA (data augmentation) method, we use the most effective strategy which is called *inversion with a transformed hypothesis* in Min et al. (2020) . For the bias model used in Reweight and BiasProduct, we use the feature based word overlap bias model[13] in Clark et al. (2019).

Detailed results on HANS Table A.7 shows detailed results for the base BERT model and each robust strategy on the HANS dataset (McCoy et al., 2019) that diagnose each of the three heuristics (the Lexical Overlap Heuristic, the Subsequence Heuristic, and the Constituent Heuristic).

[11] we use inputs which replace all tokens with pad token except for [SEP] and [CLS] as baseline of the attribution method.

[12] There are 407 premise and hypothesis pairs which contain word "*zero*" with a REFUTES label, while 122 pairs with a SUPPORTS label.

[13] https://github.com/chrisc36/debias

Model	Input text with label as hypothesis	Predicted	Gold-Std.
FEVER	**Original :** [CLS] rate current essay a zero [SEP] i want to rate a book . [SEP] (0.140) **Variation:** [CLS] rate current essay a one [SEP] i want to rate a book . Abstract

Commonsense reasoning aims to incorporate sets of commonsense facts, retrieved from Commonsense Knowledge Graphs (CKG), to draw conclusion about ordinary situations. The dynamic nature of commonsense knowledge postulates models capable of performing multi-hop reasoning over new situations. This feature also results in having large-scale sparse Knowledge Graphs, where such reasoning process is needed to predict relations between new events. However, existing approaches in this area are limited by considering CKGs as a limited set of facts, thus rendering them unfit for reasoning over new unseen situations and events. In this paper, we present a neural-symbolic reasoner, which is capable of reasoning over large-scale dynamic CKGs. The logic rules for reasoning over CKGs are learned during training by our model. In addition to providing interpretable explanation, the learned logic rules help to generalise prediction to newly introduced events. Experimental results on the task of link prediction on CKGs prove the effectiveness of our model by outperforming the state-of-the-art models.

1 Introduction

Commonsense reasoning refers to the ability of capitalising on commonly used knowledge by most people, and making decisions accordingly (Sap et al., 2020). This process usually involves combining multiple commonsense facts and beliefs to draw a conclusion or judgement (Lin et al., 2019). While human trivially performs such reasoning, current Artificial Intelligence models fail, mostly due to challenges of acquiring relevant knowledge and forming logical connections between them.

Recent attempts in empowering machines with the capability of commonsense reasoning are mostly centred around large-scale Commonsense Knowledge Graphs (CKG), such as ATOMIC and ConceptNet (Sap et al., 2019; Speer et al., 2017). Unlike conventional Knowledge Graphs (KG), CKGs usually contain facts about arbitrary phrases. For instance, “PersonX thanks PersonY" is connected to “ To express gratitude" via the link “ because X wanted". This non-canonicalised free-form text representation has resulted in having conceptually related nodes with different representation, which forms *large sparse* CKGs (Malaviya et al., 2020). Therefore, established reasoning models on conventional KGs perform poorly on CGKs (Yang et al., 2014; Sun et al., 2018; Dettmers et al., 2018; Minervini et al., 2020). In addition, the nature of commonsense reasoning encourages dynamic CKGs, where new sets of facts and phrases are introduced frequently. Most existing models in this realm are based on a static set of facts and phrases, which results in poor generalisation (Malaviya et al., 2020; Shang et al., 2019). Nevertheless, the inference process in existing approaches is like a *black box*, where internal behaviour of the model is hardly interpretable.

To overcome these limitations, we propose a neural-symbolic reasoning model based on backward-chaining. While traditional theorem proving algorithms (Bratko, 2001) work based on a set of predefined rules and unification over discrete symbols, we leverage a continuous relaxation of weak unification and a rule learner module. The weak unification over continuous embedding representation helps to address the challenges of unseen sparsity of CKGs. The rule learner module, in addition to providing interpretability, is used to generalise prediction to unseen data points to mitigate the problem of *large-scale dynamic* CKGs. The experiments on the task of link prediction confirm the superiority of our model, by a margin of up to 22 points, over the state-of-the-art models.

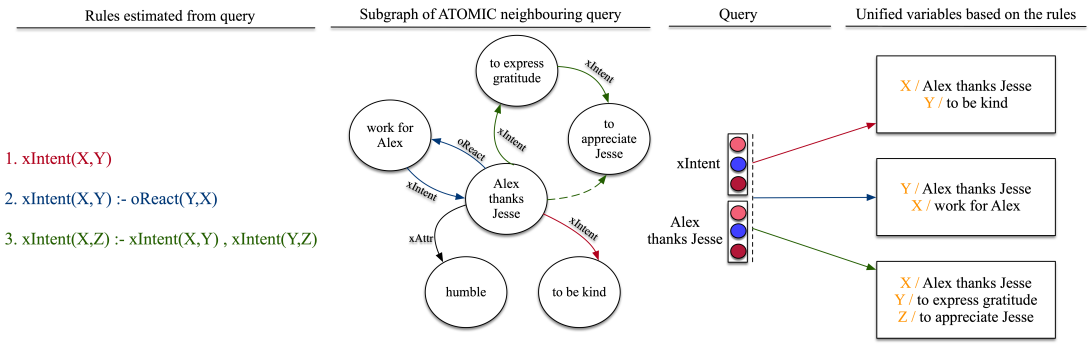

Figure 1: A visual representation of rules and new relations estimated by our model for a sample query, *xIntent(Alex thanks Jesse, ?)*. Based on the subject of the query, a subgraph of ATOMIC is retrieved for the reasoning process (middle). Sets of rules estimated from relation of the query is generated using our proposed rule creation module (left). Based on our reasoning model, the answers to query are predicted by unification module (right).

2 Related Works

Recent approaches in knowledge base completion task have mostly relied on a graph and entity-relation embedding methods (Yang et al., 2014; Dettmers et al., 2018). In these approaches, entities and relations are embedded in a complex space, and using a scoring function plausibility of a triple is estimated (Bordes et al., 2013; Trouillon et al., 2016; Sun et al., 2018). In addition to node embedding, graph embedding methods have also been used to capture the structural complexity of knowledge bases (Schlichtkrull et al., 2018; Shang et al., 2019). Language generative models also have been applied on knowledge bases in order to use the rich information of pre-trained models to address CKG completion task (Bosselut et al., 2019; Moghimifar et al., 2020). Malaviya et al. (2020) proposed a method based on using language models and graph networks to solve the problem of the sparsity of CKGs, by taking structural and contextual characteristics of CKGs into account. However, the aforementioned models are highly dependant on training on a set of static entities, and fail to perform when new triples are presented.

3 Our Approach

A CKG $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, where $\mathcal{N}$ is the set of nodes and $\mathcal{E}$ is the set of edges in $\mathcal{G}$, consists of triples in form of $r(h, t)$, where $h, t \in \mathcal{N}$ are referred to as the head and the tail of the triple, and $r \in \mathcal{E}$ denotes their relation. The goal of the CKG completion task is to estimate probable t given a query $q = r(h, ?)$. As the target node may not pose a direct link to h via r, this task requires a model capable of multi-step reasoning.

Given a query $r_q(h_q, ?)$, we try to identify an implication rule and apply it to prove $r_q(h_q, t)$ for a target entity or event t. A rule $\mathcal{R}$ takes the form of $r_q(X, Z) :- r_0(X, Y_0), ..., r_k(Y_{k-1}, Z)$, where capitalised letters denote variables, $r_q(X, Z)$ is the rule head, and the rule body is a conjunction of atoms. We apply such a rule by unifying atoms with triples in the given CKG to obtain $r_q(h_q, t_k) :- r_0(h_0, t_0), r_1(t_0, t_1), ..., r_k(t_{k-1}, t_k)$, which entails $r_q(h_q, t_k)$. Since semantically equivalent/similar events or entities in a CKG often have different surface forms, we consider weak unification of an atom with a triple instead of only considering exact match of two atoms, a weak unification operator (Sessa, 2002) unifies two different symbols by measuring the similarity of their representations.

Given a query, we do not know the target rule in advance. As shown in the example in Fig. 1, we successively create a new rule by appending the body of the previous rule with an atom in the form of $r(t_{k-1}, X)$. Whenever such a new atom is added, we query the CKG to find triples as candidates of unification. This step enables reasoning on large scale KBs. In contrast, the prior works (Minervini et al., 2020; Ren and Leskovec, 2020) require comparison with each node in a CKG. After applying the weak unification operator to each of the triples, we find top$k$ most similar nodes and use each of the entity/event in the place of X to create a new atom for a new rule. The process is repeated until the maximal rule length is reached.

The above mentioned reasoning process is delivered by a a neural-symbolic reasoner. It consists of a query module, a weak unification operator, and a rule creation module.

Dataset	#Nodes	#Edges	Avg. In-degree	Density	Unseen Nodes	Unseen Edges	#Relations
ATOMIC	382823	785952	2.25	1.6e-5	38.36%	27.91%	9
ConceptNet-100k	80994	102400	1.25	9.0e-6	11%	8%	34

Table 1: Statistics on ATOMIC and ConceptNet-100k. Unseen Nodes is the ratio of the nodes in test set that are not in train set to all of the nodes in test set. Unseen edges is the ratio of edges where either the head or tail nodes are not in train set to the number of all edges in test set.

Query Given a rule with a rightmost atom $r_{k-1}(t_{k-1}, X)$ in the rule body, we send the representation of t_{k-1} as query to the given CKG to retrieve unification candidates. A node in a CKG is a word sequence. To support comparison of nodes w.r.t. their semantic similarities, we encode queries and nodes in a CKG with a pre-trained BERT (Devlin et al., 2019) into embeddings. To this end, a node is converted into $[CLS]+node+[SEP]$, and fed into the model, and we use the representation of $[CLS]$ token from the last layer of BERT as representation of node $node$. We apply FAISS[1] (Johnson et al., 2019) to index embeddings of an CKG, because it supports fast retrieval of k nearest neighbours of a dense vector. For each node v in the top$k$ list, we collect a set of triples $\mathcal{C}(v)$, which are all triples having v as the head in the CKG. As a result, we have k such sets and form a candidate set $\mathcal{C}$ by taking the union of them.

Weak Unification From a candidate set $\mathcal{C}$ we identify top$k$ most relevant triples to unify $r_{k-1}(t_{k-1}, X)$. First, we formulate a set of hypotheses $\mathcal{H}$ by replacing X with possible tails. In practice, we use all tails of the triples in C. Furthermore, we construct a bipartite graph between $\mathcal{C}$ and $\mathcal{H}$, in which an edge denotes the unification between a triple from $\mathcal{C}$ and another from $\mathcal{H}$. We measure unification scores by using cosine similarity and obtain an similarity matrix $\mathbf{U} \in \mathbb{R}^{|\mathcal{C}|\times|\mathcal{H}|}$. The final unification score of candidate triple i is computed by $\max_j \mathbf{U}_{ij}$. We keep only top$k$ highest scored candidate triples.

Rule creation Given the top$k$ highest scored candidate triples and a rule $\mathcal{R}_k$ with a rightmost atom $r_{k-1}(t_{k-1}, X)$, we create a new rule based on $\mathcal{R}_k$ for each triple k by substituting it for $r(t_{k-1}, X)$ and append another atom $r_k(t_k, X)$. The relation r_k is estimated by a relation predictor $\boldsymbol{f_\theta}(r_{k-1}, k)$, where both r_{k-1} and the current step k are mapped to the corresponding embeddings.

$$P_{\boldsymbol{\theta_f}}(r_k|r_{k-1}, k) = \sigma(\boldsymbol{f_\theta}([r_{k-1}; k]).\mathbf{W} + b) \quad (1)$$

[1]https://github.com/facebookresearch/faiss

where $\boldsymbol{\theta_f} := \{\mathbf{W}, b\}$ contains the Rule creation module's parameters, and σ is the sigmoid function. The relation predictor aims to generalise relation co-occurrence patterns in rules. We implement it by using a neural networks with two blocks of hidden layers, followed by a softmax layer. Each block is composed of a linear layer and a ReLU layer.

Given a query $r_q(h_q, ?)$, we initialise the first rule as $r_q(h_q, X)$. After reaching the pre-defined maximal rule length, we consider the score of a rule after unification as the lowest unification score associated with the rule, following (Sessa, 2002). We rank all rules by their scores and select the tails in the rule heads of the top$k$ highest scored rules as the results.

Another benefit of our reasoner is that humans can easily collect evidences to interpret reasoning results. The model can yield the rules and unified triples in a human-friendly format, which are generated at each step. In contrast, prior work (Malaviya et al., 2020) on commonsense reasoners produces only hard-to-understand distributed representations in intermediate steps.

Training We convert all the triples in $\mathcal{G}$ into a set of queries ($\mathcal{Q} = \{r_1(h_1, ?), r_2(h_2, ?), \ldots, r_n(h_n, ?), \}$), where each query of $r_i(h_i, ?)(i < n)$ is associated with a set of gold answers $\mathcal{T}_i = \{q_{i_1}, q_{i_2}, \ldots, q_{i_m}\}$. The goal of training our model is to learn the embedding representations by minimising a cross-entropy loss function ($\mathcal{L}_\theta$) on final scores associated with each estimated predictions and the set of gold answer:

$$\mathcal{L}_{\boldsymbol{\theta}} = -\sum_{q_{p_k}\in\mathcal{T}} \log(Pr(q_{p_k}|\mathcal{G}; \boldsymbol{\theta})) - \sum_{q_{p_k}\notin\mathcal{T}} \log(1 - Pr(Pr(q_{p_k}|\mathcal{G}; \boldsymbol{\theta}))) \quad (2)$$

where $\boldsymbol{\theta}$ denote all the parameters of our model. The relation predication module of our model is also trained by minimising loss in equation 2, where the relation embeddings are decoded by

4 Experiments

To evaluate the performance of our model [2] in the task of CKG completion, in this section, we report the results of our model in comparison with the baselines.

Evaluation Metrics: Following previous works on Knowledge Base completion (Dettmers et al., 2018; Malaviya et al., 2020), we report the results of HITS and Mean Reciprocal Rank. Similar to Dettmers et al. (2018), when computing the scores for a gold target entity, we filter out all remaining valid entities. Furthermore, for each triple (h, r, t), the score is the average of scores measured from $(h, r, ?)$ and $(t, r^{-1}, ?)$.

Baselines For comparison, we report the performance of state-of-the-art models in CKG and KB completion. We compare our model to DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016), ConvE (Dettmers et al., 2018), RotatE (Sun et al., 2018), and Malaviya (Malaviya et al., 2020). The first four models are high performance models in conventional KB completion, whereas the latter is proposed for CKG completion.

4.1 Datasets

ATOMIC [3] is a CKG consisting of commonsense facts in form of triples, based on *if-then* relations (Sap et al., 2019). This dataset consists of more 877K facts, and more than 300K entities.

ConceptNet-100K [4] is a subset of ConceptNet 5 (Speer et al., 2017), containing Open Mind Common Sense (OMCS) entries, introduced by (Li et al., 2016). This dataset contains general commonsense facts in form of triples.

In order to evaluate the performance of the models in dynamic CKG completion, we choose a subset of the test set of ATOMIC and ConceptNet-100K, where for any (h, r, t) either h or t is not seen by the model in the train set. Statistics on ATOMIC and ConceptNet-100k are provided in table 1. To train our model, each triple in form $r(h, t)$ in train set was also converted to $r^{-1}(t, h)$, to account for reverse relations as well. We have used the embedding size of 1024 for both node and relation embedding layer. To embed the nodes in CKGs, we have fine-tuned uncased BERT-Large (Devlin et al., 2019) for the objective of masked language model. For this purpose, a node is converted into $[CLS] + n_i + [SEP]$ and fed into BERT. The representation of the token $[CLS]$ from the last layer of BERT is then used as node n_i embedded representation. We used the maximum sequence of 128, and batch size of 64. Our relation predication module consists of two Linear layer. For all non-linearities in our model we have used ReLU. For optimisation purpose, SGD has been used, with staring learning rate of $10e-4$, and decay rate of 0.9, if the loss of development set does not decrease after each epoch. We set the maximum depth of three for reasoning process. We have trained the model for 200 epochs. Followed by Malaviya et al. (2020), we have trained all the baselines for 200 epochs. During training the models were evaluated on development set, every 10 and 30 epochs, for ConceptNet-100K and ATOMIC, respectively. The checkpoint with the highest MRR was then selected for testing.

4.2 Results

Table 2 summarises the results of the conducted experiment on ConceptNet-100K and ATOMIC. On ConceptNet-100K our proposed model outperforms the baselines by up to 22 points on MRR. The gap between our model and the second best model decrease as we move from HITS@1 to HITS@10.

ATOMIC
xIntent(X,Y):-xIntent(X,Z),xIntent(Z,Y)
xNeed(X,Y):-xReact(Y,X)
xIntent(X,Y):-oWant(Y,X)
ConceptNet-100K
causes(X,Y):-causes(X,Z),causes(Z,Y)
isa(X,Y):-partof(X,Z),isa(Z,Y)
relatedto(X,Y):-relatedto(X,Z),relatedto(Z,Y)

Table 3: Examples of rules learned by our proposed relation prediction module.

This suggested that on contrary to the baselines our model performs better in estimating the probability of query with higher accuracy. On ATOMIC our model achieves a MRR of 46.41, which is 23 points higher than the second best model. As it can be seen from table 2, comparison of performance of different models on ConceptNet-100K and ATOMIC shows a noticeable drop in performance for models which rely on structural information of CKGs. This observation suggests that larger and sparser (lowest density) CKG are more challenging to reason over.

Table 3 provides examples of generated rules by our model on ATOMIC and ConceptNet-100k. On ATOMIC, the first rule is based on transition, and the second and third rules are inverse rules. Similarly, on ConceptNet-100K the first and third rules are transitive, and the second rule is a compositional rule. All provided rules are diverse and meaningful, and can be used for explaining the inference process of our model. For instance, consider a query of *xIntent(Alex drives Jesse there, ?)*. Based on first rule from Table 3, `X` is unified by *Alex drives Jesse there*, and `Z` is unified by *Alex helps Jesse* (from triples of ATOMIC). Then, the query is updated to *xIntent(Alex helps Jesse, ?)* and `Y` is unified by *to be of assistance* (from triples of ATOMIC), hence the answer to query. The path generated by this example is *Alex drives Jesse there* $\xrightarrow{\text{xIntent}}$ *Alex helps Jesse* $\xrightarrow{\text{xIntent}}$ *to be of assistance*. Therefore, two nodes are connected via a new link: *Alex drives Jesse there* $\xrightarrow{\text{xIntent}}$ *to be of assistance*.

Consider the following query from ConceptNet-100K, $HasProperty(novel, ?)$. Based on the relation of the query, our rule creator module can estimate the following rule: According to this rule,

```
HasProperty(X,Y):-IsA(X,Z),HasProperty(Z,Y)
```

`X` is unified by *novel*, and `Z` is unified by *book* (from triples of ConceptNet-100K). Then, the query is updated to *HasProperty(book, ?)* and `Y` is unified by *expensive* (from triples of ConceptNet-100K), resulting the answer to the query, by generating the following path: *novel* $\xrightarrow{\text{IsA}}$ *book* $\xrightarrow{\text{HasProperty}}$ *expensive*, hence *novel* $\xrightarrow{\text{HasProperty}}$ *expensive*.

5 Conclusion

In this work, we propose a neural-symbolic reasoning model over Commonsense Knowledge Graphs (CKGs). Our proposed model leverages a relation prediction module, which provides capability of multi-step reasoning. This ability, alongside weak unification, helps generalising our model to large-scale unseen data. We showed that our model yields state-of-the-art results when applied to large-scale sparse CKGs, and the inference step is interpretable.

Abstract

According to the self-determination theory, the levels of satisfaction of three basic needs (competence, autonomy and relatedness) have implications on people's everyday life and career. We benchmark the novel task of automatically detecting those needs on short posts in English, by modelling it as a ternary classification task, and as three binary classification tasks. A detailed manual analysis shows that the latter has advantages in the real-world scenario, and that our best models achieve similar performances as a trained human annotator.

1 Introduction

Motivation is one of the most crucial aspects of human behaviour with implications ranging from daily life to career and educational contexts. Self-determination theory (SDT) provides a meta-framework for understanding the broad, as well as specific, nutriments of the function and application of the concept of motivation (Deci and Ryan, 2000; Ryan and Deci, 2017a).

SDT differs from the other motivational theories from the psychology literature in two substantial aspects (Ryan and Deci, 2000; Rigby and Ryan, 2018): (1) Unlike the drive theories that explain motivation as a function of its deficit (e.g. people are motivated by success to compensate its deficit), SDT focuses on growth and constructivism (e.g. people are naturally and universally motivated by success), thus giving the theory a more realistic understanding of the human behaviour, and making it applicable to wider contexts; and (2) Due to the applicability advantage, SDT is based on strong behavioural evidence and is thus not only a well-validated model but also sustainable and actionable.

The SDT framework is supported by a body of cross-cultural studies strengthening the universality of the theory. Studies conducted in diverse countries showed that the basic needs are essentially represented across cultures (Chen et al., 2015; Jang et al., 2009). Although universal, the SDT framework is also able to point out the impact of sociocultural environment on the variations of basic needs in different cultures. For example, a study conducted in 11 countries showed that the need for competence was more linked to school performance in Eastern cultures than in the West (Nalipay et al., 2019).

One of the central pillars of SDT are three basic psychological needs that drive the initiation of a behaviour and the maintenance of motivation:

- **Autonomy**: the basic need to be the owner and controller of one's decisions and behaviours.
- **Competence**: the basic need to feel competent, effective and master-like.
- **Relatedness**: the basic need to belong, bond and connect with others.

According to SDT, those three needs are universal and their importance does not change across individuals and situations. However, different contexts and time periods would require different support and resources for the maintenance of the motivations. For instance, cultivating autonomy need in students creates more engagement and willingness, thus leading to higher academic performance, lower dropouts, and more self-esteem in the long run (Ryan and Deci, 2020). Similarly, the SDT framework is used to increase levels of employee satisfaction and engagement, supportive leadership and parenting skills, healthier relationships, satisfactory consumer experience and better designed digital media and well-being tools (Slemp et al., 2018; Rigby and Ryan, 2018; Ryan and Deci, 2017b; Knee et al., 2002; Gilal et al., 2019; Peters et al., 2020; Peng et al., 2012).

Need	Post
Autonomy	Just treated myself to a Roland TB-3. Should arrive this evening. #excited
Autonomy	One thing's for sure, I will not let you ruin my dreams, HIV. #determined
Competence	What an achievement. Finally getting some credit. #Fury #SPOTY
Competence	I fell asleep with socks on... I disgust myself.
Relatedness	I'm so lucky to have my best friend and boyfriend rolled into one! #soppy #proud
Relatedness	You know what I feels like to be #ALONE in this cold world?

Table 1: Annotated examples from the dataset (either satisfied or unsatisfied need).

Traditionally, basic motivations are assessed via questionnaires which provide intensity-based scores for each dimension. The scores represent the degree to which that particular dimension is satisfied (Deci and Ryan, 2000). Although these questionnaires were developed and validated via laboratory and field studies which provide a strong empirical basis, they could suffer from biases commonly observed in questionnaire respondents such as social desirability bias (Krumpal, 2011) and the reference-group effect (Heine et al., 2002). The basic motivations can also be revealed in a more implicit way, by collecting subjects' narratives while showing them pictures and images (Murray, 1943; McClelland, 1979). Although being more expensive and time-consuming, as it requires the inclusion of trained assessors, this method shows that implicit motivations can be assessed from texts. A few studies attempted at automatic detection of basic motivations on the basis of their linguistic aspects from such naratives (Pennebaker and King, 1999; Johannssen and Biemann, 2019).

To the best of our knowledge, our study is the first that attempts to automatically detect the three basic needs from short posts. In this study, we:

- Benchmark the task of automatic detection of basic needs from English Twitter data using several architectures on an already existing manually annotated dataset.
- Provide a manual analysis which shed light on the complexity of the task and its usability.
- Discuss the limitations of the existing dataset, and suggest better annotation strategies.

2 Dataset

For our experiments, we used the first two layers of the Basic Psychological Needs Corpus (Alharthi et al., 2017), which is publicly available.[1] The corpus contains Twitter posts annotated with five layers of annotation as the intention was to provide freely available multilayered annotated corpus for a wide range of applications (Alharthi et al., 2017). The manual annotation was performed by three annotators in three stages, encompassing thorough training sessions and detailed annotation guidelines, one round of collectively labelling tweets, one round of independently labelling the same posts for calculating inter-annotator agreement (IAA), and the final round of independently labelling the rest of the posts. The average pairwise agreement and the Fleiss Kappa (κ) were 90% and 0.815 for whether or not the post contains enough content for assigning one of the three basic needs (autonomy, relatedness, or competence), and 89% and 0.819, respectively, for the assigned label (Alharthi et al., 2017).

The final dataset with manual annotations of basic needs was already pre-filtered for non-emotional posts and those that do not contain enough signal (Alharthi et al., 2017). It contains 6334 posts with the following distribution of the labels: 1229 posts labelled with *competence*, 1771 with *autonomy*, and 3334 with *relatedness* label. In our experiments, we used this dataset and only the labels of the second layer of annotation (basic needs). Several examples are given in Table 1. Here is important to note that the original dataset also contains, in the third layer, the annotation for the satisfaction level (satisfied, dissatisfied, neutral) of the assigned basic need. We acknowledge that the combination of the basic needs and their level of satisfaction are often used together, e.g. as indicators of person's well-being (Deci and Ryan, 2011), violence and conflict possibility (Christie, 1997), stress and coping (Ntoumanis et al., 2008; Weinstein and Ryan, 2011). However, we opted for discarding these additional labels for three reasons: (1) because the inter-annotator agreement was significantly lower for this annotation layer

[1] We obtained the original dataset directly from the authors.

(the average pairwise agreement was 75% and the κ was 0.640); (2) so that we do not increase the total number of classes (to nine instead of three) and therefore significantly lower the number of instances in each class; (3) because this task appears similar to the task of assigning the sentiment polarity of the post (Alharthi et al., 2017), and therefore might be modelled with various other datasets.

3 Experimental Setup

3.1 Preprocessing

The instances were already cleaned in the original dataset by removing all usernames (@username) and URLs, while preserving emoticons, punctuation marks, social acronyms and abbreviations, which might contain psycholinguistic signals (Alharthi et al., 2017). Furthermore, the dataset does not contain any duplicated instances, tweets with less than three words, or tweets with more than three hashtags (Alharthi et al., 2017). We noticed that for this particular task, the hashtags may help the models, e.g. *#proud* usually signalizes *competence*, *#relationship* signalizes *relatedness*. To better assess how well the models would perform on a different type of texts, we experimented with two versions of the dataset: WITHOUT HASHTAGS and WITH HASHTAGS.

3.2 Data Splits

We randomly choose 15% of the instances for testing, and then 15% from the rest of the data for development, while maintaining the class ratio (Table 2). During our experiments, we found that applying upsampling on the minority classes (*competence* and *autonomy*) slightly improved the performances of some models, and had no change on others. Thus, we only report the results obtained by using upsampling.

3.3 Task Definition

We approached the problem of detecting basic needs with two different scenarios: (1) as a ternary classification problem (assigning one of the three possible basic needs to each post), and (2) as three binary classification tasks (for each basic need, assigning either *yes* or *no* label). The ternary classification is a more natural choice for this particular dataset, as all instances were annotated with only one of the three basic needs. However, according to the SDT, each person have at all times the all three needs just with different intensities and satisfaction levels (Section 1). It is thus reasonable to assume that some posts will also contain signals of multiple basic needs. Therefore, we also performed three binary tasks which would allow us to model each basic need separately. By using three binary classifiers instead of one ternary, posts could be automatically labelled with none of, or any combination of, basic needs.

Need	ORIGINAL			REPORTED		
	TRAIN	DEV	TEST	TRAIN	DEV	TEST
Autonomy	1248	228	290	2416	404	290
Competence	868	168	204	2416	404	204
Relatedness	2416	404	508	2416	404	508

Table 2: Dataset splits.

3.4 Evaluation Metrics

For both types of classification tasks (binary and ternary), we used the per-class precision, recall, and F_1-score, and the macro-averaged F_1-score for evaluating the performances of the models.

3.5 Architectures

In order to assess the importance of both lexical and semantic aspects of texts, we tested various approaches that use different text representations:

- **BOW**: word unigrams and bigrams model with the TF-IDF weighting scheme (Salton and Buckley, 1988) using a Support Vector Machines (Chang and Lin, 2011) classifier with a linear kernel.[2,3]
- **Char-CNN**: a Convolutional Neural Networks (CNN) architecture similar to the one proposed in (Zhang et al., 2015) but using a trainable character embedding layer as input.
- **BiLSTM**: a bidirectional Long Short-Term Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) neural network that uses FastText word embeddings (Bojanowski et al., 2017) to represent texts. The BiLSTM hidden states are fed to an attention layer (Yang et al., 2016), and then the attention output is processed with a fully connected layer. As an output, a softmax layer is used to obtain the final classification.

[2]We also explored logistic regression, random forest, Naive Bayes, and support vector machines, with different kernels, during the prototyping phase.

[3]Character n-grams were also tested but as they did not lead to better performances, we do not report their results.

Table 3: Results of the ternary classification task. The last two rows present the results on a subset of the test set that was annotated by a trained human annotator and contains 40 instances of each class.

- **BERT**: the neural language model, well-known for providing text representations that show leading performances on several natural language processing benchmarks (Devlin et al., 2019). We fine-tune BERT and use its hidden representation of the special [CLS] token to represent the full input text and feed it to a softmax output layer.

- **BERT+BiLSTM**: this model combines the previous two approaches. Instead of FastText word representation, the fine-tuned BERT embeddings are post-processed by the BiLSTM architecture defined above. We observed that such architectures help BERT to adapt to the target task and obtain better classification results in scenarios with small training datasets.

4 Results and Discussion

4.1 Ternary Classification

All models performed noticeably better on the original than on the cleaned dataset, thus supporting our hypothesis that the presence of the hashtags leads to better model performances (Table 3). As expected, the models that are based on transfer learning (BERT and BERT+BiLSTM) performed best. Interestingly, the non-neural model (BOW) outperformed the BiLSTM and Char-CNN models on the *competence* class using the cleaned dataset (F_1-score of 0.52 against 0.47 and 0.34, respectively).

In all models, most misclassifications were observed between the *competence* and *autonomy* classes. A possible reason for this might lie in the SDT theory, as autonomy and competence are self-originated needs, whereas relatedness includes both self and others (Vansteenkiste et al., 2020). This might lead to theme/topic overlaps between autonomy and competence due to the self-focus, while relatedness might be easier to distinguish due to including self and the others.

4.2 Human Performance and Error Analysis

To assess the expected performance ceiling, we hired a psychologist, well-versioned in SDT, provided the annotation guidelines with several examples, and asked to annotate randomly selected 150 instances from the cleaned test set (50 from each class). The annotator was allowed to assign as many classes as needed to each post.

Our guidelines were based on a thorough review of psychology research by Ryan and Deci (2020, 2017a,b, 2000) who studied observable behavioural outcomes. We selected the following cues for each basic need:

- Autonomy: focus of initiative, ownership of self-actions, feelings of restriction by any type of external control.

- Competence: focus on behaviours associated with mastery, achievements, success, and growth (both positive and negative), search for personal or contextual challenges, well-structured environments, and positive feedback.

- Relatedness: focus on spending and appreciating time with significant others, search for community and connection, sense of nurturing and caring for others.

The annotator assigned two classes in 14 cases (9.3%). Some of those were the cases in which our best system (BERT+BiLSTM) made 'wrong' prediction, which turned out to be the same as one of the classes assigned by the human annotator

Gold	Predicted	Post
Relatedness	Autonomy	Wishing I was home this Christmas, maybe next year #homesick #holidays
Relatedness	Competence	I work with an amazing team. They work so hard and are so dedicated. Truly a top comms team #proud

Table 4: Examples of penalized predictions which actually caught the secondary signal. For those examples, the human annotator assigned both classes (the gold and the predicted one).

Table 6: Results of the binary classification tasks on the datasets WITHOUT HASHTAGS.

(Table 4). Therefore, we took 120 instances for which the human annotator assigned only one class, and additionally ran our best model on that portion of the test set, to fairly compare its performance with the human performance (the last two rows in Table 3).

4.3 Binary Classifications

The results of the best performing architecture (BERT+BiLSTM) on the binary tasks using the datasets WITH HASHTAGS and WITHOUT HASHTAGS are presented in Tables 5 and 6.

To assess the performance of those systems in the real-world scenario, we took 100 random new tweets and ran all three models on them. At the same time, we asked the psychologist to annotate each post (without showing the obtained automatic predictions) by assigning one of the three labels (*no*, *low*, *high*) for each basic need. For example, *"@matchbox_sized Wait, you've seen it already? Thought it aired on Sunday nights?"* was annotated as *low* for *relatedness*, *high* for *autonomy*, and *no* for *competence*. For the same example, the three best binary models assigned the following probabilities to each of the corresponding classes: $p(autonomy) = 0.88$, $p(relatedness) = 0.70$, and $p(competence) = 0.30$.

We further investigated whether or not the class probabilities obtained by the binary models were related to the labels assigned by the annotator. On those 100 examples, we found that the manually assigned label *no* corresponds to the $p(yes) \in [0, 0.5)$ (obtained by the models) in 90% of the cases, the manually assigned label *low* to the $p(yes) \in [0.5, 0.75)$ (obtained by the models) in 100% of the cases, and manually assigned label *high* to the $p(yes) \in [0.75, 1]$ (obtained by the models) in 98% of the cases. These findings indicate that it might be possible to use the binary models in a more general setup, i.e. on the posts which are not pre-filtered for containing emotions or needs signals, and on posts that reflect more than one need. Furthermore, it seems that those models could capture the intensity of the signals.

5 Conclusions

In this study, we benchmarked the automatic detection of basic motivations on short (Twitter) posts in English, framing the problem as a ternary classification task, as well as three binary classification tasks. On the ternary classification task, our BERT+BiLSTM model performed almost equally well as a trained human annotator.

We showed that modelling this problem as three binary classification tasks, instead of modelling it as one ternary classification task, allows for better applicability of the models. The proposed setup with three binary models assigns none of the basic motivations to those posts without any signal (all three models assign a *no* class), and multiple basic motivations to those posts with signals from multiple motivations (more than one model assigns a *yes* class), achieving a high agreement with the human annotator. We also found a high association between the class probabilities of the binary models and the human-perceived motivation intensities.

6 Ethics/Impact Statement

6.1 Intended Use

The goal of our experiments was to investigate if there is a possibility to automatically detect basic needs from short posts, and to benchmark this novel NLP task. As we do not have any demographic information in the dataset used, and we did not thoroughly investigate performances of our models on different text types, demographic groups, and in different contexts, we do not encourage the use of these particular models in real-world applications. Instead, the contribution of our study lies in setting the ground for future models of automatic detection of basic needs from short texts, by benchmarking the task with various machine learning architectures on a specific dataset, experimenting with both ternary and binary setups, providing performance ceiling estimation via human annotations, and discussing the usability of presented approaches. Our study thus provides the foundations for future models which, if trained on carefully sampled data (representative data with strict bias control), have the potential to speed up and provide additional quality checks for traditional questionnaire-based basic needs estimation procedures, which are already widely used for: (1) providing supportive information about the user in organizational contexts such as leadership style and team building processes (Rigby and Ryan, 2018); and (2) prompting learner perspectives in educational contexts such as designing motivation-supportive settings and activities (Schneider et al., 2018).

6.2 Failure Modes

To try to estimate how the model would perform if trained on different type of data, i.e. non-Twitter data, we evaluated models trained on posts with hashtags and models trained on the same posts but after removing all hashtags. However, it is not certain how would the reported models perform on different types of data, neither whether training models with different data sources would lead to similar results or not. On the used Twitter datasets, we found most misclassifications between *autonomy* and *competence* classes.

6.3 Biases

Given that we do not have any demographic information about the authors of the posts in the used dataset, and that the dataset was prefiltered for emotional and needs signals (Alharthi et al., 2017), the presented models might suffer from various algorithmic biases. Furthermore, it is known that certain age groups or socio-economic groups are more present in Twitter than others (Tufekci, 2014; Morstatter et al., 2014), and that certain personality types are more active on particular media platforms (Goby, 2006).

6.4 Misuse Potential

Using automatic detection of basic needs in decision-making processes during hiring and placement could lead to a potential misuse and unfair decisions due to: (1) algorithmic biases and imperfections of the models; (2) giving too much weight to the estimation of basic needs instead of taking it only as one of many aspects of the employee (e.g. personality, educational background) and team work.

Basic needs could be used in combination with other psychological variables (e.g. personality) for marketing and consumer targeting purposes. Tailoring marketing materials for different personalities can be beneficial for consumers by leading them to spend their money on personality-matching items (Matz et al., 2016). However, it can also be misused by leading people to act against their best interests, e.g. by persuading them to gamble (Matz et al., 2016).

6.5 Potential Harm to Vulnerable Populations

As any other psychological modelling, when combined with demographic characteristics (e.g. age, gender, socio-economic background), machine learning models could potentially harm vulnerable groups such as immigrants or people with mental health issues. The models could potentially detect people who suffer from psychological and emotional instability, as it is highly likely that those people may be unsatisfied about their basic needs. To avoid such unintended harms, special attention should be given to carefully collecting a representative sample for any intended use (Williams et al., 2018).

Abstract

Recent studies on semantic frame induction show that relatively high performance has been achieved by using clustering-based methods with contextualized word embeddings. However, there are two potential drawbacks to these methods: one is that they focus too much on the superficial information of the frame-evoking verb and the other is that they tend to divide the instances of the same verb into too many different frame clusters. To overcome these drawbacks, we propose a semantic frame induction method using masked word embeddings and two-step clustering. Through experiments on the English FrameNet data, we demonstrate that using the masked word embeddings is effective for avoiding too much reliance on the surface information of frame-evoking verbs and that two-step clustering can improve the number of resulting frame clusters for the instances of the same verb.

1 Introduction

Semantic frame induction is a task of mapping frame-evoking words, typically verbs, into semantic frames they evoke (and the collection of instances of words to be mapped into the same semantic frame forms a cluster). For example, in the case of example sentences from FrameNet (Baker et al., 1998) shown in (1) to (4) in Table 1, the goal is to group the examples into three clusters according to the frame that each verb evokes; namely, {(1)}, {(2)}, and {(3), (4)}. Unsupervised semantic frame induction methods help to automatically build high-coverage frame-semantic resources.

Recent studies have shown the usefulness of contextualized word embeddings such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) for semantic frame induction. For example, the top three methods (Arefyev et al., 2019; Anwar et al., 2019; Ribeiro et al., 2019) in Subtask-A of SemEval-2019 Task 2 (QasemiZadeh et al., 2019) perform clustering of contextualized word embeddings of frame-evoking verbs. However, these methods have two potential drawbacks.

(1)	We'll not get there before the rain comes.	(ARRIVING)
(2)	The problem continued to get worse.	(TRANSITION_TO_STATE)
(3)	You may get more money from the basic pension.	(GETTING)
(4)	We have acquired more than 100 works.	(GETTING)

Table 1: Example sentences of verbs "get" and "acquire" and frames that each verb evokes in FrameNet. (FRAME)

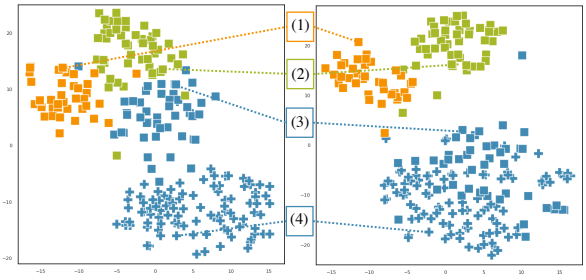

Figure 1: 2D projections of BERT embeddings of verbs (left) and masked verbs (right). Numbers in the figure correspond to numbers in Table 1, ■ and + are verbs "get" and "acquire", respectively, and each color indicates ARRIVING, TRANSITION_TO_STATE, and GETTING frame.

First, the contextualized word embeddings of the frame-evoking verbs strongly reflect the superficial information of the verbs. The left side of Figure 1 shows a 2D projection of contextualized embeddings of instances of the verbs "get" and "acquire" extracted from example sentences in FrameNet. Specifically, we extracted instances of "get" and "acquire" from FrameNet, obtained their embeddings by using a pre-trained BERT, and projected them into two dimensions by using t-distributed stochastic neighbor embedding (t-SNE) (Maaten and Hinton, 2008). As shown in the figure, among instances of "get", those that evoke the GETTING frame tend to be located close to instances of "acquire" that evokes the same GETTING frame. However, we can see that the difference be-

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 811–816
August 1–6, 2021. ©2021 Association for Computational Linguistics

tween verbs is larger than the difference between the frames that each verb evokes.

To remedy this drawback, we propose a method that uses a masked word embedding, a contextualized embedding of a masked word. The right side of Figure 1 shows a 2D projection of masked word embeddings for instances of the verbs "get" and "acquire". The use of masks can hide the superficial information of the verbs, and consequently we can confirm that instances of verbs that evoke the same frame are located close to each other.

The second drawback is that these methods perform clustering instances across all verbs simultaneously. Such clustering may divide instances of the same verb into too many different frame clusters. For example, if there are outlier vectors that are not typical for a particular verb, they tend to form individual clusters with instances of other frames in most cases. To solve this problem, we propose a two-step clustering, which first performs clustering instances of the same verb according to their meaning and then performs further clustering across all verbs.

2 Proposed Method

The proposed semantic frame induction method uses masked word embeddings and two-step clustering. We explain these details below.

2.1 Masked Word Embedding

A masked word embedding is a contextualized embedding of a word in a text where the word is replaced with a special token indicating that it has been masked, i.e., "[MASK]" in BERT. Our method leverages masked word embeddings of frame-evoking verbs in addition to standard contextualized word embeddings of frame-evoking verbs. In this paper, we consider the following three types of contextualized word embeddings.

v_{WORD}: Standard contextualized embedding of a frame-evoking verb.

v_{MASK}: Contextualized embedding of a frame-evoking verb that is masked.

$v_{\text{W+M}}$: The weighted average of the above two, which is defined as:

$$v_{\text{W+M}} = (1-\alpha) \cdot v_{\text{WORD}} + \alpha \cdot v_{\text{MASK}}. \quad (1)$$

Here, $v_{\text{W+M}}$ is the weighted average of contextualized word embeddings with and without masking the frame-evoking verb. By properly setting the weight α using a development set, we expect to obtain embeddings that properly adjust the weight of superficial information of the target verb and information obtained from its context. $v_{\text{W+M}}$ is identical to v_{WORD} when α is set to 0 and identical to v_{MASK} when α is set to 1.

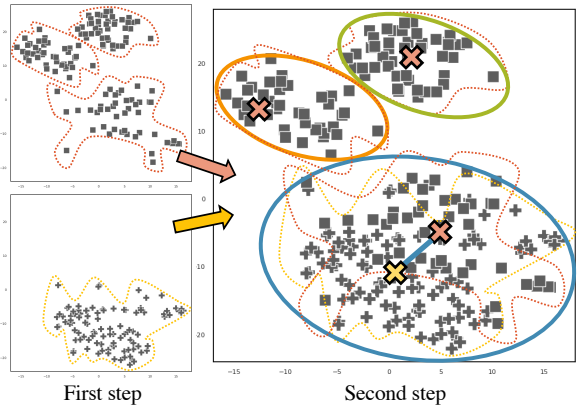

Figure 2: Flow of the two-step clustering. ■ and + denote the embeddings of "get" and "acquire", respectively.

2.2 Two-Step Clustering

In the two-step clustering, we first perform clustering instances of the same verb according to the semantic meaning and then perform further clustering across verbs. Finally, each generated cluster is regarded as an induced frame. Figure 2 shows the flow of the two-step clustering using the instances of "get" and "acquire" from FrameNet. As a result of the clustering in the first step, the instances of "get" are grouped into three clusters and the instances of "acquire" into one cluster. In the second step, one of the clusters of "get" and the cluster of "acquire" are merged. Consequently, three clusters are generated as the final clustering result. The details of each clustering are as follows.

Clustering Instances of the Same Verb The clustering in the first step aims to cluster instances of the same verb according to their semantic meaning. Since all the targets of the clustering are the same verbs, there should be no difference in the results between the cases using v_{WORD} and v_{MASK} as embeddings. Therefore, we use only v_{MASK} for this process. We adopt X-means (Pelleg and Moore, 2000) or group average clustering based on a Euclidean distance as the clustering algorithm.

While X-means automatically determine the number of clusters, group average clustering requires a clustering termination threshold. In the group average clustering, the distance between two

clusters is defined as the average distances of all instance pairs between clusters, and the cluster pairs with the smallest distance between clusters are merged in order. The clustering is terminated when there are no more cluster pairs for which the distance between two clusters is less than or equal to a threshold θ. In this study, θ is shared across verbs, not determined for each verb. Note that when θ is set to a sufficiently large value, the number of clusters is one for all verbs. To set θ to an appropriate value, we gradually decrease θ from a sufficiently large value and fix it to a value where the number of the generated frame clusters is equal to the actual number of frames in the development set.

In the theory of Frame Semantics (Fillmore, 2006) on which FrameNet is based, the association between a word and a semantic frame is called a lexical unit (LU). Since each cluster generated as the result of clustering in the first step is a set of instances of the same verb used in the same meaning, it can be considered to correspond to an LU. Therefore, we refer to it as pseudo-LU (pLU).

Clustering across Verbs The clustering in the second step aims to cluster the pLUs generated as the result of the first-step clustering across verbs according to their meaning. This step calculates average contextualized embeddings of each pLU and then clusters the pLUs by using the calculated embeddings across verbs. We adopt Ward clustering or group average clustering based on a Euclidean distance as the clustering algorithm.

We need a termination criterion for both clustering algorithms. A straightforward approach is to use the ratio of the number of frames to the number of verbs. However, this approach does not work well in this case since there is an upper limit to the number of frame types and the number of frames to be generated does not increase linearly with the number of verbs. Therefore, in this study, we use the ratio of pLU pairs belonging to the same cluster as the termination criterion. Specifically, the clustering is terminated when the ratio of pLU pairs belonging to the same cluster $p_{\mathrm{F}_1=\mathrm{F}_2}$ is greater than or equal to the ratio of LU pairs belonging to the same frame in the development set $p_{\mathrm{C}_1=\mathrm{C}_2}$. Here, $p_{\mathrm{F}_1=\mathrm{F}_2}$ is calculated as:

$$p_{\mathrm{F}_1=\mathrm{F}_2} = \frac{\text{\# of pLU pairs in the same cluster}}{\text{\# of all pLU pairs}}. \quad (2)$$

While the number of all pLU pairs is constant regardless of clustering process, the number of pLU pairs belonging to the same cluster monotonically increases as the clustering process progresses. $p_{\mathrm{C}_1=\mathrm{C}_2}$ can be calculated as well as $p_{\mathrm{F}_1=\mathrm{F}_2}$ and $p_{\mathrm{C}_1=\mathrm{C}_2}$ reaches 1 when the number of the entire cluster becomes one cluster. Therefore, $p_{\mathrm{C}_1=\mathrm{C}_2}$ is guaranteed to be greater than or equal to $p_{\mathrm{F}_1=\mathrm{F}_2}$ during the clustering process. Since the probability that randomly selected LU pairs belong to the same frame is not affected by the data size, the criterion is considered valid regardless of the data size.

Table 2: Statistics of the dataset from FrameNet.

3 Experiment

We conducted an experiment of semantic frame induction to confirm the efficacy of our method. In this experiment, the objective is to group the given frame-evoking verbs with their context according to the frames they evoke.

3.1 Setting

Dataset From Berkeley FrameNet data release 1.7[1] in English, we extracted verbal LUs with at least 20 example sentences and used their example sentences. That is, all target verbs in the dataset have at least 20 example sentences for each frame they evoke. We limited the maximum number of sentence examples for each LU to 100 and if there were more examples, we randomly selected 100. Note that we did not use the SemEval-2019 Task 2 dataset because the dataset is no longer available as described on the official web page.[2]

The extracted dataset contained 1,272 different verbs as frame-evoking words. We used the examples for 255 verbs (20%) as the development set and those for the remaining 1,017 verbs (80%) as the test set. Thus, there are no overlapping frame-evoking verbs or LUs between the development and test sets, but there is an overlap in the frames evoked. We divided the development and test sets so that the proportion of verbs that evoke more than one frames would be the same. The development set was used to determine the alpha of $v_{\mathrm{W+M}}$

and the termination criterion for the clustering in each step and layers to be used as contextualized word embeddings. Table 2 lists the statistics of the dataset.

Models We compared four models, all combinations of group average clustering or X-means in the first step and Ward clustering or group average clustering in the second step. We also compared a model that treats all instances of one verb as one cluster (1-cluster-per-verb; 1cpv) and models that treat all instances of one verb as one cluster (1cpv') in the first step and then perform the clustering in the second step.

In addition, we compared our models with the top three models in Subtask-A of SemEval-2019 Task 2. Arefyev et al. (2019) first perform group average clustering using BERT embeddings of frame-evoking verbs. Then, they perform clustering to split each cluster into two by using TF-IDF features with paraphrased words. Anwar et al. (2019) use the concatenation of the embedding of a frame-evoking verb and the average word embedding of all words in a sentence obtained by skip-gram (Mikolov et al., 2013). They perform group average clustering based on Manhattan distance by using the embedding. Ribeiro et al. (2019) perform graph clustering based on Chinese whispers (Biemann, 2006) by using ELMo embeddings of frame-evoking verbs.

To confirm the usefulness of the two-step clustering, we also compared our models with models that perform a one-step clustering. For the model, we used Ward clustering or group average clustering as the clustering method and $v_{\text{W+M}}$ as the contextualized word embedding. We gave the oracle number of clusters to these models, i.e., we stopped clustering when the number of human-annotated frames and the number of cluster matched.

Metrics and Embeddings We used six evaluation metrics: B-CUBED PRECISION (BCP), B-CUBED RECALL (BCR), and their harmonic mean, F-SCORE (BCF) (Bagga and Baldwin, 1998), and PURITY (PU), INVERSE PURITY (IPU), and their harmonic mean, F-SCORE (PIF) (Karypis et al., 2000). We used BERT (bert-base-uncased) in Hugging Face[3] as the contextualized word embedding.

3.2 Results

Table 3 shows the experimental results.[4] When focusing on BCF, which was used to rank the systems in Subtask-A of SemEval-2019 Task 2, our model using X-means as the first step and group average clustering as the second step achieved the highest score of 64.4. It also got the highest PIF score of 73.0. The number of human-annotated frames was 393, while the number of generated clusters was 410. These results demonstrate that the termination criterion of the two-step clustering works effectively.

In all two-step clustering methods, α was tuned between 0.0 and 1.0, which shows that both v_{WORD} and v_{MASK} should be considered. In addition, α was close to 1.0 for these methods, which indicates that v_{MASK} is more useful for clustering instances across verbs. In contrast, $v_{\text{W+M}}$ in the one-step clustering methods was equivalent to v_{WORD} with $\alpha = 0.0$. This indicates that there is no effect of using v_{MASK}

[3] https://huggingface.co/transformers/

[4] The performance of the top three models in Subtask-A of SemEval-2019 Task 2 is lower than reported in the task because the dataset used in this study has a high proportion of verbs that evoke multiple frames and is, therefore, a challenging dataset.

for the one-step clustering-based methods.

The two-step clustering-based models that use group average clustering as the second clustering algorithm tended to achieve high scores. This indicates that the two-step clustering-based approach, which first cluster instances of the same verb and then cluster across verbs, is effective. However, as to the first clustering, 1cpv' strategy, which treats all the instances of the same verb as one cluster, achieved a higher accuracy than the clustering of the group average method, and achieved an accuracy close to the clustering of X-means, and thus we can say that 1cpv' strategy is effective enough for this dataset. We think this is due to the fact that the dataset used in this study is quite biased towards verbs that evoke only one frame, and we believe that the effectiveness of the 1cpv' may be limited in a more practical setting. Further investigation of this is one of our future works.

4 Conclusion

We proposed a method that uses masked word embeddings and two-step clustering for semantic frame induction. The results of experiments using FrameNet data showed that masked word embeddings and two-step clustering are quite effective for this frame induction task. We will conduct experiments in a setting where nouns and adjectives are also accounted for as frame-evoking words. The future goal of this research is to build a frame-semantic resource, which requires not only the induction of semantic frames but also the determination of the arguments required by each frame and the induction of semantic roles of the arguments. A possible extension of our approach is to utilize contextualized word embeddings of arguments of verbs to see if it is possible to generalize our approach for achieving this goal.

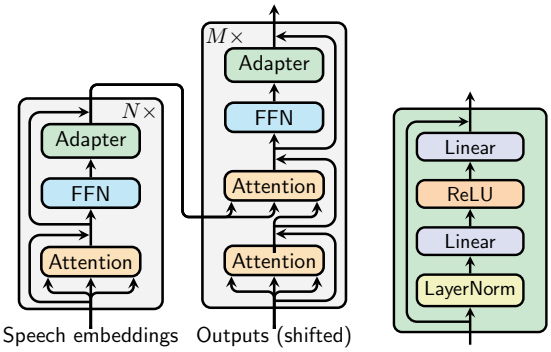
Abstract

Adapter modules were recently introduced as an efficient alternative to fine-tuning in NLP. Adapter tuning consists in freezing pre-trained parameters of a model and injecting lightweight modules between layers, resulting in the addition of only a small number of task-specific trainable parameters. While adapter tuning was investigated for multilingual neural machine translation, this paper proposes a comprehensive analysis of adapters for multilingual speech translation (ST). Starting from different pre-trained models (a multilingual ST trained on parallel data or a multilingual BART (mBART) trained on non-parallel multilingual data), we show that adapters can be used to: (a) efficiently specialize ST to specific language pairs with a low extra cost in terms of parameters, and (b) transfer from an automatic speech recognition (ASR) task and an mBART pre-trained model to a multilingual ST task. Experiments show that adapter tuning offer competitive results to full fine-tuning, while being much more parameter-efficient.

1 Introduction

The question of *versatility* versus *specialization* is often raised in the design of any multilingual translation system: is it possible to have a single model that can translate from any source language to any target one, or does it have to be multiple models each of which is in charge of one language pair? The former is referred to as a *multilingual* model, while the latter are *bilingual* ones. These two paradigms have their own strengths and limitations. From a practical point of view, a multilingual model seems to be highly desirable due to its simplicity in *training* and *deployment*, in terms of both time and space complexities. However, in terms of *accuracy*, a multilingual model could be outperformed by its bilingual counterparts, especially on high-resource language pairs.



(a) Transformer with adapters. (b) An adapter cell.

Figure 1: (a) Transformer with adapters at its FFN sub-layers. For simplicity, layer normalization (Ba et al., 2016) is omitted. During fine-tuning, only the adapters are trained. (b) A typical adapter architecture.

In practice, a certain trade-off between the aforementioned factors (and thus more generally between versatility and specialization) has often to be made, and depending on the application, one can be favored more than the other. One way to move along the spectrum between multilingual and bilingual models is to use adapter tuning which consists in freezing pre-trained parameters of a multilingual model and injecting lightweight modules between layers resulting in the addition of a small number of language-specific trainable parameters. While adapter tuning was investigated for multilingual neural machine translation (NMT) (Bapna and Firat, 2019), to our knowledge, this paper proposes the first comprehensive analysis of adapters for multilingual speech translation.

Our contributions are the following: (1) we show that both versatility and specialization can be achieved by tuning language-specific adapter modules on top of a multilingual system. Bilingual models with higher accuracy than the original multilingual model are obtained, yet keeping a low maintenance complexity; (2) starting from a different initialization point, we show that adapters can also be

used as a glue to connect off-the-shelf systems (an automatic speech recognition (ASR) model and a multilingual denoising auto-encoder mBART (Liu et al., 2020; Tang et al., 2020)) to perform the multilingual ST task. Extensive experiments on the MuST-C dataset (Di Gangi et al., 2019) show that adapter-based fine-tuning can achieve very competitive results to full fine-tuning—while being much more parameter-efficient—in both standard and low-resource settings. Our code based on FAIRSEQ S2T (Wang et al., 2020) is publicly available.[1]

2 Related Work

Adapter layers (or *adapters* for short) were first proposed in computer vision (Rebuffi et al., 2017), then explored for text classification tasks in NLP (Houlsby et al., 2019). Adapters are generally inserted between the layers of a pre-trained network and finetuned on the adaptation corpus. Bapna and Firat (2019) studied adapters in the context of NMT and evaluated them on two tasks: domain adaptation and massively multilingual NMT. Philip et al. (2020) later introduced monolingual adapters for zero-shot NMT. Other research groups made contributions on the use of adapters in NLP (Pfeiffer et al., 2020b, 2021) and a framework built on top of HuggingFace Transformers library (Wolf et al., 2020) was also released to facilitate the downloading, sharing, and adapting state-of-the-art pre-trained models with adapter modules (Pfeiffer et al., 2020a). Also very relevant to our paper is the work of Stickland et al. (2021) where adapters are used to adapt pre-trained BART (Lewis et al., 2020) and mBART25 (multilingual BART pre-trained on 25 languages) (Liu et al., 2020) to machine translation.

As far as speech processing is concerned, adapters were mostly used in ASR (Kannan et al., 2019; Lee et al., 2020; Winata et al., 2020; Zhu et al., 2020). Recently, they have also been explored for ST as well but in a limited scope. Escolano et al. (2020) addressed a very specific setting (zero-shot ST), while Li et al. (2020) used only a single adapter after a Transformer encoder.

3 Adapters for Speech Translation

In this section, we describe the integration of adapters into a given backbone model for speech translation. As the Transformer (Vaswani et al., 2017) has become increasingly common in speech processing,[2] it will be used as our backbone. Our method, however, can be easily applied to any other architectures, e.g., dual-decoder Transformer (Le et al., 2020).

Adapter modules can be introduced into a Transformer in a *serial* or *parallel* fashion. Consider a layer represented by a function f that produces an output $\mathbf{y}$ from an input $\mathbf{x}$, i.e., $\mathbf{y} = f(\mathbf{x})$. This can be an entire encoder or decoder layer, or just one of their sub-layers (e.g., the self-attention or the final feed-forward network (FFN) component). Suppose that our adapter layer is represented by a function g. The new "adapted" output is then given by:

$$\mathbf{y}_{\text{serial}} = g(f(\mathbf{x})), \quad \mathbf{y}_{\text{parallel}} = f(\mathbf{x}) + g(\mathbf{x}).$$

Intuitively, a serial adapter modifies the output directly, while a parallel one performs the operations in parallel before merging its output to the layer. In Figure 1a, we show an example of serial adapters being integrated to the Transformer, or more precisely to its FFN sub-layers. A common adapter module (Bapna and Firat, 2019) is presented in Figure 1b. Here g is a small FFN with a residual connection. The first linear layer is typically a down projection to a bottleneck dimension, and the second one projects the output back to the initial dimension. Bottleneck allows us to limit the number of parameters. Other adapter architectures also exist, e.g., Stickland and Murray (2019) explored parallel adapters consisting of a multi-head attention (MHA) layer in a multi-task setup.

For multilingual ST, we adopt the following general recipe for adapter-based fine-tuning. Starting from a pre-trained backbone, an adapter is added for each language pair and then finetuned on the corresponding bilingual data (while the rest of the backbone is frozen). The pre-trained backbone plays a crucial role in this recipe. We explore two common scenarios to obtain this pre-trained model, namely *refinement* and *transfer learning*. We present them in details, together with extensive experimental results, in Section 5 and 6. In the next section, we present our experimental setup.

4 Experimental Setup

4.1 Dataset

MuST-C We evaluate our recipes on MuST-C (Di Gangi et al., 2019), a large-scale one-to-many

Table 1: BLEU on MuST-C dev set for **refinement**. In the **Dict** column, mono and multi mean, respectively, monolingual and multilingual dictionary. D is the Transformer hidden dimension. In the **Adapter** group, d is the adapter bottleneck dimension, ENC and DEC mean adding adapters to encoder and decoder, respectively; and idem for the **Finetune** group. Rows 1–2 and rows 9–10 represent our bilingual and multilingual baselines for each D. Values lower than the multilingual baselines are colored in blue. The highest values in each group of D are underlined, while the highest values of each column are in **bold** face. Furthermore, we select the top configurations (6, 8, 14, 18) and perform statistical significance test using bootstrap re-sampling (Koehn, 2004). Results passing the test (compared to the corresponding multilingual baselines, with p-value < 0.05) are marked with a star.

ST dataset from English to eight target languages including Dutch (nl), French (fr), German (de), Italian (it), Portuguese (pt), Romanian (ro), Russian (ru), and Spanish (es). Each direction includes a triplet of speech, transcription, and translation. Sizes range from 385 hours (pt) to 504 hours (es).

MuST-C-Imbalanced We built a low-resource version of MuST-C, called MuST-C-Imbalanced, in which we randomly keep only $X\%$ of the original training data, where $X = 100$ for es, fr; $X = 50$ for ru, it; $X = 20$ for nl, ro; and $X = 10$ for de, pt (same order of the languages in the original MuST-C if we sort them in decreasing amount of data). The amount of speech data ranges from 41 hours (de) to 504 hours (es) in this version, better reflecting real-world data imbalance scenarios.

4.2 Implementation details

Our implementation is based on the FAIRSEQ S2T toolkit (Wang et al., 2020). We experiment with two architectures: a small Transformer model with dimension $D = 256$ and a medium one where $D = 512$. All experiments use the same encoder with 12 layers. The decoder has 6 layers, except for the transfer learning scenario where we used the mBART decoder for initialization. We used 8k and 10k unigram vocabulary (Kudo and Richardson, 2018) for bilingual and multilingual models, respectively. The speech features are 80-dimensional log mel filter-bank. Utterances having more than 3000 frames are removed for GPU efficiency. We used SpecAugment (Park et al., 2019) with LibriSpeech basic (LB) policy for data augmentation.

We used the Adam optimizer (Kingma and Ba, 2015) with learning rate linearly increased for the first 10K steps to a value $\eta_{\max}$, then decreased proportionally to the inverse square root of the step counter. For all adapter experiments, $\eta_{\max}$ is set to $2\text{e}{-3}$. For the others, however, we perform a grid search over three values $\{2\text{e}{-3}, 2\text{e}{-4}, 2\text{e}{-5}\}$ and select the best one on the dev set, as they are more sensitive to the learning rate.

5 Refinement

In this section, a fully trained multilingual ST backbone is further refined on each language pair to boost the performance and close potential gaps with bilingual models. We compare adapter tuning with other fine-tuning approaches as well as the bilingual and multilingual baselines (the latter being the starting point for all fine-tuning approaches) (Bapna and Firat, 2019). Starting from

Table 3: BLEU on MuST-C test set. Our method compares favorably with (Li et al., 2020).

these backbones, we either add language-specific adapters and train them only, or we finetune the backbone on each language pair, either fully or partially. All these trainings are performed on MuST-C. The results are shown in Table 1. There are two main blocks corresponding to two architectures: $D = 256$ (small) and $D = 512$ (medium). Rows 1 and 9 provide the bilingual baselines, while rows 2 and 10 serve as the multilingual baselines for each block. In addition, we compare adapter-tuning with full fine-tuning and multilingual-training (baseline) on MuST-C-Imbalanced. Table 2 displays the results for this set of experiments.

Bilingual vs. Multilingual For the small architecture ($D = 256$), the bilingual models slightly outperform their multilingual counterpart (rows 1, 2). Looking further into the performance of each language pair, the multilingual model is able to improve the results for 4 out of 8 pairs (de, nl, pt, ru), mainly those in the lower-resource direction, but the joint multilingual training slightly hurts the performance of higher-resource pairs such as es, fr, it, and ro. Finally, we observe that the medium model ($D = 512$) performs better in the multilingual setting than the bilingual one (rows 9, 10).

Adapter tuning vs. Fine-tuning Both recipes yield improvements over the multilingual baseline and recover the lost performance of higher-resource directions compared to the bilingual baseline for the small model ($D = 256$). For the medium one ($D = 512$), one adapter tuning (row 14) can slightly improve the scores in all directions and even approach the results of the best fine-tuning experiment (row 17) while maintaining much lower model sizes (95.5M vs. 8× 36.3M parameters).

Low-resource scenario The obtained results on small models show that adapter-tuning achieved the best performance, producing clear improvements over the baseline, especially for the low-resource languages: +1.1 BLEU on average on nl, ro, de, pt; +0.3 BLEU on average on es, fr, ru, it; which is competitive to full fine-tuning (+0.9 and +0.4 BLEU, respectively) while being more parameter-efficient as well as simpler for training and deployment (one model with adapters versus eight separate models). For larger models, however, the improvement is smaller: +0.4 BLEU on average on the lower-resource pairs and +0.1 on the higher-resource ones; while those of full fine-tuning are +0.4 and roughly no improvement, respectively.

Results on test set We select the best-performing fine-tuning recipes on the dev set (rows 16 and 17 in Table 1) for evaluation on the test set. For reference, we also include the multilingual baseline (row 10). Moreover, to go beyond conventional fine-tuning approaches, we also compare our recipes with a contemporary work in which only several components of the network are finetuned (Li et al., 2020). For a fair comparison, we did not use large pre-trained components such as wav2vec (Baevski et al., 2020) or mBART (Tang et al., 2020) but instead considered the same pre-trained compo-

	Adapter			Finetune	# params (M)

Table 4: BLEU on MuST-C dev set for **transfer learning** from pre-trained ASR and mBART models. We compare the results with the bilingual baselines (trained from scratch), shown in row 1 (which is identical to row 1 in Table 1). The column "Finetune xattn" means updating the cross-attention parameters. We refer to Table 1 for other notation.

nents used in our previous experiments. Following (Li et al., 2020), we considered six variants: fine-tuning LayerNorm + Attention in the encoder (LNA-E), or the decoder (LNA-D), or both (LNA-E,D); each with or without the length adapter. We found that adding the length adapter did not help in our experiments. Table 3 shows that our approach compares favorably with (Li et al., 2020) in terms of both performance and parameter-efficiency.

Other comments For small models, the encoder adapters boost the performance (0.3–0.4 BLEU on average) in all directions (rows 3 and 4, 5 and 6, Table 1), indicating that language-specific adapters can tweak the encoder representations to make them better suited for the decoder. In larger models, however, the impact of the encoder adapters is varied depending on languages and bottleneck dimensions. We also notice that increasing the bottleneck dimension slightly improves performance while remaining parameter-efficient. Fine-tuning remains the best option to optimize the models in most cases but leads to much larger model sizes. The adapter-tuning approach is competitive to fine-tuning while being much more parameter-efficient.

6 Transfer Learning

In this section, we show that adapters can be used to combine available pre-trained models to perform a multilingual ST task. In particular, we initialize the encoder using a pre-trained ASR encoder (on MuST-C)[3] provided by Wang et al. (2020) and the decoder using mBART50, a multilingual denoising auto-encoder pre-trained on 50 languages (Tang et al., 2020). We tune language independent cross-attention and language-specific adapters on top of these backbone models (using MuST-C as well). The results presented in Table 4 highlight that fine-tuning cross-attention is crucial to transfer to multilingual ST (rows 3 and 5 show poor results without doing so). Adding adapters to the backbone decoder (row 4) or to both encoder and decoder (row 6) further boosts performance, demonstrating the ability of adapters to connect off-the-shelf models in a modular fashion. The best-performing model in this recipe (row 6) also outperforms bilingual systems (row 1) despite having fewer trainable parameters (190M vs. 248M). It is also important to mention that while we experiment on 8 target languages of MuST-C corpus, the multilingual ST model of row 2 should be practically able to decode into 50 different target languages. Investigating such a zero-shot ST scenario is left for future work.

[3]Pre-training on ASR data and then transferring to ST is not new but rather standard. See, e.g., Bansal et al. (2019).

7 Conclusion

We have presented a study of adapters for multilingual ST and shown that language-specific adapters can enable a fully trained multilingual ST model to be further specialized in each language pair. With these adapter modules, one can efficiently obtain a single multilingual ST system that outperforms the original multilingual model as well as multiple bilingual systems while maintaining a low storage cost and simplicity in deployment. In addition, adapter modules can also be used to connect available pre-trained models such as an ASR model and a multilingual denoising auto-encoder to perform the multilingual speech-to-text translation task.

A Parallel Adapters

In this section, we present our preliminary experiments in which we explore different positions of the parallel adapters: in parallel with either Transformer layers or their sub-layers. We perform experiments where the adapters are added to the decoder. The results are shown in Table 5.

	Adapter			# params (M)	
	d	h	type	trainable/total	en-de
1	-	-	-	32.1/32.1	22.37
2	128	-	`ser`	0.4/32.5	22.45
3	128	4	`par-TL`	0.8/32.9	21.67
4	128	4	`par-SA`	0.8/32.9	19.55
5	128	4	`par-XA`	0.8/32.9	19.22

Table 5: BLEU on dev set for **parallel vs. serial adapters**. In the "Adapter" block, d is the adapter's dimension, h is the number of heads, `ser` stands for serial adapters, and `par` stands for parallel ones. The suffixes denote the position of the parallel adapters: in parallel with the Transformer layer (`TL`), or with self-attention sub-layer (`SA`), or with cross-attention sub-layer (`XA`).

Among the parallel variants, the one that performs operations in parallel with a full layer produces the best result. However, its performance still could not surpass the serial adapter (row 2) as well as the starting point (row 1).

B Specializing

In addition to the refinement recipe where language-specific adapters tailor the frozen multilingual ST model to translate in the corresponding direction, we also propose a recipe to facilitate the specialization in individual language pairs: by replacing the multilingual vocabulary by the monolingual ones corresponding to each target language. This recipe allows us to transfer from multilingual models to monolingual ones. A practical benefit is that one can easily leverage pre-trained multilingual models for new languages.

Table 6: BLEU on MuST-C dev set for **specialization**. We refer to Table 1 for all notation.

Table 6 displays the results of the specializing recipe. Starting from a trained multilingual ST model, one can obtain an improvement of 1.3–1.4 BLEU on average (row 8 vs. row 1 and 2) compared to the bilingual and multilingual baselines trained from scratch for the small architecture where $D = 256$. However, for a larger network ($D = 512$), the gain is more modest (0.4 BLEU on average).

Parameter Selection: Why We Should Pay More Attention to It

Jie-Jyun Liu[1], Tsung-Han Yang[1], Si-An Chen[1,2], and Chih-Jen Lin[2]

Abstract

The importance of parameter selection in supervised learning is well known. However, due to the many parameter combinations, an incomplete or an insufficient procedure is often applied. This situation may cause misleading or confusing conclusions. In this opinion paper, through an intriguing example we point out that the seriousness goes beyond what is generally recognized. In the topic of multi-label classification for medical code prediction, one influential paper conducted a proper parameter selection on a set, but when moving to a subset of frequently occurring labels, the authors used the same parameters without a separate tuning. The set of frequent labels became a popular benchmark in subsequent studies, which kept pushing the state of the art. However, we discovered that most of the results in these studies cannot surpass the approach in the original paper if a parameter tuning had been conducted at the time. Thus it is unclear how much progress the subsequent developments have actually brought. The lesson clearly indicates that without enough attention on parameter selection, the research progress in our field can be uncertain or even illusive.

1 Introduction

The importance of parameter selection in supervised learning is well known. While parameter tuning has been a common practice in machine learning and natural language processing applications, the process remains challenging due to the huge number of parameter combinations. The recent trend of applying complicated neural networks makes the situation more acute. In many situations, an incomplete or an insufficient procedure for parameter selection is applied, so misleading or confusing conclusions sometimes occur. In this opinion paper, we present a very intriguing example showing that, without enough attention on parameter selection, the research progress in our field can be uncertain or even illusive.

In the topic of multi-label classification for medical code prediction, Mullenbach et al. (2018) is an early work applying deep learning. The evaluation was conducted on MIMIC-III and MIMIC-II (Johnson et al., 2016), which may be the most widely used open medical records. For MIMIC-III, besides using all 8,922 labels, they follow Shi et al. (2017) to check the 50 most frequently occurring labels. We refer to these two sets respectively as

MIMIC-III-full and MIMIC-III-50.

We will specifically investigate MIMIC-III-50. Based on Mullenbach et al. (2018), many subsequent works made improvements to push the state of the art. Examples include (Wang et al., 2018; Sadoughi et al., 2018; Xie et al., 2019; Tsai et al., 2019; Cao et al., 2020a,b; Ji et al., 2020; Teng et al., 2020; Chen, 2020; Vu et al., 2020; Dong et al., 2021).

For the data set MIMIC-III-full, Mullenbach et al. (2018) tuned parameters to find the model that achieves the best validation performance. However, when moving to check the set MIMIC-III-50, they *applied the same parameters without a separate tuning.* We will show that this decision had a profound effect. Many works directly copied values from Mullenbach et al. (2018) for comparison and presented superior results. However, as demonstrated in this paper, if parameters for MIMIC-III-50 had been separately tuned, the approach in Mullenbach et al. (2018) easily surpasses most subsequent developments. The results fully indicate that parameter selection is more important than what is generally recognized.

This paper is organized as follows. In Section 2, we analyze past results. The main investigation is in Section 3, while Section 4 provides some discussion. Some implementation details are in the appendix. Code and supplementary materials can be found at http://www.csie.ntu.edu.tw/~cjlin/papers/parameter_selection.

2 Analysis of Works that Compared with Mullenbach et al. (2018)

The task considered in Mullenbach et al. (2018) is to predict the associated ICD (International Classification of Diseases) codes of each medical document. Here an ICD code is referred to as a label. The neural network considered is

$$\begin{aligned} &\text{document} \rightarrow \text{word embeddings} \\ &\rightarrow\text{convolution} \rightarrow \text{attention} \rightarrow \text{linear layer}, \end{aligned} \tag{1}$$

where the convolutional operation was based on Kim (2014). A focus in Mullenbach et al. (2018) was on the use of attention, so they detailedly compared the two settings[1]

CNN: (1) without attention,
CAML: (1).

For the data set MIMIC-III-full, CAML, which includes an attention layer, was shown to be significantly better than CNN on all criteria; see Table 1a. However, for MIMIC-III-50, the subset of the 50 most frequent labels, the authors reported in Table 1b that CAML is not better than CNN.

The paper (Mullenbach et al., 2018) has been highly influential. By exactly using their training, validation, and test sets for experiments, many subsequent studies have proposed new and better approaches; see references listed in Section 1. Most of them *copied* the CNN and CAML results from (Mullenbach et al., 2018) as the baseline for comparison. Table 2 summarizes their superior results on MIMIC-III-50.[2]

While using the same MIMIC-III-50 set, these subsequent studies differ from Mullenbach et al. (2018) in various ways. They proposed sophisticated networks and may incorporate additional information (e.g., label description, knowledge graph of words, etc.). Further, they may change settings not considered as parameters for tuning in Mullenbach et al. (2018). For example, Mullenbach et al. (2018) truncated each document to have at most 2,500 tokens, but Vu et al. (2020) used 4,000.

3 Investigation

We investigate the performance of the CNN and CAML approaches in Mullenbach et al. (2018) for the set MIMIC-III-50. Some implementation details are left in supplementary materials.

3.1 Parameter Selection in Mullenbach et al. (2018)

Mullenbach et al. (2018) conducted parameter tuning on a validation set of MIMIC-III-full. By considering parameter ranges shown in Table 3, they applied Bayesian optimization (Snoek et al., 2012) to choose parameters achieving the highest precision@8 on the validation set; see the selected values in Table 3 and the definition of precision in Table 1. However, the following settings are fixed instead of being treated as parameters for tuning.

- Each document is truncated to have at most 2,500 tokens. Word embeddings are from the CBOW method (Mikolov et al., 2013) with the embedding size 100.
- The stochastic gradient method Adam implemented in PyTorch is used with its default setting. However, the batch size is fixed to be 16 and the learning rate is considered as a parameter. Binary cross-entropy loss is considered.
- The Adam method is terminated if the precision@8 does not improve for 10 epochs. The model achieving the highest validation preision@8 is used to predict the test set for obtaining results in Table 1a.

Interestingly, for the 50-label subset of MIMIC-III, Mullenbach et al. (2018) did not conduct a parameter-selection procedure. Instead, a decision was to *use the same parameters selected for the*

[1] After convolution, each word is still associated with a short vector and attention is a way to obtain a single vector for the whole document. For CNN where attention is not used, Mullenbach et al. (2018) followed Kim (2014) to select the maximal value across all words.

[2] We exclude papers that used the same MIMIC-III-50 set but did not list values in Mullenbach et al. (2018) for comparison. Anyway, results in these papers are not better than what we obtained in Section 3.

Table 2: MIMIC-III-50 results from past works that have *directly listed values* in Mullenbach et al. (2018) for comparison. For Macro-F1, please see a note on its definition in the appendix.

	Macro-F1	Micro-F1	P@5	Code	Notes
Baseline considered					
CNN (Mullenbach et al., 2018)	0.576	0.625	0.620	Y	
CAML (Mullenbach et al., 2018)	0.532	0.614	0.609	Y	
New network architectures					
MVC-LDA (Sadoughi et al., 2018)	0.597	0.668	0.644	N	multi-view convolutional layers
DACNM (Cao et al., 2020b)	0.579	0.641	0.616	N	dilated convolution
BERT-Large (Chen, 2020)	0.531	0.605	-	N	BERT model
MultiResCNN (Li and Yu, 2020)	0.606	0.670	0.641	Y	multi-filter convolution and residual convolution
DCAN (Ji et al., 2020)	0.615	0.671	0.642	Y	dilated convolution, residual connections
G-Coder without additional information (Teng et al., 2020)	-	0.670	0.637	N	multiple convolutional layers
LAAT (Vu et al., 2020)	0.666	0.715	0.675	Y	LSTM before attention
New network architectures + additional information (e.g., label description, label co-occurrence, label embeddings, knowledge graph, adversarial learning, etc.)					
LEAM (Wang et al., 2018)	0.540	0.619	0.612	Y	label embeddings used
MVC-RLDA (Sadoughi et al., 2018)	0.615	0.674	0.641	N	label description used
MSATT-KG (Xie et al., 2019)	0.638	0.684	0.644	N	knowledge graph
HyperCore (Cao et al., 2020a)	0.609	0.663	0.632	N	label co-occurrence and hierarchy used
G-Coder with additional information (Teng et al., 2020)	-	0.692	0.653	N	knowledge graph, adversarial learning
Results of our investigation in Section 3 are listed below for comparison (values averaged from Table 4)					
CNN	0.606	0.659	0.634	Y	parameter selection applied
CAML	0.635	0.684	0.651	Y	

Table 3: Parameter ranges considered in Mullenbach et al. (2018) and the values used.

Parameter	Range	Values used	
		CNN	CAML
d_c: # filters	50-500	500	50
k: filter size	2-10	4	10
q: dropout prob.	0.2-0.8	0.2	0.2
η: learning rate	0.0003, 0.0001, 0.003, 0.001	0.003	0.0001

full-label set. Further they switch to present precision@5 instead of precision@8 because on average each instance is now associated with fewer labels.

The decision of not separately tuning parameters for MIMIC-III-50, as we will see, has a profound effect. In fact, because in Table 1b CAML is slightly worse than CNN, Mullenbach et al. (2018) have suspected that a parameter tuning may be needed. They stated that "we hypothesize that this[3] is because the relatively large value of $k = 10$ for CAML leads to a larger network that is more suited to larger datasets; tuning CAML's hyperparameters on this dataset would be expected to improve performance on all metrics." However, it seems no subsequent works tried to tune parameters of CNN or CAML on MIMIC-III-50.

3.2 Reproducing Results in Mullenbach et al.

To ensure the correctness of our implementation, first we reproduce the results in Mullenbach et al. (2018) by considering the following two programs.

- The public code by Mullenbach et al. (2018) at `github.com/jamesmullenbach/caml-mimic`.
- Our implementation of CNN/CAML by following the description in Mullenbach et al. (2018). The code is part of our development

[3]Here "this" means that CAML is not better than CNN.

Table 4: MIMIC-III-50 results after parameter selection. We consider three random seeds, where 1,337 was used in Mullenbach et al. (2018). Under each seed, we select the five models achieving the best validation precision@5, use them to predict the test set, and report mean/variance.

	Seed	Macro-F1	Micro-F1	P@5
CNN	1337	0.608 ± 0.006	0.659 ± 0.005	0.634 ± 0.002
	1331	0.601 ± 0.013	0.660 ± 0.007	0.634 ± 0.003
	42	0.608 ± 0.007	0.658 ± 0.006	0.633 ± 0.003
CAML	1337	0.640 ± 0.004	0.686 ± 0.004	0.650 ± 0.002
	1331	0.631 ± 0.004	0.682 ± 0.003	0.651 ± 0.001
	42	0.634 ± 0.009	0.684 ± 0.004	0.651 ± 0.002

on a general multi-label text classification package LibMultiLabel.[4]

Parameters and the random seed used in Mullenbach et al. (2018) are considered; see Table 3.

After some tweaks, on one GPU machine both programs give *exactly the same results* in the following table

	Macro-F1	Micro-F1	P@5
CNN	0.585	0.626	0.617
CAML	0.532	0.610	0.609

Values are very close to those in Table 1b. The small difference might be due to that our GPUs or PyTorch versions are not the same as theirs.

We conclude that results in Mullenbach et al. (2018) are reproducible.

3.3 Parameter Selection for MIMIC-III-50

We apply the parameter-selection procedure in Mullenbach et al. (2018) for MIMIC-III-full to MIMIC-III-50; see details in Section 3.1. A difference is that, because training MIMIC-III-50 is faster than MIMIC-III-full, instead of using Bayesian optimization, we directly check a grid of parameters that are roughly within the ranges given in Table 3. Specifically, we consider

$$d_c = 50, 150, 250, 350, 450, 550$$
$$k = 2, 4, 6, 8, 10$$
$$q = 0.2, 0.4, 0.6, 0.8$$

Because Mullenbach et al. (2018) switched to report test precision@5 for MIMIC-III-50, for validation we also use precision@5.

To see the effect of random seeds, besides the one used in Mullenbach et al. (2018), we checked two other seeds 1,331 and 42, selected solely because they are the lucky numbers of an author.

[4] https://github.com/ASUS-AICS/LibMultiLabel

3.4 Results and Analysis

Table 4 shows CNN/CAML results after parameter selection and we have the following observations.

- Both CNN and CAML achieve better results than those reported in Table 1b by Mullenbach et al. (2018). The improvement of CAML is so significant that it becomes better than CNN.
- From details in supplementary materials, for some parameters (e.g., d_c and q for CAML), the selected values are very different from those used by Mullenbach et al. (2018). Thus parameters selected for MIMIC-III-full are not transferable to MIMIC-III-50 and a separate tuning is essential.
- Results are not sensitive to the random seeds.[5]
- A comparison with Table 2 shows that most subsequent developments cannot surpass our CAML results. Some are even inferior to CNN, which is the baseline of all these studies.
- We checked if subsequent developments conducted parameter selection. A summary is in the supplementary materials.

Based on our results, how much progress past works have made is therefore unclear.

4 Discussion and Conclusions

The intention of this paper is to provide constructive critiques of past works rather than place blame on their authors. For the many parameter combinations, it is extremely difficult to check them. However, what our investigation showed is that if resources or time are available, more attention should be paid to the parameter selection. For Mullenbach et al. (2018), as they have done a comprehensive selection on a super-set MIMIC-III-full, the same procedure on the simpler MIMIC-III-50 is

[5] CNN is slight more sensitive to seeds than CAML. More investigation is needed.

entirely feasible. The decision of not doing so leads to a weak baseline in the subsequent developments.

In conclusion, besides proposing new techniques such as sophisticated networks, more attention should be placed on the parameter selection. In the future this helps to ensure that strong baselines are utilized to check the progress.

A Additional Implementation and Experimental Details

Before a stochastic gradient step on a batch of data, Mullenbach et al. (2018) pad sequences with zeros

so that all documents in this batch have the same number of tokens. Thus results of the forward operation depend on the batch size. This setting causes issues in validation because a result independent of the batch size is needed. Further, for many applications one instance appears at a time in the prediction stage. Thus we follow Mullenbach et al. (2018) to use

$$\text{batch size} = 1$$

in validation and prediction.

After the convolutional layer, Mullenbach et al. (2018) consider the tanh activation function. For both convolutional and linear layers, a bias term is included.

Before the training process, Mullenbach et al. (2018) sort the data according to their lengths. In the stochastic gradient procedure, data are not reshuffled. Therefore, instances considered in each batch are the same across epochs. While this setting is less used in other works, we follow suit to ensure the reproducibility of their results.

In the stochastic gradient procedure, we follow (Mullenbach et al., 2018) to set 200 as the maximal number of epochs. This setting is different from the default 100 epochs in the software LibMultiLabel employed for our experiments. In most situations, the program does not reach the maximal number of epochs. Instead, it terminates after the validation P@5 does not improve in 10 epochs. This criterion also follows from Mullenbach et al. (2018).

All models were trained on one NVIDIA Tesla P40 GPU compatible with the CUDA 10.2 platform and cuDNN 7.6. Note that results may slightly vary if experiments are run on different architectures.

B A Note on Macro-F1

Mullenbach et al. (2018) report macro-F1 defined as

F1 value of macro-precision and macro-recall,

where macro-precision and macro-recall are respectively the mean of precision and recall over all classes. This definition is different from the macro-F1 used in most other works. Specifically, F1 values are obtained for each class first and their mean is considered as Macro-F1; see the discussion of the Macro-F1 definitions in Opitz and Burst (2021). Because works mentioned in Table 2 may not indicate if they use the same Macro-F1 formula as Mullenbach et al. (2018), readers should exercise caution in interpreting Macro-F1 results in Table 2. However, based on Micro-F1 and P@5 results the main point of this paper still stands.

Distinct Label Representations for Few-Shot Text Classification

Abstract

Few-shot text classification aims to classify inputs whose label has only a few examples. Previous studies overlooked the semantic relevance between label representations. Therefore, they are easily confused by labels that are semantically relevant. To address this problem, we propose a method that generates distinct label representations that embed information specific to each label. Our method is widely applicable to conventional few-shot classification models. Experimental results show that our method significantly improved the performance of few-shot text classification across models and datasets.

1 Introduction

Few-shot text classification (Ye and Ling, 2019; Sun et al., 2019; Gao et al., 2019; Bao et al., 2020) has been actively studied aiming to classify texts whose labels have only a few examples. Such infrequent labels are pervasive in datasets in practice, which are headaches for text classifiers because of the lack of training examples. Snell et al. (2017) showed that the conventional text classifiers are annoyed by the over-fitting problem when the distribution of labels is skewed in a dataset.

Few-shot classification has two approaches: metric-based and meta-learning based methods. The metric-based methods conduct classification based on distances estimated by a certain metric, *e.g.*, cosine similarity (Vinyals et al., 2016), euclidean distance (Snell et al., 2017), convolutional neural networks (Sung et al., 2018), and graph neural networks (Satorras and Estrach, 2018). Metric-based methods in natural language processing focus on representation generation that are suitable for few-shot classification using the attention mechanism with various granularity (Sun et al., 2019), local and global matching of representations (Ye and Ling, 2019), and word co-occurrence patterns in attention mechanisms (Bao et al., 2020). In contrast, meta-larning based methods *learn to learn* for achieving higher accuracy by learning parameter generation (Finn et al., 2017), learning rates and parameter updates (Li et al., 2017; Antoniou et al., 2019), and parameter updates using gradients (Andrychowicz et al., 2016; Ravi and Larochelle, 2017; Li and Malik, 2017).

TECH	Apple confirms it slows down old iPhones as their batteries age Self-driving cars may be coming sooner than you thought
BIZ	Apple apologizes for slowed iPhones, drops price of battery replacements Wall Street isn't too worried about first self-driving Tesla death

Table 1: Examples from Huffpost (BIZ: BUSINESS)

All of these previous studies overlooked the effects of the semantic relevance between label representations, which confuses few-shot classifiers. As a result, the classifiers tend to fail distinguishing examples with semantically relevant labels. Table 1 shows examples with labels sampled from Huffpost (Misra, 2018). The label pair of TECH and BUSINESS is semantically relevant, for which the classifiers are easily confused.

To address this problem, we propose a mechanism that compares label representations to derive distinctive representations. It learns semantic differences between labels and generates representations that embed information specific to each label. Our method can be easily applied to existing few-shot classification models.

We evaluated our method using the standard benchmarks of Huffpost and FewRel (Han et al., 2018). Experimental results showed that our method significantly improved the performance of previous few-shot classifiers across models and datasets, and achieved the state-of-the-art accuracy.

2 Few-Shot Text Classification

This section describes the problem definition and a general form of conventional few-shot classifiers.

2.1 Problem Definition

In few-shot text classification, sets of supports and queries are given as input. A support set S consists of pairs of text x and corresponding label y: $S = \{(x_i, y_i)|i \in \{1, 2, \cdots, NK\}\}$. N is the number of label types in the support set and K is the number of samples per label type. A query set Q consists of M texts to be classified: $Q = \{q_j|j \in \{1, 2, \cdots, M\}\}$. Note that S and Q have the same set of label types. A few-shot text classifier aims to predict a label for each q_j.

In few-shot classification, training and evaluation are performed on a subset of a dataset called as *episode* (Vinyals et al., 2016). A setting of $N = n$ and $K = k$ is called as n-way k-shot classification. A training episode is created by sampling $k + m$ examples with n types of labels from a training set, and then by dividing them into support and query sets, where $m = \frac{M}{n}$. An evaluation episode is created in the same manner using an evaluation set. Note that labels in the training and evaluation episodes are exclusive, *i.e.*, the classifier is required to predict labels that it has not been exposed during training. The performance of a model is measured using the macro-averaged accuracy of all episodes.

2.2 General Form of Few-shot Text Classification Models

A classification model first converts texts in the support and query sets into vector representations. We denote a subset $S_l \subset S$ as $S_l = \{(x_l^p, y_l^p)|y_l^p = l, p \in \{1, 2, \cdots, K\}\}$ in which all texts have the same label l. An encoder $E(\cdot)$ converts x_l^p and a query q_j to vectors, $\boldsymbol{x}_i^p \in \mathbb{R}^d$ and $\boldsymbol{q}_j \in \mathbb{R}^d$ (d is the dimension of representations), respectively:

$$\boldsymbol{x}_l^p = E\left(x_l^p\right), \quad \boldsymbol{q}_j = E(q_j). \tag{1}$$

$E(\cdot)$ can be any text encoder, such as recurrent neural networks (Yang et al., 2016), convolutional neural networks (Kim, 2014), and pre-trained language models like BERT (Devlin et al., 2019).

Second, the classification model generates a label representation for l. Let $C(\cdot)$ be the function that generates the label representation $\boldsymbol{l} \in \mathbb{R}^d$:

$$\boldsymbol{l} = C\left(\boldsymbol{x}_l^1, \boldsymbol{x}_l^2, \cdots, \boldsymbol{x}_l^K\right). \tag{2}$$

$C(\cdot)$ is typically a pooling function, such as average pooling and max pooling.

Finally, the model calculates the similarity between $\boldsymbol{q}_j$ and each label representation $\boldsymbol{l}_i$ ($i \in \{1, 2, \cdots, N\}$) using a function $R(\cdot)$, and predicts a label whose representation is most similar to that of the query. The probability distribution of the i-th label is computed as:

$$p(i|\boldsymbol{l}_1, \cdots, \boldsymbol{l}_N, \boldsymbol{q}_j) = \frac{e^{R(\boldsymbol{l}_i, \boldsymbol{q}_j)}}{\sum_i e^{R(\boldsymbol{l}_i, \boldsymbol{q}_j)}}. \tag{3}$$

$R(\cdot)$ can be any metrics for estimating similarity. In natural language processing, cosine similarity is a standard choice.

As a loss function L_c, negative log-likelihood is commonly used:

$$L_c = -\frac{1}{M}\sum_{i=1}^{M} \log p(y_j), \tag{4}$$

where y_j is the gold-standard label of q_j.

3 Proposed Method

Figure 1 shows the overview of our method. It adds a mechanism for learning to generate distinctive label representations into conventional few-shot classification models by converting its training into multi-task learning. Our method adds a difference extractor (Section 3.1) and a loss function based on mutual information (Section 3.2) to an arbitrary few-shot classification model.

3.1 Difference Extractor

The difference extractor compares a set of N label representations $\boldsymbol{l}_i$ obtained by Equation (2) with each other and generates representations that retains only the information specific to each label. For doing so, a label representation should depend on a query q_j as classification is conducted based on similarity between the query and labels as shown in Equation (3) (Ye and Ling, 2019). Hence, we model both the label and query representations simultaneously. Specifically, the label representations $\boldsymbol{l}_1, \cdots, \boldsymbol{l}_N$ and the query representation $\boldsymbol{q}_j$ are transformed as:

$$\boldsymbol{H} = \text{MultiHeadAttention}(\boldsymbol{l}_1, \cdots, \boldsymbol{l}_N, \boldsymbol{q}_j), \tag{5}$$

$$\hat{\boldsymbol{l}}_i = \text{GELU}(\boldsymbol{W}_1\boldsymbol{H}_{l_i} + \boldsymbol{b}_1)\boldsymbol{W}_2 + \boldsymbol{b}_2, \tag{6}$$

$$\hat{\boldsymbol{q}}_j = \text{GELU}(\boldsymbol{W}_1\boldsymbol{H}_{q_j} + \boldsymbol{b}_1)\boldsymbol{W}_2 + \boldsymbol{b}_2, \tag{7}$$

where MultiHeadAttention$(\cdot)$ is a self-attention mechanism (Vaswani et al., 2017) that outputs

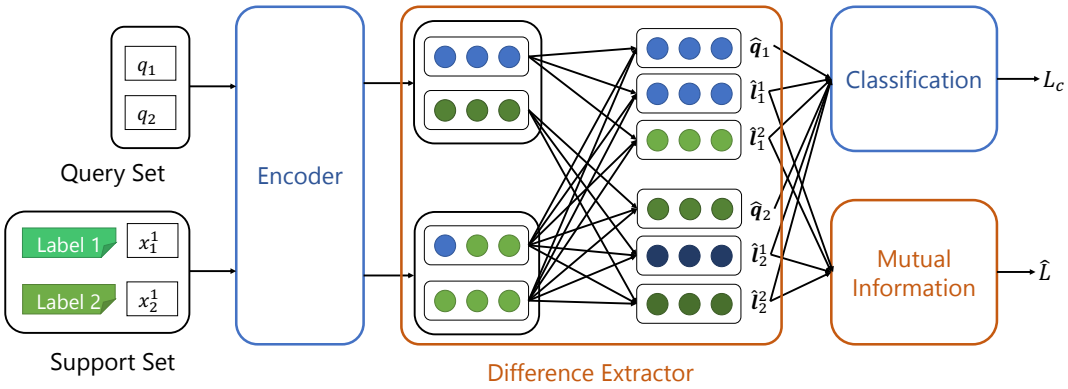

Figure 1: Outline of our method: Components of red boxes are applied to conventional few-shot classifiers.

$\boldsymbol{H} \in \mathbb{R}^{d\times(N+1)}$ hidden representations. $\boldsymbol{H}_{l_i} \in \mathbb{R}^d$ is an output of the self-attention corresponds to l_i, and similarly, $\boldsymbol{H}_{q_j} \in \mathbb{R}^d$ is that of q_j. These hidden representations are further transformed by fully-connected layers with the activation function of GELU$(\cdot)$ (Hendrycks et al., 2020).

3.2 Design of Loss Function

We assume that an ideal representation $\hat{\boldsymbol{l}}_i$ retaining only information specific to an i-th label satisfies that $I(\hat{\boldsymbol{l}}_i; \hat{\boldsymbol{l}}_r) = 0$ for all $\hat{\boldsymbol{l}}_r \ \ (i \neq r)$, where $I(\cdot)$ computes mutual information (MI). That is, each label representation is independent. Hence, we propose an MI-based loss function $\hat{L}$, which constrains such that a label representation $\hat{\boldsymbol{l}}_i$ contains only information specific to the i-th label by minimizing:

$$\hat{L} = \sum_{1\leq i,r\leq N, i\neq r} I(\hat{\boldsymbol{l}}_i, \hat{\boldsymbol{l}}_r). \tag{8}$$

Because the exact value of Equation (8) is difficult to calculate in practice, we minimize its upper-bound following Cheng et al. (2020):

$$\hat{I}(\hat{\boldsymbol{l}}_i; \hat{\boldsymbol{l}}_r) = \sum_{j=1}^{|Q|} R_j, \tag{9}$$

$$R_j = \left[\log p_\theta(\hat{\boldsymbol{l}}_i^j | \hat{\boldsymbol{l}}_r^j) - \frac{1}{|Q|} \sum_{j'=1}^{|Q|} \log p_\theta(\hat{\boldsymbol{l}}_i^j | \hat{\boldsymbol{l}}_r^{j'}) \right],$$

where $p_\theta(\cdot)$ is a neural network which approximates the conditional probability $p(\hat{\boldsymbol{l}}_i^j | \hat{\boldsymbol{l}}_r^j)$.

Finally, the overall loss function is:

$$L = L_c + \alpha \hat{L}, \tag{10}$$

where $\alpha(> 0)$ balances the effect of $\hat{L}$.

4 Experiment

We evaluated our method on different few-shot classification models using the standard benchmarks.

4.1 Benchmark Datasets

Following previous studies (Bao et al., 2020; Gao et al., 2019; Ye and Ling, 2019; Sun et al., 2019), we use Huffpost and FewRel as benchmarks.[1] Following these previous studies, we evaluated the performance of each model using $1,000$ episodes. Because episode generation involves random sampling from a dataset, we repeated this process for 10 times and computed the macro-averaged accuracy as the final score. The statistic significance was measured using a bootstrap significance test.

Huffpost This dataset consists of titles extracted from HuffPost[2] articles. The task is a prediction of a category of an article from its title. The training, validation, and test sets contain 20, 5, and 16 types of labels, respectively. The number of examples per label is 900.

FewRel The task is a prediction of a relation between entities. The training, validation, and test sets contain 65, 5, and 10 types of labels, respectively. The number of examples per label is 700.

4.2 Compared Models and Training Settings

We applied our method on three few-shot classifiers to investigate its effects on different models. As the de-facto standard of metric-based and

meta-learning based models, we employed ProtoNet (Snell et al., 2017) and MAML (Finn et al., 2017), respectively. Besides, we employed MLMAN (Ye and Ling, 2019), which is the state-of-the-art few-shot classification model on FewRel. We also compared to Bao et al. (2020), which achieved the sate-of-the-art on HuffPost.

As the Encoder $E(\cdot)$ and pooling function $C(\cdot)$ for each model, we used the BERT-base, uncased[3] and average pooling, respectively, which showed strong performance in various text classification tasks (Devlin et al., 2019). We used PyTorch and Huggingface Transformers (Wolf et al., 2020) for implementation.[4]

We applied our difference extractor and MI-loss function (denoted as "+ DE + $\hat{L}$") to ProtoNet, MAML, and MLMAN. For the difference extractor, we used 1-layer self-attention mechanism with 8-heads. As an ablation study, we also compared our method that only applies the difference extractor (denoted as "+ DE"), which is trained only with the classification loss (Equation (4)).

We trained all models with 5-way 1-shot setting. We then tested the models on different ways and shots. As an optimizer, we used Adam (Kingma and Ba, 2015). A learning rate and α in Equation (10) were searched in ranges of $[1e-5, 3e-5, 5e-5]$ and $[1e-6, 1e-4, 1e-2, 1]$, respectively, to maximise accuracy on the validation set.

4.3 Overall Results

As Table 2 shows, our method significantly improved all of the baseline models across datasets.[5] For MAML and MLMAN, our difference extractor always improved the performance of the original models. By combination with the MI-loss, the performance improved by from 0.61 up to 7.68 points. In contrast, applying only the difference extractor to ProtoNet, *i.e.*, ProtoNet + DE, deteriorated its original performance on FewRel dataset. These results confirm that both the difference extractor and MI-loss are crucial for ProtoNet. By using both, ProtoNet + DE + $\hat{L}$ consistently improved the baseline by from 0.39 up to 2.13 points.

4.4 Impact of DE and MI-loss on Baselines

The experimental results confirmed that the combination of our difference extractor and MI-loss function consistently improved the few-shot classification models. In particular, MI loss is more effective for a simpler model, *i.e.*, ProtoNet. MLMAN has an internal mechanism for comparing supports and queries, and MAML has a mechanism for updating the model parameters to accurately classify supports. These internal mechanisms allow to learn label representations that boost classification accuracy. Hence, the functionality of MI loss is partly achieved by these internal mechanisms. On the other hand, ProtoNet has the simplest architec-

[5] Note that the performance of ProtoNet was higher than that in (Ye and Ling, 2019) and (Bao et al., 2020). This is because we tuned the learning rate using the development set.

ProtoNet + DE + $\hat{L}$	$1e-4$	$1e-4$
MLMAN + DE + $\hat{L}$	$1e-4$	$1e-2$
MAML + DE + $\hat{L}$	$1e-6$	$1e-4$

Table 3: Weight of MI loss determined to maximise the performance on the development set

ture as described in Section 2.2 without additional mechanisms. Hence, both of the difference extractor and our loss function are crucial for ProtoNet.

Another factor affecting the performance of MI loss is the number of labels in a datset. When the number of labels is large, semantically relevant labels more likely exist, where MI loss plays a role. This assumption was empirically confirmed by the fact that FewRel, where MI loss (DE + $\hat{L}$) outperformed DE for most cases, has 80 labels. On the other hand, Huffpost has about half the number of labels (i.e., 41 labels).

4.5 Impact of Hyperparameters

Table 3 shows the settings of α tuned on the development set. Overall, the values of α on FewRel are larger than those on Huffpost. Larger α values increase the influence of MI loss on models, which is effective on datasets with a large number of labels like FewRel.

Figure 2 shows the accuracy measured on the development set when varying α. The performance tends to decrease when α is set too large. We suspect that too large α forces models to extract differences irrelevant to the classification task. For example, the second examples in Table 1 are about self-driving cars, where only the `BIZ` example contains named entities of `Wall Street` and `Tesla`. It is a noticeable difference; however, unlikely be useful for the classification task. Label representations of such spurious distinctiveness may degrade the classification performance.

5 Conclusion and Future Work

In this paper, we introduced a novel method shedding light on semantic relations between labels. Our method improved the classification accuracy of representative few-shot classifiers on both Huffpost and FewRel datasets, confirming the reasonable applicability of the proposed method.

Technically, our method can be applied to other classification problems that handle semantic labels,

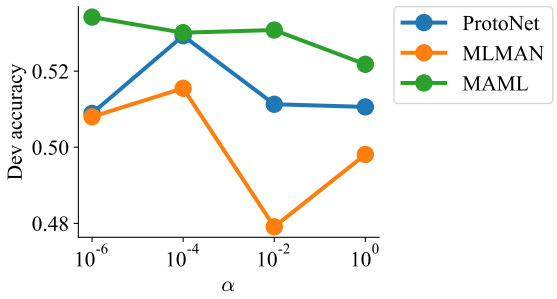

Figure 2: Accuracy on the Huffpost development set when varying α values

such as image and entity classifications. We will conduct evaluation to see its effects on various types of classifcations.

Abstract

In real scenarios, a multilingual model trained to solve NLP tasks on a set of languages can be required to support new languages over time. Unfortunately, the straightforward retraining on a dataset containing annotated examples for all the languages is both expensive and time-consuming, especially when the number of considered languages grows. Moreover, the original annotated material may no longer be available due to storage or business constraints. Re-training only with the new language data will inevitably result in Catastrophic Forgetting of previously acquired knowledge. We propose a Continual Learning strategy that updates a model to support new languages over time, while maintaining consistent results on previously learned languages. We define a Teacher-Student framework where the existing model "teaches" to a student model its knowledge about the languages it supports, while the student is also trained on a new language. We report an experimental evaluation in several tasks including Sentence Classification, Relational Learning and Sequence Labeling.

1 Introduction

In Natural Language Processing (NLP), multilingualism refers to the capability of a single model to cope with multiple languages. Recently, different Transformer-based architectures have been extended to operate over multiple languages, as in Conneau et al. (2020); Conneau and Lample (2019); Pires et al. (2019). Despite these models can be applied in the zero-shot setting (Xian et al., 2019; Artetxe and Schwenk, 2019), in many practical applications their quality will not be satisfactory. Instead, fine-tuning over annotated material in each target language is needed to obtain competitive results, as the experimental results in Lewis et al. (2019); Tran and Bisazza (2019) suggest. Having annotated material for all the languages is not always possible, especially when the model has to support an incremental number of new languages over time. In fact, the original fine-tuning material may no longer be available for storage, business or privacy constraints. For example, in a real-world application, customers may request deletion of their data, or the service itself may provide specific data retention policies, or the adopted model may be provided by a third party that did not release the training data (Chen and Moschitti, 2019). In these cases, new language support can be added in a Continual Learning (CL) setting (Lange et al., 2019), that is fine-tuning the model only using the annotated material for the new language(s). However, this approach is vulnerable to the *Catastrophic Forgetting* (CF) (McCloskey and Cohen, 1989) of previously learned languages, a well-documented concern discussed in Chen et al. (2018): when a model is incrementally fine-tuned on new data distributions, it risks forgetting how to treat instances of the previously learned ones.

In this paper, we propose a CL strategy for updating a model over an incremental number of languages, so that at each step the model requires only annotated examples of the new language(s). Our goal is to remove the dependency on the original fine-tuning material and reduce the need for annotated data at each training step. We propose a Teacher-Student framework inspired by the *Knowledge Distillation* (KD) literature (Hinton et al., 2015). Although this technique is traditionally used for the purpose of model compression (Sanh et al., 2019), recent works in Computer Vision applied KD to incrementally learn image processing tasks (Li and Hoiem, 2018). Here, we adopt KD to miti-

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 837–847
August 1–6, 2021. ©2021 Association for Computational Linguistics

gate CF when incrementally training Transformer-based architectures (Devlin et al., 2019) for semantic processing tasks. The existing model (here the teacher) imparts knowledge to a (student) model about the languages it already supports, while this is trained on new languages.

We evaluated our approach using multilingual BERT-based models on three semantic processing tasks, involving Sentence Classification, Paraphrase Identification and Sequence Tagging. Results suggest that the model can progressively learn new languages, while maintaining or even improving its quality over previously observed ones.

2 Related Work

Continual Learning (CL) (Chen et al., 2018) studies how to train a machine from a stream of data, which can evolve over time by changing the input distribution or by incorporating new tasks. CL aims to gradually extend the knowledge in a model (Lange et al., 2019), while avoiding Catastrophic Forgetting (Goodfellow et al., 2013). Previous work has mostly focused on Computer Vision (Shmelkov et al., 2017; Li and Hoiem, 2018; Rannen et al., 2017) by using Knowledge Distillation (KD) (Hinton et al., 2015) as the base framework.

CL in NLP, as opposed to Computer Vision, is still nascent (Greco et al., 2019; Sun et al., 2020). This reflects in the small number of proposed methods to alleviate CF, as discussed in Biesialska et al. (2020). In this context, some works focus on the Online Learning aspect of the CL (Filice et al., 2014). In NLP, KD has been mainly adopted to compress models (Kim and Rush, 2016; Sanh et al., 2019), and was only recently applied for CL in Named Entity Recognition (Monaikul et al., 2021).

In the context of multilingual analysis, most of the works leverage Domain Adaptation techniques within Machine Translation (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016; Johnson et al., 2017; Tan et al., 2019) in order to apply a machine translation model to an increasing set of languages.

To the best of our knowledge, this is the first work adopting CL to mitigate CF when training Transformer-based models in an incremental number of languages for semantic processing tasks.

3 CL for Multilingual processing

Multilingual Continual Learning. In the targeted scenario, we have a multilingual neural model, namely $\mathcal{M}_{L_A}$, originally pre-trained on a set of languages $L_P = \{l_1, l_2, \ldots\}$ (such as multilingual BERT (Pires et al., 2019)) and already fine-tuned to solve a task $\mathcal{T}$ (such as sentence classification) on a given set of languages $L_A \subset L_P$. The scope is to extend such model to solve $\mathcal{T}$ on a set of new languages $L_B \subset L_P$, with $L_A \cap L_B = \emptyset$.

In the rest of the discussion, without loss of generality, we assume that $L_B = \{l_{new}\}$, i.e., we support only one new language at a time. In case $n > 1$ new languages need to be added, a sequence of n model extensions can be performed. In our setting, we assume that: (*i*) a new annotated dataset $S_{\{l_{new}\}}$ for task $\mathcal{T}$ in language l_{new} is available; (*ii*) the examples used to fine-tune $\mathcal{M}_{L_A}$ are not available anymore; (*iii*) unlabeled examples are available in each language from L_A. Since $l_{new} \in L_P$, i.e., the original pre-training stage included l_{new}, the model could already operate in a zero-shot setting (i.e., without any fine-tuning stage involving l_{new} data). However, the performance of the zero-shot setting is typically non-satisfactory and a dedicated fine-tuning on l_{new} is generally required. A *naive* CL strategy consists of fine-tuning $\mathcal{M}_{L_A}$ over $S_{\{l_{new}\}}$. However, even though this schema is supposed to produce an effective model for l_{new} instances, it is not guaranteed that the resulting model would still be competitive on languages L_A, due to CF (Greco et al., 2019; Sun et al., 2020). An alternative greedy solution consists of adopting *self-training* as in Rosenberg et al. (2005): $\mathcal{M}_{L_A}$ is used to annotate some unlabeled examples in languages L_A so that the resulting pseudo-labeled dataset $\tilde{S}_{L_A}$ can be used together with $S_{\{l_{new}\}}$ to fine-tune $\mathcal{M}_{L_A}$ and mitigate CF. Unfortunately, this can also reinforce the errors of $\mathcal{M}_{L_A}$, as discussed in Hinton et al. (2015).

Preventing Catastrophic Forgetting. CF is typically caused by the model's weights, which are pushed towards fitting the data of the latest fine-tuning stage. If the model is not trained using examples in languages L_A, it risks forgetting how to treat them. To overcome CF, we propose a method based on Knowledge Distillation (KD). We define a Teacher-Student framework where $\mathcal{M}_{L_A}$ acts as the teacher, while the student is a clone of $\mathcal{M}_{L_A}$ which is fine-tuned using the multi-loss function $\mathcal{L}_{CL} = \mathcal{L}_{\mathcal{T}} + \mathcal{L}_{KD}$. The term $\mathcal{L}_{\mathcal{T}}$ is the task-specific loss, computed on the annotated examples from $S_{\{l_{new}\}}$. $\mathcal{L}_{KD}$ is a distillation loss computed on U_{L_A}, a set of unlabeled examples written in the previous languages L_A and here processed by the

teacher model. $\mathcal{L}_{\mathcal{T}}$ thus pushes the model to learn how to solve $\mathcal{T}$ in the new language l_{new}. $\mathcal{L}_{KD}$ helps the model maintaining a consistent performance on the languages L_A, by forcing the student to mimic the teacher predictions on data resembling the data distribution observed in L_A. In order to define $\mathcal{L}_{KD}$ consistently with Hinton et al. (2015), let us define $d_i(x)$ as the output logits of the model's last layer when applied to an example x. The logits are converted into a class-probability distribution using the temperature-softmax:

$$y_i(x) = \frac{exp(d_i/T)}{\sum_j exp(d_j/T)}$$

where T is a temperature hyper-parameter, which controls the smoothness of the distribution. $\mathcal{L}_{KD}$ is thus computed as the cross-entropy between the output probability distributions provided by the student and teacher, namely y_i^s and y_i^t, i.e.:

$$\mathcal{L}_{KD}(x) = -\sum_i y_i^t(x) \log y_i^s(x)$$

Using $\mathcal{L}_{KD}$ instead of the self-training procedure preserves the uncertainty of the teacher's model and prevents the student from amplifying the teacher's errors, as demonstrated in Hinton et al. (2015).

4 Experimental Evaluation

This section presents the results of the proposed CL strategy over three semantic processing tasks, involving text classification and sequence tagging. In particular, we report the Mean Absolute Error (MAE) over the Multilingual Amazon Review Corpus (MARC) (Keung et al., 2020), i.e., a 5 category Sentiment Analysis task in 6 languages. We report the Accuracy over a sentence-pair classification task, i.e., Paraphrase Identification on the PAWS-X dataset (Yang et al., 2019) in 6 languages[1]. Finally, we report the F1 for the Named Entity Recognition (NER) in 4 languages by merging the CoNLL 2002 (Tjong Kim Sang, 2002) and 2003 (Tjong Kim Sang and De Meulder, 2003) datasets. Additional details about the datasets are in Appendix.

Experimental Setup. We foresee a setting where a BERT-based model is incrementally trained using annotated datasets in multiple languages. At each step, the model is fine-tuned using a dataset in one specific language, while the annotated material used up to that point is discarded.

We reasonably assume that a set of unlabeled data is available for the languages already observed. In order to simulate this scenario, we designed a data splitting procedure such that each annotated example is observed only in one step. Let us assume we observe languages in the order $l_1 \rightarrow, \ldots, \rightarrow l_n$. For each language l_i, its training set $D_{\{l_i\}}$ is divided into $n-i+1$ equal slices, i.e., $(D_{\{l_i\}}^{(i)}, \ldots, D_{\{l_i\}}^{(n-i+1)})$. Depending on the learning strategy, each slice will be either annotated (indicated with a S symbol) or not annotated (indicated with a U symbol). At the last step, we will have observed all the data, either annotated or not.

Learning Strategies. We compare four CL strategies. We denote with `CL-Baseline` the strategy where at step k the model $\mathcal{M}_k$ is obtained by updating $\mathcal{M}_{k-1}$ by using only the $S_k = S_{\{l_k\}}^{(1)}$ annotated dataset, only with the task loss $\mathcal{L}_T$. The second strategy is denoted with `Self-Training`: at step k, $\mathcal{M}_{k-1}$ is used to annotate the dataset $\tilde{S}_k = \bigcup_{j=1}^{k-1} \{U_{\{l_j\}}^{(k-j+1)}\}$. $\mathcal{M}_k$ is then fine-tuned by using $S_k = S_{\{l_k\}}^{(1)} \cup \tilde{S}_k$ with the task loss $\mathcal{L}_T$. We denote with `CL-KD` the strategy we propose, where at step k, $\mathcal{M}_{k-1}$ is used as the teacher in our proposed KD schema[2]. $\mathcal{M}_{k-1}$ is used to derive the target output distribution of the dataset $U_k = \bigcup_{j=1}^{k-1} \{U_{\{l_j\}}^{(k-j+1)}\}$. $\mathcal{M}_k$ is then trained by adopting $S_k = S_{\{l_k\}}^{(1)}$ with the task loss $\mathcal{L}_T$ and U_k with the loss $\mathcal{L}_{KD}$. We compared with a further competitive method, namely Elastic Weight Consolidation, here denoted with `EWC` (Kirkpatrick et al., 2017). This popular CL procedure applies a regularization technique that penalizes large variations on those model's weights that are the most important for the tasks learned so far.

As a sort of upper-bound, we report the results by adopting a non-Continual Learning strategy, i.e., `Multi-Last`, where the model is trained from scratch using an annotated dataset in all languages we want to support at step k. More formally, at step k the data is $S_k = \bigcup_{j=1}^{k} \{S_{\{l_j\}}^{(k-j+1)}\}$, i.e., the annotated data is about k times larger than the one used in the CL settings.

[1] PAWS-X contains 7 languages. We were not able to reproduce the results of Yang et al. (2019) for the Korean language. Thus, we removed this language in our evaluation.

[2] We also investigated an approach inspired by Gururangan et al. (2020): we augmented `CL-KD` with Masked Language Modeling and Next Sentence Prediction objectives to continue the pre-training. Preliminary experiments provided negligible improvements, not reported here due to lack of space.

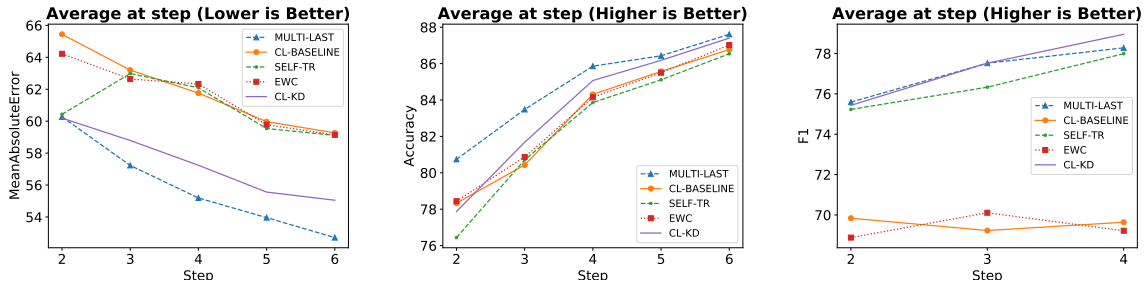
Figure 3: Average performance measures on MARC, PAWS-X and CoNLL for the language observed at step k.



(a) MARC (b) PAWS-X (c) ConLL 2002/2003

Figure 4: Average performance measures for the MARC, PAWS-X and CoNLL for the languages observed in the past steps. At each step k, we report the average score with respect to the languages observed in steps $(1, \ldots, k-1)$.

Model Training. We used the *bert-base-multilingual-cased* model in the Huggingface Transformers package (Wolf et al., 2019). We trained the models for 10 epochs with Early Stopping (patience= 3) and batch size 32. After initial experiments, we set the temperature T to 1. We repeated our experiments for 6/6/24 sequences of language permutations for MARC/PAWS-X/CoNLL, and we report the average performances.

Experimental Results and Discussion. We first run zero-shot experiments by fine-tuning a model on a subset of languages and testing it on the unobserved ones (see Figure 1). By comparing the results with the ones in Figure 2, we can observe a large gap between the results achieved on the languages still to be observed vs. the training ones. For instance, at step 1 the average gap is more than 30 MAE on MARC, about 0.8% Accuracy on PAWS-X and about 22 F1 on CoNLL. This confirms the need to fine-tune the model on each language of interest.

Figures 2a, 2b and 2c show the results on MARC, PAWS-X and CoNLL, respectively. At each step, we report the average measure computed over all the observed languages, averaged over all the permutations. Given that we are solving the same task in multiple languages, regardless the adopted strategy, the performance can improve at each step due to a cross-lingual transfer learning effect. This beneficial impact is contrasted by the CF, which is also supposed to increase at each step. In our experiments, the effect of transfer learning is generally stronger, with the only exception of `CL-Baseline` in CoNLL, where CF seems to dominate (the F1 drops from 74.29 at step 1 to 72.67 at step 4). In MARC and PAWS-X, this is alleviated: we argue that CoNLL is more challenging, as it is a word-level tagging on a smaller dataset.

The approach we propose, i.e., `CL-KD`, is able to constantly outperform its corresponding baseline `CL-Baseline`. The adoption of knowledge from the previously encountered languages is crucial in mitigating the CF phenomenon. For example, in MARC the MAE in the `CL-KD` setting is reduced from 60.62 in the first step to 53.85 in the last step. The same applies for PAWS-X where accuracy jumps from 74.57 to 87.73 and for CoNLL with F1 from 74.29 to 79.80. The performances of `CL-KD` are similar to the `Multi-Last` even if this clearly has an advantage, using a larger dataset consisting of examples written in all languages.

Figure 3 reports the average performance on the language observed during the last step only, while Figure 4 shows results on the previously acquired languages. Notice that `CL-KD` achieves comparable results between the previously acquired languages and the last learned one. Conversely, the other CL models perform significantly lower.

Notice that the `CL-KD` model achieves better results than `Self-Training`, especially for MARC and CoNLL. This means that classifying the examples with the previous model amplifies the errors of that model. In PAWS-X, the improvements achieved by `CL-KD` are less evident: we argue this is due to the nature of the dataset, where the training set in each language is derived via automatic machine translation. In any case, `CL-KD` is still performing better than `Self-Training` and `CL-Baseline`: despite automatic translation can be a viable solution, its performances will likely be sub-optimal. Notice that `EWC` is considered one of the most effective approaches for CL, but interestingly in our setting its results are not satisfactory. We investigated if the order of the languages provides significant differences. We did not notice major variations, also when the involved languages are very different[3].

Finally, we trained a full-multilingual model with all the data for all the languages. The `CL-KD` performances are not far from this model, as the difference is only 4.47, 1.56 and 2.44 for MARC, PAWS-X and CoNLL, respectively.

5 Conclusions

This paper investigated a Continual Learning strategy, based on Knowledge Distillation, for training Transformer architectures in an incremental number of languages. We demonstrated that with our approach the model maintains its robustness in processing already acquired languages without having access to annotated data for them, while learning new languages. Future work will apply our methodology to other NLP tasks, such as QA.

Acknowledgments

We would like to thank the "Istituto di Analisi dei Sistemi ed Informatica - Antonio Ruberti" (IASI) for supporting the experimentations through access to dedicated computing resources.

[3]For example, in PAWS-X when *ja* and *zh* are the first two languages, the Accuracy at the last step is 87.53. When *ja* is the third and *zh* is the fifth, the Accuracy is 87.76. Similar outcomes can be observed for the MARC dataset.

A Appendix

A.1 Datasets

Sentence Classification. We used the Multilingual Amazon Reviews Corpus (MARC) (Keung et al., 2020), i.e., a Sentiment Analysis dataset. MARC is a large-scale collection of Amazon reviews in 6 languages (English, German, Spanish, French, Japanese and Chinese). The dataset is made of $200,000/5,000/5,000$ reviews for each language, respectively for train, validation and test. We refer to the *fine-grained* classification (the target category is on 1-5 scale) by using the *body* of the review.

Sentence-Pairs Classification. We adopted the PAWS-X dataset (Yang et al., 2019) for the Paraphrase Identification task. The dataset is composed of about $24,000$ human translated evaluation pairs and about $296,000$ machine translated training pairs over 7 languages: English, Spanish, French, German, Japanese, Chinese, Korean. We actually didn't used the Korean languages, as in preliminary experiment we were not able to reproduce the results of the (Yang et al., 2019) paper. We suspect a problem in the encoding affected our results in this language with the bert multilingual model.

Sequence Tagging. We reported experiments on Named Entity Recognition (NER) using the CoNLL 2002 (Tjong Kim Sang, 2002) and CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003) datasets. We merged the two datasets as in Rahimi et al. (2019) to obtain a single dataset over 4 languages, i.e., English, Spanish, German and Dutch. The dataset contains $51,821/11,344/13,556$ annotated sentences, respectively for train, validation and test. Each sentence has been annotated with respect to the following entities: *Person*, *Location*, *Organization* and *Miscellaneous*.

A.2 Additional Results

In this section we report more details on the results of the experiments already discussed in Section 4.

A.2.1 Results on Observed Languages

Tables 1, 2 and 3 complement the results already shown in Figure 2 and summarizes the average performance on the languages observed till each step for MARC, PAWS-X and ConNLL respectively.

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	60.62	60.62	60.62	60.62	60.62
2	57.77	60.53	62.98	59.55	58.71
3	56.63	60.59	62.56	60.03	57.39
4	53.68	58.69	59.83	59.11	55.19
5	53.70	58.47	59.11	58.33	55.02
6	51.85	57.30	58.04	57.22	53.85

Table 1: MARC performances for the observed languages (as in Figure 2a), i.e., at each step we report the average of the measure for the languages observed including the last step (step $\leq k$). The reported measure is the Mean Absolute Error (lower is better).

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	74.57	74.57	74.57	74.57	74.57
2	81.78	79.47	78.39	79.62	79.90
3	84.89	82.34	82.61	82.46	83.42
4	85.87	84.52	84.24	84.44	85.33
5	86.81	86.09	85.71	85.98	86.75
6	87.89	87.17	86.97	87.41	87.73

Table 2: PAWS-X performances for the observed languages (as in Figure 2b), i.e., at each step we report the average of the measure for the languages observed including the last step (step $\leq k$). The reported measure is the Accuracy (higher is better).

A.2.2 Results on New Language Only

The following results show how an already fine-tuned model learn to manage a new language. While results in Figure 2 are averaged across all languages (observed up to the k-th step) the following evaluations focus

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	74.29	74.29	74.29	74.29	74.29
2	76.41	73.51	74.66	72.65	76.67
3	78.08	72.46	76.94	72.94	78.32
4	79.09	72.67	78.59	72.15	79.80

Table 3: CoNLL 2002/2003 performances for the observed languages (as in Figure 2c), i.e., at each step we report the average of the measure for the languages observed including the last step (step $\leq k$). The reported measure is the F1 (higher is better).

only on the last observed language. Figure 3 and Tables 4, 5 and 6 report the average performance on the last learned language. The average performance tends to improve at each step thanks to the cross-lingual transfer learning effect. All the models perform similarly, exception for the `Self-Training` model that exhibits generally lower results. This is probably due to the error amplification issue that somehow degrades the cross-lingual transfer.

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	60.62	60.62	60.62	60.62	60.62
2	55.28	55.62	65.53	54.88	57.22
3	55.44	55.37	61.72	54.80	54.60
4	49.17	49.45	53.05	49.45	49.04
5	52.65	52.47	57.39	52.49	52.85
6	47.58	47.49	52.67	47.65	47.85

Table 4: MARC performances for the Current Language (as in Figure 3a). At each step we report the measure for the language observed in that step (step $= k$). The reported measure is the Mean Absolute Error (lower is better).

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	74.57	74.57	74.57	74.57	74.57
2	82.81	80.60	80.33	80.81	81.93
3	87.72	86.17	86.40	85.66	86.91
4	85.88	85.14	85.37	85.30	86.13
5	88.32	88.20	88.11	87.93	89.03
6	89.29	89.13	89.12	89.37	89.40

Table 5: PAWS-X performances for the Current Language (as in Figure 3b). At each step we report the measure for the language observed in that step (step $= k$). The reported measure is the Accuracy (higher is better).

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	74.29	74.29	74.29	74.29	74.29
2	77.24	77.18	74.09	76.42	77.91
3	79.19	78.90	78.16	78.60	79.91
4	81.51	81.77	80.41	80.93	82.38

Table 6: CoNLL 2002/2003 performances for the Current Language (as in Figure 3c). At each step we report the measure for the language observed in that step (step $= k$). The reported measure is the F1 (higher is better).

A.2.3 Results on Previously Learned Languages

Figure 4 and Tables 7, 8 and 9 report the average performance for each step on the previously acquired languages. This allows us to better assess the impact of Catastrophic Forgetting. In particular, if we compare these results with the ones reported in Section A.2.2, it is possible to appreciate that model `CL-KD` achieves comparable results between the previously acquired languages and the last learned one. Conversely, the other CL models, and in particular `CL-Baseline`, provide significantly lower results on the previously acquired languages w.r.t. to the language learned during the last training step. This is clearly demonstrating the impact of the Catastrophic Forgetting effect.

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD
1	-	-	-	-	-
2	60.27	65.44	60.43	64.22	60.19
3	57.23	63.20	62.98	62.64	58.79
4	55.19	61.76	62.09	62.33	57.24
5	53.96	59.97	59.54	59.78	55.56
6	52.71	59.27	59.11	59.14	55.05

Table 7: MARC performances for the Past Languages (as in Figure 4a), i.e., at each step we report the average measure for the languages observed till that step (step $< k$). The reported measure is the Mean Absolute Error (lower is better).

Step/Model	MULTI-LAST	CL-BASELINE	SELF-TR	EWC	CL-KD

Table 11: PAWS-X performances for the Future Languages (zero-shot setting, as in Figure 1b). At each step we report the average of the measure for the languages still not observed (step $> k$). The reported measure is the Accuracy (higher is better).

This allows us to evaluate the performance of the zero-shot setting. As expected, results are pretty poor,

and the gap between the results on training languages and the zero-shot languages is very large: the gap is more than 30 MAE on MARC, about 8% Accuracy on PAWS-X and about 22 F1 on CoNLL. This confirms the need to fine-tune the model on each language of interest.

Abstract

Transformer is important for text modeling. However, it has difficulty in handling long documents due to the quadratic complexity with input text length. In order to handle this problem, we propose a hierarchical interactive Transformer (Hi-Transformer) for efficient and effective long document modeling. Hi-Transformer models documents in a hierarchical way, i.e., first learns sentence representations and then learns document representations. It can effectively reduce the complexity and meanwhile capture global document context in the modeling of each sentence. More specifically, we first use a sentence Transformer to learn the representations of each sentence. Then we use a document Transformer to model the global document context from these sentence representations. Next, we use another sentence Transformer to enhance sentence modeling using the global document context. Finally, we use hierarchical pooling method to obtain document embedding. Extensive experiments on three benchmark datasets validate the efficiency and effectiveness of Hi-Transformer in long document modeling.

1 Introduction

Transformer (Vaswani et al., 2017) is an effective architecture for text modeling, and has been an essential component in many state-of-the-art NLP models like BERT (Devlin et al., 2019; Radford et al., 2019; Yang et al., 2019; Wu et al., 2021). The standard Transformer needs to compute a dense self-attention matrix based on the interactions between each pair of tokens in text, where the computational complexity is proportional to the square of text length (Vaswani et al., 2017; Wu et al., 2020b). Thus, it is difficult for Transformer to model long documents efficiently (Child et al., 2019).

There are several methods to accelerate Transformer for long document modeling (Wu et al., 2019; Kitaev et al., 2019; Wang et al., 2020; Qiu et al., 2020). One direction is using Transformer in a hierarchical manner to reduce sequence length, e.g., first learn sentence representations and then learn document representations from sentence representations (Zhang et al., 2019; Yang et al., 2020). However, the modeling of sentences is agnostic to the global document context, which may be suboptimal because the local context within sentence is usually insufficient. Another direction is using a sparse self-attention matrix instead of a dense one. For example, Beltagy et al. (2020) proposed to combine local self-attention with a dilated sliding window and sparse global attention. Zaheer et al. (2020) proposed to incorporate a random sparse attention mechanism to model the interactions between a random set of tokens. However, these methods cannot fully model the global context of document (Tay et al., 2020).

In this paper, we propose a hierarchical interactive Transformer (*Hi-Transformer*)[1] for efficient and effective long document modeling, which models documents in a hierarchical way to effectively reduce the complexity and at the same time can capture the global document context for sentence modeling. In *Hi-Transformer*, we first use a sentence Transformer to learn the representation of each sentence within a document. Next, we use a document Transformer to model the global document context from these sentence representations. Then, we use another sentence Transformer to further improve the modeling of each sentence with the help of the global document context. Finally, we use hierarchical pooling method to obtain the document representation. Extensive experiments are conducted on three benchmark datasets. The results show that *Hi-Transformer* is both efficient and effective in long document modeling.

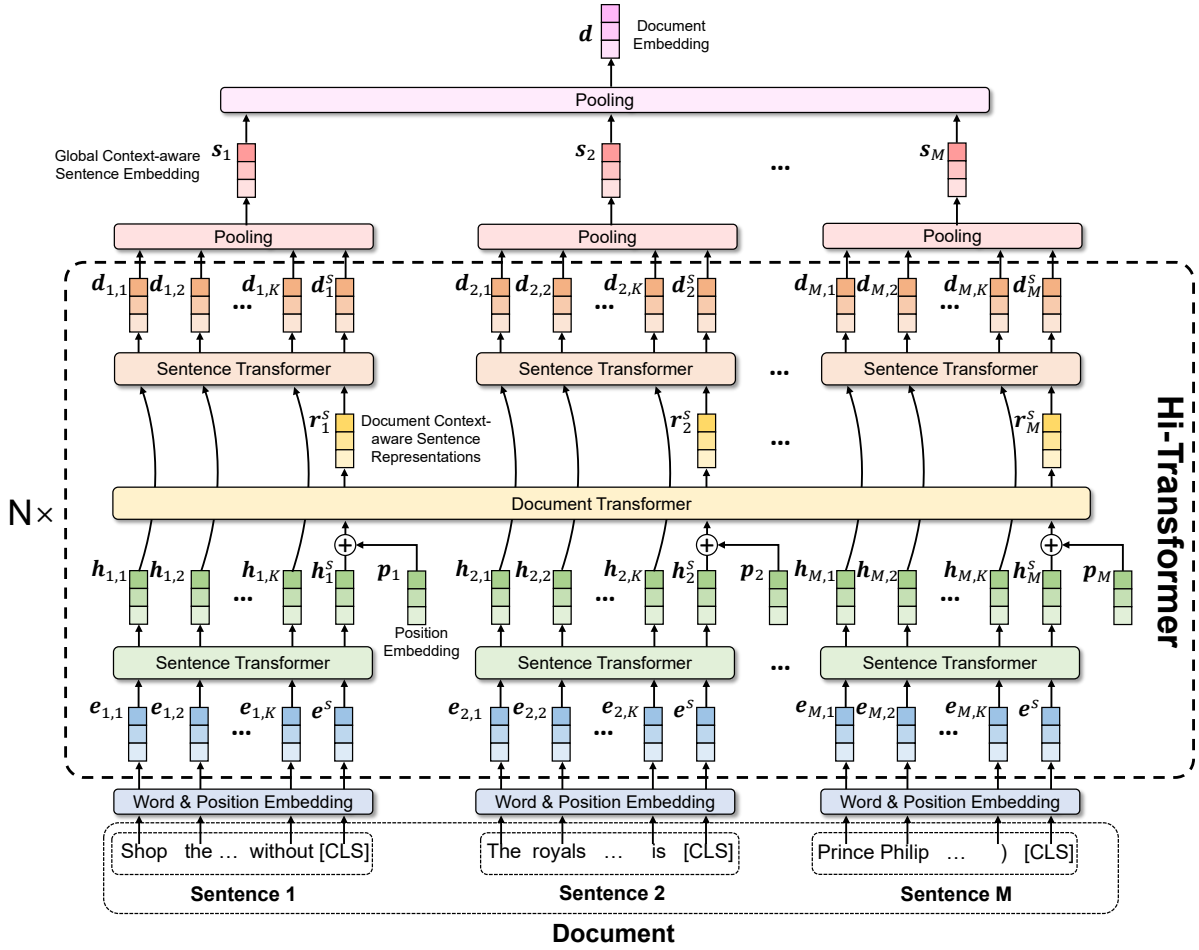

Figure 1: The architecture of *Hi-Transformer*.

2 Hi-Transformer

In this section, we introduce our hierarchical interactive Transformer (*Hi-Transformer*) approach for efficient and effective long document modeling. Its framework is shown in Fig. 1. It uses a hierarchical architecture that first models the contexts within a sentence, next models the document contexts by capturing the interactions between sentences, then employs the global document contexts to enhance sentence modeling, and finally uses hierarchical pooling techniques to obtain document embeddings. In this way, the input sequence length of each Transformer is much shorter than directly taking the word sequence in document as input, and the global contexts can be fully modeled. The details of *Hi-Transformer* are introduced as follows.

2.1 Model Architecture

Hi-Transformer mainly contains three modules, i.e., sentence context modeling, document context modeling and global document context-enhanced sentence modeling. The sentence-level context is first modeled by a sentence Transformer. Assume a document contains M sentences, and the words in the i-th sentence are denoted as $[w_{i,1}, w_{i,2}, ..., w_{i,K}]$ (K is the sentence length). We insert a "[CLS]" token (denoted as w^s) after the end of each sentence. This token is used to convey the contextual information within this sentence. The sequence of words in each sentence is first converted into a word embedding sequence via a word and position embedding layer. Denote the word embedding sequence for the i-th sentence as $[\mathbf{e}_{i,1}, \mathbf{e}_{i,2}, ..., \mathbf{e}_{i,K}, \mathbf{e}^s]$. Since sentence length is usually short, we apply a sentence Transformer to each sentence to fully model the interactions between the words within this sentence. It takes the word embedding sequence as the input, and outputs the contextual representations of words, which are denoted as $[\mathbf{h}_{i,1}, \mathbf{h}_{i,2}, ..., \mathbf{h}_{i,K}, \mathbf{h}_i^s]$. Specially, the representation $\mathbf{h}_i^s$ of the "[CLS]" token is regarded as the sentence representation.

Next, the document-level context is modeled by a document Transformer from the representations of the sentences within this document. Denote the

embedding sequence of sentences in this document as $[\mathbf{h}_1^s, \mathbf{h}_2^s, ..., \mathbf{h}_M^s]$. We add a sentence position embedding (denoted as $\mathbf{p}_i$ for the i-th sentence) to the sentence representations to capture sentence orders. We then apply a document Transformer to these sentence representations to capture the global context of document, and further learn document context-aware sentence representations, which are denoted as $[\mathbf{r}_1^s, \mathbf{r}_2^s, ..., \mathbf{r}_M^s]$.

Then, we use the document context-aware sentence representations to further improve the sentence context modeling by propagating the global document context to each sentence. Motivated by (Guo et al., 2019), we apply another sentence Transformer to the hidden word representations and the document-aware sentence representation for each sentence. It outputs a document context-aware word representation sequence for each sentence, which is denoted as $[\mathbf{d}_{i,1}, \mathbf{d}_{i,2}, ..., \mathbf{d}_{i,K}, \mathbf{d}_i^s]$. In this way, the contextual representations of words can benefit from both local sentence context and global document context.

By stacking multiple layers of *Hi-Transformer*, the contexts within a document can be fully modeled. Finally, we use hierarchical pooling (Wu et al., 2020a) techniques to obtain the document embedding. We first aggregate the document context-aware word representations in each sentence into a global context-aware sentence embedding $\mathbf{s}_i$, and then aggregate the global context-aware embeddings of sentence within a document into a unified document embedding $\mathbf{d}$, which is further used for downstream tasks.

2.2 Efficiency Analysis

In this section, we provide some discussions on the computational complexity of *Hi-Transformer*. In sentence context modeling and document context propagation, the total computational complexity is $O(M \cdot K^2 \cdot d)$, where M is sentence number with a document, K is sentence length, and d is the hidden dimension. In document context modeling, the computational complexity is $O(M^2 \cdot d)$. Thus, the total computational cost is $O(M \cdot K^2 \cdot d + M^2 \cdot d)$.[2] Compared with the standard Transformer whose computational complexity is $O(M^2 \cdot K^2 \cdot d)$, *Hi-Transformer* is much more efficient.

[2]Note that *Hi-Transformer* can be combined with other existing techniques of efficient Transformer to further improve the efficiency for long document modeling.

3 Experiments

3.1 Datasets and Experimental Settings

Our experiments are conducted on three benchmark document modeling datasets. The first one is Amazon Electronics (He and McAuley, 2016) (denoted as Amazon), which is for product review rating prediction.[3] The second one is IMDB (Diao et al., 2014), a widely used dataset for movie review rating prediction.[4] The third one is the MIND dataset (Wu et al., 2020c), which is a large-scale dataset for news intelligence.[5] We use the content based news topic classification task on this dataset. The detailed dataset statistics are shown in Table 1.

In our experiments, we use the 300-dimensional pre-trained Glove (Pennington et al., 2014) embeddings for initializing word embeddings. We use two *Hi-Transformers* layers in our approach and two Transformer layers in other baseline methods.[6] We use attentive pooling (Yang et al., 2016) to implement the hierarchical pooling module. The hidden dimension is set to 256, i.e., 8 self-attention heads in total and the output dimension of each head is 32. Due to the limitation of GPU memory, the input sequence lengths of vanilla Transformer and its variants for long documents are 512 and 2048, respectively. The dropout (Srivastava et al., 2014) ratio is 0.2. The optimizer is Adam (Bengio and LeCun, 2015), and the learning rate is 1e-4. The maximum training epoch is 3. The models are implemented using the Keras library with Tensorflow backend. The GPU we used is GeForce GTX 1080 Ti with a memory of 11 GB. We use accuracy and macro-F scores as the performance metrics. We repeat each experiment 5 times and report both average results and standard deviations.

3.2 Performance Evaluation

We compare *Hi-Transformer* with several baselines, including: (1) *Transformer* (Vaswani et al., 2017), the vanilla Transformer architecture; (2) *Longformer* (Beltagy et al., 2020), a variant of Transformer with local and global attention for long documents; (3) *BigBird* (Zaheer et al., 2020), extending *Longformer* with random attention; (4) *HI-BERT* (Zhang et al., 2019), using Transformers

Table 2: The results of different methods on different datasets.

Method	Complexity
Transformer	$O(M^2 \cdot K^2 \cdot d)$
Longformer	$O(T \cdot M \cdot K \cdot d)$
BigBird	$O(T \cdot M \cdot K \cdot d)$
HI-BERT	$O(M \cdot K^2 \cdot d + M^2 \cdot d)$
Hi-Transformer	$O(M \cdot K^2 \cdot d + M^2 \cdot d)$

Table 3: Complexity of different methods. K is sentence length, M is the number of sentences in a document, T is the number of positions for sparse attention, and d is the hidden dimension.

at both word and sentence levels. The results of these methods on the three datasets are shown in Table 2. We find that Transformers designed for long documents like *Hi-Transformer* and *BigBird* outperform the vanilla Transformer. This is because vanilla Transformer cannot handle long sequence due to the restriction of computation resources, and truncating the input sequence leads to the loss of much useful contextual information. In addition, *Hi-Transformer* and *HI-BERT* outperform *Longformer* and *BigBird*. This is because the sparse attention mechanism used in *Longformer* and *BigBird* cannot fully model the global contexts within a document. Besides, *Hi-Transformer* achieves the best performance, and the t-test results show the improvements over baselines are significant. This is because *Hi-Transformer* can incorporate global document contexts to enhance sentence modeling.

We also compare the computational complexity of these methods in Table 3. The complexity of *Hi-Transformer* is much less than the vanilla Transformer and is comparable with other Transformer variants designed for long documents. These results indicate the efficiency and effectiveness of *Hi-Transformer*.

3.3 Model Effectiveness

Nest, we verify the effectiveness of the global document contexts for enhancing sentence modeling in *Hi-Transformer*. We compare *Hi-Transformer* and its variants without global document contexts in Fig. 2. We find the performance consistently declines when the global document contexts are not encoded into sentence representations. This is because the local contexts within a single sentence may be insufficient for accurate sentence modeling, and global contexts in the entire document can provide rich complementary information for sentence understanding. Thus, propagating the document contexts to enhance sentence modeling can improve long document modeling.

3.4 Influence of Text Length

Then, we study the influence of text length on the model performance and computational cost. Since the documents in the MIND dataset are longest, we conduct experiments on MIND to compare the model performance as well as the training time per layer of *Transformer* and *Hi-Transformer* under different input text length[7], and the results are shown in Fig. 3. We find the performance of both methods improves when longer text sequences are used. This is intuitive because more information can be incorporated when longer text is input to the model for document modeling. However, the computational cost of *Transformer* grows very fast,

[7]The maximum length of *Transformer* is 512 due to GPU memory limitation.

which limits its maximal input text length. Different from *Transformer*, *Hi-Transformer* is much more efficient and meanwhile can achieve better performance with longer sequence length. These results further verify the efficiency and effectiveness of *Hi-Transformer* in long document modeling.

4 Conclusion

In this paper, we propose a *Hi-Transformer* approach for both efficient and effective long document modeling. It incorporates a hierarchical architecture that first learns sentence representations and then learns document representations. It can effectively reduce the computational complexity and meanwhile be aware of the global document contexts in sentence modeling to help understand document content accurately. Extensive experiments on three benchmark datasets validate the efficiency and effectiveness of *Hi-Transformer* in long document modeling.

Abstract

Transfer learning with large pretrained transformer-based language models like BERT has become a dominating approach for most NLP tasks. Simply fine-tuning those large language models on downstream tasks or combining it with task-specific pretraining is often not robust. In particular, the performance considerably varies as the random seed changes or the number of pretraining and/or fine-tuning iterations varies, and the fine-tuned model is vulnerable to adversarial attack. We propose a simple yet effective adapter-based approach to mitigate these issues. Specifically, we insert small bottleneck layers (i.e., adapter) within each layer of a pretrained model, then fix the pretrained layers and train the adapter layers on the downstream task data, with (1) task-specific unsupervised pretraining and then (2) task-specific supervised training (e.g., classification, sequence labeling). Our experiments demonstrate that such a training scheme leads to improved stability and adversarial robustness in transfer learning to various downstream tasks. [1]

1 Introduction

Pretrained transformer-based language models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) have demonstrated impressive performance on various NLP tasks such as sentiment analysis, question answering, text generation, just to name a few. Their successes are achieved through sequential transfer learning (Ruder, 2019): pretrain a language model on large-scale unlabeled data and then fine-tune it on downstream tasks with labeled data. The most commonly used fine-tuning approach is to optimize all parameters of the pretrained model with regard to the downstream-task-specific loss. This training scheme is widely adopted due to its simplicity and flexibility (Phang et al., 2018; Peters et al., 2019; Lan et al., 2019; Raffel et al., 2020; Clark et al., 2020; Nijkamp et al., 2021; Lewis et al., 2020).

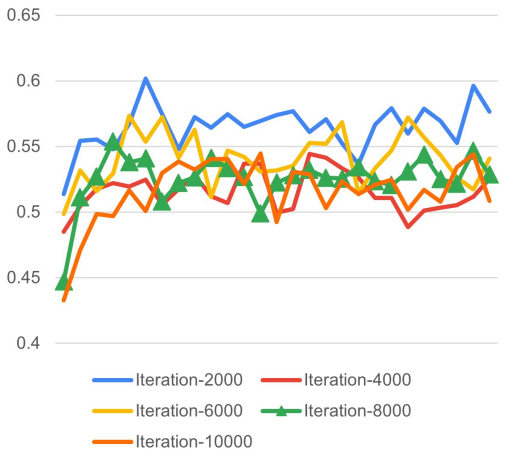

Figure 1: Learning curves of fine-tuning with the task-specific pretraining iterations varied. The curve with triangles represents the model that has converged in the 8000-th pretraining iteration.

Despite the success of the standard sequential transfer learning approach, recent works (Gururangan et al., 2020; Lee et al., 2020; Nguyen et al., 2020) have explored domain-specific or task-specific unsupervised pretraining, that is, masked language model training on the downstream task data before the final supervised fine-tuning on it. And they demonstrated benefits of task-specific pretraining on transfer learning performance. However, both standard sequential transfer learning and that with task-specific pretraining are unstable in the sense that downstream task performance is subject to considerable fluctuation while the random seed is changed or the number of pretraining and/or fine-tuning iterations is varied even after the training has converged (see Section 2 and Section 3

for details). For instance, as observed in Fig. 1, as the number of task-specific pretraining iteration varies, CoLA's performance is severely unstable in fine-tuning. Besides instability, we also observe that task-specific pretraining is vulnerable to adversarial attack. Last but not least, task-specific pretraining and/or fine-tuning on the entire model is highly parameter-inefficient given the large size of these models (e.g., the smallest BERT has 110 million parameters).

In this work, we propose a simple yet effective adapter-based approach to mitigate these issues. Adapters are some small bottleneck layers inserted within each layer of a pretrained model (Houlsby et al., 2019; Pfeiffer et al., 2020a,b). The adapter layers are much smaller than the pretrained model in terms of the number of parameters. For instance, the adapter used in (Houlsby et al., 2019) only adds 3.6% parameters per task. In our approach, we adapt the pretrained model to a downstream task through 1) task-specific pretraining and 2) task-specific supervised training (namely, fine-tuning) on the downstream task (e.g., classification, sequence labeling) by only optimizing the adapters and keeping all other layers fixed. Our approach is parameter-efficient given that only a small number of parameters are learned in the adaptation.

The adapted model learned through our approach can be viewed as a residual form of the original pretrained model. Suppose x is an input sequence and h_{original} is the features of x computed by the original model. Then the feature computed by the adapted model is,

$$h_{\text{adapted}} = h_{\text{original}} + f_{\text{adapter}}(x), \qquad (1)$$

where $f_{\text{adapter}}(x)$ is the residual feature in addition to h_{original} and f_{adapter} is the adapter learned in the adaptation process. h_{original} extracts general features that are shared across tasks, while f_{adapter} is learned to extract task-specific features. In prior work (Houlsby et al., 2019; Pfeiffer et al., 2020b), f_{adapter} is learned with task-specific supervised learning objective, distinctive from the unsupervised pretraining objective, and might not be compatible with h_{original}, as evidenced in our experiments. In our approach, f_{adapter} is first trained with the same pretraining objective[2] on the task-specific data before being adapted with the supervised training objective, encouraging the compatibility between h_{original} and f_{adapter}, which is shown to improve the downstream task performance in our experiments (see Table 1).

Some prior works have examined the potential causes of the instability of pretrained language models in transfer learning. Lee et al. (2019) proposed that catastrophic forgetting in sequential transfer learning underlined the instability, while Mosbach et al. (2020) proposed that gradient vanishing in fine-tuning caused it. Pinpointing the cause of transfer learning instability is not the focus of the current work, but our proposed method seems to able to enhance transfer learning on both aspects.

The standard sequential transfer learning or that with task-specific pretraining updates all model parameters in fine-tuning. In contrast, our approach keeps the pretrained parameters unchanged and only updates the parameters in the adapter layers, which are a small amount compared to the pretrained parameters. Therefore, our approach naturally alleviates catastrophic forgetting considering the close distance between the original pretrained model and the adapted model. On the other hand, we do not observe gradient vanishing with our transfer learning scheme (see Section 2 for more details). This might be because optimizing over a much smaller parameter space in our approach, compared to the standard sequential transfer learning scheme where all parameters are trained, renders the op-

[2]In this work, we conduct experiments with the most widely used pretraining objective, masked language modeling. The same training scheme can be extended to other pretraining objectives.

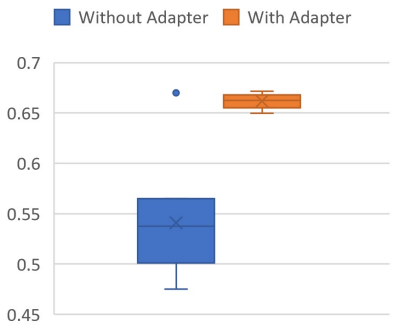

Figure 2: Distribution of dev scores on RTE from 10 random seed restarts when finetuning (1) BERT (Devlin et al., 2019) and (2) BERT with the adapter architecture.

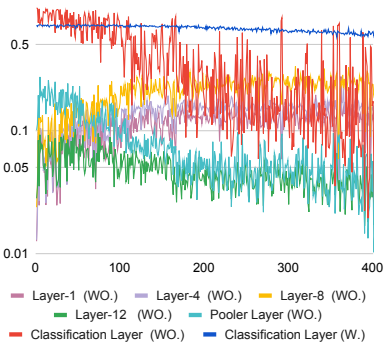

Figure 3: Gradient norms (on log scale) of intermediate layer and classification layer on RTE for with/without-adapter fine-tuning run. WO.: Without adapter. W.: With adapter.

timization easier. We leave it to future work for further theoretical analysis.

In addition to its improved stability, the proposed transfer learning scheme is also likely to be more robust to adversarial attack. Given that it updates the entire model, the standard transfer learning approach might suffer from overfitting to the downstream task, and thus a small perturbation in the input might result in consequential change in the model prediction. In turn, it might be susceptible to adversarial attack. Our approach only updates a much smaller portion of parameters, and hence might be more robust to these attacks, which is confirmed in our empirical analysis (see Section 4).

Contributions. In summary our work has the following contributions. (1) We propose a simple and parameter-efficient approach for transfer learning. (2) We demonstrate that our approach improves the stability of the adaptation training and adversarial robustness in downstream tasks. (3) We show the improved performance of our approach over strong baselines. Our source code is publicly available at https://github.com/WinnieHAN/Adapter-Robustness.git.

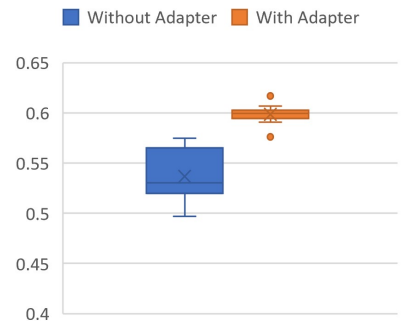

Figure 4: Box plots showing the TSP. stability of BERT with/without adapter on CoLA.

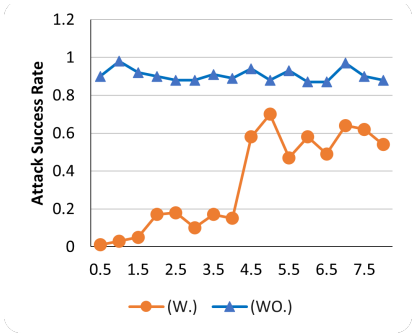

Figure 5: Attack success rate of BERT with/without adapter during task-specific pretraining. WO.: Without adapter. W.: With adapter.

2 Instability to Different Random Seeds

We first evaluate the training instability with respect to multiple random seeds: fine-tuning the model multiple times in the same setting, varying only the random seed. We conduct the experiments on RTE (Wang et al., 2018) when fine-tuning 1) BERT-base-uncased (Devlin et al., 2019) and 2) BERT-base-uncased with the adapter (Houlsby et al., 2019) [3]. As shown in Figure 2, the model without adapter leads to a large standard deviation on the fine-tuning accuracy, while the one with adapter results in a much smaller variance on the task performance.

Gradient Vanishing Mosbach et al. (2020) argues that the fine-tuning instability can be explained by optimization difficulty and gradient vanishing. In order to inspect if the adapter-based approach suffers from this optimization problem, we plot the L_2 gradient norm with respect to different layers of BERT, pooler layer and classification layer, for fine-tuning with or without adapter in

[3]For all the experiments, we use the implementation of Pfeiffer et al. (2020b): https://github.com/Adapter-Hub/adapter-transformers.git.

Figure 9: Box plots showing the fine-tuning stability of BERT with/without adapter for different TSP. iterations on CoLA. WO.: Without adapter. W.: With adapter.

Figure 3.

In traditional fine-tuning (without adapter), we see vanishing gradients for not only the top layers but also the pooler layer and classification layer. This is in large contrast to the with-adapter fine-tuning. The gradient norm in the with-adapter fine-tuning does not decrease significantly in the training process. These results imply that the adaptation with adapter does not exhibit gradient vanishing and presents a less difficult optimization problem, which in turn might explain the improved stability of our approach.

3 Instability to Pretraining and Fine-tuning Iterations

Fine-tuning with all parameters also exhibits another instability issue. In particular, fine-tuning a model multiple times on the pretrained language model, varying the task-specific pretraining iterations and fine-tuning iterations, leads to a large standard deviation in downstream task performance. As observed in Figure 1, CoLA's performance when varying the task-specific pretraining iterations is severely unstable during pretraining iterations and fine-tuning iterations. The model has converged at the pretraining iteration of 8000. However, fine-tuning based on this model does not obtain the best performance.

Pretraining Iterations. Figure 4 displays the performance on CoLA of 10 fine-tuning runs with and without the adapter. For each run, we vary only the number of pretraining iterations from 2000 to 20000 with an interval of 2000 and fix the fine-tuning epochs to 10. We clearly observe that most runs for BERT with adapter outperforms the one without adapter. Moreover, the adapter makes pretraining BERT significantly more stable than the standard approach (without adapter).

Fine-tuning Iterations. We then study the stability with regard to the number of fine-tuning iterations. We show box plots for BERT using various pretraining iterations and fine-tuning iterations, with and without adapter in Figure 9. The three sub-figures represent the early, mid, and late stages of pretraining, corresponding to the 0-th, 10000-th, and 20000-th iteration respectively. The 0-th iteration represents the original model without task-specific pretraining. The model suffers from underfitting in the 0-th iteration and overfitting in the 20000-th iteration.

In Figure 9 (a), we plot the distributions of the development scores from 100 runs when fine-tuning BERT with various fine-tuning epochs ranging from 1 to 100. In the early stage, the average development score of the model with the adapter is a little lower than the baseline model while the stability is better. After several epochs of pretraining, the adapter gradually shows improved performance in terms of the mean, minimum and maximum as demonstrated in Figure 9 (b). In the end of the pretrainig, there exists an over-fitting problem for the traditional BERT models. Pretraining transfers the model to a specific domain and fails to maintain the original knowledge. In contrast, the performance with the adapter still grows as training continues and consistently benefit from pretraining. Besides, we observe that the adapter leads to a small variance in the fine-tuning performance, especially in the late stage. Additional plots and learning curves can be found in the Appendix.

4 Adversarial Robustness

While successfully applied to many domains, the predictions of Transformers (Vaswani et al., 2017)

become unreliable in the presence of small adversarial perturbations to the input (Sun et al., 2020; Li et al., 2020). Therefore, the adversarial attacker has become an important tool (Moosavi-Dezfooli et al., 2016) to verify the robustness of models. The robustness is usually evaluated from attack effectiveness (i.e., attack success rate). We use a SOTA adversarial attack approach to assess the robustness: PWWS attacker (Ren et al., 2019). [4]. Figure 5 shows the attack success rate of BERT with/without adapter during task-specific pretraining on SST-2. The x-axis is the number of epochs for task-specific pretraining. It can be observed that the model with the adapter has better adversarial robustness.

5 Conclusion

We propose a simple yet effective transfer learning scheme for large-scale pretrained language model. We insert small bottleneck layers (i.e., adapter) within each block of the pretrained model and then optimize the adapter layers in task-specific unsupervised pretraining and supervised training (i.e., fine-tuning) while fixing the pretrained layers. Extensive experiments demonstrate that our approach leads to improved stability with respect to different random seeds and different number of iterations in task-specific pretraining and fine-tuning, enhanced adversarial robustness, and better transfer learning task performance. We therefore consider the proposed training scheme as a robust and parameter-efficient transfer learning approach.

A Hyper-Parameters Setting

We conduct the experiments on the task of GLUE tasks (Wang et al., 2018) when fine-tuning 1) BERT-base-uncased (Devlin et al., 2019) and 2) BERT-base-uncased with the adapter architecture (Houlsby et al., 2019). For all the experiments, we use the implementation from `https://github.com/Adapter-Hub/adapter-transformers.git`. For the model with adapter, we follows the setup from Mosbach et al. (2020). For all experiments, we use the default hyper-parameters except for the number of epochs. Please refer to the provided link.

The main hyper-parameters are listed in Table 2 and Table 3.

Max Sequence Length	256
Batch Size	32
Learning rate	1e-4
Number of Epochs	20

Table 2: Hyper-parameters for BERT with Adapter.

Max Sequence Length	128
Batch Size	32
Learning rate	2e-5
Number of Epochs	10

Table 3: Hyper-parameters for BERT without Adapter.

B Instability to Pretraining and Fine-tuning Iterations

We provide box plots for BERT using various pre-training iterations and fine-tuning iterations, with and without adapter on CoLA in Figure 10. The corresponding learning curves are in Figure 13.

C Instability for Large Dataset

In contrast to relatively large datasets, smaller data is more suitable and convincing as an example to analyze stability. Small dataset is easier to encounter over-fitting problems and often not stable (Devlin et al., 2019). We use MNLI to evaluate the training instability in terms of 5 random seeds with the same setup in Figure 2. The interquartile range of BERT with adapter on the distribution of dev scores is smaller than BERT without adapter. It shows that the model without adapter consistently leads to the instability issue on the fine-tuning accuracy, while the adapter architecture brings less benefit with larger dataset.

Embracing Ambiguity: Shifting the Training Target of NLI Models

Abstract

Natural Language Inference (NLI) datasets contain examples with highly ambiguous labels. While many research works do not pay much attention to this fact, several recent efforts have been made to acknowledge and embrace the existence of ambiguity, such as UNLI and ChaosNLI. In this paper, we explore the option of training directly on the estimated label distribution of the annotators in the NLI task, using a learning loss based on this ambiguity distribution instead of the gold-labels. We prepare AmbiNLI, a trial dataset obtained from readily available sources, and show it is possible to reduce ChaosNLI divergence scores when finetuning on this data, a promising first step towards learning how to capture linguistic ambiguity. Additionally, we show that training on the same amount of data but targeting the ambiguity distribution instead of gold-labels can result in models that achieve higher performance and learn better representations for downstream tasks.

1 Introduction

Ambiguity is intrinsic to natural language, and creating datasets free of this property is a hard if not impossible task. Previously, it was common to disregard it as noise or as a sign of poor quality data. More recent research, however, has drawn our attention towards the inevitability of ambiguity, and the necessity to take it into consideration when working on natural language understanding tasks (Pavlick and Kwiatkowski, 2019; Chen et al., 2020; Nie et al., 2020; Swayamdipta et al., 2020). This ambiguity stems from the lack of proper context or differences in background knowledge between annotators, and leads to a large number of examples where the correctness of labels can be debated.

ChaosNLI (Nie et al., 2020) is a dataset created by manually annotating a subset of the SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), and αNLI (Bhagavatula et al., 2020) datasets. Each of the total 4,645 samples received 100 annotations. Through this data, they were able to generate a probability distribution over the labels for these samples, which they call the human agreement distribution, with the goal of using it to evaluate the ability of current state-of-the-art models to capture ambiguity. The divergence scores between the model's predicted probability distribution and the true target distribution is computed and compared against random and human baselines. They showed that models trained using gold-labels have very poor performance on the task of capturing the human agreement distribution.

Although this is a promising first step, it remains unclear how to train models with a better understanding of ambiguity, and what tangible benefits we can obtain when actually doing so. In this work, we study the possibility of shifting the training target of models from gold-labels to the ambiguity distribution, a simple and intuitive yet until now unexplored approach in this domain. We hypothesize that when we finetune a model in this way, we can achieve lower divergence scores in the ChaosNLI benchmark. Further, we believe that it should also bring accuracy improvements in NLI and other downstream tasks. The intuition behind our performance expectations is that an ambiguity distribution offers a more informative and less misleading view on the answer to the task, which allows models to learn more from the same data.

We prepare a trial dataset with ambiguity distributions obtained from available SNLI and MNLI data, and run experiments to confirm our hypotheses. We refer to it as AmbiNLI, but we do not encourage its use in further work. Instead, we encourage the community to follow this direction by performing further data collection in this area.

Our main contributions are showing that 1) models trained on ambiguity can more closely capture

the true human distribution, 2) they are able to attain higher accuracy under otherwise equal conditions, and 3) they learn better representations for downstream tasks. We release the code used for these experiments.[1]

2 AmbiNLI

2.1 Available Data

Data containing enough information to reveal ambiguity is relatively scarce. To construct AmbiNLI we generated the label distributions from several sources. Table 1 details the available data that we have taken into consideration.

SNLI / MNLI. Both SNLI and MNLI provide labels assigned by 5 annotators on some subsets of the data (marked "Original" in Table 1). Examples where no human agreement could be reached (no majority) were given a special label (-1) and are commonly filtered out. Although the precision given by 5 labels is much lower than that of the 100 annotations provided in ChaosNLI, we believe that even a rough and inaccurate ambiguity representation is more beneficial than gold-labels only.

UNLI. UNLI (Chen et al., 2020) presents a subset of SNLI as a regression task, where each example is annotated with a real value in the range [0,1]. Values close to 0 indicate contradiction, and values close to 1 represent entailment. Each entry has one label only, but since it real-valued, it is also possible to extract a distribution from it. Even though it seems to be a less suitable data source, we do intend to investigate its effectiveness for our purposes.

ChaosNLI. ChaosNLI provides annotations from 100 humans for 3,113 examples in the development sets of SNLI and MNLI. We will call these subsets ChaosSNLI and ChaosMNLI. In order to allow for comparison with the original paper, we use them for testing only.

2.2 Creating AmbiNLI

Original SNLI and MNLI data with 5 annotations can be converted to an ambiguity distribution by simply counting the number of annotations for each label and then scaling it down into probabilities. We make sure to avoid overlap between ChaosNLI and "Original" data by removing the samples used in ChaosNLI from the data we will include in AmbiNLI. In the case of UNLI, we have taken only the 55,517 samples from the training set, so there is no overlap with ChaosNLI. We apply a simple linear approach to convert the UNLI regression value p into a probability distribution z_{NLI}, as described in the following composed function (its plot can be found in the Appendix A):

$$z_{\text{NLI}} = \begin{cases} (0, 2p, 1-2p) & p < 0.5 \\ (2p-1, 2-2p, 0) & p \geq 0.5. \end{cases}$$

The resulting AmbiNLI dataset has 18,152 SNLI examples, 18,048 MNLI examples, and 55,517 UNLI examples, for a total of 91,717 premise-hypothesis pairs with an ambiguity distribution as the target label.

[1] https://github.com/mariomeissner/AmbiNLI

3 Experiments

In our experiments, we use BERT-base (Devlin et al., 2019) with pre-trained weights and a softmax classification head. We use a batch size of 128 and learning rate of 1e-5.

Learning to capture question ambiguity. In our main experiment, we aim to judge whether is is possible to learn how to capture the human agreement distribution. We first obtain a base model in the same manner as Nie et al. (2020), by pre-training it for 3 epochs on the gold-labels of the SNLI and MNLI training sets. We observed that this pre-training step is necessary to provide the model with a general understanding of the NLI task to compensate for the low amount of ambiguity data available. We then finetune the model on our AmbiNLI dataset, setting the training objective to be the minimization of the cross-entropy between the output probability distribution and the target ambiguity distribution. For evaluation, we compute the ChaosNLI divergence scores, measured using the Jensen-Shannon Divergence (JSD), as was done in their original experiments. Furthermore, we explore what effect our ambiguity learning has on accuracy by comparing models trained on exactly the same data but with gold-label training versus ambiguous training. In order to achieve this, we prepare a version of AmbiNLI where we replace the ambiguity distributions with gold-labels. Since the two models have seen the exact same data, performance differences can be directly attributed to the process of capturing ambiguity. We report accuracy on ChaosNLI using their re-computed gold-labels.

Further accuracy analysis. To reinforce our hypothesis that accuracy improvements can be gained by leveraging the extra knowledge that models capture with ambiguity, we run an additional experiment on the ChaosMNLI dataset. We split it into three folds, and perform three-fold cross validation by training the model on two folds and evaluating on the third. Again, we start with our baseline model and compare the gold-label approach against ours.

Performance in different entropy ranges. We also study the model performance in different entropy ranges of the ChaosMNLI set. We bin the evaluation samples based on their entropy value into three equally sized ranges, and compare the model performance on each. This experiment analyzes if the model is able to perform well in both unambiguous and highly ambiguous settings.

Folds	AmbiSM Gold	AmbiSM
0	0.4371	**0.4409**
1	**0.5760**	0.5591
2	0.4897	**0.5629**
Average	0.5009	**0.5210**

Table 3: Model accuracy when performing three-fold cross validation of a BERT base model on ChaosMNLI.

Entropy Range	JSD	Accuracy
Full Range	0.2619	0.5810
[0.08 - 0.58]	0.2613	**0.6706**
[0.58 - 1.08]	**0.2472**	0.6262
[1.08 - 1.58]	0.2693	0.5087

Table 4: Entropy range performance comparison of the AmbiSM model.

Transfer learning. In this last experiment, we aim to compare the usefulness of the representations that the BERT encoder is able to learn when training on ambiguity distributions as opposed to gold-labels. We use UNLI and IMBD movie reviews (Maas et al., 2011) as the two downstream tasks for evaluation. As we want to focus on the representations learned during the ambiguity training phase, during the downstream task finetuning we freeze the BERT layers and update only the new classification head. We try with 1-layer and 2-layer heads using the ELU (Clevert et al., 2016) activation function and a hidden size of 128. We use the original train, development and test splits for UNLI, and an 80/10/10% split for IMDB movie reviews. We track development set loss and stop after two epochs without improvement. Each experiment is ran for 5 trials with different seeds and the mean and standard deviation are reported for each metric.

4 Results and Discussion

Training on the ambiguity distribution can reduce divergence scores. Table 2 details the results of our main experiment. Accuracy and JSD are provided for both the SNLI and MNLI sections in ChaosNLI. Due to differences in hyperparameters or random seeds, we were not able to exactly reproduce the base model provided in Nie et al. (2020), but achieve similar results. We follow with models further finetuned on different config-

urations of our AmbiNLI dataset. AmbiSM refers to the data originating from the original 5 label distribution only, while AmbiU refers to the data we obtained from UNLI. AmbiSMU thus refers to the full dataset. For each combination, we also trained a model on gold-labels (marked as "Gold" in the table) for comparison. With the exception of ChaosSNLI when including UNLI data, every experiment has yielded a mentionable divergence score improvement. The AmbiSM model shows a 20.5% and 21.7% JSD decrease in ChaosSNLI and ChaosMNLI respectively. This means that we can learn to capture the human agreement distribution when we use it as a training target.

UNLI's skewed distribution worsens scores. When looking at the AmbiU and AmbiSMU results in Table 2, it becomes apparent that UNLI data is not always beneficial. Specifically, it seems to worsen scores in all metrics except for ChaosMNLI accuracy. The distribution of labels in UNLI is drastically different from that of the remaining data, and we believe that when a model is finetuned on it, this distribution shift has a negative influence. We have found a very large number of samples with labels very close to 0 or 1, which translate into very extreme non-ambiguous distributions when converted. To confirm this, we filtered out all UNLI samples that had a probability label $p < 0.05$ or $p > 0.97$, and ran the "Filtered" experiments. Indeed, in AmbiU, this naive filtering process yields about 20% lower JSD scores and about 5% higher accuracy. We conclude that UNLI data, under the current conversion approach, is somewhat problematic.

Training on the ambiguity distribution can yield accuracy improvements. We have found that, for the case of AmbiSM, a model trained to target the ambiguity distribution achieves higher accuracy. This means that more precise knowledge can be acquired when learning the true underlying ambiguity of questions instead of the sometimes misleading gold-label. When using UNLI data (AmbiU and AmbiSMU) however, the results are mixed, as discussed above. Thus, to further strengthen our argument on the benefit of ambiguity data, we refer to the supplementary experiment results in Table 3, where we obtain a 2.1% accuracy improvement when performing three-fold cross-validation on the ChaosMNLI dataset. When performing a qualitative analysis on the predictions of the AmbiSM and AmbiSM Gold models, we found that the former has a stronger tendency towards neutrality, both in the number of correctly predicted neutral labels and in the average neutrality score given. However, it also resulted in some examples now being incorrectly labeled as neutral. It seems to be the case that the neutral label is the main source of ambiguity. Most ambiguous questions have a considerable amount of neutral probability, which likely produces the shift. For more details, including label counts for correct predictions as well as some prediction examples, refer to Appendix B.

Divergence scores are stable. Through the entropy range comparison of Table 4 we learn that divergence scores remain similar across different entropy subsets, showing that the model is capable of recognizing which questions are ambiguous, and appropriately adjusting the entropy level of its output. Accuracy dramatically decreases in high entropy ranges, but this goes along with our intuition, since both human annotators and the models will have doubts regarding the correct answer to the question, which leads to mismatches between the model prediction and the assigned label.

Ambiguity models learn better representations for transfer learning. Lastly, in Table 5, we observe a consistent performance improvement in transfer learning to different tasks. From the results we can infer that, by targeting the ambiguity distribution, the model can capture better linguistic representations than by targeting gold-labels. We believe that a similar trend should be visible in other tasks as well, and that the margins of improvement should increase with more ambiguity data to train on.

Is ambiguity training worth the extra labeling cost? One argument against this method is the apparent extra labeling cost required. Indeed, when comparing the gold-label and ambiguity approaches at equal number of total labels, the gold-label approach would likely attain higher performance due to the difference in number of samples. However, we argue that collecting multiple labels has several benefits other than ambiguity distribution generation. Most importantly, they help avoid mis-labelings and raise the overall quality of the dataset. In many occasions, multiple labels are already being collected for these reasons, but occasionally not released (for example, Bowman et al. (2015) didn't release the multiple labels they col-

Model	UNLI Pearson↑	UNLI MSE↓	IMDB CE Loss↓	IMDB Acc.↑

lected for 10% of the training data). They can also be used in other methods such as item response theory (Lalor et al., 2016). Furthermore, this paper's main intention is not to encourage multi-label collection at the cost of sample quantity, but rather to show the benefits of exploiting the ambiguity distribution if it is available.

5 Conclusion

We hypothesized that the intrinsic ambiguity present in natural language datasets can be exploited instead of treating it like noise. We used existing data to generate ambiguity distributions for subsets of SNLI, MNLI, and UNLI, and trained new models that are capable of more accurately capturing the ambiguity present in these datasets. Our results show that it is indeed possible to exploit this ambiguity information, and that for the same amount of data, a model trained to recognize ambiguity shows signs of higher performance in the same task as well as in other downstream tasks.

However, our dataset was created using existing resources and lacks in quality and quantity. While it was enough to show that this research direction is promising, it limited the strength of our results. In future work, we wish to obtain larger amounts of data by using crowdsourcing techniques, and expand our scope to other NLP tasks as well.

A Conversion Function

Figure 1 shows a plot of the linear conversion approach that we have taken to convert UNLI data into a probability distribution.

B Qualitative Analysis

To investigate the prediction differences between an ambiguous model and one trained on gold-labels, we compared AmbiSM and AmbiSM Gold predictions on the ChaosMNLI dataset (see Table 6). We use the new labels obtained from the ChaosNLI majority vote, instead of the original MNLI labels. We focus on two situations: 1) when only AmbiSM can predict the label correctly and 2) when only AmbiSM Gold can predict the label correctly. We picked samples from the high entropy regions to observe how the models deal with ambiguity. Generally, AmbiSM has a higher tendency towards neutrality. However, it was also able to show confidence in some samples that are more entailed or contradicted. On the other hand, we also observe some samples that were missed by AmbiSM due to its tendency, while AmbiSM Gold could predict them correctly.

Furthermore, we show the label counts for the samples that were correctly labeled by only one of the two models in Figure 2. The labels of the samples that are predicted correctly by AmbiSM Gold show the same distribution as the ChaosMNLI dataset as a whole. However, within the samples that are only predicted correctly by AmbiSM we can find a higher amount of neutral labels. This emphasizes that the behavior of the model trained on ambiguity targets can deal with neutral labels in NLI better; neutral labels are likely to be the biggest source of ambiguity.

Premise	Hypothesis	CHAOS	ASM	ASMG
Only AmbiSM is correct				
They were in rotation on the ground grabbing their weapons.	The woman rolled and drew two spears before the horse had rolled and broken the rest.	$E^{0.33}$ $\mathbf{N^{0.51}}$ $C^{0.16}$	$E^{0.178}$ $\mathbf{N^{0.522}}$ $C^{0.300}$	$E^{0.065}$ $N^{0.282}$ $\mathbf{C^{0.653}}$

Abstract

Detecting Out-of-Domain (OOD) or unknown intents from user queries is essential in a task-oriented dialog system. A key challenge of OOD detection is to learn discriminative semantic features. Traditional cross-entropy loss only focuses on whether a sample is correctly classified, and does not explicitly distinguish the margins between categories. In this paper, we propose a supervised contrastive learning objective to minimize intra-class variance by pulling together in-domain intents belonging to the same class and maximize inter-class variance by pushing apart samples from different classes. Besides, we employ an adversarial augmentation mechanism to obtain pseudo diverse views of a sample in the latent space. Experiments on two public datasets prove the effectiveness of our method capturing discriminative representations for OOD detection. [1]

1 Introduction

Detecting Out-of-Domain (OOD) or unknown intents from user queries is an essential component in a task-oriented dialog system (Gnewuch et al., 2017; Akasaki and Kaji, 2017; Tulshan and Dhage, 2018; Shum et al., 2018). It aims to know when a user query falls outside their range of predefined supported intents to avoid performing wrong operations. Different from normal intent detection tasks, we do not know the exact number of unknown intents in practical scenarios and can barely annotate extensive OOD samples. Lack of real OOD examples leads to poor prior knowledge about these unknown intents, making it challenging to identify OOD samples in the task-oriented dialog system.

Previous methods of OOD detection can be generally classified into two types: supervised and unsupervised OOD detection. Supervised OOD detection (Scheirer et al., 2013; Fei and Liu, 2016; Kim and Kim, 2018; Larson et al., 2019; Zheng et al., 2020; Zeng et al., 2021b) represents that there are extensive labeled OOD samples in the training data. In contrast, unsupervised OOD detection (Bendale and Boult, 2016; Hendrycks and Gimpel, 2017; Shu et al., 2017; Lee et al., 2018; Ren et al., 2019; Lin and Xu, 2019; Xu et al., 2020; Zeng et al., 2021a) means no labeled OOD samples except for labeled in-domain data. Specifically, for supervised OOD detection, Fei and Liu (2016); Larson et al. (2019), form a $(N+1)$-class classification problem where the $(N+1)$-th class represents the unseen intents. Further, Zheng et al. (2020) uses labeled OOD data to generate an entropy regularization term to enforce the predicted distribution of OOD inputs closer to the uniform distribution. However, these methods heavily rely on large-scale time-consuming labeled OOD data. Compared to these supervised methods, unsupervised OOD detection first learns discriminative intent representations via in-domain (IND) data, then employs detecting algorithms, such as Maximum Softmax Probability (MSP) (Hendrycks and Gimpel, 2017), Local Outlier Factor (LOF) (Lin and Xu, 2019), Gaussian Discriminant Analysis (GDA) (Xu et al., 2020) to compute the similarity of features between OOD samples and IND samples. In this paper, we focus on the unsupervised OOD detection.

A key challenge of unsupervised OOD detection is to learn discriminative semantic features via IND data. We hope to cluster the same type of IND intents more tightly and separate different types of IND intents further. Traditional softmax loss (Hendrycks and Gimpel, 2017) only focuses on whether the sample is correctly classified, and does not explicitly distinguish the relationship between

a) The in-domain intent classifier b) Using intent representations for OOD detection

Figure 1: The overall architecture of our proposed method. We first train an intent classifier on IND data using CE or SCL+CE objectives. Then, we extract the intent representation of a test sample to detect OOD.

categories. Further, Lin and Xu (2019) proposes a large margin cosine loss (LMCL) (Wang et al., 2018) which maximizes the decision margin in the latent space. LMCL forces the model to not only classify correctly but also maximize inter-class variance and minimize intra-class variance. Following the similar motivation, we aim to pull intents belonging to the same class together while simultaneously pushing apart samples from different classes to further model discriminative semantic features.

In this paper, we propose a supervised contrastive learning (SCL) model to learn discriminative semantic intent representation for OOD detection. SCL aims to minimize intra-class variance by pulling together IND intents belonging to the same class and maximize inter-class variance by pushing apart samples from different classes. Empirical results demonstrate the effectiveness of discriminative representation for OOD detection. Besides, to enhance the diversity of data augmentation in SCL, we employ an adversarial attack mechanism to obtain pseudo hard positive samples in the latent space by computing model-agnostic adversarial worst-case perturbations to the inputs. Our contributions are three-fold: (1) To the best of our knowledge, we are the first to apply supervised contrastive learning to OOD detection. (2) Compared to cross-entropy (CE) loss, SCL+CE can maximize inter-class variance and minimize intra-class variance to learn discriminative semantic representation. (3) Extensive experiments and analysis on two public datasets demonstrate the effectiveness of our method.

2 Methodology

Overall Architecture Fig 1 shows the overall architecture of our proposed method. As Fig 1(a) displays, we first train an IND intent classifier using CE or SCL+CE objectives in the training stage. Then in the test stage, we extract the intent feature of a test sample and employ the detection algorithms MSP (Hendrycks and Gimpel, 2017), LOF (Lin and Xu, 2019) or GDA (Xu et al., 2020) to detect OOD. [2] Fig 1(b) demonstrates the effectiveness of our method capturing discriminative intent representations, where SCL+CE can maximize inter-class variance and minimize intra-class variance.

Supervised Contrastive Learning We first review the classic cross-entropy (CE) loss and its improved version, large margin cosine loss (LMCL). Then we explain our supervised contrastive loss (SCL) in detail. Given an IND sample x_i and its intent label y_i, we adopt a BiLSTM (Hochreiter and Schmidhuber, 1997) or BERT (Devlin et al., 2019) encoder to get the intent representation s_i. The CE loss and LMCL are defined as follows [3]:

$$\mathcal{L}_{CE} = \frac{1}{N}\sum_{i} -\log \frac{e^{W_{y_i}^T s_i/\tau}}{\sum_j e^{W_j^T s_i/\tau}} \quad (1)$$

$$\mathcal{L}_{LMCL} = \frac{1}{N}\sum_{i} -\log \frac{e^{W_{y_i}^T s_i/\tau}}{e^{W_{y_i}^T s_i/\tau} + \sum_{j\neq y_i} e^{(W_j^T s_i + m)/\tau}} \quad (2)$$

where N denotes the number of training samples, y_i is the ground-truth class of the i-th sample, τ is the temperature factor, W_j is the weight vector of the j-th class, and m is the cosine margin. Compared to CE, LMCL adds a normalized decision margin on the negative classes and forces the model to explicitly distinguish positive class and negative classes. Our experiment 3.2 shows LMCL can slightly improve the performance of OOD detec-

[2] In this paper, we focus on the first training stage. Thus we dive into the details about the detection algorithms MSP, LOF and GDA in the appendix.

[3] For brevity, we omit the L2 normalization on both features and weight vectors for LMCL.

tion. To further model discriminative intent representations, motivated by recent contrastive learning work (Chen et al., 2020; He et al., 2020; Khosla et al., 2020; Gunel et al., 2020), we propose a supervised contrastive learning objective to minimize intra-class variance and maximize inter-class variance:

$$\mathcal{L}_{SCL} = \sum_{i=1}^{N} -\frac{1}{N_{y_i} - 1} \sum_{j=1}^{N} \mathbf{1}_{i \neq j} \mathbf{1}_{y_i = y_j} \log \frac{\exp\left(s_i \cdot s_j / \tau\right)}{\sum_{k=1}^{N} \mathbf{1}_{i \neq k} \exp\left(s_i \cdot s_k / \tau\right)} \quad (3)$$

where N_{y_i} is the total number of examples in the batch that have the same label as y_i and $\mathbf{1}$ is an indicator function. Note that we only perform SCL on the IND data since we focus on the unsupervised OOD detection where no labeled OOD data exists. As Fig 1(b) shows, SCL aims to pull together IND intents belonging to the same class and pushing apart samples from different classes, which helps recognize OOD intents near the decision boundary. In the implementation, we first pre-train the intent classifier using SCL, then finetune the model using CE or LMCL, both on the IND data. We compare iterative training and joint training in the appendix.

Adversarial Augmentation Chen et al. (2020) has proved the necessity of data augmentation for contrastive learning. However, there is no simple and effective augmentation strategy in the NLP area, which requires much handcrafted engineering. Thus, we apply adversarial attack (Goodfellow et al., 2015; Kurakin et al., 2016; Jia and Liang, 2017; Zhang et al., 2019; Yan et al., 2020) to generate pseudo positive samples to increase the diversity of views for contrastive learning. Specifically, we need to compute the worst-case perturbation $\boldsymbol{\delta}$ that maximizes the original cross-entropy loss $\mathcal{L}_{CE}$: $\boldsymbol{\delta} = \underset{\|\boldsymbol{\delta}'\| \leq \epsilon}{\arg\max} \; \mathcal{L}_{CE}\left(\boldsymbol{\theta}, \boldsymbol{x} + \boldsymbol{\delta}'\right)$, where $\boldsymbol{\theta}$ represents the parameters of the intent classifier and $\boldsymbol{x}$ denotes a given sample. ϵ is the norm bound of the perturbation $\boldsymbol{\delta}$. We apply Fast Gradient Value (FGV) (Rozsa et al., 2016) to approximate the perturbation $\boldsymbol{\delta}$:

$$\boldsymbol{\delta} = \epsilon \frac{g}{||g||}; \text{where } g = \nabla_{\boldsymbol{x}} \mathcal{L}_{CE}(f(\boldsymbol{x}; \boldsymbol{\theta}), y) \quad (4)$$

We perform normalization to g and then use a small ϵ to ensure the approximate is reasonable. Finally, we can obtain the pseudo augmented sample $\boldsymbol{x}_{adv} = \boldsymbol{x} + \boldsymbol{\delta}$ in the latent space. The pseudo samples are applied to augment positive views per anchor in SCL. Ablation study 3.3 shows adversarial augmentation significantly improves the performance of SCL for OOD detection.

3 Experiments

3.1 Setup

Datasets We use two benchmark OOD datasets, CLINC-Full and CLINC-Small (Larson et al., 2019). We report IND metrics: Accuracy(Acc) and F1, and OOD metrics: Recall and F1. OOD Recall and F1 are the main evaluation metrics in this paper. **Baselines** We adopt LSTM and BERT as our intent classifier and compare SCL with CE and LMCL. Since only using SCL can't classify in-domain intents directly, we first pre-train the classifier using SCL, then finetune the model using CE or LMCL, both on the IND data. We use three OOD detection algorithms MSP, LOF and GDA to verify the generalization capability of SCL. We present dataset statistics, implementation details, and results on MSP and LOF in the appendix.

3.2 Main Results

Tab 1 displays the main results on GDA. Combining SCL and CE/LMCL significantly outperforms all the baselines, both on OOD and IND metrics. For OOD metrics, using SCL+CE in LSTM outperforms CE by 3.08%(Recall) and 2.45%(F1) on CLINC-Full, 3.56%(Recall) and 3.37%(F1) on CLINC-Small. Similar improvements based on

models		min	max	mean	median
LSTM	CE	1.13E-07	2.63E-04	4.23E-05	1.61E-05
	SCL+CE	4.35E-08	1.85E-04	3.23E-05	1.39E-05
BERT	CE	8.26E-08	2.23E-04	3.84E-05	1.56E-05
	SCL+CE	2.86E-08	1.67E-04	3.05E-05	1.36E-05

Table 2: Intra-class variance statistics.

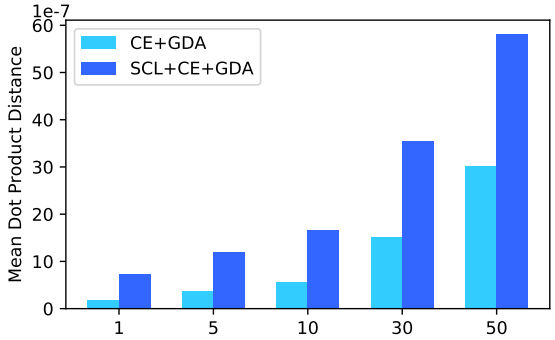

Figure 2: Comparison between inter-class distances.

LMCL are observed. The results prove the effectiveness of SCL for OOD detection. For IND metrics, using SCL+CE in LSTM outperforms CE by 0.67%(ACC) and 0.55%(F1) on CLINC-Full, 1.49%(ACC) and 2.31%(F1) on CLINC-Small. The results confirm SCL also helps IND intent detection. The difference between OOD and IND improvements is probably attributed to metric scale and data imbalance in the original test set. Besides, SCL gains higher improvements on CLINC-Small than CLINC-Full, which displays the advantage of our approach in the few-shot scenario (see details in Section 3.3). SCL also gets consistent improvements on BERT by 2.60%(Recall) and 1.86%(F1) on CLINC-Full OOD metrics, 0.84%(ACC) and 0.59%(F1) on CLINC-Full IND metrics, substantiating our method is model-agnostic for different OOD detection architectures.

3.3 Analysis

Analysis of IND feature distribution. We analyze the representation distribution of IND data on CLINC-Full dataset from two perspectives, intra-class and inter-class. We choose SCL+CE based on GDA to perform analysis. Tab 2 shows the statistics of intra-class variance, which can indicate the degree of clustering of intra-class data representations. Specifically, we average the variances of each sample normalized representation with the same intent label to its cluster center in the test set as cluster intra-class variance, then report min/max/mean/median values on all cluster intra-class variances. Results show SCL effectively decreases intra-class variances, especially in terms of max and mean values, which confirms SCL can converge intra-class intent representations.

Proportion		10%	20%	30%	40%	50%
IND F1	CE	63.31	70.77	77.84	81.55	84.30
	SCL+CE	69.50	75.14	81.45	84.18	86.61
	Relative↑	**9.78%**	**6.17%**	**4.64%**	**3.23%**	**2.74%**
OOD F1	CE	42.16	48.34	53.00	57.92	61.07

Table 3: Effect of training data size.

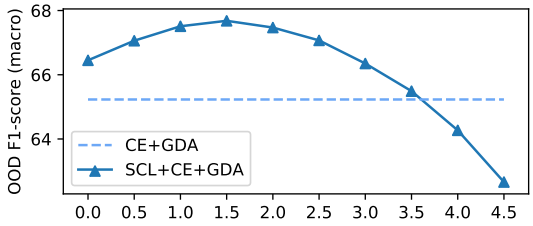

Figure 3: Effect of Adversarial Perturbation Norm.

Fig 2 shows the inter-class distances. We average dot product distances between each class center to its k nearest class centers, then average results of all classes as inter-class distance. The X-axis denotes the number of k. We observe a significant increase in SCL+CE compared to CE. When k is smaller, the increase is more obvious. It verifies SCL can maximize inter-class variance and distinguish intent classes. We also provide visualization analysis in the appendix. In summary, SCL can pull together IND intents belonging to the same class and push apart samples from different classes, which makes representations more discriminative.

Effect of IND Training Data Size. Tab 3 shows the effect of IND training data size. We randomly choose training data with a certain proportion from CLINC-Full IND data and use the original test set for evaluation. We use the LSTM+GDA setting. Results show SCL+CE consistently outperforms CE. Besides, with the decrease of training data size, the relative improvements gradually increase. It proves SCL has strong robustness for improving OOD detection, especially in the few-shot scenario.

Analysis of Adversarial Perturbation Norm. Fig 3 shows the effect of adversarial perturbation norm ϵ on OOD detection performance. We conduct the experiments on CLINC-Full dataset, using LSTM and GDA. The X-axis denotes the value of ϵ. The CE+GDA dashed line means no SCL pre-training and $\epsilon = 0.0$ in the SCL+CE+GDA solid line means no adversarial augmentation. In general, both SCL and adversarial augmentation contribute to the improvements and $\epsilon \in (1.0, 2.0)$ achieves better performances. Compared with the baseline without SCL, the SCL+CE method with a smaller adversarial perturbation can still obtain

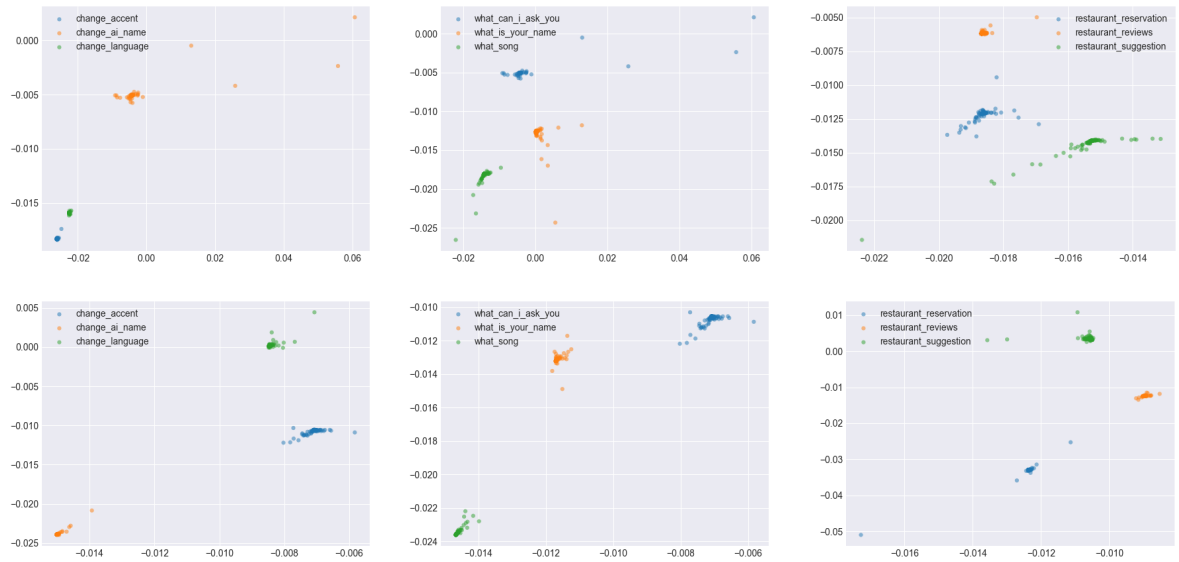

Figure 4: Visualization of in-domain representation distribution.

settings		IND		OOD

128	50	87.01	88.28	66.80	67.68
128	100	87.52	88.60	67.08	68.12
128	200	88.10	89.05	67.56	68.63
256	50	87.17	88.40	66.96	67.92
256	100	87.85	88.96	67.32	68.37
256	200	88.37	89.24	67.76	68.94
512	50	87.35	88.78	67.32	68.47
512	100	88.14	89.22	67.64	68.69
512	200	88.54	89.50	68.00	69.27

Table 4: Parameter analysis of batch size and representation dimension.

better results but lower than the results with an optimal range of perturbation, while large norms tend to damage the effect of SCL. Our method still performs well with a broad range of adversarial perturbation and is insensitive to hyperparameters.

Parameter Analysis. As our proposed SCL is a method involving contrastive learning, we analyze batch sizes and representation dimensions to further verify the effectiveness, whose results are presented in Table 4. We conduct experiments in CLINC-Full dataset, using LSTM and SCL+CE objective for training and GDA for detection. With the increase of batch size and representation dimension, both in-domain and OOD metrics are slightly improved. However, compared with the method proposed in this paper, the improvement is relatively limited. In general, our proposed method is not sensitive to hyperparameters and can show the expected effect under a wide range of reasonable settings.

Feature Visualization. As shown in Fig 4, we extract several groups of similar classes for PCA visualization analysis. The three pictures in the upper part represent training using only CE, while the three pictures in the lower part use SCL+CE for training. In the same column, we sample the same classes for observation. It is worth noting that the scale of the image has been adjusted adaptively in order to display all the data. The actual distance can be sensed by observing the marking of the coordinate axis. After SCL is added, the distance between similar classes is significantly expanded, and the data in the same classes are more closely clustered.

4 Conclusion

In this paper, we focus on the unsupervised OOD detection where no labeled OOD data exist. To learn discriminative semantic intent representations via in-domain data, we propose a novel supervised contrastive learning loss (SCL). SCL aims to minimize intra-class variance by pulling together in-domain intents belonging to the same class and maximize inter-class variance by pushing apart samples from different classes. Experiments and analysis confirm the effectiveness of SCL for OOD detection. We hope to provide new guidance for future OOD detection work.

Broader Impact

Task-oriented dialog systems have demonstrated remarkable performance across a wide range of applications, with the promise of a significant positive impact on human production mode and lifeway. However, in scenarios where information is complex and rapidly changing, models usually face input that is meaningfully different from typical examples encountered during training. Current models are prone to make unfounded predictions on these inputs, which may affect human judgment and thus impair the safety of models in practical applications. In domains with the greatest potential for societal impacts, such as navigation or medical diagnosis, models should be able to detect potentially agnostic OOD and be robust to high-entropy inputs to avoid catastrophic errors. This work proposes a novel unsupervised OOD detection method that using supervised contrastive learning to learn discriminative semantic intent representations. The effectiveness and robustness of the model are significantly improved by adding a supervised contrastive learning pre-training stage, which takes a step towards the ultimate goal of enabling the safe real-world deployment of task-oriented dialog systems in safety-critical domains. The experimental results have been reported on standard benchmark datasets for considerations of reproducible research.

A Dataset Details

Table 5 shows the details of two benchmark OOD dataset[4] CLINC-Full and CLINC-Small (Larson et al., 2019). They both contain 150 in-domain intents across 10 domains. It is worth noting that our paper does not use labeled OOD data from the training set in the training stage.

CLINC	Full	Small
Avg utterance length	9	9
Intents	150	150
Training set size	15100	7600
Training samples per class	100	50
Training OOD samples amount	100	100
Development set size	3100	3100
Development samples per class	20	20
Development OOD samples amount	100	100
Testing Set Size	5500	5500
Testing samples per class	30	30
Development OOD samples amount	1000	1000

Table 5: Statistics of the CLINC datasets.

B Baseline Details

We compare many types of unsupervised OOD detection models. Therefore, the model proposed in this paper can be divided into the training stage and detection stage. For each model LSTM or BERT, we use different detection methods to verify its performance. The innovation of this paper focuses mainly on the training stage. Due to the limitation of space, we do not detailed introduce the detection methods in the main body. We will supplement the relevant contents as follows:

MSP (Maximum Softmax Probability)(Hendrycks and Gimpel, 2017) applies a threshold on the maximum softmax probability where the threshold is set to 0.5 according to the dev set.

LOF (Local Outlier Factor)(Lin and Xu, 2019) uses the local outlier factor to detect unknown intents. The motivation is that if an example's local density is significantly lower than its k-nearest neighbor's, it is more likely to be considered as the unknown intents.

GDA (Gaussian Discriminant Analysis)(Xu et al., 2020) is a generative distance-based classifier for out-of-domain detection with Euclidean space. They estimate the class-conditional distribution on feature spaces of DNNs via Gaussian discriminant analysis (GDA) to avoid over-confidence problems and use Mahalanobis distance to measure the confidence score of whether a test sample belongs to OOD. GDA is the state-of-the-art detection methods till now, so we adopt GDA as our main detection algorithm. We also report MSP and LOF results in Section D.

C Implementation Details

We use the public pre-trained 300 dimensions GloVe embeddings (Pennington et al., 2014)[5] or bert-base-uncased (Devlin et al., 2019)[6] model to embed tokens. We use a single-layer BiLSTM as a feature extractor and set the dimension of hidden states to 128. The dropout value is fixed at 0.5. We use Adam optimizer (Kingma and Ba, 2014) to train our model. We set a learning rate to 1E-03 for GloVe+LSTM and 1E-04 for Bert. In the training stage, 100 epochs of supervised contrastive training are first conducted, then 10 epochs of finetune training are conducted with CE or LMCL. Both phases are training only on in-domain labeled data. The training stage has an early stop setting with patience equal to 5. We use the best F1 scores on the validation set to calculate the GDA threshold adaptively. Each result of the experiments is tested 5 times under the same setting and gets the average value. The norms of adversarial perturbation are obtained by the heuristic method, in which MSP and LOF are 1.0 and GDA is 1.5. The training stage of our model lasts about 10 minutes using GloVe embeddings, and 18 minutes using Bert-base-uncased, both on a single Tesla T4 GPU(16 GB of memory). The average value of the trainable model parameters is 3.05M.

D Supplementary Experimental Results

Various Detection Methods In this paper, the experiments and analysis are mainly conducted around the training stage. Different detection models are used to verify the generalization of our proposed method. Due to the limitation of space, we use GDA for most of the presentation in the main body. The main experiments of LOF and MSP using LSTM feature extractor are shown in Table 6. It is worth noting that using different detection methods can obtain the same analysis results as the main experimental in the main body.

Table 7: Results of combining two training stages in different ways

ways of two training stages on CLINC-Full dataset using LSTM and GDA detection method in Table 7. CE is the baseline that only uses the cross-entropy loss function to train the feature extractor. SCL+CE follows the paradigm of pre-training first and then finetuning, which achieves the best performance. Besides, we try two different combinations to explore the relationship between the two training stages. CE+SCL means that we first conduct training to minimize cross-entropy loss, and then conduct supervised contrastive learning. The results show that the subsequent SCL leads to a decline in metrics, especially on in-domain. This is because SCL, while optimizing the representation distribution, compromises the mapping relationship with labels. Multitask means to optimize two losses simultaneously. This setting leads to mutual interference between two tasks, which affects the convergence effect and damages the performance and stability of the model. In general, SCL should be used as a pre-training method and CE as a finetuning method. The best results can be achieved by first using SCL to learn discriminative representation and then finetuning the model by CE.

Preview, Attend and Review: Schema-Aware Curriculum Learning for Multi-Domain Dialog State Tracking

Abstract

Existing dialog state tracking (DST) models are trained with dialog data in a random order, neglecting rich structural information in a dataset. In this paper, we propose to use curriculum learning (CL) to better leverage both the curriculum structure and schema structure for task-oriented dialogs. Specifically, we propose a model-agnostic framework called **S**chema-**a**ware **C**urriculum **L**earning for Dial**og** State Tracking (SaCLog), which consists of a preview module that pre-trains a DST model with schema information, a curriculum module that optimizes the model with CL, and a review module that augments mispredicted data to reinforce the CL training. We show that our proposed approach improves DST performance over both a transformer-based and RNN-based DST model (TripPy and TRADE) and achieves new state-of-the-art results on WOZ2.0 and MultiWOZ2.1.

1 Introduction

Dialog state tracking (DST) extracts users' goals in task-oriented dialog systems, where dialog states are often represented in terms of a set of slot-value pairs (Williams et al., 2016; Eric et al., 2020). Due to the language variety of multi-turn dialogs, the concepts of slots and values are often indirectly expressed in the conversation (such as co-references, ellipsis, and diverse appearances), which are a major bottleneck for improving DST performance (Gao et al., 2019; Hu et al., 2020). Many existing DST methods have focused on designing better model architectures to tackle the problems (Dai et al., 2018; Wu et al., 2019; Kim et al., 2020), but still neglect the full exploitation of two important aspects of structural information.

The first is *curriculum structure* in a dataset. Such a structure relies on a measure of the difficulty of examples, which can be used to guide the model training in an easy-to-hard manner, imitating the meaningful learning order in human curricula. This paradigm is called curriculum learning (CL) (Bengio et al., 2009) and has been shown useful in various other problems (Wang et al., 2021). DST training examples also vary greatly in their difficulty levels. As shown in Figure 1, for the same slot *'taxi-departure'*, a user can either inform its value *'nandos'* explicitly in a simple utterance or convey her intention implicitly via multi-round interactions, requiring a complex inference process to find the value *'golden house'* referred by the slot *'restaurant-name'*. However, CL has been rarely studied in DST, and models are often trained with dialog data in a random order.

Figure 1: An easy and a hard dialog example for DST.

In addition, *schema structure* is prominent in multi-domain task-oriented dialogs. A schema is specified by a collection of all possible slots and their values, which describes semantic relations among them. Some previous work utilized the structure via an extra schema graph in a regular training process (Chen et al., 2020; Zhu et al., 2020; Wu et al., 2020). We propose to incorporate schema information into CL through a pre-curriculum process, in which a DST model can be pre-trained with schema-related objectives to prepare for upcom-

ing DST examples. To reinforce the CL training, we can also expand those examples with frequent mispredictions during CL based upon the schema, enabling the model to accumulate more experience and perform better on similar cases.

Built on these motivations, we propose a novel framework named as **S**chema-**a**ware **C**urriculum **L**earning for Dial**og** State Tracking (SaCLog), which consists of three components: 1) a **preview module** that pre-trains the base part of a DST model (e.g., BERT and RNN) with objectives capturing the connections between the schema and dialog contexts, 2) a **curriculum module** that organizes training data from easy to hard and optimizes the model with CL, and 3) a **review module** which leverages schema-based data augmentation to extend mispredicted data to boost the CL training process further. The proposed approach is model-agnostic, in the sense that it can be incorporated into different DST models. To the best of our knowledge, this is the first attempt to apply CL to the DST task. We show that our proposed approach improves DST performance over both a transformer-based and RNN-based DST model (TripPy and TRADE) and achieves new state-of-the-art results on WOZ2.0 and MultiWOZ2.1.

2 Problem Formulation

We denote a dialog context containing t turns as $X_t = \{(R_1, U_1), ..., (R_t, U_t)\}$, where R_i and U_i represent system and user utterance at the i-th turn respectively. DST is tasked to extract turn-level or discourse-level dialog states in the form of a set of slot-value pairs given X_t. A turn-level dialog state $Y_t = \{(s, v_t), s \in \mathcal{S}\}$ is the slot-value pairs extracted only from (R_t, U_t) at current turn t, where $\mathcal{S}$ is a predefined set of slot s in the schema and v_t is the corresponding value[1] of the slot s. A discourse-level dialog state Z_t is the accumulation of L_t, representing all slot-value pairs that have been expressed over the course of the dialog until the t-th turn. We denote a dialog data for DST as $d_t = \{X_t, Y_t, Z_t\}$ and the training dataset as $\mathcal{D}$.

3 Schema-Aware Curriculum Learning

In this section, we first introduce the core curriculum module about how to apply the basic CL to the DST task; we then describe the preview and review module, which exploit the schema structure to facilitate the CL training process. The overall framework of SaCLog is shown in Figure 2.

3.1 Curriculum Learning for DST

We propose curriculum learning for DST and design two sub-modules: a **difficulty scorer** that measures the difficulty level of a dialog example with respect to a DST model, as well as a **training scheduler** module that arranges the scored data as a sequence of easy-to-hard training stages.

3.1.1 The Difficulty Scorer

As a dialog example could be intuitively *complex* for humans or inherently *difficult* for neural networks (NNs), both model-based and rule-based scores should be considered. We propose to use a hybrid scoring function that combines the advantages of model predictions and rules.

For model-based difficulty, we predict scores in a cross-validation-like manner. We divide $\mathcal{D}$ into K equal-sized subsets, where $K-1$ subsets are used to train a DST model to predict the remaining one. This process is repeated K times until every subset is predicted. The score $r_t^{mod} \in [0, 1]$ is computed based on the average accuracy of all mentioned slots (whose values are not *none*) in Y_t for each d_t. In our experiment, we train six models with the same architecture and different initialization seeds to obtain the mean value $\overline{r}_t^{mod}$ of model scores.

For rule-based difficulty, we consider 4 factors to fuse human prior knowledge about DST into our curriculum design: 1) current dialog turn number t; 2) the total token number of (R_t, U_t); 3) the number of mentioned name entities like 'hotel names' in Z_t; 4) the number of newly added or changed slots in Y_t. We set the maximum values of above factors as 7/50/4/6 respectively, and normalize all factors into $r_t^{rul,i} \in [0, 1]$, where i indicates the i-th factor.

Finally, the hybrid difficulty score is calculated jointly as $r_t^{hyb} = \alpha_0 \overline{r}_t^{mod} + \sum_{i=1}^{4} \alpha_i r_t^{rul,i}$, where $r^{hyb} \in [0, 1]$ and $\sum_{i=0}^{4} \alpha_i = 1$.

3.1.2 The Training Scheduler

We adopt a widely used strategy called *baby step* (Spitkovsky et al., 2010) to organize the scored data for CL. Specifically, we divide the score uniformly into N intervals and distribute the sorted data into N buckets accordingly. The optimization starts from the easiest bucket as the initial training stage. After reaching a fixed number of maximum epochs or convergence, the next bucket is merged

[1]Each s contains two special values, *none* and *dontcare*, indicating s has no values and can take any values respectively.

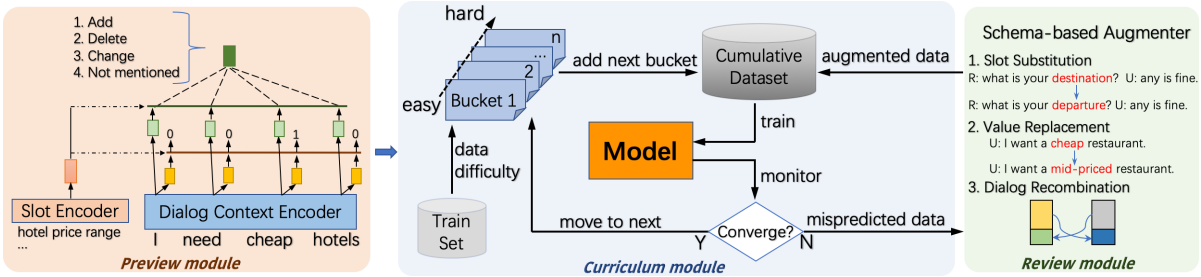

Figure 2: An overview of the SaCLog training procedures.

into the current training subset and shuffled for the next training stage. In our experiment, we set the maximum number of epochs as 3, and treat as the convergence if the training loss ceases to decrease and the loss value is within a threshold 15 for 100 steps. As the subset accumulates until all buckets are aggregated, we then continue to train the model for several extra epochs.

3.2 The Preview Module

In human learning, previewing learning materials helps develop an overall picture of what will be covering and can bring benefits to the learning process. In our task here, we propose new pre-training objectives to learn structural inductive bias of the schema structure. Specifically, our *preview* module contains a slot encoder to compute a slot embedding e_s for each input slot s, and a dialog context encoder to extract the hidden states of X_t as $E_t = [e_t^1, e_t^2, ...]$, then we have:

$$\begin{aligned} B_t^s &= [\phi_1^{sig}(e_s \oplus e_t^1), \phi_1^{sig}(e_s \oplus e_t^2), ...] \\ c_t^s &= \phi_4^{sft}(e_s \oplus \text{Att}(e_s, E_t)) \end{aligned} \quad (1)$$

where $\text{Att}(k, V)$ is the attention function using the vector k to query the vector sequence V to get a context vector and $\oplus$ the vector concatenation. $\phi_d^{sig}(\cdot)$ and $\phi_d^{sft}(\cdot)$ denote an FNN with one hidden layer having the same size as input layer, where the output layer is of size d, and is sigmoid and softmax respectively. B_t^s is a binary sequence indicates which span of X_t belongs to the value of s, while c_t^s is the classification logits indicates whether s is added, deleted, changed, or not mentioned in Y_t.

Therefore, for each slot s, we have a binary sequence loss L_{seq} and a classification loss L_{cls} to optimize. Such pre-training objectives help the encoders understand how a slot is roughly operated in the current dialog context and connected with all possible tokens regarding its values in the schema. The dialog context encoder is used for the parameter initialization of the base part of a DST model. The pre-trained corpus is constructed from MultiWOZ2.1 dialogs (Eric et al., 2020) and the off-the-shelf synthesized dialogs (Campagna et al., 2020), which contains 337,346 dialog data in total.

We also leverage the language modelling (LM) loss as an auxiliary loss L_{aux} to learn contextual representations of natural language. To be specific, we use the MLM loss (Devlin et al., 2019) as L_{aux} for transformer-based DST modes and the summation of both forward and backward LM losses (Peters et al., 2018) for RNN-based DST models. We only use the original MultiWOZ2.1 dialogs to optimize L_{aux}, considering that synthesized data is not suitable for natural language modelling. However, both the original and synthesized data are used to optimize L_{seq} and L_{cls}.

3.3 The Review Module

The process of review often help a learner consolidate difficult concepts newly learned. We design a *review* module to consider mispredicted examples as the concepts that the DST model has not grasped during CL, and utilize a schema-based data augmenter to produce similar cases from the examples. Specifically, the DST model is monitored at each stage of the CL training process. If a model is not converged at the end of an epoch in a training stage, we choose the top 10% incorrectly predicted examples according to their training losses as the resource to enlarge the cumulative dataset. The schema-based data augmenter uses three practical techniques to generate data as follows:

Slot Substitution. A mentioned slot name in (R_t, U_t) is changed into another slot name when its value is *dontcare*. Specifically, we first collect a word set for each slot name, e.g. {*'arrive', 'arriving', 'arrived'*} for the slot *'taxi-arriveby'*. Then, for a dialog data d_t where Y_t contains a slot s with the value *dontcare*, we substitute the word of s in the utterance with some word of another slot s' that is of the same domain and not mentioned in Y_t.

Value Replacement. A slot's value is replaced with another proper one when the value is explicitly contained in U_t. Specifically, we leverage the predefined schema in the dialog dataset to produce a value set for each slot and use the label map in (Heck et al., 2020) to figure out the position of value span within the utterance. The target value is then replaced with another one of the same slot.

Dialog Recombination. To recombine the dialog data d_t, we randomly search another dialog data in D that possesses the same mentioned slots (whose values are not *none*) in Y_t. We then cut and stitch their history X_{t-1} and current utterances (R_t, U_t), and exchange their Y_t to produce two new dialog data.

4 Experiments

Two popular datasets, WOZ2.0 (Wen et al., 2017) and MultiWOZ2.1 (Eric et al., 2020), are used to verify our approach. WOZ2.0 is a single-domain dataset with 1,200 dialogs and 3 slots. MultiWOZ2.1 is a multi-domain dialog dataset with 10,438 dialogs, where there are 30 slots spanning 7 domains. The data splits (train/valid/test) of WOZ2.0 and MultiWOZ2.1 are 600/200/400 and 8438/1000/1000, respectively. We use the joint goal accuracy (JGA), the ratio of dialog data whose Z_t is correct, as the evaluation metric. We apply SaCLog onto TripPy (Heck et al., 2020), a transformer-based DST model, and TRADE (Wu et al., 2019), an RNN-based DST model, to show its effect. The slot encoder and the dialog context encoder are weight-shared. We use a BERT_{base} as the encoder and the `[CLS]` embedding as the slot embedding in TripPy, and use a bi-GRU as the encoder and the concatenation of the first and last hidden state as the slot embedding for TRADE. We also follow TripPy to add 2 new slot operations (i.e. *refer/dontcare*) into the classification types of L_{cls}.

Implementation Details. For the preview module, we use Adam (Kingma and Ba, 2015) with a fixed learning rate 3e-5 for 3 epochs in the pre-training. The batch size for L_{aux} is 14 and the batch size for L_{seq} and L_{cls} is 64. For the curriculum module, we perform a warm-up strategy for Adam optimizer with a maximum learning rate 1e-4. Before CL, we train models on full dataset for 2 epochs. After all subsets are accumulated, we then train for 10 extra epochs with a minimum learning rate 1e-6. We set the bucket number $N = 10$ and the crossed fold $K = 5$. The batch size is 36 and the maximum length is 256. To simplify the review process, we conduct data augmentation after the CL training is finished.

Models	MultiWOZ2.1	WOZ2.0
GLAD (Zhong et al., 2018)	35.57%**	88.1±0.4%
SUMBT (Lee et al., 2019)	46.65%**	91.0±1.0%
DST-picklist (Zhang et al., 2019)	53.30%	–
Trippy (Heck et al., 2020)	55.29±0.28%	92.7±0.2%
SimpleTOD(Hosseini-Asl et al., 2020)	55.72%	–
CHAN (Shan et al., 2020)	58.55%	–
TripPy + ConvBERT	58.70%	93.1±0.3%*
TripPy + CoCoAug	60.53%	–
TripPy + SaCLog	**60.61±0.31%**	**94.2±0.2%**

Table 1: DST Results on MultiWOZ2.1 and WOZ2.0 in JGA. * Our implemetation. ** MultiWOZ2.0 results.

Models	JGA
TripPy (ours)	58.17±0.25%
+ CL (rule-based)	58.38±0.17%
+ CL (model-based)	58.71±0.21%
+ CL (hybrid)	**58.85±0.23%**
+ SaCLog (w/o. review)	60.19±0.26%
+ SaCLog (w/o. preview)	60.23±0.34%
+ SaCLog	**60.61±0.31%**

Table 2: Ablation results on MultiWOZ2.1. +CL means adding the curriculum module only.

4.1 Performance of TripPy+SaCLog

Tables 1 shows the results of our approach comparing to various baselines. Based upon TripPy, we obtain state-of-the-art performance on both datasets with SaCLog. The two closest baselines[2], ConvBERT (Mehri et al., 2020) and CoCoAug (Li et al., 2021), are also built upon TripPy, where ConvBERT enhances its performance by using external large-scale conversational corpora to pre-train a BERT_{base} and CoCoAug leverages a delicate counter-factual augmentation skill to produce much larger training data. Our method, however, benefits from the CL framework and improves TripPy by utilizing the preview and review modules.

Ablation Study To examine how SaCLog facilitates DST training, we conduct detailed ablation experiments on MultiWOZ2.1, as shown in Table 2. In our re-implementation, we improve the basic TripPy by around 3% JGA via training for longer epochs (30 vs.10) and pre-training a BERT_{base} on MultiWOZ2.1 corpus only with the MLM loss. First, we investigate the influence of

[2]We implemented SaCLog upon these two methods, but no significant gains are observed. We conjecture that this is due to SaCLog has already largely exploited TripPy's potential so that the additional improvement of the two methods is limited.

Model	MultiWOZ2.1	WOZ2.0
TRADE	45.6%*	88.3±0.6%
+ SaCLog	**49.3±0.5%**	**91.1±0.4%**

Table 3: Results of TRADE+SaCLog on MultiWOZ2.1 and WOZ2.0. * Reported in (Eric et al., 2020).

difficulty scores by adding the curriculum module and utilizing the same pre-trained BERT_{base}. As we can see, using the hybrid difficulty score achieves better JGA (58.85%) than using either single score, indicating that both model prediction and human knowledge are necessary. When incorporating the other two modules in the CL framework, the performance is greatly boosted further. The combination of both modules increases the JGA by 1.76%, suggesting that the schema-aware pre-training and dialog augmentation are crucial for improving DST performance in the CL training.

4.2 Performance of TRADE+SaCLog

We also apply SaCLog to the classical RNN-based generative DST model, TRADE. As Table 3 shows, SaCLog improves TRADE by around 3∼4% JGA on both datasets, demonstrating the effectiveness of SaCLog on different types of base DST models.

5 Related Work

Curriculum Learning (CL) has attracted increasing research interests in various NLP tasks, such as machine translation (Liu et al., 2020; Zhou et al., 2020), general language understanding (Xu et al., 2020), reading comprehension (Tay et al., 2019) and open-domain chatbots (Bao et al., 2020; Cai et al., 2020; Su et al., 2020). Yet, the research on using CL in task-oriented dialog systems is limited. There has been some work (Saito, 2018; Zhao et al., 2021) on using CL in dialog policy learning, but applying CL to DST has not been investigated.

Learning a structural inductive bias during pre-training has been shown beneficial in downstream tasks that require parsing semantics, such as text-to-SQL (Yu et al., 2021) and table cell recognition (Wang et al., 2020). There are also many works (Hou et al., 2018; Yoo et al., 2020; Yin et al., 2020) on dialog augmentation. We aim to integrate these methods to build a general CL framework for DST.

6 Conclusion

In this paper, we propose a model-agnostic framework named as schema-aware curriculum learning for DST, which exploits both the curriculum structure and the schema structure in task-oriented dialogs and shows to substantially improve DST performances. In the future, we plan to investigate CL approaches on other dialog modeling tasks.

Abstract

Under the pandemic of COVID-19, people experiencing COVID19-related symptoms have a pressing need to consult doctors. Because of the shortage of medical professionals, many people cannot receive online consultations timely. To address this problem, we aim to develop a medical dialog system that can provide COVID19-related consultations. We collected two dialog datasets – CovidDialog – (in English and Chinese respectively) containing conversations between doctors and patients about COVID-19. While the largest of their kind, these two datasets are still relatively small compared with general-domain dialog datasets. Training complex dialog generation models on small datasets bears high risk of overfitting. To alleviate overfitting, we develop a multi-task learning approach, which regularizes the data-deficient dialog generation task with a masked token prediction task. Experiments on the CovidDialog datasets demonstrate the effectiveness of our approach. We perform both human evaluation and automatic evaluation of dialogs generated by our method. Results show that the generated responses are promising in being doctor-like, relevant to conversation history, clinically informative and correct. The code and the data are available at https://github.com/UCSD-AI4H/COVID-Dialogue.

1 Introduction

During the COVID-19 pandemic, people who are experiencing symptoms similar to those of COVID-19 or were exposed to risk factors have a pressing need to consult doctors. However, medical professionals are highly occupied, who do not have enough bandwidth to provide COVID19-related consultations.

To address this issue, we aim to develop a COVID19-targeted dialog system. We build two medical dialog datasets that contain conversations between doctors and patients, about COVID-19 and other pneumonia: (1) an English dataset containing 603 consultations, 1232 utterances, and 90664 tokens (English words); (2) a Chinese dataset containing 1088 consultations, 9494 utterances, and 406550 tokens (Chinese characters).

While the largest of their kind, these two datasets are still relatively small compared with general-domain dialog datasets. Training complex dialog generation models on small datasets bears high risk of overfitting. To alleviate overfitting in COVID-19 dialog generation, we develop a multi-task learning approach where a masked-token prediction (MTP) (Devlin et al., 2018) task is used to regularize the training of dialog generation models. Our method performs the MTP task and the dialog generation task simultaneously. The MTP loss serves as a regularization term and is optimized jointly with the dialog generation loss. Due to the presence of the MTP task, the dialog generation model is less likely to be biased to the dialog generation task defined on the small-sized training data. We perform experiments on our collected two COVID-19 dialog datasets, where the results demonstrate the effectiveness of our approach. We perform human evaluation and automatic evaluation of dialogs generated by our approach. The results show that the generated responses demonstrate high potential to be doctor-like, relevant to patient history, clinically informative and correct.

The major contributions of this paper are:

- We collect two medical dialog datasets about COVID-19: one in English, the other in Chinese.
- We develop a multi-task learning approach, which uses a masked-token prediction task to regularize the dialog generation task to alleviate overfitting.
- We evaluate our method on the collected COVID-19 dialog datasets and the results demonstrate the

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 886–896

effectiveness of our method.

2 Related Works

Several works have studied data-driven medical dialog generation. Wei et al. (2018) proposed a task-oriented dialog system to make medical diagnosis automatically based on reinforcement learning. The system converses with patients to collect additional symptoms beyond their self-reports. Xu et al. (2019) proposed a knowledge-routed relational dialog system that incorporates medical knowledge graph into topic transition in dialog management. Xia et al. proposed an automatic diagnosis dialog system based on reinforcement learning. In these works, the neural models are trained from scratch on small-sized medical dialog datasets, which are prone to overfitting.

3 Datasets

We collected two dialog datasets – CovidDialog-English and CovidDialog-Chinese – which contain medical conversations between patients and doctors about COVID-19 and other related pneumonia. The statistics of these two datasets are summarized in Table 1.

The English Dataset The CovidDialog-English dataset contains 603 English consultations about COVID-19 and other related pneumonia, having 1,232 utterances. The number of tokens (English words) is 90,664. The average, maximum, and minimum number of utterances in a conversation is 2.0, 17, and 2 respectively. The average, maximum, and minimum number of tokens in an utterance is 49.8, 339, and 2 respectively. The conversations are from 582 patients and 117 doctors. Each consultation starts with a short description of the medical conditions of a patient, followed by the conversation between the patient and a doctor.

The Chinese Dataset The CovidDialog-Chinese dataset contains 1,088 Chinese consultations about COVID-19 and other related pneumonia, having 9,494 utterances. In this work, we develop models directly on Chinese characters without performing word segmentation. Each Chinese character in the text is treated as a token. The total number of tokens in the dataset is 406,550. The average, maximum, and minimum number of utterances in a conversation is 8.7, 116, and 2 respectively. The average, maximum, and minimum number of tokens in an utterance is 42.8, 2001, and 1 respectively. The conversations are from 935 patients and 352 doctors. Each consultation consists of three parts: (1) description of patient's medical condition and history; (2) conversation between patient and doctor; (3) (optional) diagnosis and treatment suggestions given by the doctor. In the description of the patient's medical condition and history, the following fields are included: present disease, detailed description of present disease, what help is needed from the doctor, how long the disease has been, medications, allergies, and past diseases. This description is used as the first utterance from the patient.

	English	**Chinese**
#dialogs	603	1,088
#tokens	90,664	406,550
Average #utterances per dialog	2.0	8.7
Max #utterances per dialog	17	116
Min #utterances per dialog	2	2
Average #tokens per utterance	49.8	42.8
Max #tokens per utterance	339	2,001
Min #tokens per utterance	2	1

Table 1: Statistics of the English and Chinese dialog datasets about COVID-19.

For both datasets, the dialogs are crawled from openly accessible medical websites whose owners make these dialogs visible to the public. The patients' personal information is de-identified by owners of these websites. We further checked the crawled dialogs to ensure they do not contain private information of patients. Besides, we also manually removed borderline sensitive information, such as specific dates and destinations in patients' travel histories. Experts in privacy and security domains helped to check the final version of shared data and ensured there is no breach of patient privacy or confidentiality.

4 Method

Given a dialog containing a sequence of alternating utterances between patient and doctor, we process it into a set of pairs $\{(s_i, t_i)\}$ where the target t_i is a response from the doctor and the source s_i is the conversation history – the concatenation of all utterances (from both patient and doctor) before t_i. A dialog generation model takes s as input and generates t. The model consists of an encoder which encodes s and a decoder which takes the encoding of s as input and generates t. The size of the CovidDialog datasets is small. Training neural dialog models on these small datasets has high risk of overfitting.

To solve this problem, we develop a multi-task

Split	# dialogs	# utterances	# pairs
Train	482	981	490
Validation	60	126	63
Test	61	122	61

Table 2: English dataset split statistics

	C	R	I	D
Transformer	2.24	2.57	2.53	2.29
GPT-2	2.58	2.91	2.65	3.09
BART	2.61	3.01	2.74	3.42
BART+TAPT	2.65	3.04	2.68	3.38
Ours	**2.83**	**3.16**	**2.88**	**3.47**
Groundtruth	3.26	3.63	3.51	3.55

Table 3: Human evaluation on the CovidDialog-English test set. C, R, I, and D represent correctness, relevance, informativeness, and doctor-likeness respectively. For GPT-2, the "large" version is used.

learning approach, which uses a masked-token prediction (Devlin et al., 2018) task to regularize the dialog generation task. Given the conversation histories in the training set, we encode them using an encoder. Then on top of the encodings, two tasks are defined. One is the dialog generation task, which takes the encoding of a conversation history as input and predicts its corresponding response. The prediction is conducted using a dialog decoder. The other task is masked-token prediction (MTP). In MTP, some percentage of the input tokens are masked at random. The text with masked tokens is fed into the text encoder which learns a latent representation for each token including the masked ones. The task is to predict these masked tokens by feeding the final hidden vectors (produced by the encoder) of the masked tokens into an output softmax operation over the vocabulary. The loss of the MTP task serves as a data-dependent regularizer of the encoder to prevent the encoder from overfitting to the data-deficient dialog generation task. Formally, the method solves the following optimization problem:

$$\mathcal{L}^{(g)}(H, R; W^{(e)}, W^{(g)}) + \lambda \mathcal{L}^{(p)}(H; W^{(e)}, W^{(p)})$$

where H represents the conversation histories and R represents their corresponding responses. $W^{(e)}$, $W^{(g)}$, and $W^{(p)}$ denote the encoder, decoder in the dialog generation task, and prediction head in the MTP task respectively. $\mathcal{L}^{(g)}$ denotes the generation loss and $\mathcal{L}^{(p)}$ denotes the MTP loss. λ is a tradeoff parameter.

5 Experiments

We compare with the following baselines: Transformer (Vaswani et al., 2017), GPT-2 (Radford et al., b), unregularized BART (Liu et al., 2019), unregularized BERT-GPT (Wu et al., 2019), and task adaptive pretraining (TAPT) (Gururangan et al., 2020).

5.1 Experiments on the English Dataset

5.1.1 Experimental Settings

For the English dataset, we split it into a training, a validation, and a test set based on dialogs, with a ratio of 8:1:1. Table 2 shows the statistics of the data split. The hyperparameters were tuned on the validation dataset. Our method and TAPT are both applied to the BART encoder, where the probability for masking tokens is 0.15. If a token t is chosen to be masked, 80% of the time, we replace t with a special token `[MASK]`; 10% of the time, we replace t with a random word; and for the rest 10% of the time, we keep t unchanged. For the regularization parameter λ, we set it to 0.1.

We perform human evaluation of the generated responses. Five medical students are asked to give ratings (from 1 to 5, higher is better) to generated responses in four aspects: 1) Correctness: whether the response is clinically correct; 2) Relevance: how relevant the response is to the conversation history; 3) Informativeness: how much medical information and suggestions are given in the response; and 4) Doctor-like: how the response sounds like a real doctor. The responses are de-identified: annotators do not know which method a response is generated by. The groundtruth response from the doctor is also given ratings (in an anonymous way). Human evaluation was conducted on the test examples in the CovidDialog-English dataset. The ratings from different annotators are averaged.

We also performed automatic evaluation, using metrics including perplexity, NIST-n (Doddington, 2002) (where $n = 4$), BLEU-n (Papineni et al., 2002) (where $n = 2$ and 4), METEOR (Lavie and Agarwal, 2007), Entropy-n (Zhang et al., 2018) (where $n = 4$), and Dist-n (Li et al., 2015) (where $n = 1$ and 2).

5.1.2 Results on the English Dataset

Table 3 shows the human evaluation results. From this table, we make the following observations. **First**, our method outperforms the unregularized BART on all metrics. This demonstrates the effectiveness of our method in alleviating overfitting

	Transformer	GPT-2			BART	BART+TAPT	Ours
		Small	Medium	Large			
Perplexity	263.1	28.3	17.5	18.9	15.3	15.0	**14.9**

BLEU-2	7.3%	9.6%	9.4%	**11.5%**	8.9%	7.7%	8.3%
BLEU-4	5.2%	6.1%	6.0%	**7.6%**	6.0%	3.4%	5.0%
METEOR	5.6%	9.0%	9.5%	**11.0%**	10.3%	9.2%	9.8%
Entropy-4	5.0	6.0	**6.6**	**6.6**	6.5	6.3	**6.6**
Dist-1	3.7%	9.5%	16.6%	13.9%	**16.8%**	11.5%	15.7%
Dist-2	6.4%	22.9%	**36.7%**	31.0%	35.7%	25.3%	33.1%
Avg. Len	40.0	51.3	50.1	54.4	45.4	59.8	50.8

Table 4: Performance on the CovidDialog-English test set.

Patient: i have all the symptoms except fever, i went to medicross and dr said i can get tested if i want to i'm not sure if i should. she gave me antibiotics klacid xl 500mg, she said i can take it if i feel worse i'm worried it will make immune system bad?
Groundtruth response: in brief: antibiotic i don't recommend antibiotics for a simple viral upper respiratory tract infection unless examination revealed signs of acute bronchitis or sinusitis. they are not effective for viral infections like covid 19 with no bacterial lung involvement either. if you've been exposed to someone with covid 19 or or if you or someone you were exposed to travelled to a region where it was endemic, get tested would you like to video or text chat with me?
Transformer: hello and welcome to 'ask a doctor' service.i have reviewed your query and here is my advice. i have reviewed your query. let me know if i can assist you further.
DialoGPT-large: in brief: do you have access to a telephonic consult, or do you need to go in person? would you like to video or text chat with me? i can understand your concern. i have reviewed your query and here is my advice. yes, telephonically would be best. would you be happy to chat with you? i have answered your query. let me know if i can assist you further. regards, dr jnikolla, pulmonologist
BART: yes, you should get tested for covid-19. get tested if you have fever, cough or shortness of breath. if you are a smoker or have been in contact with someone with covid, get tested. would you like to video or text chat with me?
BART+TAPT: if you have been in contact with someone who has been diagnosed with covid-19 then you should definitely get tested. it will make your immune system stronger. hope i have answered your query. let me know if i can assist you further. take care regards, dr. jnikolla
Ours: you do not need to be tested for covid-19 at this time. if you develop fever, cough, shortness of breath and/or difficulty breathing, then you need to consult your pcp and get tested.

Table 5: Generated responses on a test example in the CovidDialog-English dataset.

and improving generalization performance. Our method encourages the encoder to solve an additional MTP task, which reduces the risk of overfitting to the data-deficient response generation task on the small-sized training dialogs. **Second**, our method performs better than BART+TAPT. Our method and TAPT both leverage conversation histories for masked-token prediction. The difference is: TAPT uses these histories to pretrain the encoder while our method uses these histories to regularize the encoder during finetuning. In our method, the encoder is learned to perform the response generation task and MTP task simultaneously. Thus the encoder is not completely biased to the generation task. In TAPT, the encoder is first learned by performing the MTP task, then finetuned by performing the generation task. There is a risk that after finetuning, the encoder is largely biased to the generation task on the small-sized training data, which leads to overfitting. **Third**, our method achieves a doctor-like score that is close to the groundtruth. This indicates that the responses generated by our method have high language quality. The relevance rating of our method is higher than 3, which indicates a good level of relevance between the generated responses and conversation histories. The informativeness rating of our method is better than baselines, but still has a large gap with that of the groundtruth. Additional efforts are needed to improve informativeness, such as incorporating medical knowledge.

Table 4 summarizes the automatic evaluation results achieved by different methods. From this table, we make the following observations. **First**, our method achieves lower (better) perplexity (which is a relatively more reliable metric among various automatic metrics) than the baselines, which further demonstrates the effectiveness of our approach. **Second**, on machine translation metrics including NIST-4, BLEU-2, BLEU-4, and METEOR, the GPT2-large model achieves the highest scores. However, as noted in (Liu et al., 2016), machine translation metrics are not very reliable for evaluating dialog systems. **Third**, on diversity metrics including Entropy-4, Dist-1, and Dist-2, the GPT2-Medium model performs better than other methods. The average length of the generated responses by different methods is close to that of the groundtruth, which is around 50.

Table 5 shows an example of generating a doctor's response given the utterance of a patient. As can be seen, the response generated by our method is more relevant, informative, and human-like, compared with those generated by other baselines. It

Table 8: Human evaluation on CovidDialog-Chinese test set. C, R, I, and D represent correctness, relevance, informativeness, and doctor-likeness respectively. Our method and TAPT are based on BERT-GPT. In GPT-2, no maximum mutual information (MMI) is used.

gives correct and informative medical advice such as "if you develop fever, cough, shortness of breath and/or difficulty breathing, then you need to consult your pcp and get tested" and has correct grammar and semantics. In contrast, BART gives clinically incorrect responses such as if someone is a smoker, he or she should be tested for COVID-19. So does BART+TAPT, which incorrectly suggests that getting tested will make the immune system stronger. The responses from GPT2-large and Transformer do not contain any useful medical advice.

5.2 Experiments on the Chinese Dataset

Based on dialogs, we split the Chinese dataset into a training set, validation set, and test set, with a ratio of 8:1:1. Table 7 shows the statistics of the data split. The regularization parameter λ was set to 0.8. Human evaluation was conducted by 5 medical students, on 100 randomly-sampled examples from the test set of CovidDialog-Chinese. The ratings from different annotators are averaged.

5.2.1 Results on the Chinese Dataset

Table 8 shows the human evaluation results. Our method and TAPT are based on BERT-GPT. As can be seen, our approach outperforms unregularized BERT-GPT. This further demonstrates the effectiveness of our approach in alleviating overfitting and improving generalization performance. In addition, our method outperforms TAPT. This further demonstrates that it is more beneficial to perform MTP and dialog generation jointly than separately.

Table 6 summarizes the automatic evaluation results. Our method achieves the lowest (best) perplexity among all methods. Our method outperforms unregularized BERT-GPT and BERT-GPT-TAPT on machine translation metrics as well. GPT2-MMI achieves the highest scores on machine translation metrics. BERT-GPT-TAPT performs better than other methods on diversity metrics.

6 Conclusions

In this paper, we make the first attempt to develop dialog generation models about COVID-19. We first collected two datasets – CovidDialogs – which contain medical conversations between patients and doctors about COVID-19. To alleviate the risk of overfitting, we develop a multi-task learning approach, which uses a masked-token prediction task to regularize the dialog generation model. Human evaluation and automatic evaluation results demonstrate the effectiveness of our proposed method in alleviating overfitting and generating clinically meaningful and linguistically high-quality dialogs about COVID-19.

Broader Impact

Dialog systems developed using the collected data in this work should be used very cautiously, under the guidance and supervision of physicians and with approval from the Food and Drug Administration. These dialog systems have the potential to provide timely and accessible COVID-19 consultations to the general public, especially to those who are underserved medically. However, clinical consultation is mission-critical. If the dialog systems make clinical errors, they may cause negative health issues to users. Therefore, these dialog systems should be used as assistants to physicians, rather than operating independently without human supervision. The collected dialogs are from public medical forums, which may be largely different from the patient-doctor dialogue in clinics and hospitals. Such a bias should be paid attention to when using this dataset.

Appendix

A Related Works

A.1 Medical Dialog Generation

Many works have been devoted to developing medical dialog systems. Please refer to (Laranjo et al., 2018) for a comprehensive review. Some methods (Lucas et al., 2017; Philip et al., 2017; Tanaka et al., 2017) predefine a sequence of steps or states which are used to guide the conversation. Other methods (Rhee et al., 2014; Ireland et al., 2016; Fitzpatrick et al., 2017) use predetermined templates to extract information from the conversation history and use rules to generate responses from the filled slots in the templates. These methods rely heavily on knowledge engineering and are difficult to be quickly adapted to a new and time-sensitive task such as COVID-19 dialog generation.

A.2 Self-supervised Learning for NLP

Self-supervised learning (SSL) aims to learn meaningful representations of input data without using human annotations. It creates auxiliary tasks solely using the input data and forces deep networks to learn highly-effective latent features by solving these auxiliary tasks. In NLP, various auxiliary tasks have been proposed for SSL, such as next token prediction in GPT (Radford et al., a), masked token prediction in BERT (Devlin et al., 2018), text denoising in BART (Lewis et al., 2019), and so on. These models have achieved substantial success in learning language representations. The GPT model (Radford et al., a) is a language model (LM) based on Transformer (Vaswani et al., 2017). Unlike Transformer which defines a conditional probability on an output sequence given an input sequence, GPT defines a marginal probability on a single sequence. In GPT, the conditional probability of the next token given the historical sequence is defined using the Transformer decoder. The weight parameters are learned by maximizing the likelihood on the sequence of tokens. BERT (Devlin et al., 2018) aims to learn a Transformer encoder for representing texts. BERT's model architecture is a multi-layer bidirectional Transformer encoder. In BERT, the Transformer uses bidirectional self-attention. To train the encoder, BERT masks some percentage of the input tokens at random, and then predicts those masked tokens by feeding the final hidden vectors (produced by the encoder) corresponding to the masked tokens into an output softmax over vocabulary. BERT-GPT (Wu et al., 2019) is a model used for sequence-to-sequence modeling where a pretrained BERT is used to encode the input text and GPT is used to generate the output text. In BERT-GPT, the pretraining of the BERT encoder and the GPT decoder is conducted separately, which may lead to inferior performance. Auto-Regressive Transformers (BART) (Lewis et al., 2019) has a similar architecture as BERT-GPT, but trains the BERT encoder and GPT decoder jointly. To pretrain the BART weights, the input text is corrupted randomly, such as token masking, token deletion, text infilling, etc., then the network is learned to reconstruct the original text. ALBERT (Lan et al., 2019) uses parameter-reduction methods to reduce the memory consumption and increase the training speed of BERT. It also introduces a self-supervised loss which models inter-sentence coherence.

B Datasets

Table 9 shows an example of the English dataset.

C Experiments

C.1 Baselines

We compare the following baselines.

- **Transformer**. A conversation history is fed into the Transformer (Vaswani et al., 2017) encoder and the encoding is fed into the Transformer decoder to generate the corresponding response. The weights of the encoder and decoder are initialized randomly.
- **GPT-2**. Given a dialog history s and a ground-truth response $t = x_1, \cdots, x_n$, a GPT-2 model (Radford et al., a) is trained to maximize the following probability: $p(t|s) = p(x_1|s) \prod_{i=2}^{n} p(x_i|s, x_1, \cdots, x_{i-1})$, where conditional probabilities are defined by the Transformer decoder. For experiments on CovidDialog-English, the GPT-2 model is pretrained on English Reddit dialogs (Zhang et al., 2019). For experiments on CovidDialog-Chinese, the GPT-2 model is pretrained on Chinese chatbot corpus[1].
- **Unregularized BART** (Liu et al., 2019). This approach is the same as Transformer, except that the encoder and decoder are initialized using the pretrained BART (Lewis et al., 2019). The encoder and decoder are finetuned on CovidDialog-

[1] https://github.com/codemayq/chinese_chatbot_corpus

Description of patient's medical condition: I have a little fever with no history of foreign travel or contact. What is the chance of Covid-19?
Dialog **Patient**: Hello doctor, I am suffering from coughing, throat infection from last week. At that time fever did not persist and also did not feel any chest pain. Two days later, I consulted with a doctor. He prescribed Cavidur 625, Montek LC, Ambrolite syrup and Betaline gargle solution. Since then throat infection improved and frequent cough also coming out. Coughing also improved remarkably though not completely. From yesterday onwards fever is occuring (maximum 100-degree Celcius). I have not come in touch with any foreign returned person nor went outside. In our state, there is no incidence of Covid-19. Please suggest what to do? **Doctor**: Hello, I can understand your concern. In my opinion, you should get done a chest x-ray and CBC (complete blood count). If both these are normal then no need to worry much. I hope this helps. **Patient**: Thank you doctor. After doing all these I can upload all for further query. **Doctor**: Hi, yes, upload in this query only. I will see and revert to you.

Table 9: An exemplary consultation in the CovidDialog-English dataset. It consists of a brief description of the patient's medical conditions and the conversation between the patient and a doctor.

	Transformer	BERT-GPT	Ours	TAPT	GPT-2
GPU	TITAN Xp	GeForce RTX 2080	GeForce GTX 1080Ti	GeForce GTX 1080Ti	TITAN Xp
Num. of GPUs	1	1	1	1	1
Runtime	105	230	488	240	27

Table 10: Computing infrastructure and runtime (seconds per epoch) on CovidDialog-Chinese

English. During finetuning, no self-supervised regularization is used.

- **Unregularized BERT-GPT.** This approach is the same as Transformer, except that the encoder is initialized using pretrained BERT and the decoder is initialized using pretrained GPT-2. BERT and GPT-2 are both pretrained on large-scale Chinese corpus (Cui et al., 2019). The encoder and decoder are finetuned on CovidDialog-Chinese. During finetuning, no self-supervised regularization is used.
- **Task adaptive pretraining (TAPT)** (Gururangan et al., 2020). In this approach, given the Transformer encoder pretrained using BART/BERT on large-scale external corpora, it is further pretrained by predicting masked tokens on the input conversation histories in the CovidDialog datasets (without using output responses). Then the encoder is finetuned by predicting the responses from conversation histories. Similar to our method, TAPT also performs masked-token prediction (MTP) on conversation histories. The difference is: TAPT performs the MTP task and the generation task sequentially while our method performs these two tasks jointly.

C.2 Experimental Settings

C.2.1 Experimental Settings on the English Dataset

For GPT-2, we used three variants (Zhang et al., 2019) with different sizes: small, medium, and large, with 117M, 345M, and 762M weight parameters respectively. Maximum mutual information was not used. We used the Adam (Kingma and Ba, 2014) optimizer for the Transformer model and the AdamW (Loshchilov and Hutter, 2017) optimizer for other models. For all methods except TAPT, we used the optimizer with linear learning rate scheduling, setting the initial learning rate as 4e-5 and the batch size as 4. We perform TAPT for 100 epochs, setting the initial learning rate as 1e-4 and the batch size as 256. The objective for dialog generation is the cross entropy loss with label smoothing where the factor was set to 0.1. For pretrained models, we finetune them on the CovidDialog-English dataset for 5 epochs, while for the un-pretrained Transformer, we train it for 50 epochs. We set a checkpoint at the end of every epoch and finally take the one with the lowest perplexity on validation set as the final model. In response generation, for all models, we use beam search with beam width of 10 during decoding.

Among the automatic evaluation metrics, BLEU, METEOR, and NIST are common metrics for evaluating machine translation. They compare the similarity between generated responses and the ground-truth by matching n-grams. NIST is a variant of BLEU, which weights n-gram matches using information gain to penalize uninformative n-grams. Perplexity is used to measure the quality and smoothness of generated responses. Entropy and Dist are used to measure lexical diversity of generated responses. For perplexity, the lower, the

	Transformer	BERT-GPT	Ours	TAPT	GPT-2

TAPT	Tesla P100-PCIE-16GB $\times$ 1	150

Table 13: Computing infrastructure and runtime (seconds per epoch) on the CovidDialog-English dataset

better. For other metrics, the higher, the better. As noted in (Liu et al., 2016), while automatic evaluation is useful, they are not completely reliable. Among these metrics, perplexity is generally considered to be more reliable than others.

C.2.2 Experimental Settings on the Chinese Dataset

The hyperparameters were tuned on the validation set. We stop the training procedure when the validation loss stops to decrease. Our method and TAPT are both applied to the BERT encoder in BERT-GPT, where the probability of masking tokens is 0.15. The encoder and decoder structures in BERT-GPT are similar to those in BERT, which is a Transformer with 12 layers and the size of the hidden states is 768. Network weights are optimized with stochastic gradient descent with a learning rate of 1e-4. In the finetuning of BERT-GPT, the max length of the source sequence and target sequence was set to 400. During decoding for all methods, beam search with $k = 50$ was used.

For GPT-2, we used the DialoGPT-small (Zhang et al., 2019) architecture where the number of layers in the Transformer was set to 10. The context size was set to 300. The embedding size was set to 768. The number of heads in multi-head self-attention was set to 12. The epsilon parameter in layer normalization was set to 1e-5. Network weights were optimized with Adam, with an initial learning rate of 1.5e-4 and a batch size of 8. The Noam learning rate scheduler with 2000 warm-up steps was used. For Transformer, we used the HuggingFace implementation[2] and followed their default hyperparameter settings. We evaluated the models using perplexity, NIST-4, BLEU-2, 4, METEOR, Entropy-4, and Dist-1, 2.

C.2.3 Additional Details about Human Evaluation

In human evaluation on CovidDialog-Chinese, we randomly select 100 examples. Each example includes a conversation history, groundtruth response, and responses generated by different methods. When presented to annotators, the groundtruth and responses generated by different methods are de-identified (given a response, annotators do not know which method generated this response) and randomly shuffled for different examples. The ratings from different annotators are averaged. In human evaluation on CovidDialog-English, we perform evaluation on all test examples.

C.3 Additional Analysis on Experimental Results

Additional analysis of results in Table 3 1) Pretrained models including GPT-2 and BART perform better than Transformer. This further demonstrates the effectiveness of pretraining. 2) BART performs better than GPT-2, though GPT-2 achieves better scores on machine translation metrics. This is in accordance with the results in (Liu et al., 2016) that machine translation metrics are not good for evaluating dialogue generation.

Additional analysis of results in Table 4 1) Pretrained models including GPT-2 and BART in general perform better than un-pretrained Transformer. This demonstrates the effectiveness of transfer learning, which leverages external large-scale data to learn powerful representations of texts. 2) BART achieves lower perplexity than GPT-2

[2]https://github.com/huggingface/transformers

	Transformer	GPT-2	TAPT	BART	Ours
Num. of epochs	100	5	5	5	5
Validation loss	8.02	3.06	2.88	2.84	2.87
Validation perplexity	260.30	21.50	17.74	17.28	17.56

Table 14: Validation performance on CovidDialog-English

Transformer	36M
GPT-2	768M
BART	406M

Table 15: Number of weight parameters of each model on CovidDialog-English

models. This is probably because BART is pretrained on a much larger and more diverse corpus than GPT-2, which enables BART to better model the language. 3) GPT2-large performs better than BART on machine translation metrics including NIST, BLEU, and METEOR. This is probably because GPT2-large is pretrained on dialogue data and therefore tends to generate n-grams that are more related to dialogues. 4) On diversity-related metrics including Entropy and Dist, BART is on par with GPT-2 models.

Additional analysis of results in Table 8 1) Pretrained BERT-GPT works better than unpretrained Transformer. Though pretrained, GPT-2 is not as good as Transformer. The possible reason is the training corpora of GPT-2 is daily dialogues, which has a large domain shift from medical dialogues. The performance gap between BERT-GPT and Groundtruth is larger than that between BART and Groundtruth, despite the number of Chinese training dialogues is larger than that of English training dialogues. This indicates that it is more challenging to develop COVID-19 dialogue systems on Chinese. One major reason is the Chinese dialogues are more noisy than the English ones, with a lot of incorrect grammar, abbreviations, semantic ambiguities, etc.

Additional analysis of results in Table 6 1) Pretrained models including GPT-2 and BERT-GPT achieve lower perplexity than Transformer. This further demonstrates the effectiveness of transfer learning. 2) GPT2-MMI achieves better scores than other methods on machine translation metrics, which is consistent with the results on the CovidDialog-English dataset. 3) BERT-GPT-TAPT achieves better Dist scores than other methods. We manually checked the generated responses by BERT-GPT-TAPT. Indeed, they are more diverse than others. 4) Maximum mutual information (MMI) does not have a clear efficacy in improving the quality of generated responses.

D Computing infrastructure, runtime, validation performance, number of weight parameters, implementation details

D.1 On Chinese CovidDialog

The computing infrastructure and runtime (seconds per epoch) on CovidDialog-Chinese is shown in Table 10. The validation performance is shown in Table 11. The number of weight parameters of each model on CovidDialog-Chinese is shown in Table 12.

We use PyTorch to implement all models. The version of Torch is 1.4.0 (or above). The python package "Transformers[3]" is 2.1.1 for GPT-2 and 2.8.0 (or above) for Transformer and BERT-GPT. When testing, we calculate NIST-n (Doddington, 2002), BLEU-n (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) using NLTK[4] with version 3.5, and calculate Entropy-n (Zhang et al., 2018) and Dist-n (Li et al., 2015) based on the scripts in DialoGPT[5]. We use Gradient Accumulation in PyTorch to enlarge the mini-batch size to 32. Gradient Accumulation is a mechanism of PyTorch, which splits a large batch into smaller batches. The computation on smaller batches is executed sequentially. We set the number of gradient accumulation as 4 so that the mini-batch size is $8 * 4 = 32$.

D.2 On English CovidDialog

Table 13 shows the computing infrastructure and runtime (seconds per epoch) on the CovidDialog-English dataset. The number of epochs and validation performance of each model on CovidDialog-English are shown in Table 14. The number of weight parameters of each model on CovidDialog-English is shown in Table 15.

Constructing Multi-Modal Dialogue Dataset by Replacing Text with Semantically Relevant Images

Nyoungwoo Lee*, **Suwon Shin***, **Jaegul Choo**, **Ho-Jin Choi**, and **Sung-Hyon Myaeng**

KAIST, Daejeon, South Korea

{*leenw2, ssw0093, jchoo, hojinc, myaeng*}*@kaist.ac.kr*

Abstract

In multi-modal dialogue systems, it is important to allow the use of images as part of a multi-turn conversation. Training such dialogue systems generally requires a large-scale dataset consisting of multi-turn dialogues that involve images, but such datasets rarely exist. In response, this paper proposes a 45k multi-modal dialogue dataset created with minimal human intervention. Our method to create such a dataset consists of (1) preparing and pre-processing text dialogue datasets, (2) creating image-mixed dialogues by using a text-to-image replacement technique, and (3) employing a contextual-similarity-based filtering step to ensure the contextual coherence of the dataset. To evaluate the validity of our dataset, we devise a simple retrieval model for dialogue sentence prediction tasks. Automatic metrics and human evaluation results on such tasks show that our dataset can be effectively used as training data for multi-modal dialogue systems which require an understanding of images and text in a context-aware manner. Our dataset and generation code is available at https://github.com/shh1574/multi-modal-dialogue-dataset.

1 Introduction

Humans often use images in instant messaging services to express their meaning and intent in the dialogue context. For a dialogue system such as a chatbot to respond to human users adequately in this kind of multi-modal situations, it is necessary to understand both images and texts in their context and incorporate them in the dialogue generation process.

Training such a multi-modal dialogue system generally requires a large amount of training data involving images and texts in various contexts. However, numerous existing approaches relying on image captioning (Lin et al., 2014; Young et al., 2014) or visual question answering (Mostafazadeh et al., 2016; Das et al., 2017) techniques had to be trained with the datasets mostly irrelevant to the dialogue context. In other words, images were interpreted independently of the dialogue context, due to the lack of sufficient multi-modal dialogue datasets.

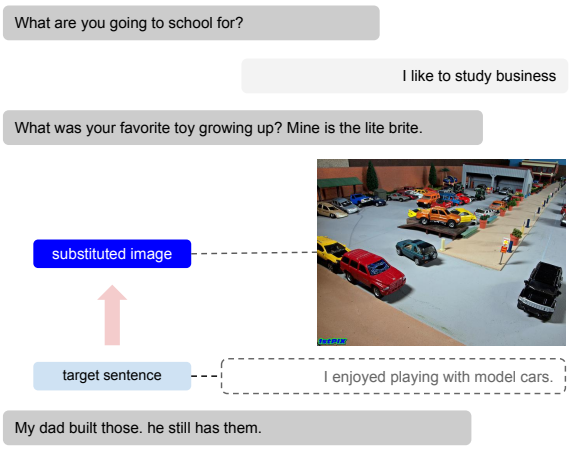

Figure 1: Example of multi-modal dialogue dataset.

Those datasets containing image-grounded conversations (Mostafazadeh et al., 2017; Shuster et al., 2020a) do not even cover the situations related to dialogue context before the image, because all conversations in the dataset always start from the given image. Although the relationship between images and texts can be learned using image-grounded conversations (Lu et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Su et al., 2020; Li et al., 2019b), it cannot still learn the dependency between the dialogue context before and after the image.

In this paper, we propose a 45k multi-modal dialogue dataset in the form of Fig. 1. Each multi-modal dialogue instance consists of a textual response and a dialogue context with multiple text

* Equal contribution.

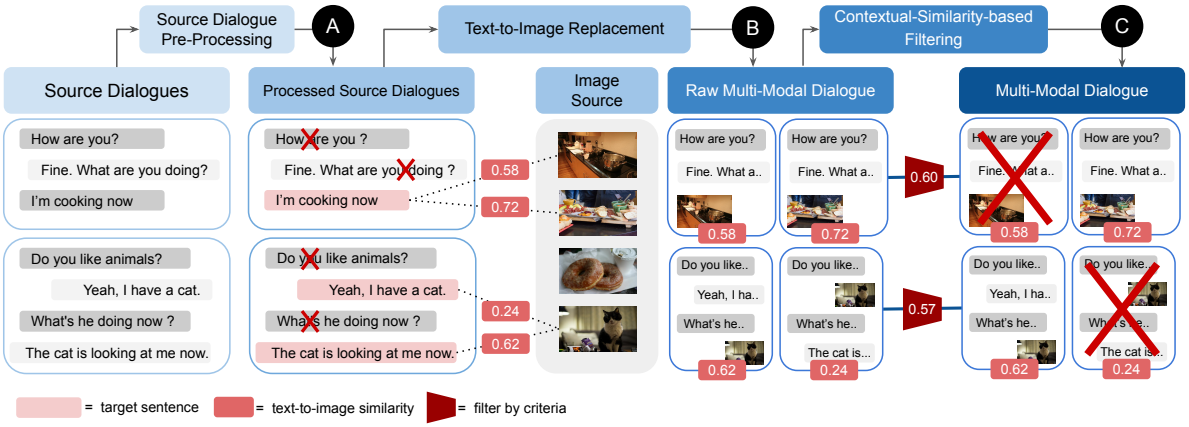

Figure 2: Overall pipeline for multi-modal dialogue dataset creation.

utterances and an image. To create this dataset, we start with existing text-only dialogue datasets as source dialogues, and then replace part of sentences in source dialogues with their semantically relevant images. The detailed steps include (1) source dialogue pre-processing, such as deleting a stop word, to improve the quality of similarity calculations, (2) creating dialogues containing an image by replacing a sentence with a similarity-based text-to-image replacement technique, and (3) pruning low-quality dialogues by employing a contextual-similarity-based filtering method. The overall process ensures that the created dataset consists of natural dialogue examples containing diverse images.

In order to validate our dataset creation process and examine the quality of our multi-modal dialogue dataset, we devise the task of predicting current and next dialogue sentences while considering the dialogue context and images. We also develop simple retrieval models to learn the relationship between images and texts for the tasks. Human evaluation results for predicting dialogue tasks show that the sentences are predicted as intended, i.e., in a context-aware manner, using the images. The results also show that our dataset can serve as practical training resources for multi-modal dialogue tasks that involve both image and dialogue context.

2 Multi-Modal Dialogue Generation

Our multi-modal dialogue dataset is constructed based on three source dialogue datasets and two image captioning datasets: DailyDialog (Li et al., 2017), EmpatheticDialogues (Rashkin et al., 2019), and Persona-Chat (Zhang et al., 2018) for the former and the MS-COCO (Lin et al., 2014) and Flicker 30k (Young et al., 2014) for the latter. The statistics of each dataset are summarized in Appendix A. After obtaining the source datasets, we replace sentences in the source dialogues with proper images by searching the image dataset to create image-mixed dialogues that maintain semantic coherence. To this end, we apply the three-stage method as shown in Fig. 2: (1) source dialogue pre-processing, (2) text-to-image replacement, and (3) contextual-similarity-based filtering.

Source Dialogue Pre-Processing We pre-process source dialogue datasets for the subsequent text-to-image replacement (A in Fig. 2). To select candidate dialogue sentences to be replaced by images, we first exclude the question sentences from the candidate dialogues because it is not realistic to infer back a question out of an image to put in the place of the question. This step filters out 25.08% of the total sentences in the source dialogue datasets. Second, we remove stop words from the source dialogue datasets, because they do not contain meaningful information. All the remaining sentences in dialogue contexts after the pre-processing step are considered as potential target sentences to replace.

Text-to-Image Replacement In this step, we create multi-modal dialogues containing images by replacing target sentences from the candidate dialogue sentences with appropriate images in the image dataset based on text-to-image similarity (B in Fig. 2). We calculate the similarity by the pre-trained Visual Semantic Reasoning Network (VSRN) (Li et al., 2019a), a state-of-the-art image-

text matching model based on text-to-image similarity. We first identify target sentences and then select candidate images for replacement using the threshold ensuring context coherence, as will be discussed in the subsequent contextual-similarity-based filtering step. Because we aim to maintain the comprehensive flow of the dialogue, we replace only one sentence with an image per dialogue. If multiple image candidates exist for a single sentence, we separate them into distinct image-mixed dialogue instances. In detail, such separated instances are all made up of the same dialogue context and text response except for substituted images.

Contextual-Similarity-based Filtering We employ a contextual-similarity-based filtering step to enhance the context coherence of the created image-mixed dialogues (C in Fig. 2). We filter out the dialogues where text-to-image similarity does not exceed the threshold determined by human annotators. For human annotators on the matching quality of an image, a total of 300 test dialogues are selected for each combination. Since we used three source dialogue datasets and two image datasets, we create six combinations of each dialogue dataset and each image dataset. Automatically created image-mixed dialogue instances are divided into ten segments based on the similarity values, and 30 are selected randomly from each. We hired a total of 18 annotators to evaluate 1,800 instances sampled from these six combinations. The evaluation system is described in Appendix C.

The human evaluation was conducted based on three questions for each instance:

- Q1: How well does the substituted image contain **key objects** in the target sentence?
- Q2: How well does the substituted image represent the **meaning** in the target sentence?
- Q3: When the image is substituted for the target sentence, how **consistent** is it with the **context** of the conversation?

Q1 and Q2 ask whether the substituted image contains the core meaning of the target sentence (on a 3-point scale). Q3 evaluates the context coherence of the created dialogue containing the image (on a 5-point scale). We assume that dialogues above the median of the evaluation score (2 for Q1, Q2, and 3 for Q3) are suitable for use as training instances. Based on this assumption, we determine the threshold for each combination by interpolating the median in the correlation graph of the evaluation results and the similarity (Appendix B). We then analyze the correlation between the score for each question and text-to-image similarity using Spearman's correlation analysis as shown in Table 1. Overall, the similarity values are positively correlated with the scores obtained for the questions. Since Q2 and Q3 are reasonably correlated with semantic similarity, the substituted images tend to reflect the meaning of the target and context sentences. Thus, the evaluation results indicate that the automatically created image-text pairs with high similarity can be used as multi-modal dialogues. We filter the generated multi-modal dialogues based on the determined similarities, and then set the filtered dialogues as our final dataset. The statistics of the final dataset are summarized in Table 2.

	Similarity	Q1	Q2	Q3
Similarity		**0.5893**	0.4422	0.4334
Q1			0.7103	0.6646
Q2				**0.7570**
Q3				

Table 1: Spearman's correlation ρ between three questions and text-to-image similarity.

	train	valid	test
# total dataset	**39956**	**2401**	**2673**
Avg length of dialogue turns	13.01	13.62	13.59
Avg length of sentences	51.47	50.76	50.70
# total unique images	12272	334	682
# total unique dialogues	13141	2148	2390
# total unique target sentences	21495	2400	2671
Avg # of substituted images in a dialogue	1.86	1.00	1.00
Avg # of targets in a dialogue	1.64	1.12	1.12

Table 2: Multi-modal dialogue dataset statistics for splits of training, validation, and test set.

Data Quality We evaluate the quality of our dataset to validate the proposed dataset creation method. To this end, we randomly sample 300 image-mixed dialogues from our final dataset. The evaluation proceeds in the same manner as before, but we add a new question Q4, which asks to choose the intent of the image used in the dialogue as one among (1) answering the question, (2) expressing emotional reactions, (3) proposing a new topic, and (4) giving additional explanations for the previous context. For Q1, Q2, and Q3, the average scores evaluated by three annotators are shown to be 2.56, 2.17, and 3.13, respectively, indicating that

Model	Task	R@1	R@5	Mean Rank
IR Baseline	Current	21.62	49.49	30.04
IR Baseline	Next	8.13	21.07	29.41
Retrieval Model	Current	**50.35**	**86.64**	**3.11**
Retrieval Model	Next	14.38	36.10	20.58

Table 3: Automatic evaluation results about retrieval models and an information retrieval baseline on the current and next dialogue prediction task.

the context of the conversation containing the substituted image is consistent in our dataset. For Q4, the responses from the annotators are distributed with 27.3%, 20.0%, 32.7%, and 14.7%, for the four intent types as mentioned above, indicating our dataset contains balanced intent types.

3 Experiments

3.1 Experimental Setup

We consider two dialogue sentence prediction tasks given an image and a dialogue: current dialogue prediction and next dialogue prediction for a given image. We use a simple retrieval model composed of three modules (Shuster et al., 2020a,b): Resnext-101 (Xie et al., 2017) for an image encoder, BERT (Devlin et al., 2019) for a text encoder, and the fusion module. As input for training the model, we use images and up to three dialogue sentences immediately before the images as dialogue context.

3.2 Automatic Evaluation

We perform quantitative comparisons that follow recent work (Shuster et al., 2020a) to find the optimal setting for our retrieval model (Appendix D). To evaluate the retrieval accuracy, we use the recall at 1 and 5 out of 100 candidates consisting of 99 candidates randomly chosen from the test set and 1 ground-truth sentence, called R@1/100 and R@5/100, respectively. We also use the mean reciprocal rank. We compare our model with a simple information retrieval baseline. The candidates of the baseline model are ranked according to their weighted word overlap between the target sentence and an image caption followed by dialogue context.

As shown in Table 3, the R@1 performance of the retrieval model obtained 50.35 and 14.38 on the current and next sentence prediction task, outperforming the baseline on both tasks. This result indicates that our dataset properly works as the training data to learn the relationship between images and dialogue context in dialogue sentence prediction tasks where images and dialogue context have to be considered together.

Model inputs	R@1	R@5	Mean Rank
Image Only	37.30	80.66	3.91
Dialogue Context Only	28.06	56.83	12.57
Image + Dialogue Context	**51.21**	**86.34**	**3.08**

Table 4: Ablation studies of our retrieval models on the current dialogue prediction task.

Model inputs	R@1	R@5	Mean Rank
Image Only	7.29	21.92	31.78
Dialogue Context Only	11.90	29.89	23.95
Image + Dialogue Context	**14.38**	**36.10**	**20.58**

Table 5: Ablation studies about our retrieval models on the next dialogue prediction task.

3.3 Ablation Study

We then conduct ablation studies by removing modalities (image and dialogue context) in turn to check whether unwanted correlations exist in our dataset. Since we created our training and test datasets by a semi-automatic data creation method, unwanted correlations can exist in datasets that can infer the correct answer without using the image and context simultaneously. Such correlations would prevent the model from properly learning the relationship between images and context.

As shown in Tables 4 and 5, the results first show that the recall measure for ground-truth answers in the model that considers both context and image is higher than the model considering only images. It indicates that the models in each task properly consider both images and dialogue context to predict sentences. To elaborate, the model that only considers images are likely to choose responses that do not match the dialogue context before the image. For example in a given dog photo shown during a sad mood conversation, the model that only considers images can generate an out-of-context response, such as "It is so cute.". On the other hand, in the same context, the model that considers both the context and the image could generate appropriate responses, such as "what is wrong with your dog?" or "I miss your dog.".

The overall tendency also shows that the model performance degrades when we delete each modality one by one. Such results suggest that our data creation process did not generate correlations that interfere with forming the relationship between images and dialogue context.

3.4 Human Evaluation

We create a new test set to confirm that the model can predict sentences well even on test dialogues that are not constructed in the same manner. To this end, two researchers manually created 100 multi-modal dialogues by adding images to source dialogues that were not used in our dataset generation process for human evaluation. We proceed with the evaluation with three annotators per each prediction task, using a question (on a 5-point scale) asking how much the sentences predicted by the model are relevant to the image and dialogue context. The average scores of three annotators for each task were shown to be 3.36 for the current turn prediction and 3.06 for the next turn prediction. The results indicate that the models can predict sentences in a context-aware manner even with dialogues organized by humans.

4 Conclusions

We present the multi-modal dialogue dataset consisting of 45k multi-turn dialogues containing semantically coherent images as well as the dataset creation method. Human evaluation results of our multi-modal dialogues reveal that context coherence is well maintained even if the sentence is replaced by an image, showing the validity of our dataset and data creation approach. We then evaluate our dataset using two multi-modal dialogue prediction tasks, demonstrating its effectiveness when training a dialogue system to learn the relationship between images and dialogue contexts. Our proposed data creation method can be applied when efficiently preparing large-scale multi-modal dialogue datasets that cover diverse multi-modal situations.

Daily-Flickr	0.619	141	6	5
Empathetic-COCO	0.623	245	2	11
Empathetic-Flickr	0.516	5398	281	188
Total		**39956**	**2401**	**2673**

Table 7: Number of data instances filtered by the thresholds for each combination

In this section, we analyze the human evaluation results for contextual-similarity-based filtering and determine thresholds for each dataset combination. The correlations between the similarity and evaluation results for each question are shown in Fig. 3. We assume that dialogue instances above the median of the evaluation score (2 for Q1, Q2, and 3 for Q3) are suitable for use in training. Based on the assumption, we determine the threshold for each combination by interpolating the median in the correlation graph of the evaluation results and the similarity. We select the largest one of three interpolated values of each question (Q1, Q2, and Q3). The data statistics for each combination filtered by the threshold are shown in Table 7.

Since the thresholds for each combination are determined differently, there are differences in the number of dialogue instances by combination. Such results suggest that the quality of multi-modal dialogue generation may vary depending on combining the text and image datasets. For example, the DailyDialog goes well with the MS-COCO but not with Flicker 30k. On the contrary, the EmpatheticDialogues goes well with the Flicker 30k but not with MS-COCO. Thus, we must consider finding the right combination among text and image datasets in the multi-modal dialogues generation process.

C Human Evaluation System

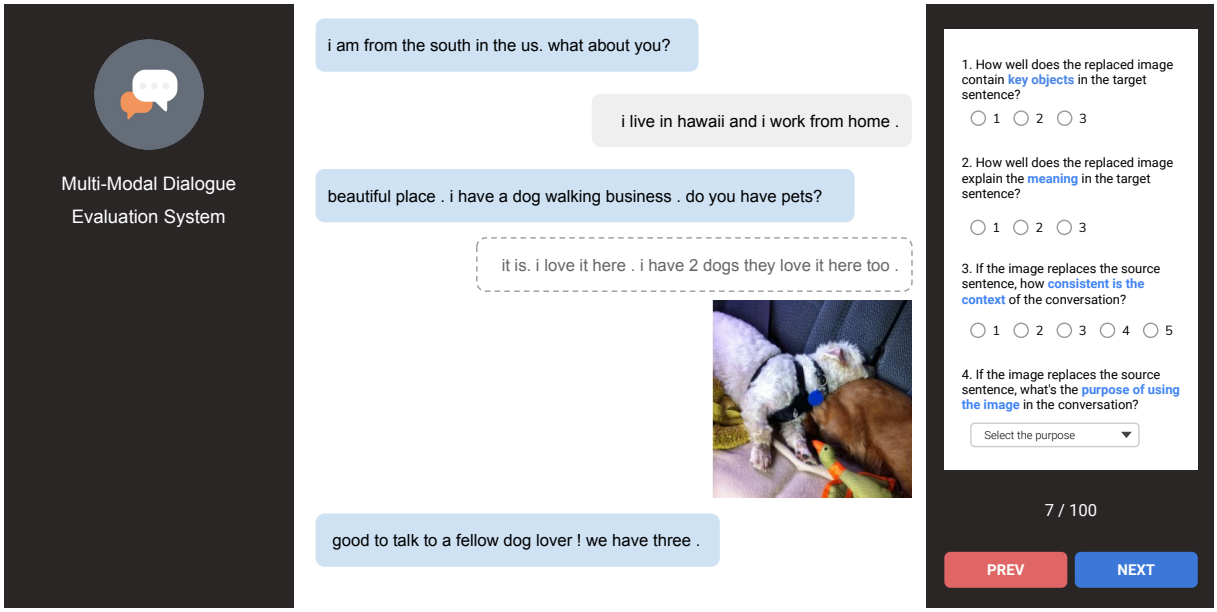

Figure 4: Human evaluation system for testing our multi-modal dialogue dataset.

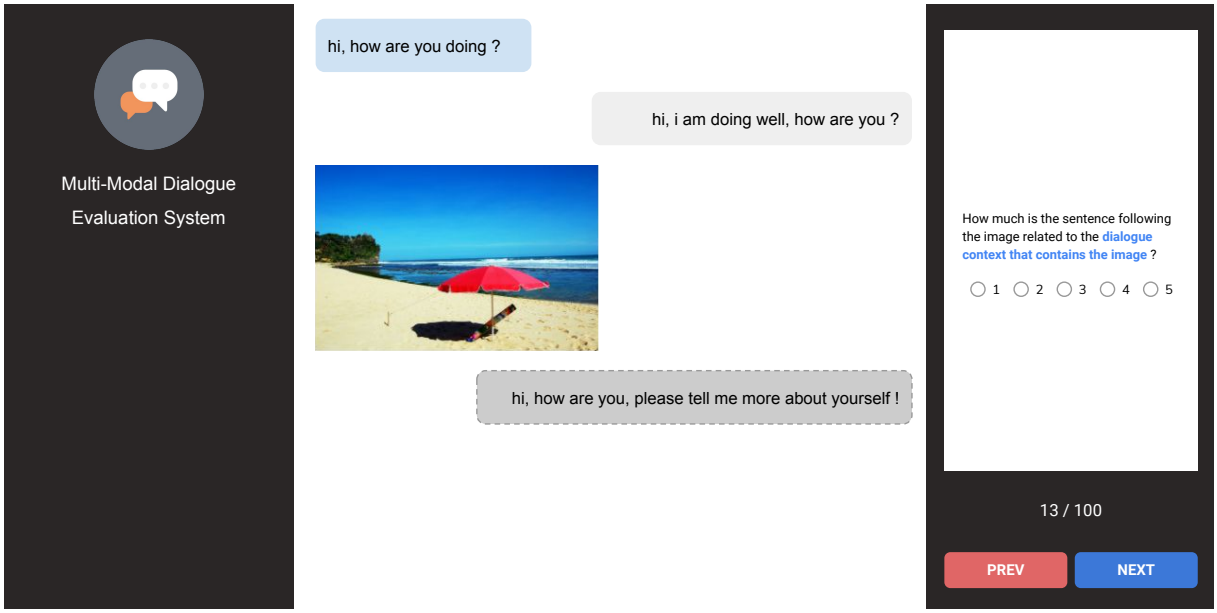

Figure 5: Human evaluation system for testing two dialogue sentence prediction tasks using our retrieval models.

In this section, we introduce the human evaluation system. We develop the system using a JavaScript library called ReactJS. Fig. 4 shows the implemented system for evaluating our multi-modal dialogue dataset. In this system, we ask users to evaluate a total of 100 dialog instances and answer three or four questions per instance. In addition to three questions described in Section 2, Q4[1] is added depending on the purpose of use. Fig. 5 shows the system for evaluating the performance of a retrieval model that performs dialog sentence prediction tasks. Similarly, we also ask users to evaluate a total of 100 dialog instances and answer one question per instance.

[1]Q4: If the image replaces the source sentence, what is the purpose of using the image in the conversation?

D Best Model Search

Model	Fusion Module	Image Encoder	Text Encoder	R@1	R@5	Mean Rank
$IRBaseline$	n/a	n/a	n/a	21.62	49.49	30.04

Table 8: Comparison tests of the current dialogue prediction task on the multi-modal dialogue dataset. We compare different module variations and training strategies for our retrieval models.

Model	Fusion Module	Image Encoder	Text Encoder	R@1	R@5	Mean Rank
$IRBaseline$	n/a	n/a	n/a	8.13	21.07	29.41
$RetrievalModel_{Att}$	Attention	Unfreeze	Freeze	2.04	9.50	40.99
$RetrievalModel_{Sum}$	Sum	Unfreeze	Freeze	3.08	12.46	36.36
$RetrievalModel_{Att}$	Attention	Unfreeze	Unfreeze	4.09	15.95	32.07
$RetrievalModel_{Sum}$	Sum	Unfreeze	Unfreeze	13.38	33.93	21.10
$RetrievalModel_{Att}$	Attention	Freeze	Unfreeze	10.02	28.49	23.71
$RetrievalModel_{Sum}$	Sum	Freeze	Unfreeze	**14.38**	**36.10**	**20.58**

Table 9: Comparison tests of the next dialogue prediction task on the multi-modal dialogue dataset. We compare different module variations and training strategies for our retrieval models.

We compare different module options of our model. Each encoder has two options: whether to freeze or not during training, and the fusion module has two options: summation, and the attention-based transformer encoder. For final image-context fused representation, context and image representations are added in the summation fusion method, while two representations are concatenated, and then fed into the attention-based two-layer transformer encoder in the attention-based method. By this comparison, we decide to freeze only the image encoder and use the summation fusion method for both current and next dialogue prediction tasks.

We additionally show the results of an information retrieval baseline, which retrieves target dialogue using the tf-idf method between candidate dialogues and the caption of an image followed by dialogue context. As shown in Tables 8 and 9, our retrieval model significantly outperforms the information retrieval baseline, indicating that comprehensive understanding of context and images is helpful in multi-modal dialogues.

Our implementation uses an NVIDA TITAN RTX GPU for training, and training each epoch takes about 15 minutes. Our retrieval model using the summation fusion method has 204M parameters, while that using the attention-based fusion method has 254M parameters.

E Multi-Modal Dialogue Dataset Example

Figure 6: Our multi-modal dialogue dataset examples

For easy understanding of our dataset, we provide two additional examples of the multi-modal dialogue dataset in Fig. 6.

F Selected Example of Current Dialogue Prediction Task

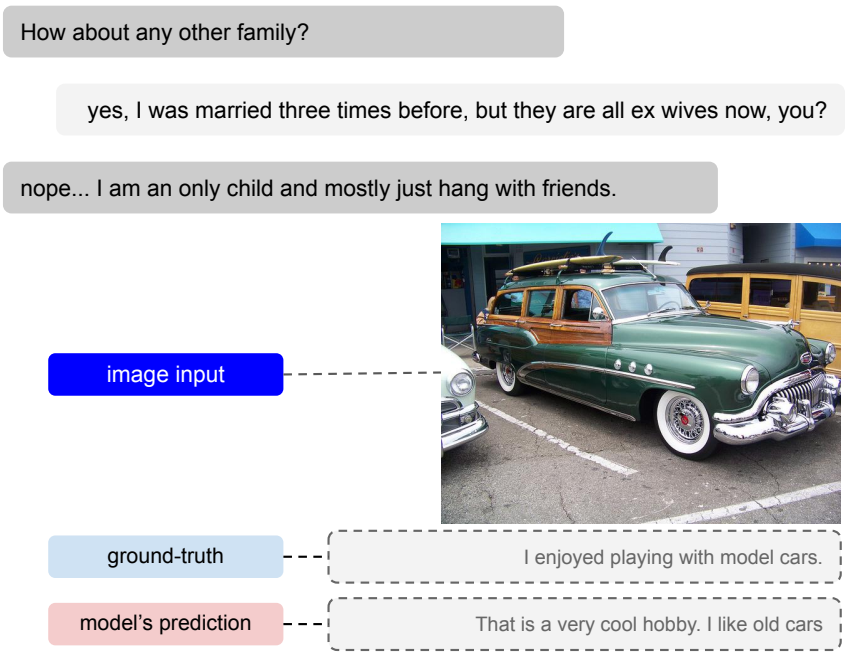

Figure 7: Ground-truth and dialogue sentence prediction example by our retrieval model used in the current turn prediction task.

Fig. 7 shows a reasonable example of a retrieved dialogue sentence by the retrieval model used in the current turn prediction task. Even if the model does not predict the ground-truth sentence, it can predict a plausible dialogue sentence.

Exposing the limits of Zero-shot Cross-lingual Hate Speech Detection

Debora Nozza

debora.nozza@unibocconi.it

Abstract

Reducing and counter-acting hate speech on Social Media is a significant concern. Most of the proposed automatic methods are conducted exclusively on English and very few consistently labeled, non-English resources have been proposed. Learning to detect hate speech on English and transferring to unseen languages seems an immediate solution. This work is the first to shed light on the limits of this zero-shot, cross-lingual transfer learning framework for hate speech detection. We use benchmark data sets in English, Italian, and Spanish to detect hate speech towards immigrants and women. Investigating post-hoc explanations of the model, we discover that non-hateful, language-specific taboo interjections are misinterpreted as signals of hate speech. Our findings demonstrate that zero-shot, cross-lingual models cannot be used as they are, but need to be carefully designed.

1 Introduction

An increasing propagation of hate speech has been detected on social media platforms (e.g., Twitter) where (pseudo-) anonymity enables people to target others without being recognized or easily traced. While this societal issue has attracted many studies in the NLP community, it comes with three important challenges. First, "hate speech" covers a **wide range of target types**, including misogyny, racism, and various other forms. While they often intersect, these types require different approaches.

Second, available labeled corpora refer to different definitions of hate speech, collection strategies, and annotation frameworks (Fortuna and Nunes, 2018). This lack of consistency strongly limits research on hate speech, which ultimately needs to apply cross-domain or transfer learning approaches for using different corpora.

Third, most of the research on hate speech detection **consider only English** and only a **limited number of labeled corpora** are available (Fortuna and Nunes, 2018; Vidgen and Derczynski, 2021; Poletto et al., 2020). However, hate speech is not specific to any one language, and approaches proposed for English may not fit other languages. Each language exhibits different complexities in dealing with gender or reflecting cultural ideas around it.

The lack of models and labeled corpora for non-English languages seems a perfect application for zero-shot, cross-lingual learning (Lamprinidis et al., 2021; Bianchi et al., 2021). But is it? In this paper, we investigate the limitations of zero-shot, cross-lingual solutions based on mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) on benchmark data sets of hate speech against immigrants and women in English, Italian, and Spanish.

Our analysis demonstrates that these approaches have significant limitations: (1) they are not able to capture common (taboo) language-specific expressions, and (2) they do not transfer to different hate speech target types. We show that the reasons for these limitations are due to the high presence of language- and target-specific taboo interjections in non-hateful contexts, like *porca puttana* or *puta*.[1] **While derogatory for women, these terms are often used as intensifiers in non-hateful context, blurring the lines for detection**. Since English does not use equivalent words in the same way, zero-shot, cross-lingual models will not observe them in the training data. Consequently, these models consider the literal meaning of these terms as individual words, treating them as misogynous hate speech. These findings demonstrate that, at the current moment, cross-lingual, zero-shot transfer learning is not a solution for solving the lack of models and labeled corpora in non-English languages for hate speech detection.

[1] We report the uncensored words to ensure non-native speaker understanding.

(a) Misclassified prediction by zero-shot, cross-lingual model trained on English and Spanish and tested on Italian data.

(b) Correct prediction by monolingual model trained on Italian and tested on Italian data.

Figure 1: Hierarchical explanations of predictions of a non-hateful Italian tweet. Literal English translation: "how the hell can you break the washing machine".

Contributions 1) We investigate different learning frameworks on benchmark corpora for the detection of hate speech targeting women and immigrants 2) We expose the limits of zero-shot, cross-lingual solutions using the multilingual BERT model (mBERT) 3) We show interpretable results through post-hoc explanation.

2 Zero-shot, Cross-lingual Hate Speech Detection

We investigate different learning settings: 1) *zero-shot, cross-lingual*, i.e., training on one language and testing on unseen languages; 2) *monolingual*, i.e., training and testing on the same language; 3) *few-shot, cross-lingual*, i.e., training on one language and a small percentage of samples from the test language and testing on the test language; 4) *augmented cross-lingual*, i.e., training on several languages and testing on a language included in the training.

Multilingual BERT Recently, *contextual embeddings* pretrained on large corpora substantially advanced research for several major Natural Language Processing (NLP) tasks (Nozza et al., 2020). In particular, multilingual BERT (mBERT) (Devlin et al., 2019), a model pretrained on monolingual Wikipedia dumps in 104 languages, has shown surprisingly good abilities for zero-shot, cross-lingual model transfer for different NLP tasks (Pires et al., 2019). In this paper, we fine-tune the mBERT model on the task of hate speech detection considering data from one or multiple languages.

Post-hoc Explanation One of the biggest limitations of using complex black-box models, such as BERT, is the lack of interpretability. Following Kennedy et al. (2020), we use the Sampling and Occlusion (SOC) algorithm (Jin et al., 2020) to generate hierarchical explanations of predictions. SOC assigns an importance score to show how much a given word or sequence of words contributes to classifying a sentence as hate speech. Then, it combines this score hierarchically following semantic compositions. Visual representation examples are given in Figures 1 and 2. The hierarchy reflects how the model captures compositional semantics (e.g., stress or negation) in making predictions. Color intensity represents how much each phrase contributes to classifying the sentence as hate speech. The label prediction is encoded in the color: blue for non-misogynous and red for misogynous.

3 Data

Test	1499	1000	800	1472	1000	799

Table 1: Corpora splits # of instances by target type.

To assess the cross-lingual evaluation framework, we use hate speech benchmark data sets with consistent definitions, annotation schema, and collection strategies (see Appendix C). For English and Spanish, we adopt the data sets proposed in the shared task of hate speech against immigrants and women on Twitter (HatEval) (Basile et al., 2019). For Italian, we consider two different corpora proposed for Evalita shared tasks (Caselli et al., 2018): the automatic misogyny identification challenge (AMI) (Fersini et al., 2018) for hate speech towards women, and the hate speech detection shared task on Facebook and Twitter (HaSpeeDe) (Bosco et al., 2018) for hate speech towards immigrants. Table 1 reports data distributions across languages and targets.

Table 2: Macro-F1 results for the two hate speech targets. Monolingual results are underlined. Zero-shot cross-lingual results are highlighted in *italic*. * = differs significantly from monolingual at $p \leq 0.05$. ** = significant difference at $p \leq 0.01$.

4 Experimental Results

Table 2 shows the macro-averaged F1 score for hate speech detection on different training and test languages (in rows and columns, respectively). Underlined numbers refer to the monolingual setting results, while zero-shot, cross-lingual results are italicized. We report as *baselines* the best performing model for each of the considered data set released in conjunction with shared tasks.[2] Since the aim of this paper is to investigate classification abilities of cross-lingual, zero-shot models, we do not aim to overcome the baselines but to provide comparable results.

4.1 Hate speech towards immigrants

Observing monolingual results (underlined numbers in Table 2), we see that training and testing in English gives the poorest performance. This behavior is due to an over-sensitivity to specific words/hashtags used during data collection (e.g. *#SendThemBack*, *#StopTheInvasion*), which leads to overfitting. In Appendix A, we report the SOC explanation of a misclassified tweet containing these hashtags. We confirm this finding by training the monolingual English model on data deprived of these hashtags, which lead to higher macro-F1 (from 0.368 to 0.438).

The zero-shot, cross-lingual configuration (italic numbers in Table 2) shows very different results between the two targets. Zero-shot learning obtains good performance for detecting hate speech towards immigrants: when testing Italian and Spanish, results are very similar; when testing on English, training on a different language is better than including English data, resulting in a 22% macro-F1 improvement on average. This is because training sets based on other languages do not contain the above-mentioned specific words and therefore do not suffer from over-sensitization.

4.2 Hate speech towards women

Concerning hate speech towards women, *the zero-shot, cross-lingual model obtains significantly lower performance for Spanish and Italian*. To better understand this substantially different finding, we analyze wrongly labeled instances. We discover that zero-shot, cross-lingual models are strongly influenced by common, language-specific taboo interjections to mislabel non-hateful text as misogynous. In particular, expressions that contain literal insults towards women but are not misogynistic per se. For example in Spanish, beyond its misogynistic meaning, the word *puta* (literally *bitch*) is also used as an exclamation of surprise (e.g., *puta mierda*). The Italian expressions *porca troia* and *porca puttana* (literally *porca* (*pig*) + *troia*/*puttana* (*slut*)) are very generic taboo interjections that do not have a misogynistic connotation. It is important to notice that these interjections are not directly translatable and usually used in combination, e.g. *porca* + *puttana*, *puta* + *mierda*.

To demonstrate this finding, in Table 3 we report the number of times a zero-shot cross-learning model correctly predicts the labels of instances containing taboo interjections for Italian and Spanish (i.e., *porca puttana, porca troia, puta*). The high frequency of instances containing taboo interjections (29% and 78% of the test set), due also to the keyword-driven collection strategy, proves the importance of understanding these linguistic expressions. The following numbers illustrate the

[2] State-of-the-art performance do not exist for every combination, since Hateval (English and Spanish) consider hate speech towards women and immigrant in conjunction.

Test Lang	Frequency	Zero-Shot, Cross-Lingual	Monolingual
IT	294 (29%)	9 (3%)	291 (99%)
ES	627 (78%)	365 (58%)	514 (82%)

Table 3: Correct predictions for instances containing Italian and Spanish taboo interjections.

impact of taboo interjections: all the 276 Italian tweets containing *porca puttana* are labeled as non-misogynous and are consistently misclassified by zero-shot, cross-lingual model; the Spanish expression *hijo de puta* appears in 64 tweets (of which 57 are non-misogynous) for which the zero-shot, cross-lingual model achieves 62% accuracy vs. 90% accuracy of the monolingual model. We confirm this finding by training models on data deprived of these taboo interjections, obtaining improvements: 0.627 for **ES⇒IT**; 0.479 for **IT⇒ES**; 0.662 for **EN⇒IT**; 0.660 for **IT⇒EN**.

Figure 1 shows the SOC explanation of a non-hateful tweet correctly classified by the monolingual Italian model and wrongly classified by the zero-shot, cross-lingual model trained on English and Spanish data. As expected, training and testing on Italian teach the model that *porca puttana* is a very general exclamation that does not imply misogyny (high importance score for non-misogynous prediction). However, when training on other languages, this taboo interjection is not recognized because it is strictly related to the *test* language. We observe that zero-shot, cross-lingual models consider the literal meaning of individual words, and consequently treat terms like *porca puttana* as misogynous regardless of their use in context.

To further validate this major finding, we conduct an additional experiment on the corpus of hate speech towards women: we train *few-shot, cross-lingual* models randomly sampling 1% of training data in the test language. The averaged results on 10 runs in terms of macro-F1 are: 0.660 for **ES+EN⇒IT**; 0.702 for **EN+IT⇒ES**. The significant improvements with respect to zero-shot performances prove that misogyny detection is strongly entangled with common, language-specific taboo interjections that are very frequent in the data set.

4.3 Hate speech towards immigrants and women

Finally, to demonstrate the *need for treating target types separately*, we run the zero-shot, cross-lingual model on the merged data sets of hate speech towards immigrants and women. The results in terms of macro-F1 are: 0.572 for **ES+IT⇒EN**; 0.513 for **ES+EN⇒IT**; 0.632 for **EN+IT⇒ES** (see Appendix B).

Following Stappen et al. (2020), these scores suggest a sufficient adaptation by the models. However, they represent a compromise between the high results of zero-shot cross-lingual hate speech detection against immigrants and the low results of hate speech detection against women. By showing the results for the two separate targets, we demonstrated that zero-shot cross-lingual models suffer from limitations when predicting hate speech detection against women and that, in general, zero-shot cross-lingual hate speech detection has yet to be solved.

4.4 Impact of language-specific taboo interjections on XLM-R

In order to understand whether common, language-specific taboo interjections play a role in other language models, we conducted experiments with XLM-R (Conneau et al., 2020). XLM-R is a large cross-lingual language model based on RoBERTa (Liu et al., 2019), trained on 2.5TB of filtered CommonCrawl data, which significantly outperformed mBERT on a variety of cross-lingual benchmarks.

XLM-R achieves high macro-F1 scores in monolingual settings for detecting hate speech towards women in Italian and Spanish (0.806 for **IT⇒IT**; 0.859 for **ES⇒ES**). Similar to the previously presented findings, we observe a significant drop of 36% in macro-F1 when considering the zero-shot cross-lingual settings (0.604 for **EN⇒IT**; 0.511 for **ES⇒IT**; 0.404 for **IT⇒ES**; 0.658 for **EN⇒ES**). This drop in macro-F1 is more evident when considering the performance when training on Spanish and testing on Italian and vice versa. These results on XLM-R bring more evidence about the role that language-specific taboo interjections have in impacting the performance.

5 Related Work

Hate speech detection has attracted great interest in the NLP community. This has led to the proposal of automatic detection approaches based on machine learning (Indurthi et al., 2019; Nozza et al., 2019; Fersini et al., 2020a; Kennedy et al., 2020; D'Sa et al., 2020, inter alia) and the creation of benchmark data sets, usually distributed through

shared tasks (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018; Bosco et al., 2018; Kumar et al., 2018; Wiegand et al., 2018; Basile et al., 2019; Fersini et al., 2018; Zampieri et al., 2020; Fersini et al., 2020b, inter alia).

Only a few studies have investigated hate speech detection across different languages. Steimel et al. (2019) asked which factors affect multilingual settings for German and English, concluding that a shared classification algorithm is not conceivable due to lack of corpora comparability. In Sohn and Lee (2019), the authors proposed a multi-channel model exploiting multilingual BERT and language-specific BERT for Chinese, English, German, and Italian. Finally, Stappen et al. (2020) proposed a novel, attention-based classification block for performing zero- and few-shot, cross-lingual learning on the HatEval data set. While they state that transfer learning is effective for hate speech detection, we argue that there is a need to investigate hate speech targets separately since these models consistently fail misogyny classification.

6 Conclusion

We demonstrate that cross-lingual, zero-shot transfer learning, in its traditional settings, is not a feasible solution for solving the lack of models and labeled corpora for hate speech detection. We argue that hate speech is language specific, and NLP approaches to identifying hate speech must account for that specificity and the adoption of related techniques must be done with care (Bianchi and Hovy, 2021). We plan to expand this evaluation to other languages and to investigate a solution based on bias mitigation (Nozza et al., 2019; Kennedy et al., 2020) and on pragmatic role-aware models (Holgate et al., 2018; Pamungkas et al., 2020) to reduce the impact of this problem on classification. Future work will also focus on modeling language's social factors (Hovy and Spruit, 2016; Hovy, 2018; Hovy and Yang, 2021), such as speaker and receiver characteristics, and study their impact on hate speech detection classifiers.

Ethical Considerations

We are aware that the inherent (gender) biases of sentence and word embeddings are affecting the model's performance on detecting hate speech towards women (Bolukbasi et al., 2016; Sheng et al., 2019; Nangia et al., 2020; Nozza et al., 2021). We believe that this issue plays a role in the classification models. However, in this paper we extensively demonstrate that the presence of taboo interjections is one of the main hurdles that specifically hinder zero-shot, cross-lingual hate speech detection results.

Finally, we want to highlight that the presented findings are specifically related to the considered languages and data sets. Hopefully, our work will generate more conscious research about the use of hate speech detection models in zero-shot, cross-lingual frameworks.

** = significant difference at $p \leq 0.01$.

C Experimental Configuration

C.1 Consistent Data sets

We use benchmark hate speech data sets with consistent definitions, annotation schema, and collection strategies. All the three data sets (Bosco et al., 2018; Fersini et al., 2018; Basile et al., 2019) refer to the same definitions of hate speech towards immigrant and women.[3] This paper focuses on the common binary classification task (hateful/non-hateful) across all data sets, ensuring the same annotation schema. Finally, all data sets have been collected by following three strategies: (1) monitoring potential victims of hate accounts, (2) downloading the history of identified haters and (3) filtering Twitter streams with keywords, i.e. words, hashtags and stems.

For experimental evaluation, we use the data set splits provided in the associated shared task for comparability with previous work.

C.2 Implementation Details

We implement the proposed work exploiting the public code implementation of the classification model presented by Kennedy et al. (2020)[4]. We use their hyperparameter configuration for training: batch size is set to 32, the learning rate of the Adam optimizer is set to 2×10^{-5}, the loss function is the binary cross entropy.

Computing Infrastructure We independently run the experiments on two machines: the first one is equipped with two NVIDIA RTX 2080TI and has 64GB of RAM. The other one is equipped with four GPUs, NVIDIA GTX 1080TI, and has 32GB of RAM.

Abstract

Neural machine translation models are often biased toward the limited translation references seen during training. To amend this form of overfitting, in this paper we propose fine-tuning the models with a novel training objective based on the recently-proposed BERTScore evaluation metric. BERTScore is a scoring function based on contextual embeddings that overcomes the typical limitations of n-gram-based metrics (e.g. synonyms, paraphrases), allowing translations that are different from the references, yet close in the contextual embedding space, to be treated as substantially correct. To be able to use BERTScore as a training objective, we propose three approaches for generating *soft predictions*, allowing the network to remain completely differentiable end-to-end. Experiments carried out over four, diverse language pairs have achieved improvements of up to 0.58 pp (3.28%) in BLEU score and up to 0.76 pp (0.98%) in BERTScore (F_{BERT}) when fine-tuning a strong baseline.

1 Introduction

Neural machine translation (NMT) has imposed itself as the most performing approach for automatic translation in a large variety of cases (Sutskever et al., 2014; Vaswani et al., 2017). However, NMT models suffer from well-known limitations such as overfitting and moderate generalization, particularly when the training data are limited (Koehn and Knowles, 2017). This mainly stems from the fact that NMT models have large capacity and are usually trained to maximize the likelihood of just a single reference sentence per source sentence, thus ignoring possible variations within the translation (e.g. synonyms, paraphrases) and potentially resulting in overfitting. A somewhat analogous problem affects evaluation, where metrics such as BLEU (Papineni et al., 2002) only consider as correct the predicted n-grams that match exactly in the ground-truth sentence. In order to alleviate the n-gram matching issue during evaluation, Zhang et al. (2020) have recently proposed the BERTScore metric that measures the accuracy of a translation model in a contextual embedding space. In BERTScore, a pretrained language model (e.g. BERT (Devlin et al., 2019)) is first used to compute the contextual embeddings of the predicted sentence, $\langle \hat{\mathbf{y}}_1, \ldots, \hat{\mathbf{y}}_k \rangle$, and the reference sentence, $\langle \mathbf{y}_1, \ldots, \mathbf{y}_l \rangle$, with k and l word-pieces, respectively. Then, recall (R_{BERT}), precision (P_{BERT}), and F1 (F_{BERT}) scores are defined as cosine similarities between the normalized contextual embeddings. For example, the recall is defined as:

$$R_{BERT} = \frac{1}{|l|} \sum_{y_i \in y} \max_{\hat{y}_j \in \hat{y}} \mathbf{y}_i^T \hat{\mathbf{y}}_j \qquad (1)$$

where the $\max$ function acts as an alignment between each word in the reference sentence (y) and the words in the predicted sentence ($\hat{y}$). Conversely, P_{BERT} aligns each word of the predicted sentence with the words of the reference sentence, and F_{BERT} is the usual geometric mean of precision and recall. Note that with this scoring function a candidate and reference sentences with similar embeddings will be assigned a high score even if they differ completely in terms of categorical words. Zhang et al. (2020) have shown that this evaluation metric has very high correlation with the human judgment.

In this work, we propose using BERTScore as an objective function for model fine-tuning. Our rationale is that BERTScore is a sentence-level objective that may be able to refine the performance of NMT models trained with the conventional, token-level log-likelihood. However, in order to fine-tune the model with BERTScore as an objective, end-to-end differentiability needs to be ensured. While the BERTScore scoring function is based on word

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 915–924
August 1–6, 2021. ©2021 Association for Computational Linguistics

embeddings and is in itself differentiable, its input derives from categorical predictions (i.e. argmax or sampling), breaking the differentiability of the overall model. In this work, we solve this problem by generating *soft predictions* during training with three different approaches. One of the approaches, based on the Gumbel-Softmax (Jang et al., 2017), also leverages sampling, allowing the model to benefit from a certain degree of *exploration*. For immediacy, we refer to our approach as *BERTTune*. The experimental results over four, diverse language pairs have shown improvements of up to 0.58 pp (3.28%) in BLEU score and up to 0.76 pp (0.98%) in BERTScore with respect to a contemporary baseline (Ott et al., 2019).

2 Related Work

In recent years, various researchers have addressed the problem of overfitting in NMT models. This problem can be specially severe for neural models, given that, in principle, their large number of parameters could allow for a perfect memorization of the training set. For instance, Ma et al. (2018) have trained an NMT model using both a reference sentence and its bag-of-words vector as targets, assuming that the space of alternative, correct translations share similar bags-of-words. Others (Elbayad et al., 2018; Chousa et al., 2018) have proposed smoothing the probability distribution generated by the decoder using the embedding distance between the predicted and target words, forcing the network to increase the probability of words other than the reference. Another line of work has proposed to explicitly predict word embeddings, using the cosine similarity with the target embedding as the reward function (Kumar and Tsvetkov, 2019; Jauregi Unanue et al., 2019).

Reinforcement learning-style training has also been used to alleviate overfitting (Ranzato et al., 2016; Edunov et al., 2018). The use of beam search removes the exposure bias problem (Wiseman and Rush, 2016), and the use of sampling introduces some degree of exploration. In addition, these approaches allow using non-differentiable, sequence-level metrics as reward functions. However, in practice, approximating the expectation of the objective function with only one or a few samples results in models with high variance and convergence issues.

Significant effort has also been recently dedicated to leveraging large, pretrained language models (Devlin et al., 2019; Radford et al., 2018; Peters et al., 2018) for improving the performance of NMT models. This includes using contextual word embeddings either as input features (Edunov et al., 2019) or for input augmentation (Yang et al., 2020; Zhu et al., 2020), and using a pretrained language model for initializing the weights of the encoder (Clinchant et al., 2019). Alternatively, Baziotis et al. (2020) have proposed using a pretrained language model as a prior, encouraging the network to generate probability distributions that have a high likelihood in the language model. In abstractive summarization, Li et al. (2019) have used BERTScore as reward in a deep reinforcement learning framework. In a similar vein, our work, too, aims to leverage pretrained language models for improving the NMT accuracy. However, to the best of our knowledge, ours is the first work to directly include a language model as a differentiable evaluation measure in the training objective. In this way, the NMT model is able to exploit the value of a pretrained language model while at the same time being fine-tuned over a task-specific evaluation metric.

3 BERTScore Optimization

Translation evaluation metrics, including BERTScore, typically require a predicted translation, $\langle \hat{y}_1, \ldots, \hat{y}_k \rangle$, and at least one reference translation, $\langle y_1, \ldots, y_l \rangle$, as inputs. At its turn, the predicted translation is typically obtained as a sequence of individual word (or token) predictions, using beam search or greedy decoding. We can express the predictions as:

$$\hat{y}_j = \arg\max_y p(y|x, \hat{y}_{j-1}, \theta) \quad j = 1, \ldots, k \quad (2)$$

where x represents the source sentence and θ the model's parameters. During model training, it is common practice to use teacher forcing (i.e., use words from the reference sentence as $\hat{y}_{j-1}$) for efficiency and faster convergence.

In brief, the computation of BERTScore works as follows: the scorer first converts the words in the predicted and reference sentences to corresponding static (i.e., non-contextual) word embeddings using the embedding matrix, $\mathbf{E}$, stored in the pretrained language model. For the predicted sequence, we note this lookup as:

$$\mathbf{e}_{\hat{y}_j} = \text{emb}_{LM}(\mathbf{E}, \hat{y}_j) \quad j = 1, \ldots, k \quad (3)$$

The sequences of static embeddings for the predicted and reference sentences are then used as

inputs into the language model to generate corresponding sequences of contextualized embeddings, $\langle \hat{\mathbf{y}}_1, \ldots, \hat{\mathbf{y}}_k \rangle$ and $\langle \mathbf{y}_1, \ldots, \mathbf{y}_k \rangle$, respectively, over which the BERTScore is finally computed. For our work, we have chosen to optimize the F_{BERT} score as it balances precision and recall. For more details on the scoring function we refer the reader to (Zhang et al., 2020).

3.1 Soft predictions

However, it is not possible to directly use the F_{BERT} score as a training objective since the argmax function in (2) is discontinuous. Therefore, in this work we propose replacing the hard decision of the argmax with "soft predictions" that retain differentiability. Let us note concisely the probability in (2) as p_j^i, where i indexes a particular word in the V-sized vocabulary and j refers to the decoding step, and the entire probability vector at step j as $\mathbf{p}_j$. Let us also note as $\mathbf{e}^i$ the embedding of the i-th word in the embedding matrix of the pretrained language model, $\mathbf{E}$. We then compute an "expected embedding" as follows:

$$\bar{\mathbf{e}}_{\hat{y}_j} = \mathbb{E}[\mathbf{E}]_{\mathbf{p}_j} = \sum_{i=1}^{V} p_j^i \mathbf{e}^i \tag{4}$$

In other terms, probabilities $\mathbf{p}_j$ act as attention weights over the word embeddings in matrix $\mathbf{E}$, and the resulting expected embedding, $\bar{\mathbf{e}}_{\hat{y}_j}$, can be seen as a trade-off, or weighted average, between the embeddings of the words with highest probability. To be able to compute this expectation, the NMT model must share the same target vocabulary as the pretrained language model. Once the expected embeddings for the whole predicted sentence, $\langle \bar{\mathbf{e}}_{\hat{y}_1}, \ldots, \bar{\mathbf{e}}_{\hat{y}_k} \rangle$, are computed, they are input into the language model to obtain the corresponding sequence of predicted contextualized embeddings, and the F_{BERT} score is computed. The fine-tuning loss is simply set as $\mathcal{L} = -F_{BERT}$. During fine-tuning, only the parameters of the NMT model are optimized while those of the pretrained language model are kept unchanged.

3.2 Sparse soft predictions

A potential limitation of using the probability vectors to obtain the expected embeddings is that they are, a priori, dense, with several words in the vocabulary possibly receiving a probability significantly higher than zero. In this case, the expected embeddings risk losing a clear interpretation. While we could simply employ a softmax with temperature to sparsify the probability vectors, we propose exploring two more contemporary approaches:

- **Sparsemax** (Martins and Astudillo, 2016): Sparsemax generates a Euclidean projection of the logits computed by the decoder (noted as vector $\mathbf{s}_j$) onto the probability simplex, Δ^{V-1}:

$$\mathbf{p}_j^{SM} = \underset{\mathbf{p}_j \in \Delta^{V-1}}{\arg\min} ||\mathbf{p}_j - \mathbf{s}_j||^2 \tag{5}$$

  The larger the logits, the more likely it is that the resulting $\mathbf{p}_j^{SM}$ vector will have a large number of components equal to zero. The sparsemax operator is fully differentiable.

- **Gumbel-Softmax** (Jang et al., 2017; Maddison et al., 2017): The Gumbel-Softmax is a recent reparametrization technique that allows sampling *soft* categorical variables by transforming samples of a Gumbel distribution. The transformation includes a temperature parameter, τ, that allows making the resulting soft variables more or less sparse. By noting a sample from the Gumbel distribution as g^i, the Gumbel-Softmax can be expressed as:

$$p_j^{i\,GS} = \frac{\exp((\log p_j^i + g^i)/\tau)}{\sum_{v=1}^{V} \exp((\log p_j^v + g^v)/\tau)} \tag{6}$$

  where $p_j^{i\,GS}$, $i = 1, \ldots, V$, are the components of the probability vector used in (4). In the experiments, τ has been set to 0.1 to enforce sparsity. In addition to obtaining more "selective" predictions, the Gumbel-Softmax leverages sampling, allowing the fine-tuning to avail of a certain degree of *exploration*. The Gumbel-Softmax, too, is fully differentiable.

4 Experiments

4.1 Datasets

We have carried out multiple experiments over four, diverse language pairs, namely, German-English (de-en), Chinese-English (zh-en), English-Turkish (en-tr) and English-Spanish (en-es), using the datasets from the well-known IWSLT 2014 shared task[1], with 152K, 156K, 141K and 172K training sentences, respectively. Following Edunov et al. (2018), in the de-en dataset we have used $7,000$ samples of the training data for validation, and *tst2010*, *tst2011*, *tst2012*, *dev2010* and

Table 1: Average BLEU, F_{BERT} and MoverScore (MS) results over the test sets. (†) refers to statistically significant differences with respect to the baseline computed with a bootstrap significance test with a p-value < 0.01 (Dror et al., 2018). The bootstrap test was carried out at sentence level for F_{BERT} and MS, and at corpus level for BLEU.

dev2012 as the test set. For the other language pairs, we have used the validation and test sets provided by the shared task. More details about the preprocessing are given in Appendix A.

4.2 Models and training

We have implemented the fine-tuning objective using the *fairseq* translation toolkit[2] (Ott et al., 2019). The pretrained language models for each language have been downloaded from Hugging Face (Wolf et al., 2020)[3]. As baseline, we have trained a full NMT transformer until convergence on the validation set. With this model, we have been able to reproduce or exceed the challenging baselines used in (Zhang et al., 2020; Xia et al., 2019; Miculicich et al., 2018; Wu et al., 2020). The fine-tuning with the F_{BERT} loss has been carried out over the trained baseline model, again until convergence on the validation set. For efficient training, we have used teacher forcing in all our models. During inference, we have used beam search with beam size 5 and length penalty 1. As performance measures, we report the BLEU, F_{BERT} and MoverScore (MS) (Zhao et al., 2019) results over the test sets averaged over three independent runs. Including BLEU and MS in the evaluation allows us to probe the models on metrics different from that used for training. Similarly to F_{BERT}, MS, too, is a contextual embedding distance-based metric, but it leverages soft alignments (many-to-one) rather than hard alignments between words in the candidate and reference sentences. To make the evaluation more probing, for MS we have used different pretrained language models from those used with F_{BERT}. For more details on the models and hyperparameter selection, please refer to Appendix A.

[2]https://github.com/ijauregiCMCRC/fairseq-bert-loss
[3]https://huggingface.co/models

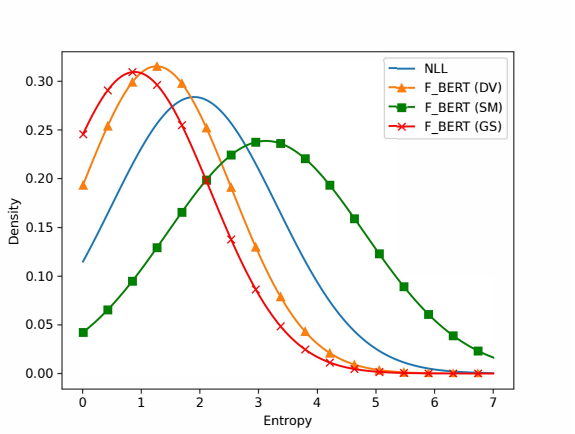

Figure 1: Entropy of the probability vectors generated by the different approaches over the de-en test set.

4.3 Results

Table 1 shows the main results over the respective test sets. As expected, fine-tuning the baseline with the proposed approach has generally helped improve the F_{BERT} scores. However, Table 1 also shows that it has often led to improvements in BLEU score. In the majority of cases, the best results have been obtained with the Gumbel-Softmax (GS), with more marked improvements for de-en and en-tr ($+0.36$ pp BLEU and $+0.76$ pp F_{BERT} and $+0.72$ pp MS for de-en, and $+0.58$ pp BLEU, $+0.20$ pp F_{BERT} and $+0.03$ pp MS for en-tr). Conversely, the dense vectors (DV) and sparsemax (SM) have not been as effective, with the exception of the dense vectors with the zh-en dataset ($+0.25$ pp BLEU, $+0.49$ pp F_{BERT} and $+0.54$ pp MS). This suggests that the Gumbel-Softmax sampling may have played a useful role in exploring alternative word candidates. In fairness, none of the proposed approaches has obtained significant improvements with the en-es dataset. This might be due to the fact that the baseline is much stronger to start with, and thus more difficult to improve upon. In general, both the embedding-based metrics (i.e., F_{BERT} and MS) have ranked the approaches in the same order, with the exception of the en-es dataset.

To provide further insights, similarly to Baziotis et al. (2020), in Figure 1 we plot the distribution of the entropy of the probability vectors generated by the different approaches during inference over the de-en test set. Lower values of entropy correspond to sparser predictions. The plot shows that the models fine-tuned with the dense vectors and the Gumbel-Softmax have made test-time predictions that have been sparser on average than those of the baseline, with the Gumbel-Softmax being the sparsest, as expected. Conversely, and somehow unexpectedly, the model fine-tuned with the sparsemax has made predictions denser than the baseline's. We argue that this may be due to the scale of the logits that might have countered the aimed sparsification of the sparsemax operator. In all cases, the sparsity of the predictions seems to have positively correlated with the improvements in accuracy. For a qualitative analysis, Appendix B presents and discusses various comparative examples for different language pairs.

Finally, Figure 2 shows the effect of the proposed objective over the measured metrics on the de-en validation set at different fine-tuning steps. The plots show that the model rapidly improves the performance in F_{BERT} and MS scores during the first epoch (steps $1 - 967$), peaking in the second epoch ($\approx$ step $1,200$). After that, the performance of the model starts dropping, getting back to the baseline levels in epoch 4. This suggests that training can be limited to a few epochs only, to prevent overfitting. On the other hand, the plots also show a trade-off between the metrics, as the model's improvements in F_{BERT} and MS come at cost of a decrease in BLEU. However, this phenomenon has not been visible on the test set, where all the fine-tuned models have outperformed the baseline also in BLEU score. This suggests that for this dataset the distributions of the training and test sets may be more alike.

5 Conclusion

In this work, we have proposed fine-tuning NMT models with BERTScore, a recently proposed word embedding-based evaluation metric aimed to overcome the typical limitations of n-gram matching. To be able to use BERTScore as an objective function while keeping the model end-to-end differentiable, we have proposed generating *soft* predictions with differentiable operators such as the sparsemax and the Gumbel-Softmax. The experimental results over four language pairs have showed that the proposed approach – nicknamed *BERTTune* – has been able to achieve statistically significant improvements in BLEU, F_{BERT} and MS scores over a strong baseline. As future work, we intend to explore the impact of key factors such as the dataset size, the sparsity degree of the predictions and the choice of different pretrained language models, and we also plan to evaluate the use of beam search/sequential sampling during training to leverage further exploration of candidate translations.

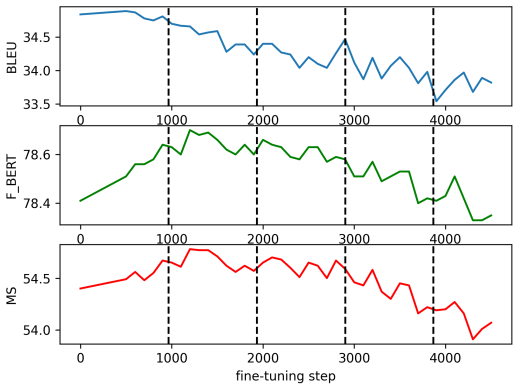

Figure 2: BLEU, F_{BERT} and MS scores of the BERTTune (GS) model over the de-en validation set at different fine-tuning steps. Step 0 is the score of the baseline model, and the vertical dashed lines delimit the epochs.

Appendix A: Preprocessing and hyperparameters

This appendix provides detailed information about the preprocessing of the datasets and the hyperparameter selection to facilitate the reproducibility of the experiments. All the code will be released after the anonymity period.

As part of the preprocessing of the datasets, all sentences have been tokenized and lowercased. The source languages have been tokenized with the Moses tokenizer[4], except for Chinese that has been tokenized using Jieba[5]. The target languages have instead been tokenized with the tokenizer learned by the pretrained language model. As language models for BERTScore, we have used `bert-base-uncased` (en), `dbmdz/bert-base-turkish-uncased` (tr) and `dccuchile/bert-base-spanish-wwm-uncased` (es) from Hugging Face. As language model for the MoverScore, we have used the suggested language model for English[6], `dbmdz/distilbert-base-turkish-cased` for Turkish and `mrm8488/distill-bert-base-spanish-wwm-cased-finetuned-spa-squad2-es` for Spanish, the last two from Huggingface. The few sentences longer than 175 tokens have been removed from all datasets as in the original fairseq preprocessing script. Additionally, further tokenization at subword level has been performed over the source languages using byte-pair encoding (BPE) (Sennrich et al., 2016) with $32,000$ merge operations. An important step in the preprocessing has been to force the decoder and the language model to share the same vocabulary. Therefore, we have assigned the decoder with the vocabulary from the selected pretrained language model, ensuring that both used identical `bos`, `eos`, `pad` and `unk` tokens.

For training a strong transformer baseline, we have followed the recommendations in fairseq[7]. The architecture is the predefined `transformer_iwslt_de_en` architecture (79M parameters) with word embedding and hidden vector dimension size of 512, and 6 transformer layers. We have set the training batch size to $4,096$ tokens, the dropout rate to 0.3 and the `clip_norm` gradient clipping parameter to 0.0. The objective function is the label-smoothed negative log-likelihood, with the smoothing factor set to 0.1. We have used the Adam optimizer (Kingma and Ba, 2015) with a $5e-4$ learning rate and beta values $\beta_1 = 0.9$ and $\beta_2 = 0.98$. We have set the warm-up steps to $4,000$ with an initial learning rate of $1e-7$. During training, we have reduced the learning rate with an inverse square-root scheduler and the weight decay set to 0.001. We have trained the model until convergence of the BLEU score on the validation set, with checkpoints at each epoch and patience set to 3, or until the learning rate dropped below $1e-9$.

For fine-tuning with F_{BERT}, we have initialized the transformer models with the trained weights of the baseline. We have kept all hyperparameters identical, except for the learning rate which has been reduced by an order of magnitude to $5e-5$, following common fine-tuning strategies. The models have been fine-tuned until convergence over the validation set, with patience set to 3. Since the changes have only involved the training objective, the number of trainable parameters has remained exactly the same (79M). At test time, we have used beam search decoding with beam size 5 and length penalty 1.

For all the experiments we have used an NVIDIA Quadro P5000 GPU card with 16 GB of memory.

Appendix B: Translation examples

This appendix shows a few translation examples from the de-en and zh-en language pairs to provide further insights into the behavior of the different models.

The example in Table 2 shows that only the BERTTune model with the Gumbel-Softmax has been able to translate phrases such as *at the moment* and *it was as if / it was like*. This model seems to have been able to capture the exact meaning of the source German sentence, even though it has translated it with a slightly different wording (note that the Gumbel-Softmax fine-tuning explores a larger variety of predictions). The other BERTTune models, too, have translated this sentence better than the baseline.

In the example in Table 3, the baseline has not been able to correctly pick the name of the artist (*bono*, lowercased from *Bono*), choosing instead word *bonobos* (primates). All the BERTTune mod-

[4] https://github.com/moses-smt/mosesdecoder
[5] https://github.com/fxsjy/jieba
[6] https://github.com/AIPHES/emnlp19-moverscore/releases/download/0.6/MNLI_BERT.zip
[7] https://fairseq.readthedocs.io/en/latest/index.html

els have instead made the correct prediction. In this example, it is possible that the BERTTune models have benefited from the fine-tuning with a pretrained language model: word *bono* might not have been present in the limited translation training data, but might have been encountered in the large unsupervised corpora used to train the language model. Another possibility is that they have simply used the copy mechanism more effectively.

In the example in Table 4, all the BERTTune models have correctly translated the phrase *part of the national statistics*, while the baseline has incorrectly translated it as *part of the world record*. In turn, the BERTTune models have translated the phrase *in a decade or two* as *in 10 or 20 years* which is a correct paraphrase, whereas the baseline has used the exact phrase as the reference. We also note that although both the baseline and BERTune translations have scored a BLEU score of 0.0 in this case, the F_{BERT} score has been able to differentiate between them, assigning a score of 72.36 to the BERTTune translation and 72.10 to the baseline. This also shows that small gains in F_{BERT} score can correspond to significant improvements in translation quality.

Finally, in the example in Table 5 only the BERTTune models with dense vectors and Gumbel-Softmax have been able to translate the beginning of the sentence (*i was the guy beaten up*) with acceptable paraphrases (i.e. *and i was the kind of person who had been beaten up / i was that guy who had been beaten*). Conversely, the baseline has translated the ending part of the sentence (*until one teacher saved my life*) with a phrase of antithetical meaning (*until a teacher turned me into this kind of life*).

Entity Enhancement for Implicit Discourse Relation Classification in the Biomedical Domain

Wei Shi[§,†] and **Vera Demberg**[†,‡]

{w.shi, vera}@coli.uni-saarland.de

Abstract

Implicit discourse relation classification is a challenging task, in particular when the text domain is different from the standard Penn Discourse Treebank (PDTB; Prasad et al., 2008) training corpus domain (Wall Street Journal in 1990s). We here tackle the task of implicit discourse relation classification on the biomedical domain, for which the Biomedical Discourse Relation Bank (BioDRB; Prasad et al., 2011) is available. We show that entity information can be used to improve discourse relational argument representation. In a first step, we show that explicitly marked instances that are content-wise similar to the target relations can be used to achieve good performance in the cross-domain setting using a simple unsupervised voting pipeline. As a further step, we show that with the linked entity information from the first step, a transformer which is augmented with entity-related information (K-BERT; Liu et al., 2020) sets the new state of the art performance on the dataset, outperforming the large pre-trained BioBERT (Lee et al., 2020) model by 2% points.

1 Introduction

Discourse relation classification (DRC) involves automatically inferring the logical link between different text segments (such as causal, contrastive, temporal etc.). It has been shown to be a valuable preprocessing step to many downstream natural language processing tasks such as machine translation (Guzmán et al., 2014; Meyer et al., 2015), text summarization (Gerani et al., 2014) and question-answering (Jansen et al., 2014). A main obstacle to a wider usage of automatic DR classifiers however lies in getting the classifiers to work reliably on domains other than the WSJ, that discourse relation parsers are usually trained on PDTB (Prasad et al., 2008) and RST (Carlson et al., 2003).

Moving to a different domain is particularly challenging in DRC because the overall distribution of relations typically differs between domains, and because many of the content words that classifiers may rely on are very different between domains. We here focus on the most challenging subtask of *implicit discourse relation classification*, which involves classifying those relations that are not linked by any explicit connectives like "because" or "but". In order to correctly recognize implicit relations, the classifier needs to recognize subtle surface cues (which may differ between domains) and learn about typical content-related relations. For instance, from the example "it's hot outside, therefore I'd like to eat an icecream", the words "hot outside" and "icecream" are relevant cues for the relation. An overview of typical cues for determining a coherence relation is provided in Das and Taboada (2018).

The key to improving automatic DRC on a new domain hence consists of better encoding of the discourse relational arguments. As we will show below (in line with earlier findings by Shi and Demberg, 2019b), it makes a big difference to have at least a small amount of in-domain discourse annotated data.

We here explore DRC on the biomedical domain, which seems particularly suitable because a discourse-annotated corpus is available (BioDRB; Prasad et al., 2011), which we can use for evaluation, as well as a setting with a small amount of in-domain training data. Furthermore, the biomedical domain does have large raw text corpora available. An example instance from BioDRB (Prasad et al., 2011) is shown below:

1. *[These abnormalities in active RA are thought to be induced mainly after chronic exposure to high concentrations of IL-6.]*$_{Arg1}$ *(**Implicit=thus**) [The limited efficacy of IL-10*

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 925–931
August 1–6, 2021. ©2021 Association for Computational Linguistics

treatment of RA patients may be explained in part by the unresponsiveness to IL-10 of inflammatory cells, including T cells .]$_{Arg2}$

—Implicit, Contingency.Cause

Scientific texts such as those from the biomedical domain are well known to express much of the content in nominal phrases, and less in verb phrases (Halliday, 2006). Concretely, for the above example, understanding the relation between the RA (Rheumatoid Arthritis) and inflammatory cells (including T cells) is important to correctly understanding the relation. The high importance of entities in these texts is a crucial insight on which we base our approach.

In this paper, we first propose an unsupervised method using information retrieval and knowledge graph techniques for identifying text passages that are similar content-wise to the coherence relation we want to label. The underlying assumption here is that if two instances share the same entities in both the relational arguments, it is possible that they have the same or a similar discourse relation. This part of the method is applicable to any domain for which large amounts of in-domain text are available, but no in-domain discourse relation annotations. We find that this method helps to improve results substantially compared to a Bi-LSTM baseline model, but doesn't reach state of the art performance (which is set by transformer models).

We therefore proceed to enrich a transformer model with the knowledge extracted from the unlabelled texts, using the K-BERT model (Liu et al., 2020). The model is fine-tuned on the discourse-annotated in-domain BioDRB data. We show that this setting sets the new state of the art on discourse relation classification on the biomedical domain, achieving an accuracy of 69.57%.

2 Related Work

Early approaches on BioDRB use probabilistic classifiers such as Naïve Bayes, Maximum Entropy, etc. to predict the relation (Xu et al., 2012). Bai and Zhao (2018) combine representations from different types of embeddings including contextualized word vectors from ELMo (Peters et al., 2018) and achieve 55.9% accuracy on BioDRB for in-domain training, and 29.52% in the cross-domain setting (reported in Shi and Demberg (2019b)).

Shi and Demberg (2019b) also explore the performance of BERT (Devlin et al., 2019) models on the DRC task on BioDRB using cross-domain (fine-tuning on PDTB, testing on BioDRB) as well as in-domain (fine-tuning on BioDRB and testing on BioDRB) settings. They find a very good performance of the BERT model, which they attribute to its "next sentence prediction" task in pre-training. Comparing the original BERT model to BioBERT (Lee et al., 2020), which was trained on biomedical text, they however find that BioBERT has only a limited ability for learning domain specific representations: Cross-domain performance is no better than for the BERT model, and in-domain performance improvements are moderate at only 1.5% points. Given that the entities play an important role in inferring implicit discourse relation in scientific texts, putting an emphasis on entities seems vital for achieving further improvements.

In contrast with previous studies that (largely unsuccessfully) attempted to train on explicit discourse relations for learning to classify implicit classifiers in supervised ways, such as Marcu and Echihabi (2002); Sporleder and Lascarides (2008); Biran and McKeown (2013); Qin et al. (2017); Shi et al. (2017) etc., we here propose an unsupervised voting pipeline and achieve good performance even comparing with supervised models like BERT and BioBERT. We believe that the key difference lies in the fact that previous methods tried to learn *surface cues* from explicit relations and tried to use them for implicits (which does not work, because these features differ between explicits and implicits, see e.g., Sporleder and Lascarides (2008); Asr and Demberg (2012)), while our method focuses on the content of the discourse relational arguments.

3 Unsupervised Method with Information Retrieval System

The successful usage of a memory network in Shi and Demberg (2019a) showed that instances that share the same relation have close representations. We believe that for sparse data like BioDRB, which has only around 2,000 labeled implicit instances in total, it is essential to use similar explicit instances to help find the latent patterns they share. In this section, we introduce an unsupervised method for implicit DRC, which is inspired by a recent information retrieval method.

The core idea is as follows: we use information retrieval methods to identify explicitly marked coherence relations from the corpus which are content-wise similar to the relation we want to la-

bel. We then automatically label these explicitly marked instances (relying on the high DRC accuracy of ca. 96% for explicit relations) and assign the majority label from the explicit instances to the implicit instance from our test set.

3.1 Retrieval of similar instances from a large corpus

Figure 1 illustrates the overall pipeline of the proposed method. First, each instance from BioDRB (Prasad et al., 2011) is seen as a query and fed into the PubMed[1] and PMC[2] databases.

PubMed and **PMC** are free full-text archives of biomedical and life sciences journal literature at NIH National Library of Medicine. The database we use here is a corpus created from a subset of the whole PubMed and PMC collections, consisting of 7,079 documents in total (1,376 for pubMed and 5,703 for PMC).

With the query and candidate documents, we employ TF-IDF to extract the top 10 relevant documents. The candidate documents are then fed into a discourse parser; we here use the PDTB-style end-to-end parser by Lin et al. (2014). The outputs of the parser contain the two arguments, the explicit discourse connective and a discourse relation label.

The Quasi Knowledge Graphs System, proposed by Lu et al. (2019), is designed to answer complex questions. It is a novel method that computes answers by dynamically building up a knowledge graph that fits the query. It consists of several steps including the extraction of subject-predicate-object (SPO) triples, knowledge graph construction, and a graph algorithm. We here only use the first step from this pipeline, extracting SPO triples, and actually only use the subject and object, not the predicate, to match with the noun phrases in the query. For example, from the relation instance in Example 1 above, the system would extract SPO triples *(NETosis, enhanced in, RA)* and *(autoantibodies, known risk factors for, RA)*, from which we further employ only *NETosis, RA; autoantibodies, RA*.

After extracting the SPO triples from all the explicit discourse instances, we employ two types of matching strategies to connect them with the query:

[2]PubMed Central (PMC) [Internet]. Bethesda (MD): National Library of Medicine (US), National Center for Biotechnology Information; 2000. Available from: https://www.ncbi.nlm.nih.gov/pmc/

Methods	Cross-domain
Majority class	20.66
Bai and Zhao (2018)	29.52
Bi-LSTM + Word2Vec	32.97
BERT	44.79
BioBERT	44.33
Hard-matching	35.29
Soft-matching	41.95

Table 1: Performances on BioDRB across domains. Across domains means that the model is trained on PDTB and tested on BioDRB. Majority class here is the majority relation of explicits.

(i) **Hard matching**, which means that if the subject or object appear in the query, we count it as a vote. (ii) **Soft matching**. We find that with the hard matching, lots of positive samples have been filtered out and very few explicit instances are identified. Therefore, we use the cosine similarity between the subject or object and the noun phrases in the query, to detect similar entities. Cosine similarities are estimated based on the BioBERT encoding of the entities. We define a threshold for deciding when an explicit instance is similar enough to be counted as a valid vote or not. It is seen in the training phase as a hyper-parameter to be fine-tuned on the validation set. This method for detecting similar explicit instances is also used in our second approach described in Section 4.

With the steps described above, eventually each query has been connected to a number of similar explicit instances and the prediction for the query is the majority vote from all of them with their explicit discourse sense labels.

3.2 Experiments and results

On average 813.99 explicit instances are extracted for each query. With the hard matching, 7.91 similar entities are matched with the Subject or the Object in the query. For the soft matching, we randomly choose 10% of the total instances acting as validation set in order to help set the threshold for the cosine similarity score.

The experimental results are shown in Table 1. We compare the results with related work by Bai and Zhao (2018) as well as several models reported in Shi and Demberg (2019b).

Our proposed unsupervised method achieves an accuracy of 35.29% with hard-matching and 41.95% with soft-matching. These results outper-

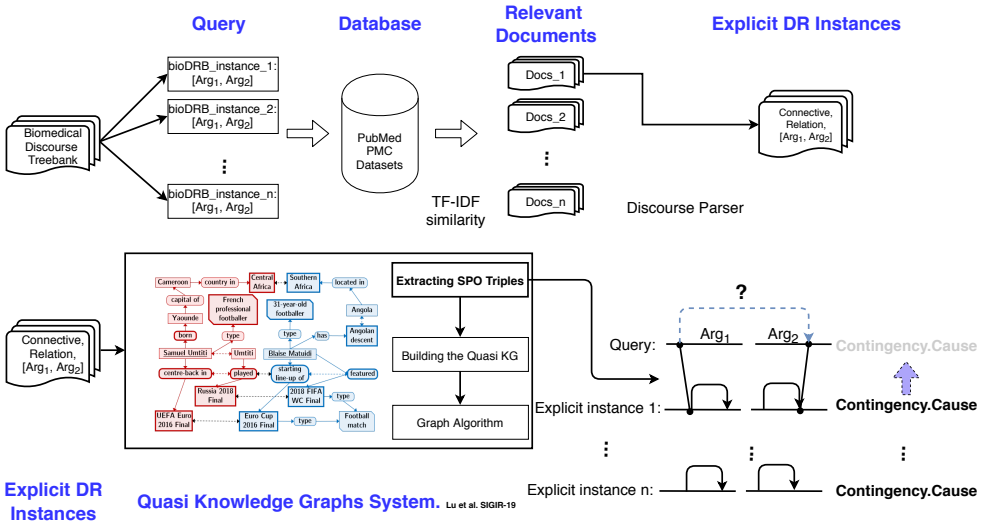

Figure 1: The Pipeline of the Proposed Method.

form other non-transformer approaches by a large margin. Comparing the hard and soft matching variants, our results show that identifying instances with similar entities leads to a larger set of relevant documents, which then help to increase robustness in the majority vote.

The table also shows that the approach almost reaches the performance of recent very strong transformer models: the BERT model achieves a performance of 44.79% accuracy in the cross-domain setting (Shi and Demberg, 2019b).

The approach proposed here could be further refined by using better argument representations than simple matching of subject and object entities, and by learning the classification decisions instead of using simple majority voting, and by moving to transformer architectures. Our second approach addresses these points by employing a transformer architecture which can take the SPO triple information into account for more richly encoding the relational arguments.

4 DRC with an entity-augmented transformer

Integrating external domain-specific knowledge into the model is beneficial for this task has been found by Kishimoto et al. (2018), who integrated the ConceptNet relations as additional knowledge into the LSTM network and achieved better performance on the PDTB.

We here aim to explore whether model performance can be further improved by exploiting richer entity representations in specialized texts

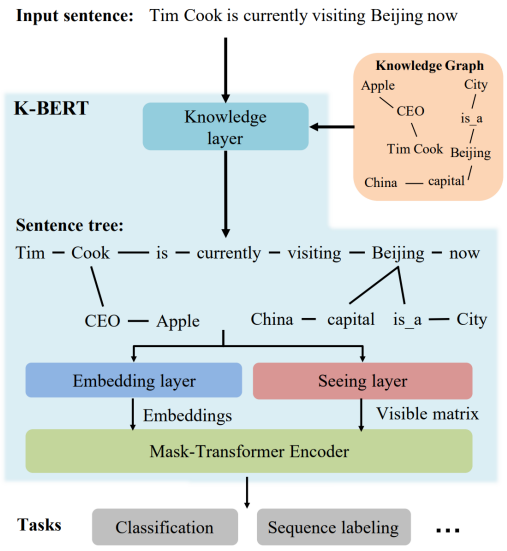

Figure 2: The structure of K-BERT. It is equipped with an editable knowledge graph which can be adapted to its application domain. Picture taken from Liu et al. (2020).

like the biomedical domain. The pipeline with soft-matching proposed in the above section provides us with SPO triples from related documents for each implicit relation instance in the test set. We here employ the recently proposed **Knowledge-enabled Language Representation model** (Liu et al., 2020, K-BERT) to integrate the external entity knowledge into the pre-trained language model for better argument representations.

4.1 K-BERT

Due to the domain gap between the pre-training and fine-tuning, unsupervised language models (such

as BERT etc.) do not perform well on knowledge-driven tasks (Liu et al., 2020). Integrating domain specific knowledge into pre-trained model can alleviate this problem. However, the process of knowledge acquisition can be inefficient and expensive.

In order to tackle the heterogeneous embedding space and knowledge noise problems, Liu et al. (2020) proposed a Knowledge-enabled Bidirectional Encoder Representation from Transformers (K-BERT), as illustrated in Figure 2. With the knowledge layer and the external knowledge graph, the input sentence has been expanded into a sentence tree, which is then fed into into the embedding layer and the "seeing" layer. The seeing layer controls when the model has access to the original sentence and when it has access to the additional information.

However, knowledge graphs are not available for all domains. We therefore here replace information from the knowledge graph with the SPO triples extracted from related raw texts. Compared to a general knowledge graph, our extracted SPO triples have attached more importance on the discourse relations since that they are extracted from the explicit instances, and are specifically selected to be on-topic. For each input sentence, we attach the top 2 (default number from the K-BERT) similar SPO triples to the entities and convert it into a sentence tree. We train K-BERT on the BioDRB as a classification task. The input sequence of the Example 1 is shown below, where the words in italics are the linked entities.

2. These abnormalities in active *NETosis enhanced in autoantibodies known risk factors for* RA *result in Neutrophil Chemotaxis* are thought to be induced mainly after chronic exposure to high concentrations of IL-6. The limited efficacy of IL-10 treatment of RA patients *reduced complement activation* may be explained in part by the unresponsiveness to IL-10 of inflammatory cells, including T cells *isolated from CTCL patient*.

The whole sentence tree has been flattened into a sequence with the position index. The visible matrix is generated to keep the interactions of each of the tokens within the original sentence and also inside the knowledge graph triples. The visible matrix controls the self-attention layers in the transformer not to look into tokens other than the corresponding entities.

Methods	In-domain
Bai and Zhao (2018)	55.90
Bi-LSTM + Word2Vec	46.49
BERT	63.02
BioBERT	67.58
proposed model using K-BERT	**69.57***

Table 2: Performances on BioDRB within domain. Within domain here means 5-folds cross validation (see also Shi and Demberg (2017)) on BioDRB. * denotes significant improvement over BioBERT with $p<0.05$.

4.2 Experiments and Results

The experimental results are illustrated in Table 2. We compare the results with the previous state of the art on the BioDRB dataset (Shi and Demberg, 2019b). K-BERT, which is initialized with the original BERT parameters, achieves 69.57% accuracy and outperforms BERT without entity augmentation by 6.5% points, and the the gigantic in-domain continuously pre-trained BioBERT by around 2%. In addition, we tried to remove the relevant entities. The model then performed similar to the basic BERT, which is consistent with the results reported in Liu et al. (2020). These results confirm that adding related entities improves argument encoding and help improve the DRC task.

5 Conclusion

In this paper, we address the task of implicit discourse relation classification on BioDRB in the biomedical domain. Due to the importance of entities in scientific text, we decided to address this problem by identifying explicitly marked relations containing the same instances, and using a simple majority voting system. While this setting showed good performance in the unsupervised setting, much better results are achieved when at least a small amount of labelled data is available. We show that when a transformer model is augmented with entity information from the domain, the previous state of the art on the task is exceeded by 2% points.

Unsupervised Pronoun Resolution via Masked Noun-Phrase Prediction

Abstract

In this work, we propose Masked Noun-Phrase Prediction (MNPP), a pre-training strategy to tackle pronoun resolution in a fully unsupervised setting. Firstly, We evaluate our pre-trained model on various pronoun resolution datasets without any finetuning. Our method outperforms all previous unsupervised methods on all datasets by large margins. Secondly, we proceed to a few-shot setting where we finetune our pre-trained model on WinoGrande-S and XS separately. Our method outperforms RoBERTa-large baseline with large margins, meanwhile, achieving a higher AUC score after further finetuning on the remaining three official splits of WinoGrande.

1 Introduction

Co-reference resolution is an important NLP task that aims to find all expressions that refer to the same entity in a text. The resolution of an ambiguous pronoun, known as pronoun resolution, is a longstanding challenge for the NLU community and an essential step for various high-level NLP tasks such as natural language inference (Bowman et al., 2015; Williams et al., 2018), question answering (Rajpurkar et al., 2016), and relation extraction (Zhang et al., 2017).

The most successful approach to pronoun resolution is first fine-tuning a large pre-trained language model such as BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019) on a human-labeled pronoun resolution dataset such as Definite Pronoun Resolution Dataset (DPR) (Rahman and Ng, 2012) or WinoGrande (WG) (Sakaguchi et al., 2020), and then either directly transferring to a smaller dataset such as Winograd Schema Challenge (WSC) (Levesque et al., 2012) or Pronoun Disambiguation Problems (PDP) (Morgenstern et al., 2016) or further finetuning on a downstream dataset such as SuperGLUE-WSC (Wang et al., 2019a). However, all the pipelines above can not avoid the phase of pre-training on a large human-labeled pronoun resolution dataset. Crowd-sourced "unbiased" labels that do not introduce annotation-artifacts (Gururangan et al., 2018) are shown to be costly and challenging to collect, requiring a well-designed annotation interface and dedicated annotators. To this end, we propose the unsupervised Masked Noun-Phrase Prediction task to pre-train a language model without any pronoun resolution training signal and directly transfer the pre-trained model to downstream datasets such as WSC.[1] Two examples of WSC are listed in Table 1. Our work improves on all previous unsupervised methods by large margins and even outperforms several strong supervised methods on all datasets we study.

WSC Sentences	Candidate Choices
The trophy doesn't fit in the suitcase because **it** is too small.	**A.** the trophy **B.** the suitcase
The trophy doesn't fit in the suitcase because **it** is too big.	**A.** the trophy **B.** the suitcase

Table 1: Above are two WSC examples. A system is required to resolve the bold pronoun **"it"** to "the suitcase" in the first sentence and to "the trophy" in the second sentence.

We then proceed to the few-shot setting where we finetune our best zero-shot model on WinoGrande-S and XS respectively. MNPP gives a large margin of improvements over strong baselines including CSS (Klein and Nabi, 2020), RoBERTa-large (Sakaguchi et al., 2020), and UnifiedQA-BART-large (Khashabi et al., 2020). We further finetune on the remaining three data splits and achieve a higher AUC score on all five splits of WinoGrande over RoBERTa-large baseline.

*Equal Contribution

[1] We refer to unsupervised or zero-shot transfer as without training on any pronoun resolution dataset.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 932–941
August 1–6, 2021. ©2021 Association for Computational Linguistics

In summary, our main contributions in this work are threefold.

- **First**, we propose the MNPP pre-training task and study how different synthetic dataset properties affect zero-shot performances.
- **Second**, we show MNPP outperforms all previous fully unsupervised methods and even several strong supervised baselines on all pronoun resolution datasets we study.
- **Finally**, we show that under few-shot settings, MNPP pre-training gives a significant performance boost on WinoGrande-S and XS and furthermore achieves a higher AUC score over all five splits of WinoGrande.

2 Related Works

In this work, we mainly compare with unsupervised methods.[2] On WSC, Zhang and Song (2018) propose the first unsupervised model where they modify Skip-Gram (Mikolov et al., 2013) objective to predict semantic dependencies then use this additional information during testing. Wang et al. (2019b) propose Unsupervised Deep Structured Semantic Models (UDSSM), which utilizes BiLSTM (Hochreiter and Schmidhuber, 1997) to compute contextual word embedding and uses models ensemble. Klein and Nabi (2019) directly explore the inner attention layers of BERT. Ye et al. (2019) adapt a masking and predicting strategy, called align, mask, and select (AMS), where entities that are connected with ConceptNet (Speer and Havasi, 2012) are masked and the model is required to select from a given list of candidate entities. An ensemble of large pre-trained models is first utilized by Trinh and Le (2018). GPT-2 is directly evaluated on WSC in Radford et al. (2019). Prakash et al. (2019) extend a language model with a knowledge hunting strategy. Kocijan et al. (2019b) and Kocijan et al. (2019a) are the most similar works to us and we will discuss the details in Section 3.1. Most recently, Klein and Nabi (2020) study a contrastive self-supervised learning approach (CSS) for WSC and DPR and also establish the first unsupervised baseline for KnowRef (Emami et al., 2019). On WinoGrande, knowledge hunting (Prakash et al., 2019) and language models ensemble (Sakaguchi et al., 2020) have been studied.

[2]Please refer to supplemental materials for more details on supervised methods.

3 Masked Noun-Phrase Prediction

We treat MNPP as a binary classification task. Given the sentence: *"She put the cup on the chair, but he knocked over the chair, and the cup fell."*, the underlined *"the chair"* will be masked and a pair of replacement phrases for this masked position is given as {*"the cup"*, *"the chair"*}. One of the candidates is the masked phrase,*"the chair"*, and the other candidate is a different phrase in the sentence, *"the cup"* extracted from *"She put the cup on the chair"*. The constraint we impose is that both the ground-truth noun-phrase and the alternative candidate need to appear before the masked phrase location, which mimics the pronoun resolution task. We sample sentences following the above constraint to create our synthetic datasets for pre-training.

We convert the sentence into the format of {[CLS] *first_half* **option** *second_half* [SEP]} where *first_half* refers to *"She put the cup on the chair but he knocked over "* and *second_half* refers to *", and the cup fell."*. The **option** is replaced by candidates, *"the cup"* or *"the chair"*. We compute P(*the chair*|*sentence*, θ) and P(*the cup*|*sentence*, θ) and optimize θ, the parameters of the model, using cross-entropy loss. We use the final layer [CLS] vector from transformer-based language models and pass it through a single layer feed-forward network to calculate the logits.

3.1 Discussion

The intuition behind MNPP is that given sufficient samples that mimic pronoun resolution task, the model can learn rich knowledge to perform well on human-annotated pronoun resolution datasets. Such idea is also in-line with recent advances in unsupervised QA (Lewis et al., 2019; Li et al., 2020; Banerjee and Baral, 2020; Banerjee et al., 2020, 2021), where synthetic QA datasets are created from unannotated corpora to perform unsupervised pre-training. Strictly speaking, MNPP is even more unsupervised since our synthetic datasets are not created with true pronoun resolution signals, whereas synthetic QA datasets in works cited above contain true question-answer pairs.

As mentioned in previous Section 2, similar to our work, Kocijan et al. (2019b) studied such pre-training strategy by constructing a synthetic dataset, called MaskedWiki, which is crawled from English Wikipedia. However, our work is significantly different from theirs in the following ways. First, their

Dataset \ Source	CNN	QUOREF	Gutenberg	Knowledge	Total
Hybrid Source	100,556	51,451	6,381	-	158,388
Hybrid Source w/ Knowledge	189,376	98,844	19,424	75,993	383,637

Table 2: Number of instances from each source of two hybrid-source synthetic datasets in the first group.

Synth. Dataset \ Downstream	WinoGrande (AUC)	WSC	DPR	KnowRef	COPA
Hybrid Source (160k)	58.08 (**0.6961**)	**79.48**	82.27	79.83	71.29
Hybrid Source w/ Know. (380k)	58.56 (0.6821)	78.39	**83.88**	79.04	73.27
Gutenberg-10k	57.93 (-)	75.09	81.21	77.15	79.21
Gutenberg-50k	57.40 (-)	76.19	77.84	75.10	74.26
Gutenberg-100k	58.56 (-)	72.53	75.00	74.40	75.25
Gutenberg-300k	57.38 (-)	75.82	81.56	76.44	78.22
Gutenberg-500k	**59.19** (0.6748)	76.56	80.50	79.12	**85.51**
Gutenberg-Easy (33k)	56.43 (-)	69.60	70.92	75.10	77.23
Gutenberg-Medium (33k)	57.00 (-)	75.10	80.32	78.17	79.21
Gutenberg-Hard (33k)	57.54 (-)	75.82	80.67	**79.98**	74.36

Table 3: Zero-shot transfer performances (%) on downstream datasets. AUC scores of WinoGrande are calculated after finetuning on all 5 splits of WinoGrande training sets. Difficulty level is decided using cosine similarity between the two candidate word vectors. Hard samples are the top 33% of samples when they are sorted in descending order using similarity score. Easy are bottom 33%, with Medium in-between.

pipeline requires further finetuning on another pronoun resolution task before transferring to downstream datasets, whereas our method can be directly evaluated on downstream datasets. Second, the size of MaskedWiki is 2.4 millions, which is 15 times the size of our best performing synthetic dataset. Third, we study how different properties of synthetic datasets affect zero-shot performances. Finally, they use a masked token prediction loss, and we model it as a classification task. Kocijan et al. (2019a) also construct another synthetic dataset called WikiCREM following the same masking principle but with only personal names masked.

4 Experiments and Results

4.1 Synthetic Dataset

We study three properties of synthetic dataset: source style, size, and difficulty level. The sources we choose include various styles of texts, including CNN stories (See et al., 2017), Wikipedia, and PG-19 language modeling benchmark (Rae et al., 2020). We study 3 groups and a total of 10 different synthetic datasets. The first group contains two synthetic datasets collected from all sources with and without knowledge hunting strategy (Prakash et al., 2019). The second group contains five synthetic datasets collected only from PG-19 but with varying sizes from 10k to 500k. The third group contains three synthetic datasets collected from PG-19 but with easy, medium, and hard samples with the same size of 33k each.[3] Datasets' names are listed in the first column of Table 3 and statistics of the first group are described in Table 2.

4.2 Unsupervised Pronoun Resolution

The downstream datasets we test on are the WinoGrande test set (17k instances), DPR test set (564 instances), KnowRef test set (12k instances), and COPA validation set (101 instances). Although COPA (Wang et al., 2019a) is a cause and effect identification dataset, Sakaguchi et al. (2020) show that directly transferring from a WinoGrande-finetuned RoBERTa-large model to COPA already achieves a good performance, indicating that finetuning on WinoGrande can serve as a resource for common sense knowledge. We also investigate whether learning through MNPP can serve as a resource for common sense. Note that we also provide evaluation on the GAP dataset (Webster et al., 2018) in Table 5 for reference although the authors of GAP explicitly mention in their paper that they urge the community to not treat GAP as a Winograd-style task but a co-reference resolution task without gold mention provided.

4.2.1 Results

We report our experiment results in Table 3 and Table 4. Table 3 shows that different downstream

Table 4: Comparisons of zero-shot transfer performance (%) among baselines and MNPP. Works highlighted with gray are supervised methods either directly finetuned on downstream datasets or additionally finetuned on another pronoun resolution dataset. Works highlighted with cyan are fully unsupervised methods. Best performances are in bold. We also underline supervised methods that our method outperforms. Note that AUC score for MNPP is obtained after finetuning on all WinoGrande data splits. (Model-A-B stands for model finetuned on A and B sequentially.)

dataset benefits from different property of the synthetic dataset. The hybrid-source synthetic dataset of size 160k outperforms PG-500k by a large margin on both WSC and DPR. It shows that pre-training on text of various styles instead of larger size is probably a better guarantee for better zero-shot performance on WSC and DPR. However, on WinoGrande and KnowRef, text style and dataset size both seem to impact zero-shot performance. On WinoGrande, larger size matters slightly more, whereas on KnowRef, synthetic dataset with various styles of texts gives better performance. On COPA, it is clear that using books as the source and with larger size at the same time is the key, probably because fictional event descriptions describing day-to-day activities in books contain more common sense, whereas CNN or Wikipedia articles contain precise, factual, non-fictional event descriptions. Finally, pre-training on more challenging examples helps on all tasks except COPA.

Compared with previous methods in Table 4, MNPP outperforms all unsupervised methods on all datasets and is comparable with several strong supervised methods. Current best unsupervised methods on WinoGrande is either random guess or below it, however, MNPP outperforms all of them by a margin of at least 8%. Even compared with a supervised baseline where BERT is first finetuned on DPR, our method outperforms it by 8%. On WSC, MNPP also outperforms all SOTA unsupervised methods by more than 8% and outperforms most supervised methods by at least 4% except RoBERTa-large finetuned on another pronoun resolution dataset. On DPR, our method outperforms the SOTA unsupervised baseline over 3% and also achieves only 1% behind the strong supervised baseline that finetunes BERT on MaskedWiki and DPR sequentially or only on WinoGrande. On KnowRef, MNPP outperforms the only unsuper-

	M	F	B	O
BERT (Kocijan et al., 2019a)	75.3	75.1	1.00	75.2
CorefBERT$_{\text{LARGE}}$ (Ye et al., 2020)	-	-	-	76.8
BERT-WIKICREM-GAP (Kocijan et al., 2019a)	76.4	78.4	1.03	77.4
CorefRoBERTa$_{\text{LARGE}}$ (Ye et al., 2020)	-	-	-	77.8
BERT-WIKICREM-ALL-GAP (Kocijan et al., 2019a)	76.7	79.4	1.04	**78.0**
BERT-WIKICREM (Kocijan et al., 2019a)	60.5	57.5	0.95	59.0
MNPP (this work)	71.3	75.2	1.05	**73.3**

Table 5: Performance comparisons among previous works and MNPP on GAP measured in F1. M stands for male, F stands for female, B stands for bias, and O stands for overall. Works highlighted with lightgray are supervised methods and works highlighted with cyan are fully un-supervised methods.

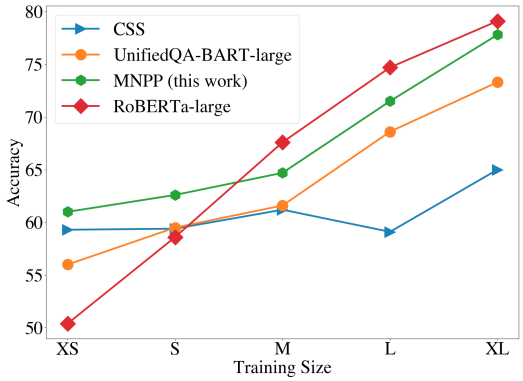

Figure 1: Performances (%) on WinoGrande test set after finetuning on 5 sizes of WinoGrande training set.

vised baseline by nearly 15% and achieves only 5% behind SOTA supervised model. Finally, on COPA, we show that MNPP gives models better common sense knowledge than finetuning on WinoGrande.

Meanwhile, we are not surprised that SOTA supervised methods still outperform unsupervised methods, including ours, considering the supervision itself and huge models with billions of parameters such as T5-11B.

4.3 Few-Shot Pronoun Resolution

We further proceed to the few-shot setting on WinoGrande-S and XS. We take the top three performance zero-shot models on WinoGrande development set and finetune them on WinoGrande-XS (160 instances) and S (640 instances) separately. After few-shot evaluation, we also finetune on the remaining three data splits, which are WinoGrande-M, L, and XL. Best performances on all 5 data splits are reported in Fig. 1 and AUC scores are reported in thrid column of WinoGrande section in Table 4.

4.3.1 Results

As indicated in Figure 1, MNPP outperforms CCS, UnifiedQA-BART-large, and RoBERTa-large on WinoGrande-S and XS with a large margin, and more importantly, achieves a higher AUC score as indicated in Table 4. It is clear that MNPP pretraining gives the model crucial additional information in the few-shot setting where only minimal data is available. We also notice that in the AUC column of Table 3, there is a negative correlation between zero-shot performance and AUC score, which means higher zero-shot performance does not guarantee better finetuning results.

Again we need to mention that we are not comparing with SOTA performances from billions-parameters models such as UnifiedQA-T5-11B from Khashabi et al. (2020) or T5-3B from Lin et al. (2020).

5 Conclusion

In this work, we propose MNPP pre-training to tackle unsupervised pronoun resolution and study how different properties of the synthetic pre-training dataset impact zero-shot performance on downstream datasets. Without finetuning on any pronoun resolution signal, MNPP outperforms all previous fully unsupervised methods on all tasks we study and even several strong supervised baselines. In the few-shot case where we finetune the zero-shot transfer model on WinoGrande-S and XS respectively, our model outperforms baselines by large margins, and further achieves a higher AUC score.

This work shows the effectiveness of unsupervised task definitions on text-based pronoun-resolution and common sense reasoning tasks. It would be interesting to design such tasks for multi-modal common sense reasoning (Zellers et al., 2019; Fang et al., 2020).

A Related Work on Supervised Methods

WSC & DPR. Opitz and Frank (2018) is the first work to propose transfer learning from another pronoun resolution dataset such as DPR to WSC. He et al. (2019) use a hybrid model of Wang et al. (2019b) and Kocijan et al. (2019b). Ruan et al. (2019) explore BERT's next sentence prediction with finetuning on DPR. Ye et al. (2020) finetune a new language representation model called CorefBERT, which is trained with a novel task to strengthen the co-referential reasoning ability of BERT, on DPR and then test on DPR and WSC. The SOTA supervised performance is provided by Sakaguchi et al. (2020) where they finetune a RoBERTa-large model on WinoGrande or DPR and evaluate on WSC and DPR without and with further finetuning. A detailed review of WSC and WSC related dataset can be found at Kocijan et al. (2020).

KnowRef. In Emami et al. (2019), an end-to-end neural system (Lee et al., 2018) is trained on CoNLL2012 shared task (Pradhan et al., 2012) and then tested under three settings: directly applying to KnowRef test set, retraining on KnowRef, and retraining on KnowRef plus CoNLL2012. Sakaguchi et al. (2020) transfer a WinoGrande-finetuned RoBERTa-large model and DPR-finetuned RoBERTa-large model to KnowRef test set respectively.

WinoGrande. The authors of WinoGrande finetune a RoBERTa-large on WinoGrande training set and evaluate on the test set in standard supervised setting, and Lin et al. (2020) finetune a T5-3B model instead. Sakaguchi et al. (2020) also study finetuning BERT and RoBERTa with only local context (only tokens near the pronoun location are available instead of the whole sentence). Ye et al. (2020) finetune WinoGrande using CorefBERT. Klein and Nabi (2020) finetune their unsupervised CSS model. Finally, UnifiedQA (Khashabi et al., 2020), which is pre-trained on eight seed QA datasets spanning four different formats in a unified way, is finetuned on WinoGrande.

B Synthetic Datasets Construction

For the first synthetic dataset in the first group, we choose 5000 stories in CNN stories, a small portion of Gutenberg books, and the whole training set of QUOREF (Dasigi et al., 2019), which is a reading comprehension dataset that requires resolving coreference among entities crawled from Wikipedia, and these sources result in the size of 160k. The second synthetic dataset in the first group comprises the same sources as above plus extra knowledge crawled by Google query using the knowledge hunting strategy introduced in Prakash et al. (2019). Following their strategy, we scrap 6531 and 69462 knowledge sentences for WSC and WinoGrande respectively. We relax the filtering process to allow longer sentences than those in the first synthetic dataset and lead to 380k samples in total. We then fix the text style and study the influence of data size on pre-training. We use 2000 books from PG-19 as the source and create five synthetic datasets with size of 500k, 300k, 100k, 50k, and 10k as the second group. We further study how difficulty levels of samples affect the downstream zero-shot performance. We select 100k samples from the PG-19 books described above and evenly split them into three synthetic datasets with low, medium, and high similarity scores between candidate choices as the third group. As a result, we create 3 groups of synthetic datasets with ten synthetic datasets in total. We used spaCy[4] to pre-process raw text, including removing blank spaces, special characters, sentences that are too short or too long, and extracting noun-phrases.

C Zero-shot Experiment Details

Recent study (Khot et al., 2020) has shown that finetuning a RACE-finetuned (Lai et al., 2017) RoBERTa model as a start point is much more stable than directly finetuning a RoBERTa model from scratch, we follow the same strategy to start finetuning a RACE-finetuned RoBERTa-large model on all synthetic datasets. We use Hugging Face Transformers[5] as our codebase. We set Adam optimizer with an initial learning rate of $1e-5$ and epsilon of $1e-8$, and without weight decaying for all settings. For a synthetic dataset whose size is larger or equal to 100k, we choose the batch size of 32 and train for 20 epochs, otherwise, we choose the batch size of 16 and train for 50 epochs. We checkpoint every X steps, with X in [50,500].

D Few-shot Experiment Details

We set Adam optimizer with an initial learning rate of $1e-5$ and epsilon of $1e-8$, without weight decaying, and batch size between 16 and 32 for all

[4] https://spacy.io/
[5] https://github.com/huggingface/

sizes. We finetune 20 epochs for WinoGrande-XL, L, and M, 40 epochs for S, and 160 epochs for XS. We checkpoint every X steps, with X in [50,500].

Addressing Semantic Drift in Generative Question Answering with Auxiliary Extraction

Abstract

Recently, question answering (QA) based on machine reading comprehension has become popular. This work focuses on generative QA which aims to generate an abstractive answer to a given question instead of extracting an answer span from a provided passage. Generative QA often suffers from two critical problems: (1) summarizing content irrelevant to a given question, (2) drifting away from a correct answer during generation.

In this paper, we address these problems by a novel Rationale-Enriched Answer Generator (REAG), which incorporates an extractive mechanism into a generative model. Specifically, we add an extraction task on the encoder to obtain the rationale for an answer, which is the most relevant piece of text in an input document to a given question. Based on the extracted rationale and original input, the decoder is expected to generate an answer with high confidence. We jointly train REAG on the MS MARCO QA+NLG task and the experimental results show that REAG improves the quality and semantic accuracy of answers over baseline models.

1 Introduction

Question Answering (QA) has come a long way from answer sentence selection, relationship QA to machine reading comprehension (MRC). Recently, QA has become an essential problem in natural language understanding and a major milestone towards human-level machine intelligence. Current mainstream approaches (Chen et al., 2017; Wang et al., 2018; Yan et al., 2018) treat MRC as a process of extracting a consecutive piece of text from a document to a given question.

Despite the great success in extractive MRC (Wang et al., 2018; Chen et al., 2020), in real-world applications, correct answers may span different passages or even not be literally present in the passages. Directly extracting a consecutive answer span is often inadequate. Therefore, the ability of generating an abstractive answer is needed, which requires a QA model to summarize the main content in a paragraph that is relevant to a given question.

Question	does gameplay programmer need math skill
Passage	A good computer programmer is more of a problem solver and logical thinker than a math buff. Besides, the industry is peppered with many computer programmers who do not really know much about mathematics.
Gold	no, gameplay programmer does not need math skill.
PALM	yes, gameplay programmer is a math buff.
REAG	no, gameplay programmer does not need math skill.

Table 1: An example of the "semantic drift" issue in generative reading comprehension from the MARCO dataset (Nguyen et al., 2016). The text span of words in blue is the rationale extracted by REAG.

Answering questions in natural language can be beneficial to a variety of QA applications, and has led to the development of smart devices such as Siri, Cortana and Alexa. However, compared with answer extraction, answer generation for reading comprehension is more challenging, and has been less explored. A major challenge in generative reading comprehension comes from out-of-control generation of abstractive answers. Although much work has been done in neural language generation (NLG), e.g., KIGN(Li et al., 2018) for summarization, out-of-control generation remains an open question for generative QA which aims to produce correct and coherent answers. Specifically, we observed that generative models often generate answers semantically drifting away from the given

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 942–947
August 1–6, 2021. ©2021 Association for Computational Linguistics

passage and question, known as the "semantic drift" problem. As shown in Table 1, the baseline generative model PALM (Bi et al., 2020) generates an answer that has almost contrary semantics with the gold answer. In general, a generative model often suffers from two critical problems: (1) summarizing content irrelevant to a given question, and (2) drifting away from a correct answer during generation.

In this paper, we address these problems by a novel Rationale-Enriched Answer Generator (REAG), which incorporates an extractive mechanism into a generative model in order to leverage relevant information to a given question in the contextual passage. Specifically, we add an extraction task on the encoder to obtain the rationale for an answer, which is the most relevant piece of text in an input document to the given question. On one hand, the introduction of the supervised extraction task enables the encoder to learn the relevance between a question and a passage; On the other hand, the extracted rationale can be further used to guide the answer generation. Based on the extracted rationale and original input, the decoder is expected to summarize content relevant to a given question and generates an answer with high confidence. Finally, we jointly train REAG on the MS MARCO QA+NLG task based on the common bottom layers. The experimental results show that REAG improves the semantic accuracy of answers over the other state-of-the-art models.

2 Related Work

2.1 Machine Reading Comprehension

In recent years, machine reading comprehension has made great progress with the development of SQuAD (Rajpurkar et al., 2016) and MS MARCO (Nguyen et al., 2016). The current mainstream studies treat machine reading comprehension as answer span extraction from one passage (Rajpurkar et al., 2016, 2018) or multi-passages (Nguyen et al., 2016), which is usually done by predicting the start and end position of an answer. SLQA (Wang et al., 2018) improved answer quality with a hierarchical attention fusion network, which conducted attention and fusion horizontally and vertically across layers between a passage and a question. Recently, the BERT model Devlin et al. (2019) has proved effective for reading comprehension via unsupervised pre-training.

2.2 Generative Reading Comprehension

Bi et al. (2019) proposed a Knowledge-Enriched Answer Generator (KEAG) to compose a natural answer by exploiting and aggregating evidence from all four information sources available: question, passage, vocabulary and knowledge. Nishida et al. (2019a) proposed a multi-style generative model to generate an abstractive summary from the given question, passages and multi-style.

2.3 Reliable Text Generation

Compared with answer extraction, answer generation for reading comprehension is more challenging, and the major challenge in generative reading comprehension lies in out-of-control generation. Recently, some studies have been carried out on increasing the reliability of generation in the encoder-decoder framework(Liu et al., 2018; Li et al., 2018).

3 Rationale-Enriched Answer Generation

3.1 Rationale Span Extraction

In a generative reading comprehension task, every answer has its corresponding rationale, an extractive span in the passage, which can be derived by matching the passage text with the answer. The rationale can usually be located in a certain continuous area of the passage. We use continuous text span as the rationale to minimize the difficulty of the extraction task. Compared with the gold answer, the text span with the highest F1-score in passage is identified as the rationale for training supervision.

Based on the identified rationale, we introduce a rationale extraction task into the encoder. It enables the encoder to learn the relevance between the input question and the passage. Specifically, the encoder predicts whether each token of the passage should be included in the rationale. Every token in the rationale is labeled by 1 and the rest is labeled by 0.

Given input question Q and passage P, we first concatenate them together into an input sequence $X = \{x_1, x_2, ..., x_N\}$. Then we use a shared word embedding layer to project each of the vectors into d-dimensional vectors, and add to each the corresponding position embedding. The resulting vectors are then fed into the Transformer encoder to map the text into a sequence of encoder hidden states $\{h_1, h_2, ..., h_N\}$.

The encoder hidden states can be used to predict whether each token of the passage should be included in the rationale. Therefore, we add a fully connected layer with the sigmoid activation on top of the encoder, to compute the probability for each input word:

$$p_i^r = \text{sigmoid}(w_1 \cdot \text{relu}(W_2 h_i)) \quad (1)$$

where $h_i \in R^d$ is the output hidden state of the encoder for the i^{th} token.

This gives the probability p_i^r that the i^{th} token should be included in the rationale. We then calculate the averaged cross entropy, similar to(Ju et al., 2019), for the rationale extraction loss:

$$\mathcal{L}_{RE_j} = -\frac{1}{N}\sum_{i=1}^{N}(y_{ji}^r \log p_{ji}^r + (1-y_{ji}^r)\log(1-p_{ji}^r)), \quad (2)$$

where N is the number of input tokens. y_i^r is the rationale label for the i^{th} token, and $\mathcal{L}_{RE_j}$ represents the rationale loss for the j^{th} example in the training set.

3.2 Rationale-Enriched Answer Generation

This layer uses a stack of Transformer decoder blocks on top of the embeddings provided by the encoder's word embedding layer. The decoder is similar in structure to the encoder except that it includes a standard attention mechanism after each self-attention layer that attends to the output of the encoder. The rationale-aware hidden states output by the encoder are used for rationale extraction.

In calculating the decoder states s_t, an cross attention is introduced into the decoder to attend to the rationale-aware encoder hidden states. This results in the rationale-aware decoder hidden state s_t:

$$p(y_t|y_1, ..., y_{t-1}) = \text{softmax}(W^e(W^v s_t + b^v) + b^e) \quad (3)$$

During training, we minimize the negative log-likelihood of the answer word at each decoding time step. Let y_t^* denote the target word in the decoding time step t. The overall loss is then defined as:

$$\mathcal{L}_{GEN} = -\frac{1}{T}\sum_{t=1}^{T}\log p(y_t^*|y_1^*, ..., y_{t-1}^*, x, \theta) \quad (4)$$

where T denotes the length of a gold answer.

3.3 Joint Training and Prediction

The rationale extraction task and the answer generation task are designed to share the same embedding and the encoder. Therefore, we propose to train them together as multi-task learning. The joint objective function is formulated as follows:

$$\mathcal{L} = \mathcal{L}_{GEN} + \beta\mathcal{L}_{RE} \quad (5)$$

where β is a hyper-parameter that controls the weight of the rationale extraction task. During the training process, we use a linear decay schedule on the value of β, in order to rely more on the rationale extraction task for addressing the semantic drift problem at the early stage, following by more focus on the target generation task subsequently.

4 Experiments

4.1 Experiment Configuration

Dataset and Evaluation Metric. Given our objective of generating natural answers by document reading, the MARCO dataset [1] (Nguyen et al., 2016) released by Microsoft is a good fit for benchmarking REAG and other answer generation methods. We use the latest MARCO V2.1 dataset and focus on the "QA + Natural Language Generation" task in the evaluation. The data has been split into a training set (150k QA pairs), a dev set (12k QA pairs) and a test set (110k questions). Since true answers are not available in the test set and the task is retired now, we hold out the dev set for evaluation in our experiments, and test models for each question on its associated passages by concatenating them all together. Following Bi et al. (2019), we tune the hyper-parameters by cross-validation on the training set.

Implementation Details. Our REAG is based on PALM (Bi et al., 2020), an encoder-decoder generative language model pre-trained on a large corpus. It consists of a 12-layer encoder and 12-layer decoder with 768 embedding/hidden size, 3072 feed-forward filter size and 12 attention heads. REAG is trained with a dropout of 0.1 on all layers and attention weights. During training and testing, we truncate the text to 512 tokens and limit the length of the answer to 50 tokens. At test time, answers are generated using beam search with a beam size 5.

✗ pre-training	69.54	68.12

Table 3: Ablation tests of REAG on the MARCO Q&A+NLG dataset.

4.2 Model Comparisons

Table 2 gives the comparison of other state-of-the-art QA models on the MARCO Q&A+NLG dataset in ROUGE-L and BLEU-1. From this table, we observe that generative QA models (e.g., REAG, PALM) are consistently superior to extractive models (e.g., BiDAF) in answer quality. Therefore, generative QA models establish a strong base architecture to be enhanced with the extra signals, which motivates this work. Among the generative models, REAG outperforms all the other state-of-the-art models with an improvement of over 2.8% BLEU-1 point and 1.1% ROUGE-L. Part of the results in the Table 2 are from (Bi et al., 2019), which re-running other researchers' code.

4.3 Ablation Study

We conduct ablation studies to assess the individual contribution of every component in REAG. Table 3 reports the results of full REAG and its ablations on the MS MARCO Q&A NLG dataset.

We evaluate how much rationale-span extraction contributes to generation quality by removing it from the REAG model. This ablation results in a drop from 70.98 to 69.87 on Rouge-L, demonstrating the role of the rationale-span extraction in REAG. In addition, we ablate the linear-decay joint-training which proves to be critical with over 0.5% drops on the metrics after the ablation. In order to exclude the influence of the pre-trained model, we ablate pre-training, retaining the rationale-span extraction. This ablation leads to a drop from 70.98 to 69.54 on Rouge-L, which demonstrates the power of REAG in generating high-quality answers without pre-training.

Method	Semantic Acc	ROUGE-L	BLEU-1
PALM	81.67	69.87	66.31
REAG	**84.33**	**70.31**	**68.59**

Table 4: Comparison of the semantic accuracy, ROUGE-L and BLEU-1 of REAG with those of PALM

	ROUGE-L	BLEU-1
Generated Answers	47.25	50.34
Gold Answers	38.14	43.12

Table 5: Agreement of generated/gold answers with extracted rationales for REAG

4.4 Quantitative Analysis on Semantic Drift

For generative reading comprehension, it is difficult to make the answer completely correct, because even if the semantics are correct, there may be some expression differences from the gold answer. Since neither ROUGE-L nor BLEU-1 can measure it, we conduct a human evaluation of the semantic accuracy. We randomly select 100 questions from the MARCO dev set, and manually evaluate whether the generated answers to these questions are semantically drifted. Table 4 reports the semantic accuracy of REAG and PALM obtained by human. Our REAG model surpasses PALM in generating correct answers without semantic drift. Although our REAG model improves over PALM by 1.1% in automatic evaluation metric ROUGE-L, it gives a 3.26% improvement in semantic accuracy. This shows the fact that in some cases automatic evaluation metrics, such as ROUGE-L and BLEU-1, do not reflect semantic accuracy.

In addition, we compute the agreement of generated/gold answers with extracted rationales for

Example 1	
Relevant Passage	Yes | No Thank you! Flu shots are not made for children under the age of 6 months. If you read the vaccine insert and studies regarding the flu shot and kids, you will see that flu shots don't even work for children under the age of 2.
Question	can a child get a flu vaccine under 6 months?
Gold Answer	No, a child under 6 months can't be given a flu vaccine.
PALM Answer	Yes, a child can get a flu vaccine under 6 months.
REAG Answer	No, a child cannot get a flu vaccine under 6 months.

Example 2	
Relevant Passage	Modesto, Stanislaus County Sales Tax Rate. Details. The sales tax in Modesto is 7.625%, which is about average for cities in Stanislaus County and lower than average for California (8%). Modesto is one of 21 cities in Stanislaus County with a distinct sales tax as listed by the California Board of Equalization. See all cities in Stanislaus County. Advertisement.
Question	what is the sales tax in california
Gold Answer	The sales tax in California is 8%.
PALM Answer	The sales tax in California is 7.625%
REAG Answer	The sales tax in California is 8%

Table 6: Examples of the output of REAG and PALM on the MARCO dataset. The text span of words in blue is the rationale extracted by REAG

REAG in ROUGE-L and BLEU-1. As shown in Table 5, the generated answers are strongly correlated with the rationales, demonstrating the effectiveness of leveraging the rationale signal. Also, the fact that the gold answers have a lower agreement with the rationales indicates that a generative model, as opposed to an extractive one, is needed for the MARCO Q&A+NLG task.

4.5 Case Study

Table 6 gives two examples to show the answers generated by the REAG model and the PALM model. In addition to the answers, we provide the rationales predicted by REAG's encoder to demonstrate the effectiveness of rationale extraction. In both examples, the rationale extraction module identifies the correct rationales, e.g., *Flu shots are not made for children under the age of 6 months.* and *California (8%)*.

In Example 1, PALM is confused by the noise "*Yes*" in the beginning of the passage, which leads to the contrary semantics of its generated answer. With the correctly extracted rationale, our REAG model generates an answer semantically consistent with the gold answer. In Example 2, PALM fails to identify a correct sales tax rate *8%* for California, so the response is incorrect and useless, even if it results in high ROUGE and BLEU scores against the gold answer. In contrast, based on the extracted rationale *California (8%)*, our REAG generates a semantically correct answer.

5 Conclusion and Future Work

This paper presents a novel model REAG that is designed to incorporate an extractive mechanism into a generative QA model. REAG introduces a new task on the encoder to extract rationales. Based on these rationales and original input, a rationale-enriched decoder is proposed to generate an answer with high confidence. The experimental results show that REAG significantly improves the quality and semantic accuracy of generated answers over state-of-the-art models.

Demoting the Lead Bias in News Summarization via Alternating Adversarial Learning

Linzi Xing*, **Wen Xiao***, **Giuseppe Carenini**

Abstract

In news articles the lead bias is a common phenomenon that usually dominates the learning signals for neural extractive summarizers, severely limiting their performance on data with different or even no bias. In this paper, we introduce a novel technique[1] to demote lead bias and make the summarizer focus more on the content semantics. Experiments on two news corpora with different degrees of lead bias show that our method can effectively demote the model's learned lead bias and improve its generality on out-of-distribution data, with little to no performance loss on in-distribution data.

1 Introduction

Neural extractive summarization, which produces a short summary for a document by selecting a set of representative sentences, has shown great potential in real-world applications, including news (Cheng and Lapata, 2016; Nallapati et al., 2017) and scientific paper summarization (Cohan et al., 2018; Xiao and Carenini, 2019). Typically, a general-purpose extractive summarizer learns to select the most important sentences from a document to form the summary by considering their content salience, informativeness and redundancy. However, when restricted to a specific domain, the summarizer can learn to exploit particular biases in the data, the most famous of which is the *lead bias* in news (Nenkova et al., 2011; Hong and Nenkova, 2014); namely that sentences at the beginning of a news article are more likely to contain summary-worthy information. As a result, not surprisingly, such bias is strongly captured by neural extractive summarizers for news, for which the sentence positional information tends to dominate the actual content of the sentence in model prediction (Jung et al., 2019; Grenander et al., 2019; Zhong et al., 2019a,b).

While learning a summarizer reflecting the biases in the training dataset is completely fine when the summarizer is going to be deployed to summarize documents having similar biases, it would be problematic when the model was applied to deal with documents coming from a mixture of datasets with different degrees of such biases. In this paper, we address this problem in the context of the lead bias in the news domain by exploring ways in which an extractive summarizer for news can be trained so that it learns to balance the lead bias with the content of the sentences, resulting in a model that can be applied more effectively when the target documents belong to news datasets in which the lead bias is present in rather different degrees.

Recently, Grenander et al. (2019) proposes two preliminary solutions. One is to pretrain the summarizer on an automatic generated "unbiased" corpus where the document sentences are randomly shuffled, which however has the negative effects of preventing the learning of inter-sentential information. The other, which can be only applied to RL-based summarizers, is to add an explicit auxiliary loss to directly balance position with content. Alternatively, Zhong et al. (2019b) and Wang et al. (2019) investigate strategies to train the summarizer on multiple news datasets with different degrees of lead bias, but this may still be problematic when we apply the trained summarizer to the documents with lead bias not covered in the training data. Outside the summarization area, methods have also been proposed to eliminate data biases for other NLP tasks like text classification or entailment (Kumar et al., 2019; Clark et al., 2019, 2020).

Inspired by Kumar et al. (2019), we have developed an alternating adversarial learning technique to demote the summarizer lead bias, but also maintain the performance on the in-distribution

data. We introduce a position prediction component as an adversary, and optimize it along with the neural extractive summarizer in an alternating manner. Furthermore, in contrast with Grenander et al. (2019) and Wang et al. (2019), our proposal is model-independent and only requires one type of news dataset as training input.

In this paper, we apply our proposed method to a biased transformer-based extractive summarizer (Vaswani et al., 2017) trained on CNN/DM training set (Hermann et al., 2015) and conduct experiments on two test sets with different degrees of lead bias: CNN/DM and XSum (Narayan et al., 2018), for in-distribution and generality evaluation respectively. The experimental results indicate that our proposed "debiasing" method can effectively demote the lead bias learned by the neural news summarizer and improve its generalizability, while still mostly maintaining the model's performance on the data with a similar lead bias.

2 Proposed Debiasing Method

Our method aims to demote the lead bias learned by the summarizer and encourage it to select content based more on the semantics covered in sentences. As shown in Figure 1, our method comprises two components: one for *Summarization* (red) and the other for sentence *Position Prediction* (green).

2.1 Summarization Component

Following previous work, we formulate extractive summarization as a sequence labeling task (Xiao and Carenini, 2019, 2020; Xiao et al., 2020). For a document $d = \{s_1, s_2, ..., s_k\}$, each sentence will be assigned a score $\alpha \in [0, 1]$. The summary will then be formed with the highest scored sentences. We adopt a transformer-based model (Vaswani et al., 2017) as our basic "biased" summarization component (red in Fig. 1), as shown to be heavily impacted by the lead bias (Zhong et al., 2019a). This component contains a transformer-based encoder Enc_{θ_t} and a multilayer perceptron (MLP) decoder Dec_{θ_s}, parameterized by θ_t and θ_s respectively. We use the averaged word embedding from Glove as sentence embedding as suggested in Kedzie et al. (2018). We optimize this summarization system by minimizing the loss:

$$L_1 = -\frac{1}{N}\sum_{i=1}^{N} CE(\alpha_i, y_i) \qquad (1)$$
$$\alpha_i = Dec_{\theta_s}(Enc_{\theta_t}(s_i))$$

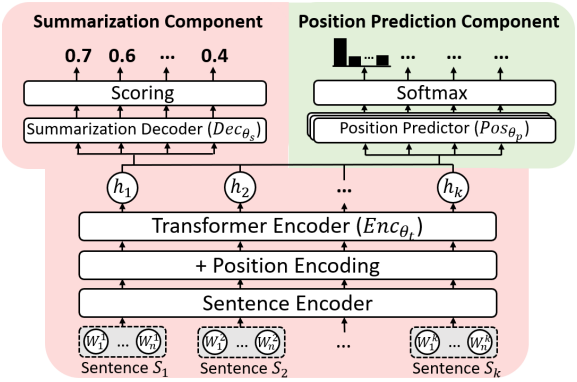

Figure 1: The overall architecture of our proposed lead bias demoting method.

where CE denotes the cross-entropy loss and $y_i \in \{0, 1\}$ is the ground truth label for sentence s_i, representing if s_i is selected to form the summary.

2.2 Position Prediction Component

Our goal is to train the summarization model to make accurate predictions based more on the sentence semantics, rather than whether the sentence is in the lead position. More specifically, we aim to design an encoder network Enc_{θ_t} to output the set of contextualized sentence representations $\mathbf{H} = \{h_1, ..., h_k\}$ which cover less sentence positional information, so that the following decoder Dec_{θ_s} will make predictions depending less on such positional information. To achieve this, the first step is to understand how much and in what form the positional information is encoded in Enc_{θ_t}. Therefore, we propose a position prediction network to learn to predict the position of sentences in a document based only on $\mathbf{H}$. Intuitively, the higher accuracy this component can achieve, the more positional information is contained in $\mathbf{H}$. This position prediction component will then play the role of an adversary module to demote the influence of lead bias presented in the training phase of the summarization component.

Concretely, because predicting the exact position for each sentence would require an extremely large set of labels with a skewed distribution, we choose to predict the portion of the document each sentence belongs to. In particular, once we obtain the set of contextualized sentence representations $\mathbf{H}$ from the encoder network Enc_{θ_t}, we initialize a MLP (parameterized by θ_p and followed by Softmax) as the position prediction component Pos_{θ_p} (green in Fig 1). In essence, this component Pos_{θ_p} takes $\mathbf{H}$ as input and outputs a M-dimensional multinomial distribution for each

sentence to represent its position in a document. More formally, $Pos_{\theta_p}(h_i) = (\hat{p}_1^{(i)}, .., \hat{p}_j^{(i)}, .., \hat{p}_M^{(i)})$ where $\sum_{j=1}^{M} \hat{p}_j^{(i)} = 1$. $\hat{p}_j^{(i)}$ is the predicted probability of the ith sentence belongs to the jth portion of a document when the document is divided into M parts (M is a tunable hyperparameter). We use the cross-entropy loss to optimize Pos_{θ_p} to extract sentence positional signals encoded in the system:

$$L_2 = -\frac{1}{N}\sum_{i=1}^{N} CE(Pos_{\theta_p}(h_i), p_i) \qquad (2)$$

where p_i is the true position of sentence i.

2.3 Alternating Adversarial Learning

To demote the influence of positional bias and balance it with the sentence semantics in the summarization system, we want to modify the encoder to produce **H**, which can still be accurate for summary generation but fail at sentence position prediction. We achieve this by alternatingly executing "Position learning" and "Position debiasing", as proposed in Kumar et al. (2019) and presented in Algorithm 1. In the "Position learning" phase, once a pretrained summarization system is obtained, we first fix its weights and train an adversary network $Pos^*_{\theta_p}$ (sentence position predictor) to extract the positional information contained in the encoder. Then in the "Position debiasing" phase, we fix the weights of $Pos^*_{\theta_p}$ and update the parameters of the summarization component to maximize the position prediction loss of adversary (L_{adv} in eq 3) while minimizing the summarization loss L_1:

$$\begin{aligned} L_3 &= \beta L_1 + (1-\beta) L_{adv} \\ L_{adv} &= -\frac{1}{N}\sum_{i=1}^{N} CE(Pos^*_{\theta_p}(h_i), U_M) \end{aligned} \qquad (3)$$

To maximize the position prediction loss, the fixed adversary $Pos^*_{\theta_p}$ should ideally output the uniform distribution, $U_M = (\frac{1}{M}, ..., \frac{1}{M})$, for the position prediction of each sentence. β is the trade-off parameter tuned at validation stage to control the degree of lead bias demoting.

In practice, we notice that reusing the same adversary for all iterations will make the positional signals not weakened but instead encoded in a different way. To avoid this problem, we follow Kumar et al. (2019) to use multiple adversaries (parameterized with $[\theta_p^{(1)}, ..., \theta_p^{(N)}]$ in Algorithm 1), making it more difficult for the encoder to keep the sentence positional signals by encoding them into a more implicit format for position predictor to learn.

Algorithm 1: Alternating Adversarial Learning

  for *p steps* **do**
    Randomly initialize $\theta_p^{(i)}$;
    Sample a minibatch of training samples;
    Fix θ_t, θ_s, update $\theta_p^{(i)}$ with gradients regarding L_2;
  end — Position Learning
  for *s steps* **do**
    Sample a minibatch of training samples;
    Randomly select $\theta_p^{(cur)}$ from $[\theta_p^{(1)}, \cdots, \theta_p^{(i)}]$;
    Fix $\theta_p^{(cur)}$, update θ_t and θ_s with gradients regarding L_3;
  end — Position Debiasing
  $i = i + 1$;
end

3 Experiments and Analysis

3.1 Datasets

We use the standard CNN/DM dataset (204,045 training, 11,332 validation and 11,334 test data) (Hermann et al., 2015) for training since it is one of the mainstream news datasets with observed lead bias (Jung et al., 2019; Grenander et al., 2019). For model evaluation, we use the test set of CNN/DM to evaluate model's in-distribution performance, as well as the test set of XSum (Narayan et al., 2018), which consists of 11,334 datapoints, to evaluate model's generality when transferred to less biased data. The empirical analysis in Narayan et al. (2018) and Jung et al. (2019) shows the documents and summaries in XSum are shorter and have less lead bias compared to CNN/DM.

3.2 Experimental Design

Baselines: We compare our proposal with various baselines (see Table 1). The top section of Table 1 presents ***Lead*** baseline and ***Oracle***. For CNN/DM, lead baseline refers to ***Lead-3*** and for XSum, it refers to ***Lead-1***. The middle section of Table 1 contains the basic transfomer-based summarizer accepting "sentence representation + position encoding" as input, and its two variants, one without positional encoding, while the other with only positional encoding as input. The bottom section contains ***Shuffling*** (Grenander et al., 2019), which

is a method proposed lately for summarization lead bias demoting, and ***Learned-Mixin*** (Clark et al., 2019), which is a general debiasing method proposed to deal with NLP tasks when the type of data bias in the training set is known and bias-only model is available. In our case, the data bias is lead bias and the bias-only model is the transformer trained with only positional encoding as input.

Implementation Details: All the transformer-based models have the same setting as the standard transformer (Vaswani et al., 2017), with 6 layers, 8 heads per layer, and $d_{model} = 512$. We use Adam to train all the models with scheduled learning rate with warm-up (initial learning rate $lr = 2e - 3$). We choose the top-3 sentences to form the final summary for CNN/DM and the top-1 sentence for XSum due to the different average summary lengths. The class number of sentence position M is set to 10 and trade-off parameter β is set to 0.9 (searched from 0 to 1, by increasing 0.1 for each step). We tune these hyper-parameters on a "balanced" validation set sampled from the standard CNN/DM validation data.

3.3 Results and Analysis

Table 1 reports the performance of the chosen baselines and our proposal on CNN/DM test set, which has the same data distribution as the training data, and XSum test set, which is from another news resource and with much less lead bias than CNN/DM.

From the middle section of Table 1, we observe that if we withhold the position cues (*No Position Encoding*) by using only semantic representation as input, the model's performance drops considerably on CNN/DM, but remarkably increase on XSum. In contrast, if we merely use position cues as input (*Only Position Encodings*), the decrease of the performance on CNN/DM becomes much more modest, while there is substantial performance drop on XSum. These results confirm that positional signal is a rather important feature for bias-relied neural summarizers. However, relying too much on it will also limit model's generality when applied to the dataset with less bias than the training samples. Therefore, seeking strategies to balance the semantics and position features is crucial for the neural extractive summarization for news.

When we compare the lead bias demoting methods presented at the bottom of Table 1, our proposal and *Shuffling* give significant performance boosting on XSum, while *Learned-Mixin* results in performance decrease on both datasets. Comparing our method and *Shuffling* directly, while they are essentially equivalent on maintaining the performance on the in-distribution CNN/DM data (0.09 difference in terms of the average of ROUGE scores (ROUGE-Mean)), our method provides a significant improvement on XSum, and outperforms *Shuffling* and the basic transformer by 0.14 and 0.29 on ROUGE-Mean respectively. It is noteworthy that the transformer without position encoding achieves

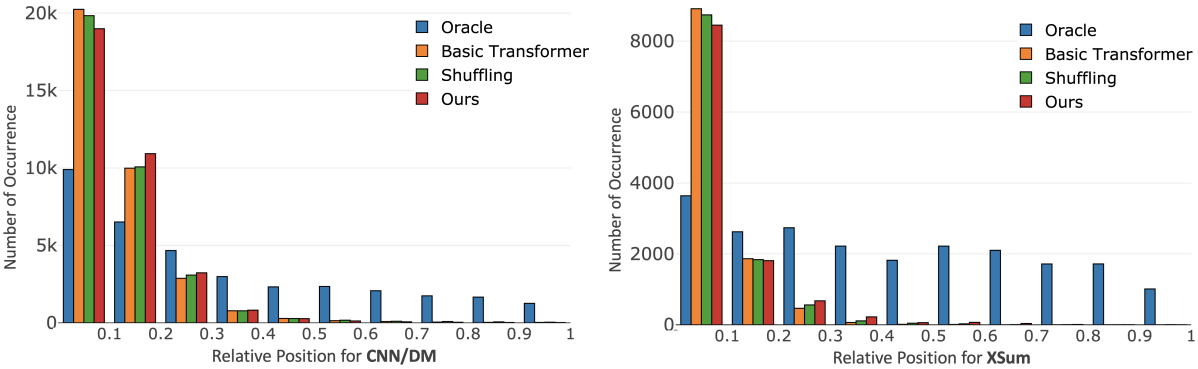

Figure 2: Relative position distributions of selected sentences in the original document of two testing corpora (CNN/DM and XSum), obtained by different lead bias demoting strategies.

the best performance on XSum. However, it is the worst system on in-distribution data. Throughout all the comparisons, our proposal can best balance the sentence position and content semantics.

To more deeply investigate the behavior of our demoting method on the documents whose summary sentences are from different document portions, we follow Grenander et al. (2019) to create three subsets, D_{early}, D_{middle}, D_{late}, from the CNN/DM testing set. Documents are ranked by the mean of their summary sentences' indices in ascending order, and then the top-ranked 100 documents, the 100 documents closest to the median, and the bottom-ranked 100 documents are selected to form D_{early}, D_{middle}, D_{late}[2]. Results in Table 2 show that even if our model does not match the basic transformer on documents in D_{early}, it does yield benefits for both D_{middle} and D_{late} with significant improvements, while the competitive baseline *Shuffling* only achieves that on D_{late}.

Position of Selected Content: To more explicitly investigate how well the prediction of different models fits the ground-truth sentence selection (*Oracle*), we compare the relative position of the selected content of our method with the undebiased model (*Basic Transformer*) and the most competitive debiased model (with *Shuffling*), as illustrated in Figure 2. We can observe that: (1) CNN/DM contains much more lead bias than XSum, shown by a more right-skewed histogram for *Oracle*. Thus, the basic transformer trained on it is also heavily impacted by the lead bias and tends to select sentences $\in [0, 0.1]$ with much higher probability even on the less biased XSum. (2) While *Shuffling* and our method can both effectively demote the extreme trend towards selecting sentences in the lead position, our method seems to be sightly better at encouraging the model to select sentences with higher relative position.

[2]Due to the common generation mechanism of oracles, the number of sentences in the oracle is not fixed. For fair comparison, we only consider adding documents with the oracle having exactly 3 sentences into D_{early}, D_{middle}, D_{late}.

4 Conclusion and Future Work

We propose a lead bias demoting method to make news extractive summarizers more robust across datastets, by optimizing a position prediction and a summarization component in an alternating way. Experiments indicate that our method improves model's generality on out-of-distribution data, while still largely maintaining its performance on in-distribution data. As such, it represents the best viable solution when at inference time input documents may come from an unknown mixture of datasets with different degrees of position bias.

For the future, we plan to explore more sophisticated and effective methods (e.g., adjusting the lead bias online) and infuse them together with neural abstractive summarization models, known to generate more succinct and natural summaries. Another interesting direction for future work can be exploring the potential of applying our proposed bias demoting strategy to other tasks, which can also be framed as the sequence labeling problem and possibly troubled by biases in the training data (e.g., Topic Segmentation (Xing et al., 2020) and Semantic Role Labeling (Ouchi et al., 2018)).

Abstract

Machine reading comprehension (MRC) is a crucial task in natural language processing and has achieved remarkable advancements. However, most of the neural MRC models are still far from robust and fail to generalize well in real-world applications. In order to comprehensively verify the robustness and generalization of MRC models, we introduce a real-world Chinese dataset – DuReader$_{\text{robust}}$. It is designed to evaluate the MRC models from three aspects: over-sensitivity, over-stability and generalization. Comparing to previous work, the instances in DuReader$_{\text{robust}}$ are natural texts, rather than the altered unnatural texts. It presents the challenges when applying MRC models to real-world applications. The experimental results show that MRC models do not perform well on the challenge test set. Moreover, we analyze the behavior of existing models on the challenge test set, which may provide suggestions for future model development. The dataset and codes are publicly available at https://github.com/baidu/DuReader.

1 Introduction

Machine reading comprehension (MRC) requires machines to comprehend text and answer questions about it. With the development of deep learning, the recent studies of MRC have achieved remarkable advancements (Seo et al., 2017; Wang and Jiang, 2017; Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020). However, previous studies show that most of the neural models are not robust enough (Jia and Liang, 2017; Ribeiro et al., 2018b; Talmor and Berant, 2019a; Welbl et al., 2020) and fail to generalize well (Talmor and Berant, 2019b).

To further promote the studies of robust and well generalized MRC, we construct a Chinese dataset – DuReader$_{\text{robust}}$ which comprises natural questions and documents. In this paper, we focus on evaluating the robustness and generalization from the following aspects, where robustness consists of over-sensitivity and over-stability:

(1) **Over-sensitivity** denotes that MRC models provide different answers to the paraphrased questions. It means that the models are overly sensitive to the difference between the original question and its paraphrased question. We provide an example in Table 1a.

(2) **Over-stability** means that the models might fail into a trap span that has many words in common with the question, and extract an incorrect answer from the trap span. Because the models overly rely on spurious lexical patterns without language understanding. We provide an example in Table 1b.

(3) **Generalization**. The well-generalized MRC models have good performance on both in-domain and out-of-domain data. Otherwise, they are less generalized. We provide an example in Table 1c.

In previous work, the above issues have been studied separately. In this paper, we aim to create a dataset namely DuReader$_{\text{robust}}$ to comprehensively evaluate the three issues of neural MRC models. Previous work mainly studies these issues by altering the questions or the documents. Ribeiro et al. (2018b); Iyyer et al. (2018); Gan and Ng (2019) evaluate the over-sensitivity issue via paraphrase questions generated by rules or generative models. Jia and Liang (2017); Ribeiro et al. (2018a); Feng et al. (2018); Talmor and Berant (2019a) focus on evaluating the over-stability issue by adding distracting sentences to the documents or reducing question word sequences. However, the altered questions and documents are not natural texts and rarely appear in the real-world applications. It is not clear that how the evaluation based

Passage 近年来，随着琥珀蜜蜡市场的兴起，蜜蜡与琥珀的价格都有不断上涨的趋势，其中蜜蜡首饰的价格一般是琥珀首饰价格的2–4倍，最近几年二者价格差距更大.....	**Passage** *In recent years, with the rise of the amber market, the price of amber keeps going up. The price of opaque amber is generally 2–4 times the price of clear amber ...*
Original Question 琥珀和蜜蜡哪一个比较贵 **Golden Answer**： 蜜蜡 **Predicted Answer**： 蜜蜡 ($BERT_{base}$)	**Original Question** *Which is more expensive, clear amber or opaque amber?* **Golden Answer** : *opaque amber* **Predicted Answer** : *opaque amber* ($BERT_{base}$)
Paraphrase Question 蜜蜡和琥珀哪个价格高 **Golden Answer**： 蜜蜡 **Predicted Answer**： 琥珀 ($BERT_{base}$)	**Paraphrase Question** *Which has the higher price, opaque amber or clear amber?* **Golden Answer** : *opaque amber* **Predicted Answer** : *clear amber* ($BERT_{base}$)

(a) An example illustrates the over-sensitivity issue, where $BERT_{base}$ gives different predictions to the original question and the paraphrased question.

Passage 包粽子的线以前人们认为是来自麻叶子，其实是棕榈树，粽子的音就来自棕叶子。	**Passage** *Many people argue that the zongzi (rice dumpling) leaves are made of hemp. Actually, it is the palm tree, the real origin, that endows zongzi with the special pronunciation.*
Question 包粽子的线来自什么 **Golden Answer**： 棕榈树 **Predicted Answer**： 麻叶子 ($BERT_{base}$)	**Question** *What is the raw material of zongzi leaves?* **Golden Answer** : *palm tree* **predicted Answer** : *hemp* ($BERT_{base}$)

(b) An example illustrates the over-stability issue. The underlined span in the passage appears as a trap because it has many words in common with the question. $BERT_{base}$ falls into the trap.

Passage *cos(2x)'=-sin(2x)*(2x)'=-2sin(2x)* 属于复合函数的求导。	**Passage** *cos(2x)'=-sin(2x)*(2x)'=-2sin(2x) This is the derivative of a compound function.*
Question *cos2x*的导数是多少？ **Golden Answer** : *-2sin(2x)* **Predicted Answer** : *-sin(2x)* ($BERT_{base}$)	**Question** *What is the derivative of cos2x?* **Golden Answer** : *-2sin(2x)* **Predicted Answer** : *-sin(2x)* ($BERT_{base}$)

(c) An example illustrates the generalization issue. Although $BERT_{base}$ is sufficiently trained on large-scale open-domain data, it fails to predict the answer to a math question.

Table 1: The examples of over-sensitivity, over-stability and generalization issues.

on such unnatural texts can help the improvements of the neural models in real-world applications. By contrast, all the instances in $\text{DuReader}_{\textbf{robust}}$ are natural texts and collected from the Baidu search.

We conduct extensive experiments based on $\text{DuReader}_{\textbf{robust}}$. The experimental results show that the models based on pre-trained language models (LMs) (Devlin et al., 2019; Sun et al., 2019; Liu et al., 2019) do not perform well on the challenge set. Besides, we have the following findings on the behaviors of the models: (1) if a paraphrased question contains more words rephrased from the original question, it is more likely that MRC models provide different answers; (2) the trap spans which share more words with the questions easily mislead MRC models; (3) domain knowledge is a key factor that affects the generalization ability of MRC models.

2 Dataset: $\text{DuReader}_{\textbf{robust}}$

$\text{DuReader}_{\textbf{robust}}$ is built on DuReader, a large-scale Chinese MRC dataset (He et al., 2018). In DuReader, all questions are issued by real users of Baidu search, and the document-level contexts are collected from search results. In $\text{DuReader}_{\textbf{robust}}$, we select entity questions and paragraph-level contexts from DuReader. We further employ crowdworkers to annotate the answer span conditioned on the question and the paragraph-level context [1]. Additionally, we used a mechanism to ensure data quality, where 10% of the annotated data will be randomly selected and reviewed by linguistic experts. If the accuracy is lower than 95%, the crowdworkers need to revise all the answers until the accuracy for the randomly selected data is higher than 95%.

Dataset	len(p)	len(q)	len(a)	#
Train	291.88	9.19	5.39	14,520
Development	288.16	9.38	6.66	1,417
Test	285.36	9.41	6.55	1,285
Challenge	132.09	11.97	7.33	3,556
All				**20,778**

Table 2: The statistics of $\text{DuReader}_{\textbf{robust}}$.

Table 3: The frequency distribution and examples of different answer types in DuReader$_{\textbf{robust}}$.

Eventually, we collect about 21K instances for DuReader$_{\textbf{robust}}$, each of which is a tuple $\langle q, p, A\rangle$, where q is a question, p is a paragraph-level context containing reference answers A. Similar to the existing MRC datasets, DuReader$_{\textbf{robust}}$ consists of training set, in-domain development set and in-domain test set, whose sizes are 15K, 1.4K and 1.3K respectively. Besides, DuReader$_{\textbf{robust}}$ contains a challenge test set, in which 3.5K instances are created to evaluate the robustness and generalization of MRC models. The challenge test set can be divided into three subsets including over-sensitivity set, over-stability set and generalization set. Table 2 shows the statistics of DuReader$_{\textbf{robust}}$. Besides, DuReader$_{\textbf{robust}}$ covers a wide range of answer types (e.g. date, numbers, person, etc.). The frequency distribution and examples of the answer types are shown in Table 3. Next, we will present our way to construct the three subsets in the challenge test set.

2.1 Over-sensitivity Subset

We build the over-sensitivity subset in the following way. First, we sample a subset of instances $\{\langle q, p, A\rangle\}$ from the in-domain test set of DuReader$_{\textbf{robust}}$. For each question q, we obtain its N paraphrases $\{q'_1, q'_2, ..., q'_N\}$ using the paraphrase retrieval toolkit (See Appendix A for further details). To ensure the paraphrase quality, we employ crowd-workers to discard all false paraphrases. Then, we replace q with the paraphrased question q'_i, and keep the original context p and answers A unchanged. This leads to the new instances $\{\langle q'_i, p, A\rangle\}$, and they are used as the model-independent instances in the over-sensitivity subset. Besides, we also employ a model-dependent way to collect instances. Specifically, we use paraphrased instances to attack the MRC models based on ERNIE (Sun et al., 2019) and RoBERTa (Liu et al., 2019). If one of the models gives a different prediction from the predicted answer of the original question, we adopt the instance, otherwise we discard it. The instances collected in the above model-dependent and model-independent ways constitute the over-sensitivity subset. The over-sensitivity subset consists of 1.2K instances. The number of model-independent instances is equal to that of model-dependent instances. Table 1a shows an example in the over-sensitivity subset.

Algorithm 1: Annotate an instance for over-stability subset

Input: $\{\langle q, p, A\rangle\}$ tuple
Output: $\{\langle q', p, A'\rangle\}$ tuple or null
Identify the named entities $\{e_1, ..., e_n\}$ along with their entity types in p
Keep the named entities $\{e_i, ..., e_m\}$ with the same types as A
if $1 < m < k$ **then**
  if *linguistic experts consider the passage* p *contains a trap* **then**
    annotate a new question q' and answers A'
    A and A' share the same named entity type
    return $\{\langle q', p, A'\rangle\}$
  else return null;
else return null;

2.2 Over-stability Subset

Intuitively, a trap span that has many words in common with the questions may easily mislead MRC models. Following this intuition, the over-stability subset is constructed as follows. First, we randomly select a set of instances $\langle q, p, A\rangle$ from DuReader. In general, a trap span may contain non-answer named entities of the same type as the reference answers A. This is because over-stable models usually rely on spurious patterns that match the correct answer types. Thus, we use a named entity recognizer [2] to identify all named entities in p along with their entity types. We keep the corresponding instance, if there are non-answer named entities that are of the same type as A. Then, we ask linguistic experts to annotate a new question q' and answers A', if they consider p contains trap spans. A and A' share the same named entity type. The annotated question q' has a high level of lexical overlap with a trap span that does not contain A. We say $\{\langle q', p, A'\rangle\}$ can be considered as a candidate instance. Each candidate instance is used to attack one of the MRC models based on ERNIE (Sun et al., 2019) and RoBERTa (Liu et al.,

2019). The candidate instance will be used to construct an overstability subset, if one of the model fails. Algorithm 1 shows the detailed procedure (See Appendix B for details). As a result, we have 0.8K instances to evaluate over-stability. Table 1b shows an example from the over-stability subset.

2.3 Generalization Subset

The in-domain test set consists merely of in-domain data (i.e., the distribution is the same as the one in the training and development sets). In order to evaluate the generalization ability of MRC models, we construct a generalization subset which comprises out-of-domain data. The out-of-domain data is collected from two vertical domains. The details are as follows.

Education We collect educational questions and documents from Baidu search, and we ask crowdworkers to annotate 1.2K high-quality tuples $\langle q, p, A \rangle$. The topics include mathematics, physics, chemistry, language and literature. Table 1c shows an example.

Finance Following Fisch et al. (2019), we leverage a dataset that was originally designed for information extraction in the finance domain for MRC. We obtain 0.4K instances of financial reports this way. The construction details are presented in Appendix C.

3 Experiments

3.1 Baselines and Evaluation Metrics

We consider three baseline models in the experiments. They are based on different pre-trained language models, including BERT$_{\text{base}}$ (Devlin et al., 2019), ERNIE 1.0$_{\text{base}}$ (Sun et al., 2019) and RoBERTa$_{\text{large}}$ (Liu et al., 2019). In Appendix D, we set the hyperparameters of our baseline models.

Following Rajpurkar et al. (2016), we use exact match (EM) and F1-score to evaluate the held-out accuracy of an MRC model. All the metrics are calculated at Chinese character level, and we normalize both the predicted and true answers by removing spaces and punctuation marks.

	DPR (%)
BERT$_{\text{base}}$	22.73
ERNIE 1.0$_{\text{base}}$	19.88
RoBERTa$_{\text{large}}$	16.44

Table 6: The DPRs of baselines on the over-sensitivity subset.

3.2 Main Results

Table 4 shows the baseline results on the in-domain development set, in-domain test set, and challenge test set. The baseline performance is close to human performance on the in-domain test set, whereas the gap between baseline performance and human performance on the challenge test set is much larger. In Appendix E, we describe the method for calculating human performance.

We further evaluate the baselines on the three challenge subsets for over-sensitivity, over-stability and generalization separately. Table 5 shows the results. We have found that baseline performance declines significantly for over-stability and generalization subsets (compared to the "In-domain test set" in Table 4). In contrast, the baseline performance degrades less significantly on the over-sensitivity subset, although there is still a noticeable gap.

3.3 Discussion 1: Over-sensitivity

First, we calculate the different prediction ratios (DPRs) of the baselines on the over-sensitivity subset. DPR measures the percentage of the paraphrased questions that yield different predictions. DPR is formulated in Appendix F . Table 6 presents the DPRs of the baselines on the over-sensitivity subset. The baselines obtained around 16% to 22% DPRs, which demonstrates that the baselines are sensitive to part of the paraphrased questions.

Second, we examine a hypothesis - if a paraphrased question contains more words rephrased from the original question, the MRC model is more likely to produce different answers. To measure how similar paraphrased questions are to the original questions, we use the F1-score. A low F1-score

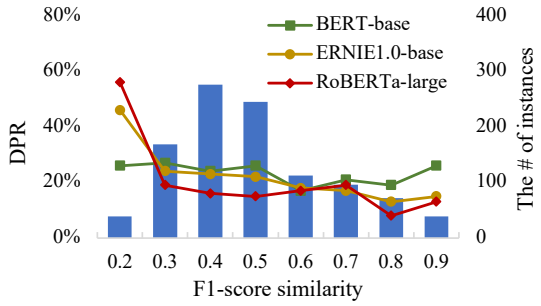

Figure 1: The correlation between DPR and F1-score based question similarity on the over-sensitivity subset.

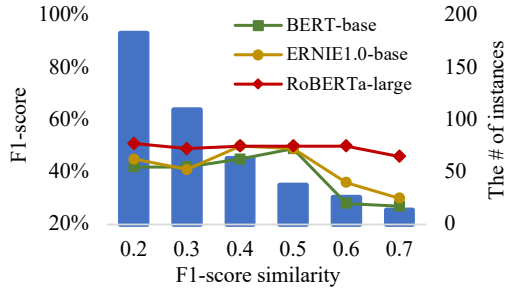

Figure 2: The correlation between the model performance and question-trap similarity on the over-stability subset.

means that many words in the original question have been rephrased. We divide the paraphrased questions into buckets based on how similar they are to the original questions, and we then examine whether there is correlation between DPR and F1-score similarity. Based on Figure 1, we can observe that the DPRs of all the baselines are negatively correlated with the F1-score similarity between the original and paraphrased questions. The results confirm the hypothesis.

3.4 Discussion 2: Over-stability

MRC models might be easily misled by trap spans that share many words with the questions. We examine whether there is a correlation between MRC performance (F1-score) and question-trap similarity in this section. Based on the similarity between trap spans and questions, we divide trap spans into buckets. According to Figure 2, the performance of the base models decreases as similarity increases and the large model (RoBERTa$_{\text{large}}$) is less over-stable than the base ones.

3.5 Discussion 3: Generalization

Table 7 shows the baseline performance in the the domains of finance and education. We can observe

	Finance		Education	
	EM	**F1**	**EM**	**F1**
BERT$_{\text{base}}$	30.73	51.16	38.70	50.83
ERNIE 1.0$_{\text{base}}$	26.53	50.53	34.67	53.11
RoBERTa$_{\text{large}}$	40.22	61.16	47.77	61.82

Table 7: The performance of baselines in the domains of education and finance.

Topcis	**EM**	**F1**	**#**
Math	19.85	34.63	136
Chemistry	37.46	53.88	323
Language	44.31	61.18	255
Others	69.63	79.28	438
All	49.13	62.88	1152

Table 8: The performance of baselines on different topics in the domain of education.

that the baselines perform poorly for both domains. Additionally, we examine how baseline models behave in the education domain. Table 8 shows the performance of RoBERTa$_{\text{large}}$ on the four topics in the education domain. The model performs much worse when it comes to math and chemistry, since these topics are rare in the training set. The results of this analysis suggest that domain knowledge is a key factor affecting the generalization ability of MRC models. More discussion can be found in Appendix G.

4 Conclusion

In this paper, we create a Chinese dataset – DuReader$_{\textbf{robust}}$ and use it to evaluate both the robustness and generalization of the MRC models. Its questions and documents are natural texts from Baidu search. This presents the robustness and generalization challenges in the real-world applications. Our experiments show that the MRC models based on the pre-trained LMs do not perform well on DuReader$_{\textbf{robust}}$ challenge set. We also conduct extensive experiments to examine the behaviors of the MRC models on the dataset and provide insights for future model development.

Acknowledgement

This research work is supported by the National Key Research and Development Project of China (No. 2018AAA0101900) and National Natural Science Foundation of China (Grants No.61773276 and No.62076174). The authors would like to thank the anonymous reviewers for their insightful comments and suggestions. Jing Liu and Yu Hong are the corresponding authors of the paper.

Ethical Considerations

We aim to provide researchers and developers with a dataset $\text{DuReader}_{\text{robust}}$ to improve the robustness and generalization ability of MRC models. We also take the potential ethical issues into account. (1) All the instances in the $\text{DuReader}_{\text{robust}}$ have been desensitised. (2) Regarding to the issue of labor compensation, we make sure that all the crowdsourcing workers are fairly compensated.

A Paraphrase Retrieval Toolkit

We use a paraphrase retrieval toolkit to obtain paraphrase questions. The toolkit is used internally at Baidu, and our manual evaluations show that the accuracy of the retrieval results is around 98%. The paraphrase retrieval toolkit consists of two basic modules as follows.

- **Paraphrase Candidate Retriever** The retriever is a light-weight module. Given a question, the retriever will retrieve top-k paraphrase candidates from the search logs of Baidu Search.
- **Paraphrase Candidate Re-ranker** The re-ranker is a model fine-tuned from ERNIE (Sun et al., 2019) by using a set of manually labeled paraphrase questions. Given a set of retrieved paraphrase candidates, the re-ranker will estimate the semantic similarity between the original question and the paraphrase candidates. If the semantic similarity is higher than a pre-defined threshold, the candidate will be used as a paraphrased question.

B The Illustration of Annotating Over-stability Instances

Figure 3 illustrates the annotation of an over-stability instance. In the instance, the answer to the original question is 30-40 minutes. The entity type of 5-10 minutes is the same as 30-40 minutes. The annotator raise a new question by revising the original question, the answer to the new question is 5-10 minutes. The sentence contains 30-40 minutes has many words in common with the new question, and it is considered as a trap sentence. The new question may mislead the model to predict the answer to the new question as 30-40 minutes.

C The Construction of Finance Data

We leverage a dataset that is originally designed for information extraction in finance domain. The original dataset contains the full texts of the financial reports as documents and the structured data that is extracted from the texts. Then, we use templates to generate questions for each data field in the structured data. Finally, we use these constructed instances for MRC. Each instance contains (1) a question generated from a template for a data field, (2) an answer that is the value in the data field and (3) a document from which the value (i.e. answer) is extracted.

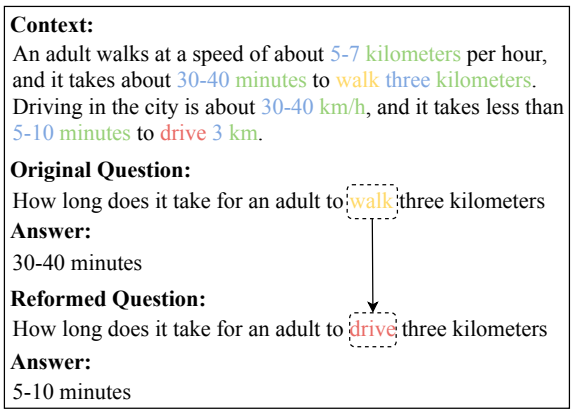

Figure 3: The illustration of annotating an over-stability instance.

D Hyperparameters

We use a number of pre-trained language models in our baseline systems. When fine-tuning different pre-trained language models, we use the same hyperparameters. The settings of hyperparameters are as follows. The learning rate is set to 3e-5 and the batch size is 32. We set the number of epochs to 5. The maximal answer length and document length are set to 20 and 512, respectively. We set the length of document stride to 128. All experiments are conducted on 4 Tesla P40 GPUs.

E Human Performance

We evaluate human performance on both the in-domain test set and challenge test set. We randomly sample two hundred instances from the in-domain test set, and three hundred instances from the challenge test set. We ask crowdworkers to provide answers to the questions in the sampled instances. Then, we use EM and F1-scores of these annotated answers as human performance.

F Different Prediction Rate

Different prediction rate (DPR) measures the percentage of paraphrase questions whose predictions are different from the original questions. Formally, we define DPR of a neural model $f(\theta)$ on a dataset D as follows.

$$DPR_D(f(\theta)) = \frac{\sum_{(q,q\prime)\in Q} \mathbb{1}[f(\theta;q) \neq f(\theta;q\prime)]}{\|Q\|}$$

where, $f(\theta;q)$ denotes the prediction of the trained MRC model $f(\theta)$. Q represents a set of pairs of

Types	# of changes (%)	# of same (%)
WR	1 (12.50)	7 (87.50)
RF	0 (00.00)	4 (100.00)
SS	6 (17.14)	29 (82.85)
AD	7 (23.33)	23 (76.66)
CO	7 (30.43)	16 (69.56)

Table 9: Distributions of paraphrases and DPRs.

Question Types	EM	F1	#
Company abbreviations	0	31.15	18
Pledgee	80.76	89.96	26
Pledgor	0	24.62	25
The pledge amount	18.36	53.84	98
Others (e.g. pledge date)	47.91	58.97	48
All	28.83	54.05	215

Table 10: The performance of RoBERTa$_{\text{large}}$ on the five topics in the domain of financial reports.

original question q and paraphrased question $q\prime$ in dataset D, and $\mathbb{1}[*]$ is an indicator function. A high DPR score means that the MRC model is overly sensitive to the paraphrased question $q\prime$, otherwise insensitive.

G Experimental Analysis

G.1 Over-sensitivity Analysis

We further analyze the prediction results to figure out what kind of paraphrases lead to different predictions. Five types of paraphrasing phenomena have been found, including (1) word reordering (WR), (2) replacement of function words (RF), (3) substitution by synonyms (SS), (4) inserting or removing content words (AD), and (5) more than one previously defined types happen in one paraphrase (CO). We randomly sample one hundred instances from the over-sensitivity subset and analyze the changes of the predictions by ERNIE (Sun et al., 2019). As shown in Table 9, most of changed predictions come from AD and CO. This analysis suggests that the models are sensitive to the changes of content words.

G.2 Generalization Analysis

In previous section, we have already analyzed the behaviors of baseline systems on education domain. In this section, we conduct analysis on financial domain. The data of financial domain contains management changes and equity pledge. The performance of RoBERTa$_{\text{large}}$ on management changes and equity pledge is 68.63% and 49.15% respectively. The model generalizes well on management changes, since the training set contains the relevant knowledge about asking person names. By contrast, the model performs worse on equity pledge. We classify the instances of equity pledge into five sets according to the question types. Table 10 shows the performance of RoBERTa$_{\text{large}}$ on the five question types. We can observe that the model performs the worst on the questions about company abbreviations, pledgee and pledgor, since there is little domain knowledge in the training set. By contrast, the model performs better on the questions about amount and date, since the model has already learnt relevant knowledge in the training set.

Sequence to General Tree: Knowledge-Guided Geometry Word Problem Solving

Shih-hung Tsai, Chao-Chun Liang, Hsin-Min Wang, Keh-Yih Su
Institute of Information Science, Academia Sinica, Taiwan
{doublebite,ccliang,whm,kysu}@iis.sinica.edu.tw

Abstract

With the recent advancements in deep learning, neural solvers have gained promising results in solving math word problems. However, these SOTA solvers only generate binary expression trees that contain basic arithmetic operators and do not explicitly use the math formulas. As a result, the expression trees they produce are lengthy and uninterpretable because they need to use multiple operators and constants to represent one single formula. In this paper, we propose sequence-to-general tree (S2G) that learns to generate interpretable and executable *operation trees* where the nodes can be formulas with an arbitrary number of arguments. With nodes now allowed to be formulas, S2G can learn to incorporate mathematical domain knowledge into problem-solving, making the results more interpretable. Experiments show that S2G can achieve a better performance against strong baselines on problems that require domain knowledge.[1]

1 Introduction

Math word problem (MWP) solving is a special subfield of question answering. It requires machine solvers to read the problem text, understand it, and then compose the numbers and operators into a meaningful equation (as shown in Table 1). This process, even for the simplest problem in elementary school, demands language understanding and numerical reasoning capabilities, making this task a long-standing challenge in AI (Bobrow, 1964; Zhang et al., 2019).

As with any QA task, solving an MWP requires the introduction of external knowledge or domain knowledge (Mishra et al., 2020). However, current state-of-the-art solvers (Xie and Sun, 2019; Zhang et al., 2020; Wu et al., 2020) do not address this issue explicitly. They learn to map the problem text into binary expression trees regardless of whether it requires any knowledge. This is counterintuitive for problems that need math concepts or formulas. As illustrated in Figure 1(a), without explicitly using the corresponding area formula, the expression tree for the problem is lengthy and uninterpretable.

To address this issue, we propose a sequence-to-general tree (S2G) architecture where the nodes

Problem: The outer radius and the inner radius of a circular annulus are 5m and 3m repsectively. Find the area of this circular annulus.
Equation: $x = 5 * 5 * 3.14 - 3 * 3 * 3.14$ **Answer:** 50.24
With formula: x = circle_area(5) - circle_area(3)

Table 1: Example problem that requires geometry knowledge.

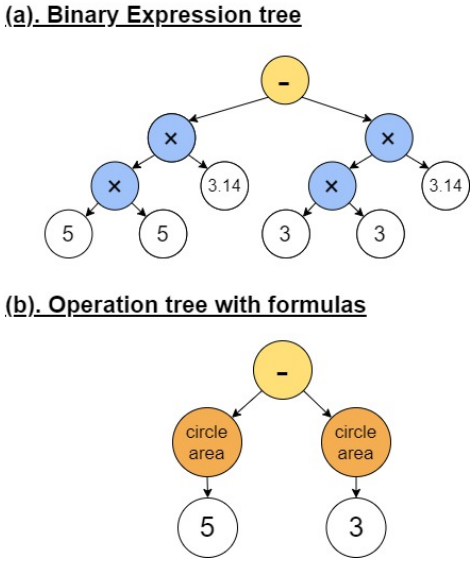

Figure 1: (a). binary expression tree and (b). operation tree along with formulas for the problem in Table 1.

[1]Data and code are available at the GitHub repository: https://github.com/doublebite/Sequence-to-General-tree/

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 964–972
August 1–6, 2021. ©2021 Association for Computational Linguistics

can be arbitrary math concepts or formulas with arbitrary number of arguments. In this way, our S2G model can learn to map the problem text into executable operation trees that contain different formulas across different domains. For example, S2G can learn to generate tree nodes that contain the required geometry formula for circles, as shown in Figure 1(b), making the result more intuitive and explainable.

In addition, we propose a knowledge-guided mechanism to guide tree-decoding using a mathematical knowledge graph (KG). To evaluate our model, we also construct a middle-sized dataset consisting of 1,398 geometry word problems which require a diversified set of formulas. Experimental results show that our S2G model can provide better performance and more interpretable results against strong baselines on problems that require domain knowledge.

The main contributions of this paper are:

1. We propose a seq-to-general tree model that learns to map the problem text into operation trees where the nodes can be formulas with arbitrary number of arguments. This helps to incorporate domain knowledge into problem solving and produce interpretable results.

2. We design a knowledge-guided mechanism that guides tree decoding using mathematical knowledge graphs and GNNs.

3. We curate a middle-sized dataset that contains 1,398 geometry word problems. In addition, we annotate them with detailed formulas that can be readily converted into operation trees.

2 Seq2seq v.s. Seq2tree v.s. Seq2general

Our goal is to design a sequence-to-general tree model that learns to map the problem text into its corresponding operation tree. Before diving into the model, we first compare the decoding mechanisms between seq-to-seq, seq-to-tree and our seq-to-general tree solvers. Figure 2 illustrates the tree decoding process of these three types of model, respectively.

For seq2seq models, their decoder basically does two things: (1) predicting the current output and (2) generating the next state. These two steps can be conditioned on different information including the current state, the current input, or a context vector calculated using attention. The decoder would repeat these two steps until it outputs an end token.

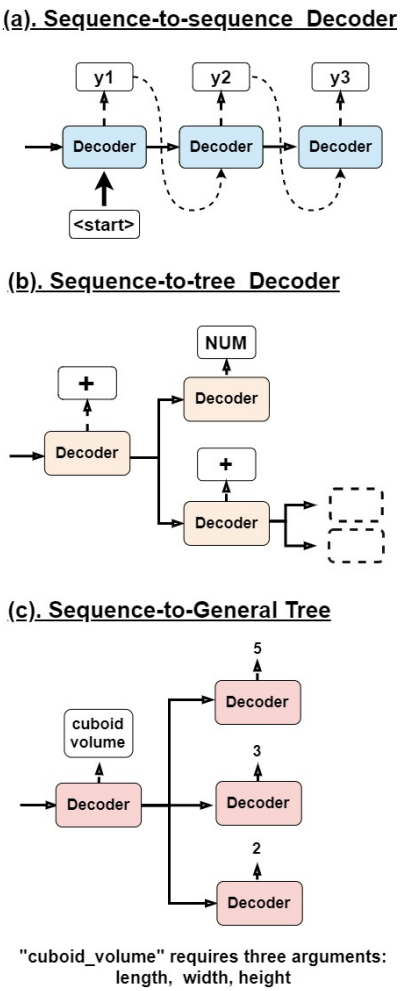

Figure 2: Comparison between three types of decoding: (a) seq2seq, (b) seq2tree, and (c) seq-to-general tree.

For seq2tree models, however, this process is slightly different. The decoder predicts the current output as in seq2seq, but it will decide whether to generate the next state based on the current output. If the current output is a arithmetic operator, the decoder knows it should produce two child states, and these states are used to expand into its left and right children. If the current output is a number, then the decoder would end the decoding process, so the current node becomes a leaf node. As a result, the whole decoding process resembles generating an expression tree in a top-down manner.

In our work, we generalize the decoding process by making the decoder produce a variable number of children based on the type of the current output. If the output is a number or operator, the decoder would produce zero or two child states as before. If the output is a formula, the decoder will generate the pre-specified number of child states for this formula.

3 Sequence-to-General Tree Model

In this section, we give a detailed description for each part of our S2G model.

3.1 Encoder

The main function of the encoder is to encode the problem text $P = (x_1, x_2, ..., x_n)$ into a sequence of hidden states $(h_1, h_2, ..., h_n)$ and their summary state $h_{encoder}$. The hidden states h_1 to h_n are expected to contain the information for each input token x_1 to x_n, while the summary state $h_{encoder}$ is expected to capture the overall information of the problem.

Specifically, we use bidirectional gated recurrent units (GRU) (Cho et al., 2014) as our encoder. Given the current input x_t, the previous state h_{t-1}, and the next state h_{t+1}, the current state $h_t \in (h_1, h_2, ..., h_n)$ can be calculated with:

$$\overrightarrow{h_t} = \mathrm{GRU}(x_t, \overrightarrow{h_{t-1}}), \quad (1)$$

$$\overleftarrow{h_t} = \mathrm{GRU}(x_t, \overleftarrow{h_{t+1}}), \quad (2)$$

where the arrows represent different directions in the bidirectional encoding. After calculating the hidden state for each input token, we combine the last state of the forward and backward directions to get the summary state for the encoder:

$$h_{encoder} = \overleftarrow{h_0} + \overrightarrow{h_n} \quad (3)$$

3.2 Geometry Knowledge Graph

To incorporate domain knowledge into problem solving, we propose to utilize the knowledge from mathematical knowledge graphs. The main idea is that given a formula predicted as the current node, we could use the physical meaning of its arguments to help us better predict its children. For example, if the current node is the formula for rectangle area, then we know its child nodes should be related to "length " and "width". We can thus use the node embeddings of "length" and "width" from a geometry KG to provide additional information for our solver.

We manually collect a geometry knowledge graph which contains the common geometry shapes (e.g., square, circle) and their geometry quantities (e.g., area, length), and we link these nodes to each other if they belong to the same shape. To embed this KG, we employ a graph convolutional network (GCN) (Kipf and Welling, 2017) that transforms the KG into some vector space and calculates the embedding of each node. Given the feature matrix X and the adjacency matrix A of the KG, we use a two-layer GCN to encode it as follows:

$$Z = \mathrm{GCN}(X, A), \quad (4)$$

where $Z = (z_1, ..., z_n)$ are the node embeddings for each node in the graph. Then, we can use the embedding to represent the physical meaning of a certain formula argument in the decoding process.

3.3 General Tree Decoder

In the decoding stage, the decoder learns to produce the target operation trees in a recursive manner. It first predicts the current output y_t in order to determine the number of children of the current node. Given the current decoder state s_t, the embedding of the last output $e_{(y_{t-1})}$, and the node embedding z_t which represents the physical meaning in the knowledge graph, the probability of the current output $P(y_t)$ is calculated using:

$$c_t = \mathrm{Attention}(\mathrm{e}_{(\mathrm{y_{t-1}})}, \mathrm{h}_1^{\mathrm{n}}) \quad (5)$$

$$z'_t = \mathrm{Attention}(\mathrm{z_t}, \mathrm{h}_1^{\mathrm{n}}) \quad (6)$$

$$P(y_t) = \mathrm{Softmax}(W_y[s_t; e_{(y_{t-1})}; c_t; z'_t]), \quad (7)$$

where h_1^n is the encoder states $(h_1, ..., h_n)$, c_t is the context vector of $e_{(y_{t-1})}$ with respect to h_1^n, and z'_t is another context vector calculated using the node embedding z_t and h_1^n. Specifically, we use additive attention (Bahdanau et al., 2015) to calculate these context vectors and use $h_{encoder}$ as the first decoder state s_0. Given the probability $P(y_t)$, we can then determine the output token $\hat{y}_t$:

$$\hat{y}_t = \mathrm{argmax} P(y_t). \quad (8)$$

Next, we predict the child states conditioned on the required number of children for $\hat{y}_t$. Unlike previous binary-tree decoders that use two distinct DNNs to predict the left and right children respectively (Xie and Sun, 2019; Zhang et al., 2020; Wu et al., 2020), we employ a GRU to predict a variable number of children. Given the current state s_t, its child states $s_{t_1}, ..., s_{t_n}$ are generated in a recurrent manner:

$$s_{t_i} = \mathrm{Decoder}(s_{t_{i-1}}; e_{(y_t)}; c_t), \quad (9)$$

where we generate the first child s_{t_1} using s_t, and the following child state s_{t_i} using its previous sibling $s_{t_{i-1}}$until we reach the required number of children. The decoder is basically a GRU followed

by a linear projection layer and an activation function:

$$s'_{t_i} = \text{GRU}([e_{(y_t)}; c_t], s_{t_{i-1}}), \quad (10)$$

$$s_{t_i} = \text{ReLU}(W_s s'_{t_i}), \quad (11)$$

where the input of GRU is the concatenation of $e_{(y_t)}$ and c_t, W_s is the linear projection layer, and ReLU is used as the activation function. After getting these child states, we push them into a stack and repeat the steps from Equation (5) to Equation (11) until all the states are realized into tokens.

3.4 Training Objective

For a problem and operation tree pair (*P, T*), we follow previous seq2tree work (Xie and Sun, 2019; Wu et al., 2020) and set our objective to minimize the negative log likelihood:

$$L(T, P) = \sum_{t=1}^{n} -logP(y_t|s_t, P, KG). \quad (12)$$

4 Dataset

To evaluate our S2G model on problems that require formulas, we curate a middle-sized dataset, *GeometryQA*, that contains 1,398 geometry word problems. These problems are collected from Math23K (Wang et al., 2017) using the keywords of common geometric objects (e.g., circle, square, etc.) and their shapes (e.g., rectangular, circular, etc.). Then, we re-annotate each problem with their associated formulas if the problem belongs to one of the six major shapes: *square*, *cubic*, *rectangle*, *cuboid*, *triangle* and *circle*. Table 2 shows the overall statistics of GeometryQA and Table 7 in Appendix B shows the 11 formulas we used to annotate these problems.

Note that not all problems in GeometryQA are annotated with formulas. About 16% of the problems belong to other shapes (e.g., *parallelogram*, *rhombus*, etc.) which currently are not covered in our formula set. About 40% are problems that contain geometric keywords but do not actually require any formulas. Table 3 shows such an example. We use these problems to test the robustness of our model. That is, S2G has to learn to apply the correct formulas or equations from misleading keywords (as shown in Table3) and has to learn to generate both binary expression trees and operation trees as a whole.

GeometryQA	
Number of problems	1,398
Number of sentences/words	5.4k / 41.1k
Vocabulary size	2,872
Annotated with formulas	604 (43.20%)
Problems of other shapes	225 (16.09%)
Formulas not required	569 (40.70%)

Table 2: Dataset statistics of GeometryQA

Problem: The perimeter of a rectangular swimming pool is 300 m. If you place a chair every 10 m all the way around its perimeter, how many chairs do you need?
Equation: $x = 300/10$ **Answer:** 30

Table 3: Example problem that contains misleading keywords (perimeter, rectangular) but do not require any geometry formulas.

5 Experiments

5.1 Implementation Details

We implement our S2G model and the GNN module using Pytorch[2] and Pytorch Geometric[3]. We set the dimension of word embedding to 128 and the dimension of the hidden state of GRU and GNN to 512. The dropout rate (Srivastava et al., 2014) is set to 0.5 and the batch size is 64. For optimization, we use ADAM (Kingma and Ba, 2015) with a learning rate of 10^{-3} and a weight decay of 10^{-5}. Besides, we use a learning rate scheduler to reduce the learning rate by half every 20 epochs. During evaluation, we use beam search (Wiseman and Rush, 2016) with a beam size of 5.

5.2 Experimental Results on GeometryQA

We evaluate our S2G model on GeometryQA to check whether it can learn to predict the corresponding operation tree for the geometry word problems. Table 4 shows the results of our S2G against other seq2tree SOTA models. S2G is trained using the re-annotated equations that contain formulas, while the baselines are trained using the original equations.

First, we find that S2G has about 3.8% perfor-

[2]https://pytorch.org/

[3]https://pytorch-geometric.readthedocs.io/en/latest/

mance gain over its baselines (with p-value < 0.01). We attribute this to the fact that operation trees are easier to learn and generate since they are less lengthy and complex than binary expression trees. Hence, there is a better chance for S2G to produce the correct trees and arrive at the correct answers.

Second, there is a small performance gain by adding Geometry KG. However, the improvement is not significant (with p-value$\approx$0.8). We guess that is because the dataset currently has only six geometric objects, which is not complex enough to show the effectiveness of adding knowledge graphs.

Model	Accuracy(%)
KA-S2T (Wu et al., 2020)	49.61%
GTS (Xie and Sun, 2019)	51.01%
S2G	**54.79%**
S2G + Geometry KG	**54.99%**

Table 4: Answer accuracy of S2G and other SOTA seq2tree models on GeometryQA (all evaluated with 5-fold cross validation).

6 Conclusion

In this work, we proposed a sequence-to-general tree model (S2G) that aims to generalize previous seq2tree architectures. Our S2G can learn to generate executable operation trees where the nodes can be formulas with arbitrary number of arguments. By explicitly generating formulas as nodes, we make the predicted results more interpretable. Besides, we also proposed a knowledge-guided mechanism to guide the tree decoding using KGs and constructed a dataset in which problems are annotated with associated formulas. Experimental results showed that our S2G model can achieve better performance against strong baselines.

A Data Preprocessing

In this section, we describe the data preprocessing steps required for our S2G model.

A.1 Converting to prefix notation

To perform top-down tree decoding, we follow (Xie and Sun, 2019) to convert the equations into their *prefix notation*, where the operators are placed in front of their operands, rather than in between. In this way, the order of the equation tokens would match the order of decoding. In our case, we also need to consider the formulas used in the equation. For a formula in the form "$F(arg1, arg2)$", we turn it into "$[F, arg1, arg2]$" so that it can fit into the prefix notation. Table 5 shows an example of this infix-to-prefix conversion for an equation with formulas.

Problem: The outer radius and inner radius of a circular annulus are 5m and 3m respectively. Find the area of this circular annulus.
Equation: x = circle_area(5) - circle_area(3) **Prefix form:** [-, circle_area, 5, circle_area, 3]

Table 5: Infix-to-prefix conversion for an equation with formulas.

A.2 Vocabulary

We follow the canonical sequence-to-sequence architecture (Sutskever et al., 2014) to prepare for the source vocabulary. For the target vocabulary, however, we have to take into consideration the way that humans solve MWPs. To solve a math problem, we use the numbers from the problem text (a dynamic vocabulary) and the mathematical operators learned before (a static vocabulary) and try to compose them into an equation. Sometimes, we also need to use external constant numbers (a static vocabulary) that are not in the problem text but would appear in the equation (e.g., 1, 2, or 3.14). These three types of vocabulary make up the vocabulary for the equations in arithmetic problems (equation 13).

$$V_{arith} = V_{number} \cup V_{op} \cup V_{const} \quad (13)$$

We follow (Xie and Sun, 2019) to use a copy mechanism (Gu et al., 2016) to copy the numbers from the problem text. Hence, we can dynamically get the problem numbers during decoding. Besides, we extend the original vocabulary by adding domain-specific formulas into it so that the decoder can generate formulas during decoding (equation 14). Table 6 shows the overall vocabulary that we use for our decoder.

Vocab Type	Instances
Operator	+, -, *, /, ^
Number	$\langle N0 \rangle$, $\langle N1 \rangle$, $\langle N2 \rangle$, ...
Constant	1, 2, 3.14
*Formula	circle_area, square_area, rectangle_perimeter, and so on.

Table 6: Types of the vocabulary.

$$V_{target} = V_{number} \cup V_{op} \cup V_{const} \cup V_{formula} \quad (14)$$

B GeometryQA

Table 7 shows the 11 formulas used for annotation.

Name	Formula	# args
Square		
square_area	side * side	1
square_perimeter	4 * side	1
Cubic		
cubic_volume	side*side*side	1
Circle		
circle_area	π * radius^2	1
circumference_r	2 * π * radius	1
circumference_d	π * diameter	1
Triangle		
triangle_area	base*height / 2	2
Rectangle		
rectangle_area	length * width	2
rectangle_perimeter	2 * (l+w)	2
Cuboid		
cuboid_volume	l* w* height	3
cuboid_surface	2*(l*w+w*h+l*h)	3

Table 7: Eleven geometry formulas used in annotating GeometryQA.

C Related Work

In this section, we briefly introduce the progress of MWP solvers, and then we focus on topics that are

closer to our work, including seq2tree solvers and knowledge graphs for problem solving.

C.1 Math Word Problem Solving

Ever since 1960s, efforts have been made to build automatic math word problem solving systems (Feigenbaum et al., 1963; Bobrow, 1964). Statistical solvers learn to map problem features into corresponding equation templates or operations to solve the problem (Kushman et al., 2014; Hosseini et al., 2014; Mitra and Baral, 2016; Liang et al., 2016, 2018; Roy and Roth, 2018). For example, Kushman et al. (2014) propose to align MWPs to their templates, while Hosseini et al. (2014) propose to find the operations by verb categorization. Semantic parsing approaches, on the other hand, parse the problem into intermediate representations using semantic parsers (Shi et al., 2015; Koncel-Kedziorski et al., 2015; Huang et al., 2017).

Recently, neural architectures have emerged as a dominant paradigm in math word problem solving. Wang et al. (2017) first attempt to use a seq2seq solver that utilize encoder-decoder architectures to encode the problem text and then decode into equations in a way similar to machine translation. Copy mechanism (Huang et al., 2018) or attention mechanisms (Li et al., 2019) are introduced to improvement the performance of seq2seq models. These seq2seq models, however, suffer from producing invalid equations, like a binary operator with three operands, because there is no grammatical constraint on its sequential decoding. To solve this problem, seq2tree models are proposed to bring into the grammatical constraints (Xie and Sun, 2019; Liu et al., 2019). We will give a more detailed introduction to seq2tree models in Section C.2.

C.2 Sequence-to-Tree Models

To convert text into structured representations, several research strands have utilized sequence-to-tree models. Dong and Lapata (2016) first use seq2tree on semantic parsing to translate text into structured logical forms. Similar frameworks are also adopted for code generation (Yin and Neubig, 2017; Rabinovich et al., 2017) where they translate code snippets into executable representations or abstract syntax trees (ASTs).

Inspired by their ideas, MWP solving also adopts seq2tree to map the problem text into expression trees. This introduces a constraint that the non-leaf nodes of the tree should be operators and leaf nodes be numbers, and thus the resulted equations are always guaranteed to be valid. Most seq2tree solvers choose bidirectional LSTM or GRU as their text encoder and use two separate models to predict the left and right nodes during decoding respectively (Xie and Sun, 2019; Zhang et al., 2020; Wu et al., 2020; Li et al., 2020). Our model differs from the previous that we use a single RNN-based decoder to predict a variable number of children nodes during decoding. In addition, our model can predict formulas as nodes that increase the interpretability of the model outputs, while previous solvers can only predict basic arithmetic operators.

C.3 Knowledge Graph for Math Word Problem Solving

To incorporate external knowledge into problem solving, some solvers utilize graph convolutional networks (Kipf and Welling, 2017) or graph attention networks (Veličković et al., 2018) to encode knowledge graphs (KGs) as an additional input. Wu et al. (2020) proposed to incorporate commonsense knowledge from external knowledge bases. They constructed a dynamic KG for each problem to model the relationship between the entities in the problem. For example, ”daisy” and ”rose” would be linked to their category ”flower” so that the solver can use this hyperonymy information when counting the number of flowers. Zhang et al. (2020) proposed to build graphs that model the quantity-related information using dependency parsing and POS tagging tools (Manning et al., 2014). Their graphs provide better quantity representations to the solver. Our model differs from previous models that we aim to incorporate domain knowledge from mathematical KGs rather than from commonsense knowledge bases.

Multi-Scale Progressive Attention Network for Video Question Answering

Abstract

Understanding the multi-scale visual information in a video is essential for Video Question Answering (VideoQA). Therefore, we propose a novel Multi-Scale Progressive Attention Network (MSPAN) to achieve relational reasoning between cross-scale video information. We construct clips of different lengths to represent different scales of the video. Then, the clip-level features are aggregated into node features by using max-pool, and a graph is generated for each scale of clips. For cross-scale feature interaction, we design a message passing strategy between adjacent scale graphs, i.e., top-down scale interaction and bottom-up scale interaction. Under the question's guidance of progressive attention, we realize the fusion of all-scale video features. Experimental evaluations on three benchmarks: TGIF-QA, MSVD-QA and MSRVTT-QA show our method has achieved state-of-the-art performance.

1 Introduction

Video Question Answering (VideoQA) is a popular vision-language task, which focuses on predicting the correct answer to a given natural language question based on the corresponding video. VideoQA task entails representing video features in both spatial and temporal dimensions. Compared with the visual features of a picture in Visual Question Answering, it requires a more complex attention.

Therefore, (Jang et al., 2017) employed appearance features and motion features as video representation, and designed a dual-LSTM network based on spatio-temporal attention to fuse visual and text information. Next, memory networks are widely used to capture long-term dependencies. For example, (Cai et al., 2020) applied feature augmented memory to strengthen the information augmentation of video and text. Complex relational reasoning is important for VideoQA task. Consequently, a conditional relationship network (Le et al., 2020) was designed in previous work, which can support high-order relationships and multi-step reasoning.

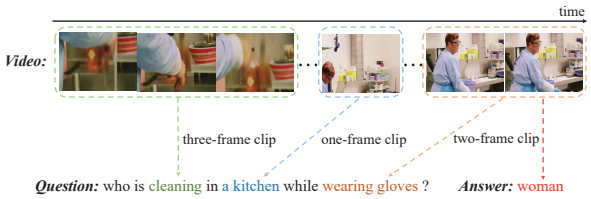

Figure 1: Understanding the video and answering the question require different levels of clips.

Many methods complete this task from a certain aspect, however, none of them have a fine-grained understanding of video information. When looking for the answer in a question-based video, the video frames corresponding to different objects in the question are of different lengths. As shown in Fig. 1, when asked "who is cleaning in a kitchen while wearing gloves?", we need to find the keywords "cleaning", "a kitchen" and "wearing gloves" from different levels of clips. Previous methods searched for the answer on the same level of clips in a video, leading to insufficient or redundant information.

Firstly, we construct clips of different lengths from the frame sequence, and regard the length of a clip as its scale information. Then, multi-scale graphs are generated separately for clips of different scales. The nodes in the multi-scale graphs indicate video features corresponding to different clips. For implementing relational reasoning, the nodes in each scale graph are first updated by using graph convolution. Most importantly, under the guidance of the question, progressive attention has been utilized to enable the fusion of multi-scale features during cross-scale graph interaction. In detail, each graph is gradually updated in top-down scale order, followed by updating each graph in bottom-up scale order. Finally, node features of a graph are fused with question embedding, and a classifier is employed to find the answer.

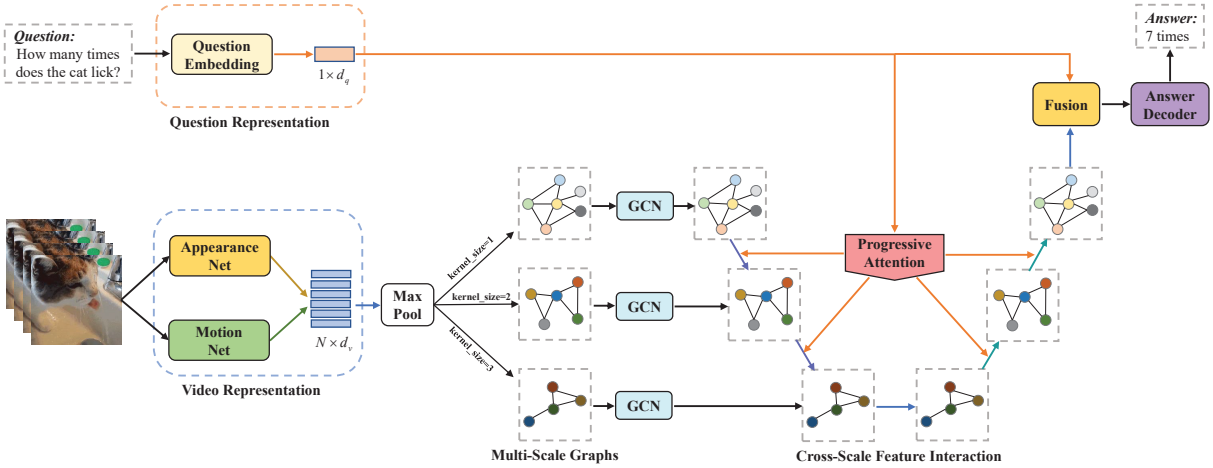

Figure 2: The model architecture of Multi-Scale Progressive Attention Network for VideoQA. Major contributions focus on the construction of multi-scale graphs and the progressive attention for cross-scale feature interaction.

2 Method

An overview of the proposed MSPAN is shown in Fig. 2. The input is a short video and a question sentence, while the output is the produced answer.

2.1 Video and Question Representation

Video representation N frames are uniformly sampled to represent the video. Then we use the pre-trained ResNet-152 (He et al., 2016) to extract video appearance features for each frame. And, we apply the 3D ResNet-152 (Hara et al., 2018) pre-trained on Kinetics-700 (Carreira et al., 2019) dataset to extract video motion features. Specifically, 16 frames around each frame are placed into the 3D ResNet-152 to obtain the motion features around this frame. Finally, we get a joint video representation by concatenating appearance features and motion features. By using a fully-connected layer to reduce feature dimension, we obtain video representation as $V = \{v_i : i \leq N, v_i \in R^{2048}\}$.

Question representation All words in question are represented as 300-dimensional embeddings initialized with pre-trained GloVe vectors (Pennington et al., 2014). And a 512-dimensional question embedding is generated from the last hidden state of a three-layer BiLSTM, i.e., $q \in R^{512}$.

2.2 Multi-Scale Graphs Generation

Each object in the video corresponds to a different number of frames, but previous methods (Seo et al., 2020; Lei et al., 2021) cannot treat various levels of visual information separately. Therefore, we construct clips of different lengths to express the visual information in the video delicately, and regard the length attribute as a scale.

We use max-pools of different kernel-sizes to aggregate frame-level visual features, and kernel-size is the scale attribute of these clips. In this way, clip-level visual features are obtained, as follows:

$$P = \{pool_i | 1 \leq i \leq K, kernel\_size_i = i\} \quad (1)$$

$$V_i = P_i(v_1, v_2, \cdots, v_N) \quad (2)$$

Where K is the range of scales, and $K \leq N$. Thus, we construct $M_i = N - i + 1$ clips at scale i:

$$V_i = \{v_j^i : 1 \leq j \leq M_i, v_j^i \in R^{2048}\} \quad (3)$$

In order to reason the relationships between different objects in a video, we separately build a graph for each scale. Each node in a graph represents the clip-level visual features. Only when two nodes contain overlapping or adjacent frames, an edge will be connected between them. Frame interval of the j-th clip at scale i is $[j, j + i - 1]$, so all edges in the K graphs can be expressed as:

$$E_i = \{(x, y) | x - i \leq y \leq x + i\} \quad (4)$$

Finally, these multi-scale graphs constructed in this paper can be denoted as $G_i = \{V_i, E_i\}$.

2.3 Cross-Scale Feature Interaction

Before cross-scale feature interaction, the original node features of K graphs are copied as $V_i^o = V_i$.

Interaction at the same scale. For all nodes with the same scale, we apply a two-layer graph convolutional network (GCN) (Kipf and Welling, 2017) to perform relational reasoning over the K

graphs. The process of graph convolution is represented as:

$$X_{l+1} = \hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}X_l W_l \quad (5)$$

Where $\hat{A}$ is the input adjacency matrix, X_l is the node feature matrix of layer l, and W_l is the learnable weight matrix. The diagonal node degree matrix $\hat{D}$ is used to normalize $\hat{A}$. Due to the small number of nodes in each graph, we decide to share the weight matrix W_l when K graphs are updated.

Interaction at top-down scale. We realize the interaction of adjacent scale graphs from small scale to large scale. Therefore, visual information is understood step by step from details to the whole through the interaction of top-down scale. Guided by the question, the nodes in graph G_i are used to update the nodes in graph G_{i+1}. Visual features at different scales show hierarchical attention to the question, so we call it progressive attention.

If the clip corresponding to node x in graph G_i has the same frames as the clip corresponding to node y in graph G_{i+1}, there will exist a directed edge from x to y. Therefore, we can use the edge to fuse the cross-scale features of these same frames.

Firstly, visual features and question embedding are fused to capture the joint features of each node in graph G_i. Then, the process of message passing from graph G_i to graph G_{i+1} can be expressed as:

$$m_{xy} = (W_1 v_y^{i+1}) \otimes ((W_2 v_x^i) \odot (W_3 q))^T \quad (6)$$

Where $\otimes$ is the outer product, $\odot$ is the hadamard product. After receiving the delivery messages, the attention weights of these messages are calculated:

$$w_{xy} = \underset{x \in \mathcal{N}_y}{soft\max}(m_{xy}) \quad (7)$$

Where $\mathcal{N}_y$ is the set of all neighbor nodes in graph G_i through cross-scale edges. Consequently, all the messages passed into node y are summed to derive the update of node y, as follows:

$$\tilde{v}_y^{i+1} = \sum_{x \in N_y} w_{xy} \cdot ((W_4 v_x^i) \odot (W_5 q)) \quad (8)$$

$$V_{i+1}^u = \{\tilde{v}_y^{i+1} : y \leq M_{i+1}, \tilde{v}_y^{i+1} \in R^{2048}\} \quad (9)$$

When updating all nodes in graph G_{i+1}, we consider the new features V_{i+1}^u and the original features V_{i+1}^o. Therefore, we use the residual connection to preserve original information of the video:

$$V_{i+1} = W_6[V_{i+1}; V_{i+1}^u] + V_{i+1}^o \quad (10)$$

Where $[;]$ is the concatenation operator. Above $W_1 \sim W_6$ are learnable weights, and they are shared in the update of graphs $G_2 \sim G_K$. To summarize, the update of $K-1$ graphs is a progressive process from small scale to large scale, hence it is referred to as top-down scale interaction.

Interaction at bottom-up scale. After an overall understanding of the video, people can accurately find all details related to the question at the second time they watch the video. Therefore, we achieve an understanding of the video from global to local through bottom-up scale interaction. After the previous interaction, we realize the interaction of adjacent graphs from large scale to small scale.

Following the same method as top-down scale interaction from Eq. 6 to Eq. 10, we apply graph G_i to update graph G_{i-1} in this interaction. But the weights $W_1 \sim W_6$ are another group in the update of graphs $G_{K-1} \sim G_1$. After this interaction, graph G_1 can grasp the all-scale video features related to the question by progressive attention.

2.4 Multimodal Fusion and Answer Decoder

After T iterations of cross-scale feature interaction, we read out all the nodes in graph G_1. Then, a simple attention is used to aggregate the N nodes. And, final multi-modal representation is given as:

$$\tilde{w}_j = soft\max(W_7(W_8 v_j^1) \odot (W_9 q)) \quad (11)$$

$$\tilde{F} = \sum_{j=1}^{N} \tilde{w}_j \cdot v_j^1 \quad (12)$$

$$F = ELU(W_{10}\tilde{F} \odot W_{11} q + b) \quad (13)$$

Where ELU is activation function, above $W_7 \sim W_{11}$ are learnable weights and b is learnable bias. We can find the answer by applying a classifier (two fully-connected layers) on multi-modal representation F. Multi-label classifier is applied to open-ended tasks, and cross-entropy loss function is used to train the model. Due to repetition count is a regression task, we use the MSE loss function.

For the multi-choice task, each question corresponds to R answer sentences. We first get the embedding of each answer in the same way as the question embedding. Then we use the multi-modal fusion method in Eq. 11∼13 to fuse the answer embedding with node features. After using two fully-connected layers, the answer scores $\{s_i\}_{i=1}^R$ have appeared. This model is trained by minimizing the hinge loss (Jang et al., 2017) of pairwise comparisons between answer scores $\{s_i\}_{i=1}^R$.

3 Experiments

3.1 Datasets

TGIF-QA (Jang et al., 2017) is a widely used large-scale benchmark dataset for VideoQA. And four task types are covered in this dataset: repeating action (Action), repetition count (Count), video frame QA (FrameQA) and state transition (Trans.). **MSVD-QA** (Xu et al., 2017) and **MSRVTT-QA** (Xu et al., 2016) are open-ended tasks which are generated from video descriptions. In both datasets, questions can be divided into 5 types according to question words: what, who, how, when and where.

3.2 Implementation Details

We evenly sample $N = 16$ frames for each video in the three datasets. The hyperparameters we set in experiments are as follows: $T = 3$, $K = 8$. When training the network, Adam is used with an initial learning rate of 10^{-4}. For TGIF-QA dataset, the batch size is 64. While the batch size is set to 128 for both MSVD-QA and MSRVTT-QA datasets.

3.3 Results

We compare our MSPAN with the state-of-the-art methods: PSAC (Li et al., 2019), HME (Fan et al., 2019), FAM (Cai et al., 2020), LGCN (Huang et al., 2020), HGA (Jiang and Han, 2020), QueST (Jiang et al., 2020) and HCRN (Le et al., 2020).

Table 1: Comparison on TGIF-QA dataset.

Method	Action	Count	FrameQA	Trans.
PSAC	70.4	4.27	55.7	76.9
HME	73.9	4.02	53.8	77.8
FAM	75.4	3.79	56.9	79.2
LGCN	74.3	3.95	56.3	81.1
HGA	75.4	4.09	55.1	81.0
QueST	75.9	4.19	59.7	81.0
HCRN	75.0	3.82	55.9	81.4
MSPAN	**78.4**	**3.57**	**59.7**	**83.3**

Results on TGIF-QA. As shown in Table 1, our method outperforms the state-of-the-art methods by **2.5%** and **1.9%** of accuracy on Action and Transition tasks. For the Count task, our method also achieves the best Mean Square Error (MSE) of **3.57** among all methods. Due to QueST used multi-dimension visual features containing more appearance information, our method can only get the same accuracy **59.7%** as QueST on the FrameQA task.

Table 2: Comparison on MSVD-QA dataset.

Method	What	Who	How	When	Where	All
	62.7%	33.9%	2.8%	0.4%	0.2%	100%
HME	22.4	50.1	73.0	70.7	42.9	33.7
QueST	24.5	52.9	79.1	72.4	50.0	36.1
HGA	23.5	50.4	**83.0**	72.4	46.4	34.7
FAM	23.1	51.6	82.2	71.4	51.9	34.5
MSPAN	**31.0**	**53.8**	77.0	**72.4**	**53.6**	**40.3**

Table 3: Comparison on MSRVTT-QA dataset.

Method	What	Who	How	When	Where	All
	68.5%	27.7%	2.5%	1.0%	0.3%	100%
HME	26.5	43.6	82.4	76.0	28.6	33.0
QueST	27.9	45.6	83.0	75.7	31.6	34.6
HGA	29.2	45.7	**83.5**	75.2	34.0	35.5
FAM	26.9	43.9	82.8	70.6	31.1	33.2
MSPAN	**31.9**	**47.2**	83.2	**77.5**	**38.4**	**37.8**

All in all, our method makes sense of the multi-scale information of the video, so that the effect on tasks related to action recognition, temporal relationship and object count are very noticeable.

Results on MSVD-QA. As shown in Table 2, our method improves the overall accuracy by **4.2%** compared to recent methods. We have achieved the best accuracy on questions whose question words are "What" , "Who", "When" and "Where". Due to a small proportion, the accuracy on the question word "How" is lower than other methods.

Results on MSRVTT-QA. As shown in Table 3, our method achieves the best overall accuracy of **37.8%**. What's more, Our method could obtain excellent accuracy on different question words.

4 Ablation Studies

To explore the potential of our network, ablation experiments are performed on TGIF-QA dataset. Default hyperparameters are: $T = 3$ and $K = 8$. We study the effectiveness of our network in the next two aspects, as shown in Table 4 and Fig. 4.

4.1 Different Structures

Considering the interaction of cross-scale graphs, three structures are designed, as shown in Fig. 3. For the dense scale in Fig. 3 (a), we apply graphs $G_1 \sim G_K$ to update each graph G_i. The other two structures have been introduced in Sec 2.3, and we will not use a graph to update itself for the three

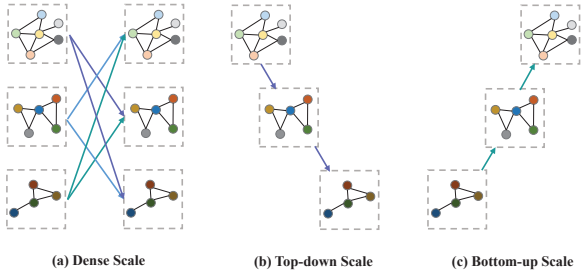

Figure 3: Three methods of cross-scale feature interaction, where the dense connection is not adopted.

structures. The readout of top-down scale interaction is graph G_K, and the readout of bottom-up scale interaction is G_1. However, the readout of dense scale interaction is all K graphs. Our network is a combination of top-down scale interaction and bottom-up scale interaction, but we will use these two structures separately for comparison.

4.2 Network structure

When choosing the pooling function to aggregate these frames in a clip, we find that max-pool is more effective than avg-pool. In reverse gradient propagation of max-pool, only the maximum of features in the previous layer receive the gradient. So, max-pool facilitates the fusion of appearance features and motion features in the previous layer.

Our experiments show that GCN is beneficial to the stable training of models. If there is no GCN, the gradient will gradually disappear as the number of interactions between the graphs increases. The role of GCN is to re-recover the features of these nodes which have lost their visual features.

As shown in Table 4, the performances of the three structures in Fig. 3 are poorer than that of our entire network. Due to dense connections between all scale graphs, the dense scale interaction will add much unnecessary computation, and make it difficult to accurately find the visual information related to the question. Although both the top-down scale interaction and the bottom-up scale interaction can achieve good performance. However, the combination of these two structures will obtain a more detailed understanding of the video.

4.3 Hyperparameters T and K

As the number of iterations T increases, the model will achieve better performance. But when $T = 4$, the effect of the model decreases, as shown in Table 4. Because too many modules will produce noise for answer generation. The improvement

Table 4: Ablation experiments of four types: (1)Replacing max-pool with avg-pool. (2)Without GCN. (3)Different structures in Fig. 3. (4)Different iterations T.

Parameters	Action	Count	FrameQA	Trans.
Avg-pool	78.0	3.56	59.5	83.3
w/o GCN	77.5	3.64	59.1	82.7
Dense scale	77.2	3.74	59.2	82.0
Top-down scale	78.1	3.62	59.6	82.8
Bottom-up scale	78.1	3.60	59.3	82.6
$T = 0$	75.2	3.86	56.7	79.9
$T = 1$	77.1	3.69	58.6	82.5
$T = 2$	77.7	3.61	**59.7**	82.9
$T = 4$	77.6	3.63	59.4	82.5
Full MSPAN	**78.4**	**3.57**	59.7	**83.3**

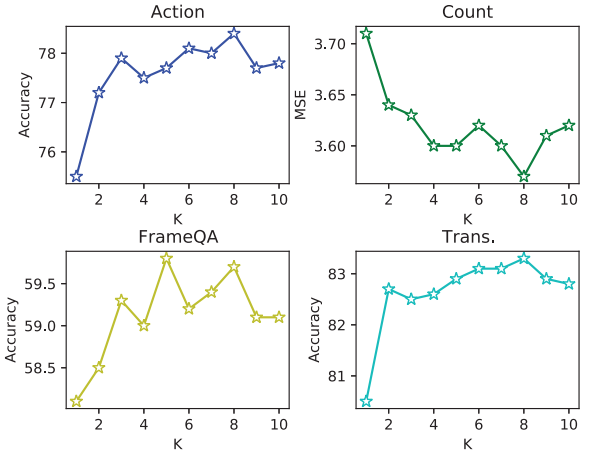

Figure 4: Ablation experiments for different scales K.

of models with the increase of K is very obvious, and best performance is obtained when $K = 8$, as shown in Fig. 4. However, the larger K also means that many multi-scale graphs, which will lead to network instability.

5 Conclusion

We introduce a multi-scale learning method to achieve a fine-grained understanding of the video. Compared with existing spatio-temporal attention, we use progressive attention to realize cross-scale feature interaction. The top-down and bottom-up structures we have designed are conducive to learning all-scale visual information of the video. For longer videos, we plan to use dilated max-pools with different strides to reduce the size of graphs. In general, we consider the VideoQA task from the perspective of multi-scale information interaction, and the proposed network is instructive.

Abstract

Most state-of-the-art open-domain question answering systems use a neural retrieval model to encode passages into continuous vectors and extract them from a knowledge source. However, such retrieval models often require large memory to run because of the massive size of their passage index. In this paper, we introduce *Binary Passage Retriever* (*BPR*), a memory-efficient neural retrieval model that integrates a *learning-to-hash* technique into the state-of-the-art Dense Passage Retriever (DPR) (Karpukhin et al., 2020) to represent the passage index using compact binary codes rather than continuous vectors. BPR is trained with a multi-task objective over two tasks: efficient candidate generation based on binary codes and accurate reranking based on continuous vectors. Compared with DPR, BPR substantially reduces the memory cost from 65GB to 2GB without a loss of accuracy on two standard open-domain question answering benchmarks: Natural Questions and TriviaQA. Our code and trained models are available at https://github.com/studio-ousia/bpr.

1 Introduction

Open-domain question answering (QA) is the task of answering arbitrary factoid questions based on a knowledge source (e.g., Wikipedia). Recent state-of-the-art QA models are typically based on a two-stage *retriever–reader* approach (Chen et al., 2017) using a *retriever* that obtains a small number of relevant passages from a large knowledge source and a *reader* that processes these passages to produce an answer. Most recent successful retrievers encode questions and passages into a common continuous embedding space using two independent encoders (Lee et al., 2019; Karpukhin et al., 2020; Guu et al., 2020). Relevant passages are retrieved using a nearest neighbor search on the index containing the passage embeddings with a question embedding as a query.

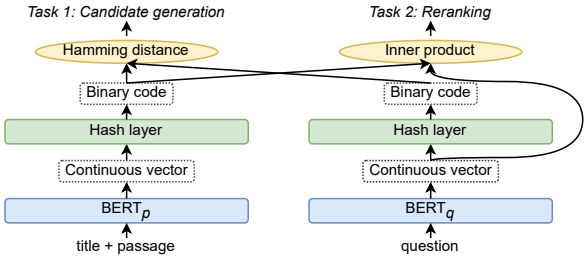

Figure 1: Architecture of BPR, a BERT-based model generating compact binary codes for questions and passages. The passages are retrieved in two stages: (1) efficient candidate generation based on the Hamming distance using the binary code of the question and (2) accurate reranking based on the inner product using the continuous embedding of the question.

These retrievers often outperform classical methods (e.g., BM25), but they incur a large memory cost due to the massive size of their passage index, which must be stored entirely in memory at runtime. For example, the index of a common knowledge source (e.g., Wikipedia) requires dozens of gigabytes.[1] A reduction in the index size is critical for real-world QA that requires large knowledge sources such as scientific databases (e.g., PubMed) and web-scale corpora (e.g., Common Crawl).

In this paper, we introduce *Binary Passage Retriever* (*BPR*), which learns to hash continuous vectors into compact binary codes using a multi-task objective that simultaneously trains the encoders and hash functions in an end-to-end manner (see Figure 1). In particular, BPR integrates our *learning-to-hash* technique into the state-of-the-art Dense Passage Retriever (DPR) (Karpukhin et al., 2020) to drastically reduce the size of the

[1]The passage index of the off-the-shelf DPR model (Karpukhin et al., 2020) requires 65GB for indexing the 21M English Wikipedia passages, which have 13GB storage size.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 979–986
August 1–6, 2021. ©2021 Association for Computational Linguistics

passage index by storing it as binary codes. BPR computes binary codes by applying the sign function to continuous vectors. As the sign function is not compatible with back-propagation, we approximate it using the scaled tanh function during training. To improve search-time efficiency while maintaining accuracy, BPR is trained to obtain both binary codes and continuous embeddings for questions with multi-task learning over two tasks: (1) candidate generation based on the Hamming distance using the binary code of the question and (2) reranking based on the inner product using the continuous embedding of the question. The former task aims to detect a small number of candidate passages efficiently from the entire passages and the latter aims to rerank the candidate passages accurately.

We conduct experiments using the Natural Questions (NQ) (Kwiatkowski et al., 2019) and TriviaQA (TQA) (Joshi et al., 2017) datasets. Compared with DPR, our BPR achieves similar QA accuracy and competitive retrieval performance with a substantially reduced memory cost from 65GB to 2GB. Furthermore, using an improved reader, we achieve results that are competitive with those of the current state of the art in open-domain QA. Our code and trained models are available at `https://github.com/studio-ousia/bpr`.

2 Related Work

Retrieval for Open-domain QA Many recent open-domain QA models depend on the retriever to select relevant passages from a knowledge source. Early works involved the adoption of sparse representations (Chen et al., 2017) for the retriever, whereas recent works (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020) have often adopted dense representations based on neural networks. Our work is an extension of DPR (Karpukhin et al., 2020), which has been used in recent state-of-the-art QA models (Lewis et al., 2020; Izacard and Grave, 2020). Concurrent with our work, Izacard et al. (2020) attempted to reduce the memory cost of DPR using post-hoc product quantization with dimension reduction and filtering of passages. However, they observed a significant degradation in the QA accuracy compared with their full model. We adopt the learning-to-hash method with our multi-task objective and substantially compress the index without losing accuracy.

Learning to Hash The objective of hashing is to reduce the memory and search-time cost of the nearest neighbor search by representing data points using compact binary codes. Learning to hash (Wang et al., 2016, 2018) is a method for learning hash functions in a data-dependent manner. Recently, many *deep-learning-to-hash* methods have been proposed (Lai et al., 2015; Zhu et al., 2016; Li et al., 2016; Cao et al., 2017, 2018) to jointly learn feature representations and hash functions in an end-to-end manner. We follow Cao et al. (2017) to implement our hash functions. Similar to our work, Xu and Li (2020) used the learning-to-hash method to reduce the computational cost of the answer sentence selection task, the objective of which is to select an answer sentence from a limited number of candidates (up to 500 in their experiments). Our work is different from the aforementioned work because we focus on efficient and scalable passage retrieval from a large knowledge source (21M Wikipedia passages in our experiments) using an effective multi-task approach. In addition to hashing-based methods, improving approximate neighbor search has been actively studied (Jégou et al., 2011; Malkov and Yashunin, 2020; Guo et al., 2020). We use Jégou et al. (2011) and Malkov and Yashunin (2020) as baselines in our experiments.

3 Model

Given a question and large-scale passage collection such as Wikipedia, a retriever finds relevant passages that are subsequently processed by a reader. Our retriever is built on DPR (Karpukhin et al., 2020), which is a retriever based on BERT (Devlin et al., 2019). In this section, we first introduce DPR and then explain our model.

3.1 Dense Passage Retriever (DPR)

DPR uses two independent BERT encoders to encode question q and passage p into d-dimensional continuous embeddings:

$$\mathbf{e}_q = \mathrm{BERT}_q(q), \quad \mathbf{e}_p = \mathrm{BERT}_p(p), \qquad (1)$$

where $\mathbf{e}_q \in \mathbb{R}^d$ and $\mathbf{e}_p \in \mathbb{R}^d$. We use the uncased version of BERT-base; therefore, $d = 768$. The output representation of the `[CLS]` token is obtained from the encoder. To create passage p, the passage title and text are concatenated (`[CLS]` *title* `[SEP]` *passage* `[SEP]`). The relevance score of passage p, given question q, is computed using the inner product of the corresponding vectors, $\langle \mathbf{e}_q, \mathbf{e}_p \rangle$.

Training Let $\mathcal{D} = \{\langle q_i, p_i^+, p_{i,1}^-, \cdots, p_{i,n}^- \rangle\}_{i=1}^m$ be m training instances consisting of a question q_i, a passage that answers the question (positive passage), p_i^+, and n passages that are irrelevant for the question (negative passages), $p_{i,j}^-$. The model is trained by minimizing the negative log-likelihood of the positive passage:

$$\mathcal{L}_{\text{dpr}} = -\log \frac{\exp(\langle \mathbf{e}_{q_i}, \mathbf{e}_{p_i^+} \rangle)}{\exp(\langle \mathbf{e}_{q_i}, \mathbf{e}_{p_i^+} \rangle) + \sum_{j=1}^n \exp(\langle \mathbf{e}_{q_i}, \mathbf{e}_{p_{i,j}^-} \rangle)}. \quad (2)$$

Inference DPR creates a passage index by applying the passage encoder to each passage in the knowledge source. At runtime, it retrieves the top-k passages employing maximum inner product search with the question embedding as a query.

3.2 Model Architecture

Figure 1 shows the architecture of BPR. BPR builds a passage index by computing a binary code for each passage in the knowledge source. To compute the binary codes for questions and passages, we add a *hash layer* on top of the question and passage encoders of DPR. Given embedding $\mathbf{e} \in \mathbb{R}^d$ computed by an encoder, the hash layer computes its binary code, $\mathbf{h} \in \{-1, 1\}^d$, as

$$\mathbf{h} = \text{sign}(\mathbf{e}), \quad (3)$$

where $\text{sign}(\cdot)$ is the sign function such that for $i = 1, ..., d$, $\text{sign}(h_i) = 1$ if $h_i > 0$; otherwise, $\text{sign}(h_i) = -1$. However, the sign function is incompatible with back-propagation because its gradient is zero for all non-zero inputs and is ill-defined at zero. Inspired by Cao et al. (2017), we address this by approximating the sign function using the scaled tanh function during the training:

$$\tilde{\mathbf{h}} = \tanh(\beta \mathbf{e}), \quad (4)$$

where β is a scaling parameter. When β increases, the function gradually becomes non-smooth, and as $\beta \to \infty$, it converges to the sign function. At each training step, we increase β by setting $\beta = \sqrt{\gamma \cdot step + 1}$, where $step$ is the number of finished training steps. We set $\gamma = 0.1$ and explain the effects of changing it in Appendix B.

3.3 Two-stage Approach

To reduce the computational cost without losing accuracy, BPR splits the task into candidate generation and reranking stages. At the candidate generation stage, we efficiently obtain the top-l candidate passages using the Hamming distance between the binary code of question $\mathbf{h}_q$ and that of each passage, $\mathbf{h}_p$. We then rerank the l candidate passages using the inner product between the continuous embedding of question $\mathbf{e}_q$ and $\mathbf{h}_p$ and select the top-k passages from the reranked candidates. We perform candidate generation using binary code $\mathbf{h}_q$ for search-time efficiency, and reranking using expressive continuous embedding $\mathbf{e}_q$ for accuracy. We set $l = 1000$ and describe the effects of using different l values in Appendix C.

3.4 Training

To compute effective representations for both the candidate generation and reranking stages, we combine the loss functions of the two tasks:

$$\mathcal{L} = \mathcal{L}_{\text{cand}} + \mathcal{L}_{\text{rerank}}. \quad (5)$$

Task #1 for Candidate Generation The objective of this task is to improve candidate generation using the ranking loss with the approximated hash code of question $\tilde{\mathbf{h}}_q$ and that of passage $\tilde{\mathbf{h}}_p$:

$$\mathcal{L}_{\text{cand}} = \sum_{j=1}^n \max(0, -(\langle \tilde{\mathbf{h}}_{q_i}, \tilde{\mathbf{h}}_{p_i^+} \rangle + \langle \tilde{\mathbf{h}}_{q_i}, \tilde{\mathbf{h}}_{p_{i,j}^-} \rangle) + \alpha). \quad (6)$$

We set $\alpha = 2$ and investigate the effects of selecting different α values and using the cross-entropy loss instead of the ranking loss in Appendix D. Note that the retrieval performance based on the Hamming distance can be optimized using this loss function because the Hamming distance and inner product can be used interchangeably for binary codes.[2]

Task #2 for Reranking We improve the reranking stage using the following loss function:

$$\mathcal{L}_{\text{rerank}} = -\log \frac{\exp(\langle \mathbf{e}_{q_i}, \tilde{\mathbf{h}}_{p_i^+} \rangle)}{\exp(\langle \mathbf{e}_{q_i}, \tilde{\mathbf{h}}_{p_i^+} \rangle) + \sum_{j=1}^n \exp(\langle \mathbf{e}_{q_i}, \tilde{\mathbf{h}}_{p_{i,j}^-} \rangle)}. \quad (7)$$

This function is equivalent to $\mathcal{L}_{\text{dpr}}$, with the exception that $\tilde{\mathbf{h}}_p$ is used instead of $\mathbf{e}_p$.

3.5 Algorithms for Candidate Generation

To perform candidate generation, we test two standard algorithms: (1) linear scan based on efficient Hamming distance computation,[3] and (2) hash table lookup implemented by building a hash table that maps each binary code to the corresponding passages and querying it multiple times by increasing the Hamming radius until we obtain l passages.

[2] Given two binary codes, $\mathbf{h}_i$ and $\mathbf{h}_j$, there exists a relationship between their Hamming distance, $\text{dist}_H(\cdot, \cdot)$, and inner product, $\langle \cdot, \cdot \rangle$: $\text{dist}_H(\mathbf{h}_i, \mathbf{h}_j) = \frac{1}{2}(const - \langle \mathbf{h}_i, \mathbf{h}_j \rangle)$.

[3] The Hamming distance can be computed more efficiently than the inner product using the POPCNT CPU instruction.

Model	Top 1		Top 20		Top 100		QA Acc. (EM)		Index	Query

BPR w/o reranking	38.0	46.1	76.5	75.9	84.9	83.4	37.9ms
BPR w/o candidate generation	41.1	49.7	77.9	77.9	85.7	84.5	457.8ms

Table 2: Results of our ablation study. Hash table lookup is used to implement candidate generation.

4 Experiments

Datasets We conduct experiments using the NQ and TQA datasets and English Wikipedia as the knowledge source. We use the following pre-processed data available on the DPR website:[4] Wikipedia corpus containing 21M passages and the training/validation datasets for the retriever containing multiple positive, *random* negative, and *hard* negative passages for each question.

Baselines We compare our BPR with DPR with linear scan and DPR with Hierarchical Navigable Small World (HSNW) graphs (Malkov and Yashunin, 2020) – which builds a multi-layer structure consisting of a hierarchical set of proximity graphs, following Karpukhin et al. (2020) – for our primary baselines. We also apply two popular post-hoc quantization algorithms to the DPR passage index: simple locality sensitive hashing (LSH) (Neyshabur and Srebro, 2015) and product quantization (PQ) (Jégou et al., 2011). We configure these algorithms such that their passage representations have the same size as that of BPR: the number of bits per passage of the LSH is set as 768, and the number of centroids and the code size of the PQ are configured as 96 and 8 bits, respectively.

Experimental settings Our experimental setup follows Karpukhin et al. (2020). We evaluate our model based on its top-k recall (the percentage of positive passages in the top-k passages), retrieval efficiency (the index size and query time), and exact match (EM) QA accuracy measured by combining our model with a reader. We use the same BERT-based reader as that used by DPR. Our model is trained using the same method as DPR. We conduct experiments on servers with two Intel Xeon E5-2698 v4 CPUs and eight Nvidia V100 GPUs. The passage index are built using Faiss (Johnson et al., 2019). Further details are provided in Appendix A.

4.1 Results

Main results Table 1 presents the top-k recall (for $k \in \{1, 20, 100\}$), EM QA accuracy, index size, and query time achieved by BPR and baselines on the NQ and TQA test sets. BPR achieves similar or even better performance than DPR in both retrieval with $k \geq 20$ and EM accuracy with a substantially reduced index size from 65GB to 2GB. We observe that BPR performs worse than DPR for $k = 1$, but usually the recall in small k is less important because the reader usually produces an answer based on $k \geq 20$ passages. BPR significantly outperforms all quantization baselines. The query time of BPR is substantially shorter than that of DPR. Hash table lookup is faster than linear scan but requires slightly more storage. DPR+HNSW is faster than BPR; however, it requires 151GB of storage.

Ablations Table 2 shows the results of our ablation study. Disabling the reranking clearly degrades performance, demonstrating the effectiveness of our two-stage approach. Disabling the can-

FiD (base) (Izacard and Grave, 2020)	T5-base	220M	48.2	65.0
FiD (large) (Izacard and Grave, 2020)	T5-large	770M	**51.4**	**67.6**
BPR ($l = 1000$)	BERT-base	110M	41.6	56.8
BPR ($l = 1000$)	ELECTRA-large	335M	49.0	65.6

Table 3: Exact match QA accuracy of BPR and state of the art models. BPR achieves performance close to FiD (large) with almost half of the parameters.

didate generation (treating all passages as candidates) results in the same performance as using only top-1000 candidates, but significantly increases the query time due to the expensive inner product computation over all passage embeddings.

Comparison with State of the Art Table 3 presents the EM QA accuracy of BPR combined with state-of-the-art reader models. Here, we also report the results of our model using an improved reader based on ELECTRA-large (Clark et al., 2020) instead of BERT-base. Our improved model outperforms all models except the large model of Fusion-in-Decoder (FiD), which contains more than twice as many parameters as our model.

5 Conclusion

We introduce BPR, which is an extension of DPR, based on a learning-to-hash technique and a novel two-stage approach. It reduces the computational cost of open-domain QA without a loss in accuracy.

Appendix for "Efficient Passage Retrieval with Hashing for Open-domain Question Answering"

A Details of Experimental Setup

A.1 Knowledge Source

As the knowledge source, we use the preprocessed Wikipedia corpus consisting of 21,015,324 Wikipedia passages available on the website of Karpukhin et al. (2020). The corpus is based on the December 20, 2018 version of the English Wikipedia and created by filtering out semi-structured data (i.e., tables, infoboxes, lists, and disambiguation pages) and splitting the remaining Wikipedia articles into multiple, disjointed text blocks of 100 words each.

A.2 Question Answering Datasets

We conduct experiments using the NQ and TQA datasets with the training, development, and test sets as in Lee et al. (2019); Karpukhin et al. (2020). A brief description of these datasets is provided as follows:

- **NQ** is a QA dataset for which questions are obtained from Google queries and answers comprise the spans of English Wikipedia articles.
- **TQA** consists of trivia questions and their answers retrieved from the Web.

We use the preprocessed datasets available on the website of Karpukhin et al. (2020).[5] The numbers of questions contained in these datasets are listed in Table 4. For each question, the dataset contains three types of passages: (1) *positive passages* selected based on gold-standard human annotations or distant supervision, (2) *random negative passages* selected randomly from all the passages, and (3) *hard negative passages* selected based on the BM25 scores between the question and all the passages.

A.3 Details of BPR

Our training configuration follows that of Karpukhin et al. (2020). In particular, for each question, we use one positive and one hard negative passage and create a mini-batch comprising 128 questions. We use the method of *inbatch-negatives*, wherein each positive passage in a mini-batch is treated as the negative passage of each question in the mini-batch if it does not correspond to the question. Our model contains 220 million parameters, and is trained for up to 40 epochs using Adam. Regarding the hyperparameter search, we select the learning rate from the search range {1e-5, 2e-5, 3e-5, 5e-5} based on the top-100 recall on the validation set of the NQ dataset. Therefore, the number of hyperparameter search trials is 4. The detailed hyperparameters are listed in Table 5.

[5] https://github.com/facebookresearch/DPR

Dataset	Train	Validation	Test
NQ	58,880	8,757	3,610
TQA	60,413	8,837	11,313

Table 4: Number of questions in the preprocessed dataset used in our experiments.

Name	Value

Adam β_2	0.999
Adam ϵ	1e-6

Table 5: Hyperparameters used to train BPR.

A.4 Details of Reader

For each passage in the top-k passages retrieved by the retriever, the reader assigns a relevance score to the passage and selects the best answer span in the passage. The final answer is the selected span from the passage with the highest relevance score.

Let $\mathbf{P}_i \in \mathbb{R}^{q \times d}$ $(1 \leq i \leq k)$ be a BERT output representation for the i-th passage, where q is the maximum token length of the passage, and d is the dimension size of the output representation. The probabilities of a passage being selected and a token being the start or end positions of an answer is computed as

$$P_{score}(i) = \mathrm{softmax}\left(\hat{\mathbf{P}}^{\top}\mathbf{w}_{score}\right)_i, \quad (8)$$

$$P_{start,i}(s) = \mathrm{softmax}\left(\mathbf{P}_i\mathbf{w}_{start}\right)_s, \quad (9)$$

$$P_{end,i}(t) = \mathrm{softmax}\left(\mathbf{P}_i\mathbf{w}_{end}\right)_t, \quad (10)$$

where $\hat{\mathbf{P}} = [\mathbf{P}_1^{[\mathrm{CLS}]}, \ldots, \mathbf{P}_k^{[\mathrm{CLS}]}] \in \mathbb{R}^{d \times k}$, $\mathbf{w}_{score} \in \mathbb{R}^d$, $\mathbf{w}_{start} \in \mathbb{R}^d$, and $\mathbf{w}_{end} \in \mathbb{R}^d$.

Name	BERT-base	ELECTRA-large
Batch size	32	32
Maximum token length	350	350
Maximum training epochs	20	20
Negative passage size	23	17
Peak learning rate	2e-5	1e-5
Learning rate decay	linear	linear
Warmup ratio	0.06	0.06
Dropout	0.1	0.1
Weight decay	0.0	0.0
Adam β_1	0.9	0.9
Adam β_2	0.999	0.999
Adam ϵ	1e-6	1e-6

Table 6: Hyperparameters used to train the reader based on BERT-base and that based on ELECTRA-large.

Configuration	Top 1	Top 20	Top 100
$\gamma = 0.025$	39.4	**76.7**	83.8
$\gamma = 0.05$	39.5	76.5	84.0
$\gamma = 0.1$	**39.8**	**76.7**	**84.1**
$\gamma = 0.2$	39.6	76.3	83.9

Table 7: Top-1, top-20, and top-100 recall of our model with $\gamma \in \{0.025, 0.05, 0.1, 0.2\}$ on the validation set of the NQ dataset.

The passage selection score of the i-th passage is given as $P_{score}(i)$, and the score of the s-th to t-th tokens from the i-th passage is given as $P_{start,i}(s) \times P_{end,i}(t)$.

During the training, we sample one positive and multiple negative passages from the passages returned by the retriever. The model is trained to maximize the log-likelihood of the correct answer span in the positive passage, combined with the log-likelihood of the positive passage being selected. We use the BERT-base or ELECTRA-large as our pretrained model. Regarding the hyperparameter search, we select the learning rate from {1e-5, 2e-5, 3e-5, 5e-5} based on its EM accuracy on the validation set of the NQ dataset. Therefore, the number of hyperparameter search trials is 4. Detailed hyperparameters are listed in Table 6.

B Effects of Scaling Parameter

To investigate how the scaling parameter, γ, affects the performance, we test the performance of our model using various γ values, where $\gamma \in \{0.025, 0.05, 0.1, 0.2\}$. The retrieval performance on the validation set of the NQ dataset is shown in Table 7. Overall, the scaling parameter has a minor impact on the performance. We select $\gamma = 0.1$ because of its enhanced performance.

#candidates	Top 1		Top 20		Top 100	
	NQ	TQA	NQ	TQA	NQ	TQA
$l = 200$	41.1	49.7	77.9	77.9	85.4	84.0
$l = 500$	41.1	49.7	77.9	77.9	85.6	84.4
$l = 1000$	41.1	49.7	77.9	77.9	**85.7**	**84.5**
$l = 2000$	41.1	49.7	77.9	77.9	**85.7**	**84.5**

Table 8: Top-1, top-20, and top-100 recall of our model with $l \in \{200, 500, 1000\}$ on test sets.

Configuration	Top 1	Top 20	Top 100
Cross entropy loss	28.6	67.8	79.8
Ranking loss $\alpha = 0.0$	39.8	76.4	84.0
Ranking loss $\alpha = 1.0$	40.0	76.5	84.0
Ranking loss $\alpha = 2.0$	39.8	**76.7**	**84.1**
Ranking loss $\alpha = 4.0$	**40.3**	**76.7**	84.0

Table 9: Top-1, top-20, and top-100 recall of our model with the various settings of the loss function $\mathcal{L}_{\text{cand}}$ evaluated on the validation set of the NQ dataset.

C Effects of Number of Candidate Passages

We report the performance of our model with the varied number of candidate passages l in Table 8. Overall, BPR achieves similar performance in all settings. Increasing the number of candidate passages slightly improves the top-100 performance until it reaches $l = 1000$.

D Effects of Loss of Task #1 with Various Settings

We investigate the effects of using various settings of the loss function $\mathcal{L}_{\text{cand}}$ in Eq.(6). Instead of using the ranking loss, we test the performance with the cross-entropy loss, similar to Eq.(2), and $\tilde{\mathbf{h}}_q$ and $\tilde{\mathbf{h}}_p$ are used instead of $\mathbf{e}_q$ and $\mathbf{e}_p$, respectively. Furthermore, we also test how the parameter α affects the performance. As shown in Table 9, the cross-entropy loss clearly performs worse than the ranking loss. Furthermore, a change in the parameter α has a minor impact on the performance. Here, we select the ranking loss with $\alpha = 2.0$ because of its enhanced performance on the top-20 and top-100 performance.

Entity Concept-enhanced Few-shot Relation Extraction

Abstract

Few-shot relation extraction (FSRE) is of great importance in long-tail distribution problem, especially in special domain with low-resource data. Most existing FSRE algorithms fail to accurately classify the relations merely based on the information of the sentences together with the recognized entity pairs, due to limited samples and lack of knowledge. To address this problem, in this paper, we proposed a novel entity CONCEPT-enhanced FEw-shot Relation Extraction scheme (ConceptFERE), which introduces the inherent concepts of entities to provide clues for relation prediction and boost the relations classification performance. Firstly, a concept-sentence attention module is developed to select the most appropriate concept from multiple concepts of each entity by calculating the semantic similarity between sentences and concepts. Secondly, a self-attention based fusion module is presented to bridge the gap of concept embedding and sentence embedding from different semantic spaces. Extensive experiments on the FSRE benchmark dataset FewRel have demonstrated the effectiveness and the superiority of the proposed ConceptFERE scheme as compared to the state-of-the-art baselines. Code is available at *https://github.com/LittleGuoKe/ConceptFERE*.

1 Introduction

Relation extraction (RE) is a fundamental task for knowledge graph construction and inference, which however often encounters challenges of long-tail distribution and low-resource data, especially in practical applications including medical or public security fields. In this case, it is difficult for existing RE models to learn effective classifiers (Zhang et al., 2019; Han et al., 2020). Therefore, FSRE has become a hot topic in both academia and industry. Existing FSRE methods can be roughly divided into two categories according to the type of adopted training data. The models of the first category only uses the plain text data, without any external information. The representative Siamese (Koch et al., 2015) and Prototypical (Snell et al., 2017) network in metric learning are used in the FSRE task to learn representation and metric function. BERT-PAIR (Gao et al., 2019b) pairs up all supporting instances with each query instance, and predicts whether the pairs are of the same category, which can be regarded as a variant of the Prototypical network. Gao (Gao et al., 2019a) and Ye (Ye and Ling, 2019) add the attention mechanism to enhance the prototype network. In order to alleviate the problem of insufficient training data, MICK (Geng et al., 2020) learns general language rules and grammatical knowledge from cross-domain datasets. Wang (Wang et al., 2020) proposes the CTEG model to solve the relation confusion problem of FSRE. Cong (Cong et al., 2020) proposes an inductive clustering based framework, DaFeC, to solve the problem of domain adaptation in FSRE.

Since the information of the plain text is limited in FSRE scenarios, the performance gain is marginal. Thus, the algorithms in the second category introduce external information, to compensate the limited information in FSRE, so as to enhance the performance. In order to improve the model's generalization ability for new relations, Qu (Qu et al., 2020) studies the relationship between different relations by establishing a global relation graph. The relations in the global relation graph

Relation	founder
Sentence	**Microsoft** was founded by **Bill Gates** and Paul Allen on April 4, 1975
Head entity concept	company, vendor, client
Tail entity concept	person, billionaire, entrepreneur

Table 1: The bold words in the sentence correspond to the head entity and the tail entity.

come from Wikidata.[1] TD-Proto (Yang et al., 2020) introduces text descriptions of entities and relations from Wikidata to enhance the prototype network and provide clues for relation prediction.

Although the introduction of knowledge of text description can provide external information for FSRE and achieve state-of-the-art performance, TD-proto only introduces one text description in Wikidata for each entity. However, this might suffer from the mismatching between entity and text description and leads to the degraded performance. Besides, since the text description for each entity is often relatively long, it is not a easy job to extract the most useful information within the long text description.

In contrast to the long text descriptions, the concept is an intuitive and concise description of an entity and can be readily obtained from concept databases, like YAGO3, ConceptNet and Concept Graph, etc. Besides, the concept is more abstract than the specific text description for each entity, which is an idea compensation to the limited information in FSRE scenarios.

As shown in Table 1, intuitively knowing that the concept of head entity is a *company* and the concept of tail entity is an *entrepreneur*, the relation corresponding to the entity pair in the sentence can be limited to a range: *ceo*, *founder*, *inauguration*. On the other hand, some relations should be wiped out, e.g., *educated at*, *presynaptic connection*, *statement describes*. The semantic information of concept can assist determining the relation: *founder* predicted by the model.

To address the above challenges, we propose a novel entity CONCEPT-enhanced FEw-shot Relation Extraction scheme (ConceptFERE), which introduces the entity concept to provide effective clues for relation prediction. *Firstly*, as shown in Table 1, one entity might have more than one concept from different aspects or hierarchical levels and only one of the concepts might be valuable for final relation classification. Therefore, we design a concept-sentence attention module to choose the most suitable concept for each entity by comparing the semantic similarity of the sentence and each concept. *Secondly*, since the sentence embedding and pre-trained concept embedding are not learned in the same semantic space, we adopt the self-attention mechanism (Devlin et al., 2018) for word-level semantic fusion of the sentence and the selected concept for final relation classification. Experimental results on benchmark dataset show that our method achieves state-of-the-art FSRE performance.

2 Model

2.1 System Overview

Figure 1 shows the structure of our proposed ConceptFERE. The sentence representation module uses BERT to obtain the sentence embedding, the concept representation adopts the pre-trained concept embedding (Shalaby et al., 2019), which uses the skip-gram model to learn the representation of the concept on the Wikipedia text and the Concept Graph. Relation classifier can be implemented by the fully connected layer. The remaining modules of the model will be described in detail below.

2.2 Concept-Sentence Attention Module

Intuitively, one needs to pay more attention to the concept of high semantic correlation with the sentence, which can provide more effective clues for RE. Firstly, since the pre-trained concept embedding (v_c) and sentence embedding (v_s) are not learned in the same semantic space, we can not compare the semantic similarity directly. So the semantic transformation is performed by multiplying the v_c and v_s by the projection matrix P to get their representations v_cP and v_sP in the same semantic space, where P can be learned by fully connected networks. Secondly, by calculating the semantic similarity between sentence and each concept of entity, the similarity value is obtained the dot product of the concept embedding v_c and the sentence embedding v_s as similarity sim_{cs}. Finally, in order to select a suitable concept from the calculated similarity value, we design the 01-GATE.

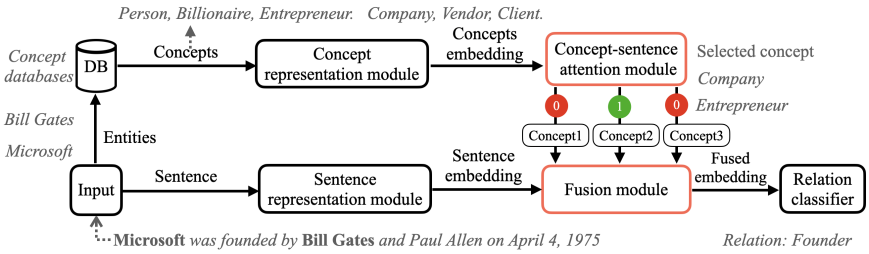

Figure 1: Structure diagram of ConceptFERE model.

The similarity value is normalized by the Softmax function. If sim_{cs} is less than the set threshold α, 01-GATE assigns 0 to the attention score of the corresponding concept, and this concept will be excluded in subsequent relation classification. We choose the suitable concept with the attention score of 1, which is used as a effective clue to participate in relation prediction.

2.3 Self-Attention based Fusion Module

Since concept embedding and the embedding of words in sentences are not learned in the same semantic space, we design a self-attention (Devlin et al., 2018) based fusion module to perform word-level semantic fusion of the concept and each word in the sentence. First, the embedding of all words in the sentence and the selected concept embedding are concatenated, and then fed to the self-attention module. As shown in Figure 2, the self-attention module calculates the similarity value between the concept and each word in the sentence. It multiplies the concept embedding and the similarity value, and then combine with its corresponding word embedding as follow:

$$fusion_{v_i} = \sum_{j=1}^{N} sim\left(q_i, k_j\right) v_j \qquad (1)$$

where $fusion_{v_i}$ represents the embedding of v_i after v_i performs the word-level semantic fusion. The q_i, k_j, and v_j are derived from self-attention, they represent the concept embedding or the word embedding.

3 Experiment

3.1 Dataset, Evaluation and Comparable Models

Dataset: In order to verify our proposed method, we use the most commonly used FSRE dataset FewRel (Han et al., 2018), which contains 100 relations and 70,000 instances extracted from

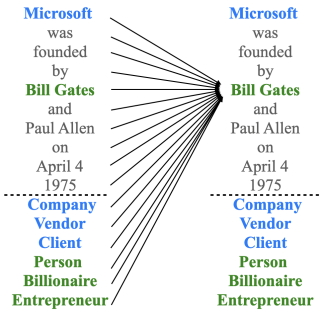

Figure 2: The word-level semantic fusion.

Wikipedia, with 20 relations in the unpublished test set. So we follow previous work (Yang et al., 2020) to re-split the published 80 relations into 50, 14 and 16 for training, validation and testing, respectively.

Evaluation: N-way-K-shot (N-w-K-s) is commonly used to simulate the distribution of FewRel in different situations, where N and K denote the number of classes and samples from each class, respectively. In N-w-K-s scenario, accuracy is used as the performance metric.

Comparable Models: We choose excellent baseline models, GNN (Garcia and Bruna, 2017), SNAIL (Mishra et al., 2017), Proto (Snell et al., 2017), HATT-Proto (Gao et al., 2019a), MLMAN (Ye and Ling, 2019) and TD-proto (Yang et al., 2020) for comparison, and their experimental results are derived from (Yang et al., 2020).

3.2 Model Training Details

The BERT parameters are initialized by bert-base-uncased, and the hidden size is 768. The threshold α is 0.7. Hyperparameters such as learning rate follow the settings in (Gao et al., 2019b). The entity concept is obtained from Concept Graph[2]. Concept Graph is a large-scale common sense conceptual knowledge graph developed by Microsoft, which contains concept of entities stored in triplets (Entity,

IsA, Concept) and can provide concept knowledge for entities in ConceptFERE. The concept embedding adopts the pre-trained concept embedding[3] (Shalaby et al., 2019).

Our proposed scheme is implemented on top of BERT-PAIR, since the concept provided by ConceptFERE can be used as an effective clue.

3.3 Performance and Comparisons

Table 2 tabulates the performance of different comparable models on the test set, where the algorithms in the first group are those state-of-the-art schemes without using any external information, while the TD-Proto in the second group uses external information of text descriptions of entities, and finally our proposed scheme in the third group. It should be noted that, due to the insufficient computing power of our GPU, the performance of the proposed ConceptFERE scheme is tested only under 5way1shot and 10way1shot scenarios. It can be observed from Table 2 that the proposed ConceptFERE model achieves the best performance, as compared to all the comparable schemes. More specifically, ConceptFERE achieves respectively 4.45 and 1.4 gains over the latest TD-Proto using external entity descriptions. And a performance gain of 6.64 and 2.35 is registered as compared to Bert-PAIR, the best model in the first category, under the 5way1shot and 10way1shot scenarios, respectively. This might due to that the generalization ability of concepts is stronger than text description and it is more suitable for FSRE. In theory, 1-shot relation extraction is a more difficult task than 5-shot relation extraction. The experimental results of 1-shot relation extraction have illustrated the effectiveness and superiority of our approach. We believe that our ConceptFERE scheme would also achieve the best performance under the other two scenarios.

w/o FUSION	83.11
w/o ATT	84.03
w/o ATT & FUSION	82.57

Table 3: Results of ablation study with ConceptFERE.

3.4 Ablation Study

In this section, to verify the effectiveness of the proposed concept-sentence attention module and self-attention based fusion module, presented in 2.2 and 2.3, respectively. As shown in Table 3, without using the concept-sentence attention and fusion module, the model performance of ConceptFERE (simple) drops sharply. This proves that the proposed concept-sentence attention module (ATT) and fusion module (FUSION) can effectively select appropriate concepts and perform word-level semantic integration of concepts and sentences. On the other hand, we present a simplified version of the ConceptFERE model, denoted as ConceptFERE (Simple), in which both the concept selection and fusion module are removed and the concepts and sentences are concatenated and inputted into the relation classification model. Specifically, we can input the concatenated sentences and concepts into BERT-PAIR (Gao et al., 2019b). As shown in Table 2, ConceptFERE (simple) achieves much better performance as compared to Bert-PAIR, the best model in the first category, under all four scenarios. This further validates the effectiveness of introducing the concept in enhancing the RE performance. More importantly, it can be easily applied to other models. As mentioned above, we only need to in-

put the concatenated entity concepts and sentences into the model.

4 Conclusion

In this paper, we have studied the FSRE task and presented a novel entity concept-enhanced FSRE scheme (ConceptFERE). The concept-sentence attention module was designed to select the appropriate concept from multiple concepts corresponding to each entity, and the fusion module was designed to integrate the concept and sentence semantically at the word-level. The experimental results have demonstrated the effectiveness of our method against state-of-the-art algorithms. As a future work, the commonsense knowledge of the concepts as well as the possible relations between them will be explicitly considered to further enhance the FSRE performance.

Improving Model Generalization: A Chinese Named Entity Recognition Case Study

Guanqing Liang, Cane Wing-Ki Leung
Wisers AI Lab, Wisers Information Limited
{quincyliang, caneleung}@wisers.com

Abstract

Generalization is an important ability that helps to ensure that a machine learning model can perform well on unseen data. In this paper, we study the effect of data bias on model generalization, using Chinese Named Entity Recognition (NER) as a case study. Specifically, we analyzed five benchmarking datasets for Chinese NER, and observed the following two types of data bias that may compromise model generalization ability. Firstly, the test sets of all the five datasets contain a significant proportion of entities that have been seen in the training sets. These test data are therefore not suitable for evaluating how well a model can handle unseen data. Secondly, all datasets are dominated by a few fat-head entities, i.e., entities appearing with particularly high frequency. As a result, a model might be able to produce high prediction accuracy simply by keyword memorization. To address these data biases, we first refine each test set by excluding seen entities from it, so as to better evaluate a model's generalization ability. Then, we propose a simple yet effective entity rebalancing method to make entities within the same category distributed equally, encouraging a model to leverage both name and context knowledge in the training process. Experimental results demonstrate that the proposed entity resampling method significantly improves a model's ability in detecting unseen entities, especially for company, organization and position categories.

1 Introduction

Named Entity Recognition (NER) is a fundamental building block for various downstream natural language processing tasks such as relation extraction (Bunescu and Mooney, 2005), event extraction (Ji and Grishman, 2008), information retrieval (Chen et al., 2015), question answering (Diefenbach et al., 2018), etc. Due to the ambiguous word boundaries and complex composition (Gui et al., 2019), Chinese NER task is more challenging compared with English NER.

Recently, by leveraging upon the pretrained language model (e.g, BERT (Devlin et al., 2018), etc.), we have witnessed superior performances on Chinese NER datasets, including: MSRA, Weibo, Ontonotes 4.0 and Resume (Li et al., 2020, 2019; Xuan et al., 2020). Despite the superior performance of the fine-tuned models, we argue that there are two types of data bias that can compromise the model generalization ability.

First, we observe that in widely used Chinese NER datasets, 50% to 70% entities in test data are seen in the training data. Such test data would therefore not be able to evaluate the true generalization ability of a model.

Second, the datasets are dominated by a few fat-head entities, i.e., entities appearing with particularly high frequency. For example, within the organization category of Cluener (Xu et al., 2020), fat-head entity 曼联 (Manchester United) appears 59 times, while 法兰克福队 (Eintracht Frankfurt) occurs only once. As a result, a model might be encouraged to memorize those fat-head entities rather than leveraging context knowledge during training process. The rationale is that given the same entity and diverse contexts, the easiest way for model convergence is to memorize the entity rather than extracting patterns from the diverse contexts.

To address these data biases, we first refine each test set by excluding seen entities from it, so as to better evaluate a model's generalization ability. Then, we propose a simple yet effective entity rebalancing method to make entities within the same category distributed equally, encouraging a model to leverage both name and context knowledge in the training process.

The contributions of this paper are as follows.

Resume	CONT, EDU, LOC, NAME, ORG, PRO, RACE, TITLE	3821	463	477
Weibo	GPE.NAM, GPE.NOM, LOC.NAM, LOC.NOM, ORG.NAM, ORG.NOM, PER.NAM, PER.NOM	1350	270	270
Cluener	movie, organization, company, game, book, scene, name, government, address, position	10748	1343	1345

Table 1: Chinese NER datasets overview: entity categories and the sentence number in train/dev/test data.

- We analyze five benchmarking Chinese NER datasets and identify two types of data bias that can compromise model generalization ability.

- We refine each test set by excluding seen entities from it, which can measure real model generalization. Specifically, the competitive BERT+CRF model only achieves 33.33% and 65.10% F1 score on detecting unseen organization entities of Cluener and MSRA dataset respectively, which are far from satisfactory.

- We design a simple yet effective algorithm to rebalance the entity distribution. The experiments show that the proposed method significantly improves the model generalization. In particular, the F1 score has been improved by 12.61% and 37.14% on the organization category of Cluener and MSRA dataset respectively.

2 Dataset Observation

2.1 Dataset Overview

In this study, we analyze five benchmarking Chinese NER datasets, including: (1) MSRA (Levow, 2006), (2) Ontonotes 4.0 (Weischedel et al.), (3) Resume (Zhang and Yang, 2018), (4) Weibo (Peng and Dredze, 2015) and (5) Cluener (Xu et al., 2020). The statistics of these datasets are shown in Table 1.

2.2 Seen vs Unseen Entity

If an entity in dev/test data has been covered by the training data, we refer it as a seen entity. Otherwise, it is an unseen entity. To quantify the degree to which entities in the dev/test data have been seen in the training data, we define a measurement called entity coverage ratio. The entity coverage ratio of data D^{te} is denoted by $r(D^{te})$, which is calculated using the below equation.

$$r(D^{te}) = \frac{|Ent(D^{te}) \bigcap Ent(D^{train})|}{|Ent(D^{train})|} \quad (1)$$

where $Ent(.)$ denotes a function to obtain the list of annotated entities and D^{train} represents the training data. As Table 2 shows, the entity coverage ratios of the dev and test data in different benchmarking datasets are very high, ranging from 0.429 to 0.709.

Dataset	r(dev)	r(test)
MSRA	0.554	0.709
OntoNotes 4.0	0.505	0.514
Resume	0.540	0.544
Weibo	0.498	0.429
Cluener	0.615	-

Table 2: Entity coverage ratio of dev and test data in different Chinese NER datasets.

Observation 1 The test sets of Chinese NER datasets contain a significant proportion of seen entities.

2.3 Fat-head vs Long-tail Entity

Fat-head entity is defined as the entity appearing with particularly high frequency, while long-tail entity is defined as the entity with very few mentions. To identify the existence of fat-head entity, we use kurtosis (Balanda and MacGillivray, 1988), a statistical measure that defines how heavily the tails of a distribution differ from the tails of a normal distribution. Usually, high kurtosis (greater than 3) indicates the existence of outliers, i.e., fat-head entities.

Table 3 shows the kurtosis score of each category in different datasets. For example, the kurtosis score of PER category of training data in MSRA dataset is 984.1, which is very high. We find that 1% distinct entities with the highest frequency contribute 21% of the overall annotation.

Observation 2 Fat-head entities prevail in different categories of Chinese NER datasets.

We think this finding is also valid in other NER datasets, since the annotated corpus is usually collected within a certain time frame when some entities (e.g., celebrities, organizations) get much more exposure than others.

We hypothesize that the dominance of fat-head entities will cause the model to simply memorize

those high-frequency entities without fully leveraging context knowledge. The rationale is that given the same entity and diverse contexts, the easiest way for model convergence is to memorize the entity rather than extracting patterns from the diverse contexts.

Dataset	Training	Test
MSRA	ORG : 609.2 PER : 984.1 LOC : 1272.1	ORG : 66.3 LOC : 226.6 PER : 387.4

Table 3: Kurtosis score of different categories in various Chinese NER datasets.

3 Method

To improve model's generalization ability in detecting unseen entities, we argue that the model should be trained to leverage both name and context knowledge (Nie et al., 2020; Lin et al., 2020). Thus, we propose a simple yet effective entity rebalancing algorithm. The main idea is to make the annotated entity equally distributed within the same category.

There are two major reasons why the proposed entity rebalancing algorithm works. First, the equal distribution will encourage the model to leverage both name knowledge and context knowledge, since there are no simple statistical cues (Niven and Kao, 2019) to exploit due to uneven distribution. Second, different entities within the same category should be interchangeable semantically in most cases, which avoids the train-test discrepancy.

The proposed algorithm works as follows. First, rebalance the annotated entity frequency in the training data. Let C_l denotes the original entity frequency counter of category l. For example, given $C_l = \{e_1 : 11, e_2 : 1, e_3 : 1\}$, which means entity e_1 is annotated 11 times, and both e_2 and e_3 are annotated once in the category l, which is very imbalanced. Then we turn C_l to the balanced entity frequency counter C_l^b, which is $C_l^b = \{e_1 : 5, e_2 : 4, e_3 : 4\}$. In C_l^b, the difference between the maximum and minimum entity frequency is 1 at most. Second, replace the fat-head entity with randomly sampled entity of the same category, once its accumulated occurrence surpasses the rebalanced frequency in C_l^b. Details are shown in **Algorithm 1**.

Algorithm 1: Entity replacement algorithm

```
foreach sentence in Dataset do
    foreach ent_text, ent_label in sentence do
        l = ent_label;
        if C_l^b[ent_text] > 0 then
            keep ent_text as it is;
            C_l^b[ent_text] -= 1;
        else
            sample ent_s from c_l^b if c_l^b[ent_s] > 0;
            replace ent_text with ent_s;
            C_l^b[ent_s] -= 1;
```

4 Experiments

4.1 Experiment Settings

According to observation 1, the test sets of Chinese NER datasets contain a significant proportion of seen entities, which fails to evaluate the true model generalization ability. In our study, the test sample will be excluded if it contains entities that are covered in training data. For Cluener (Xu et al., 2020), we split the original training set into 90% train and 10% dev, and use the development set for test, as the test set is not publicly available. For Resume (Zhang and Yang, 2018) and Weibo (Peng and Dredze, 2015) datasets, we report evaluation results on the selected categories, since there are zero or very few unseen entities on other categories.

We use the BIOES tagging scheme to label named entities, since previous studies have shown optimistic improvement with this scheme (Ratinov and Roth, 2009). We report span-level micro-averaged F1 score obtained from `seqeval` (Nakayama, 2018) toolkit using IOBES scheme.

We use BERT+CRF as the model architecture. In particular, we use bert-base-chinese pre-

trained model [1] (12-layer, 768-hidden, 12-heads) released by google (Devlin et al., 2018). The hyperparameters of the model are tuned on the development set using grid search method (details are reported in Appendix A.). As shown in Table 4, the adopted BERT+CRF model is competitive with the complicated state-of-the-art models.

Model	MSRA	OntoNotes	Resume	Weibo
Glyce-BERT (Meng et al., 2019)	95.54	81.63	96.54	67.60
BERT+FLAT (Li et al., 2020)	96.09	81.82	95.86	68.55
BERT+CRF (Ours)	95.57	**82.29**	95.71	**69.89**

Table 4: Comparison between BERT+CRF and the state-of-the-art models using the same train/dev/test splits as (Li et al., 2020, 2019; Xuan et al., 2020)

4.2 Results

Table 5 presents the comparisons between the proposed method and the baseline on five Chinese NER datasets. The baseline uses the original training data, while the proposed applies entity rebalancing algorithm on the original training data.

For Cluener, MSRA and OntoNotes datasets with over 10K training samples, our proposed method outperforms the baseline on different categories. One exception is on the address category of Cluener dataset when the proposed method performs worse than the baseline by -2.58%. We believe it is due to the fact that the address category contains both geopolitical entities and location entities, which are not interchangeable semantically.

For Weibo dataset, the proposed outperforms the baseline by 8.89% in PER.NAM category, but performs worse in PER.NOM category. Note that the PER.NOM category contains entities such as man, woman and friend, which are hard to generalize based on context knowledge. For Resume dataset, the proposed method does not work well. We think it is due to the structure of the resume corpus, which is the mere concatenation of name, education and organization, etc. Thus, there is very few context knowledge to leverage.

Overall, the proposed entity rebalancing method is able to improve model's generalization ability in detecting unseen entities. However, the proposed method only works for categories which meet certain conditions. First, the entities of the same category require to be interchangeable semantically. Second, the entities should be dependent of context knowledge.

5 Conclusion and Future Work

In this paper, we take Chinese NER as a case study, aiming to improve the model generalization by mitigating the data bias. We first refine each test set by excluding seen entities from it, so as to better evaluate a model's generalization ability. Then, we propose an entity rebalancing method to make entities within the same category distributed equally. Experimental results show that the proposed entity rebalancing method significantly improves a model's ability in detecting unseen entities.

As future work, we will first investigate the generalizability of this study to non-Chinese NER. Second, we will improve the entity replacement algorithm by leveraging language model so that the replaced entity is more semantically plausible.

Abstract

Document-level Relation Extraction (RE) is a more challenging task than sentence RE as it often requires reasoning over multiple sentences. Yet, human annotators usually use a small number of sentences to identify the relationship between a given entity pair. In this paper, we present an embarrassingly simple but effective method to heuristically select evidence sentences for document-level RE, which can be easily combined with BiLSTM to achieve good performance on benchmark datasets, even better than fancy graph neural network based methods. We have released our code at https://github.com/AndrewZhe/Three-Sentences-Are-All-You-Need.

1 Introduction

The task of relation extraction (RE) focuses on extracting relations between entity pairs in texts, and has played an important role in information extraction. While earlier works focus on extracting relations within a sentence (Lin et al., 2016; Zhang et al., 2018), recent studies begin to explore RE at document level (Peng et al., 2017; Zeng et al., 2020a; Nan et al., 2020a), which is more challenging as it often requires reasoning across multiple sentences.

Compared with sentence level extraction, documents are significantly longer with useful information scattered in a larger scale. However, given a pair of entities, one may only need a few sentences, not the entire document, to infer their relationship; reading the whole document may not be necessary, since it may introduce unrelated information inevitably. As we can see in Figure 1, $S[1]$ is sufficient to recognize *Finland* as the country of *Espoo*, and recognizing the rest two instances requires just 2 sentences as supporting evidence as well. Although the document contains 6 sentences and evidence may span from $S[1] \sim S[6]$, identifying *each* relation instance can be achieved by just reading through 1 or 2 related sentences. This naturally leads us to consider a question: *given an entity pair, how many sentences are required to identify a relationship between them?* We perform a pilot study across 3 widely-used document RE datasets, DocRED (Yao et al., 2019), CDR (Li et al., 2016) and GDA (Wu et al., 2019). As shown in Table 1, we find that more than 95% instances require no more than 3 sentences as supporting evidence, and 87% even requires only 2 or less.

Figure 1: A case extracted from the DocRED dataset. While the document has 6 sentences, only 1 or 2 sentences form the evidence for each relation instance.

Our preliminary finding suggests that, instead of taking the entire document as context, a case-specific selection may be more useful to help a model focus on the most relevant and informative evidence. Previous studies apply graph neural networks (GNNs) for this filtering process (Christopoulou et al., 2019; Zeng et al., 2020b). Here, GNNs are used to collect relevant information from the entire context through an aggregation scheme (Nan et al., 2020a) and achieve great performance, but the selection of crucial evidence from documents is still implicit and lacks interpretability. If, as indicated by our pilot study, most entity relationships can be decided with just $1 \sim 3$ evidence sentences, is there a simpler method that can filter the document explicitly while maintaining the

crucial information?

We take a closer look at how entity pairs are contextually related in the annotated supporting evidence, and find that annotators tend to select sentences that can connect the two entities. We therefore design three heuristic rules to extract a small set of *paths* from the document, which can be seen as an approximation of the supporting evidence. Specifically, the *Consecutive Paths* consider the scenario where the head and tail entities are close in the context: if they are within 3 consecutive sentences, we regard these sentences as one path. The *Multi-Hop Paths* correspond to the entity pairs in distant sentences, which can be bridged via other entities that co-occur with the head entity and tail entity in different sentences. As the third relation in Figure 1 shows, *Finland* co-occurs with *The Espoo Cathedral* in S[1] and with *the EC Parish* in S[6], which makes it a bridge to connect *The Espoo Cathedral* and *the EC Parish*. In this case, S[1] and S[6] compose a multi-hop path. When neither of the above rules applies, we collect all the pairs of sentences where one contains head entity and the other contains tail entity as *Default Paths*.

By comparing our path set with human-annotated supporting evidence, we find that up to 87.5% of the supporting evidence can be fully covered by our heuristically selected paths. In other words, our straightforward and interpretable rules serve as an effective proxy to select supporting evidence from documents. We further feed our selected paths to a simple neural network model and obtain surprisingly good performance on DocRED, showing that our selected evidence can retain sufficient information from the entire document to support document-level relation extraction.

2 Do we need the entire document?

For document RE, the major challenge is that the subject and object involved in a relationship may appear in different sentences. Thus, more than one sentence is required to capture the relations. Nonetheless, how many sentences from the entire document are required to identify the relationship between an entity pair? To address this question, we analyze the supporting evidence presented in DocRED. The supporting evidence for a relation instance refers to all the sentences that can be used to decide whether this relation holds between the entity pair, labeled by human annotators (Yao et al., 2019). Table 1 shows the proportions of entity relation instances with different number of supporting sentences. As can be seen, more than 96% of the DocRED instances are associated with at most 3 supporting evidence. These only take up 37.5% of a document, since the average document length is 8 sentences. This means that reading a small part of a document is adequate for one to identify an entity relation instance.

We further extend our study to two widely used document RE datasets, CDR (Li et al., 2016) and GDA (Wu et al., 2019), where CDR is manually constructed and GDA is distantly supervised. In order to find the minimal number of sentences required, we ask annotators to label a minimal set of sentences that are exactly sufficient to identify an entity relation instance, instead of including all relation-associated sentences as the original DocRED pattern. We randomly select 100 instances respectively from CDR and GDA for this further annotation, and the results are shown at the bottom of Table 1[1]. Although the average length of documents in GDA and CDR are longer than DocRED, it turns out that one can still use no more than 3 supporting sentences to identify over 95% of the entity relation instances. The results on CDR and GDA confirm our previous finding that, a very small number of sentences (or more exactly, no more than 3 sentences) would make it sufficient for human annotators to recognize almost all entity relation instances in a document in widely-used benchmark datasets.

3 Which sentences are decisive?

Now our question is how to select the supporting sentences that are sufficient to identify an entity relation instance. Intuitively, the supporting evidence should be the sentences that build up the *connection* between a pair of entities. Thus, we aim to extract sentence *paths* from the head entity to the tail entity to describe how they are connected. As for the simplest case, if there exists one sentence that contains

[1] As GDA is a distantly supervised dataset, 7 instances that are found wrongly labeled are discarded.

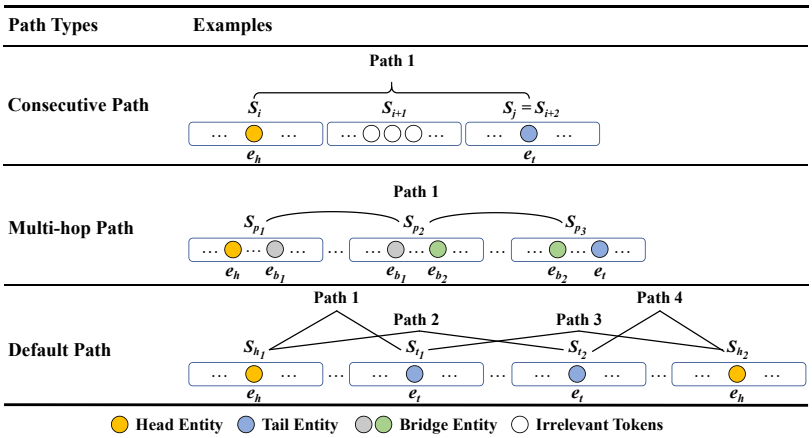

Figure 2: Types of paths connecting head and tail entities. The rounded rectangles represent sentences and the circles are mentions of involved entities or other irrelevant tokens. e_h and e_t stands for a mention of head and tail entities respectively, and S_* represents a sentence.

both the head and tail entities, the sentence itself can be seen as a path (the intra-sentence case). For more complex situations where the head and tail entities do not co-occur in one sentence, we define the following 3 types of paths which indicate how the head and tail entities can be possibly related in the context. Figure 2 provides a visualization of the three types of paths.

Consecutive Paths Previous studies have shown that the majority of inter-sentence relations are often in nearby text (Swampillai and Stevenson, 2010; Quirk and Poon, 2017). We thus select the consecutive sentences to form a path when the head and tail entities are in nearby sentences. Formally, if one mention of the head entity appears in sentence S_i and one mention of the tail entity is in sentence S_j, these two sentences along with the sentence in between, i.e., sentence S_{i+1}, ..., S_{j-1} (or S_{j+1}, ..., S_{i-1} when $i \geq j$) forms a possible path that connects the two entities.

Given that no more than 3 sentences would suffice for inference, we limit the length of these *Consecutive Paths* to be at most 3, which means $|j - i| \leq 2$. Note that this definition can be naturally extended to the intra-sentence case where $j = i$. We thus consider the intra-sentence case as a type of the Consecutive Path. A pair of entities can correspond to multiple consecutive paths since they can be mentioned more than once.

Multi-Hop Paths Another typical case for inter-sentence relation instances is the multi-hop relation (Yao et al., 2019; Zeng et al., 2020a). In such cases, the head and tail entities are far from each other in the document but can be connected through *bridge entities*, just like the entity *The Espoo Cathedral* in Figure 1 bridges *the EC Parish* and *Finland* in sentence 1 and 6.

For these cases, we start from the head entity, go through all the bridge entities, arrive at the tail entity, and select all the corresponding sentences in this route as a path. Formally, for the head entity e_h and the tail entity e_t, the multi-hop relation indicates that there exist a list of bridge entities e_{b_1}, ..., e_{b_k} such that (e_h, e_{b_1}), (e_{b_1}, e_{b_2}), ..., (e_{b_k}, e_t) form $k+1$ intra-sentence relations respectively in sentence $S_{p_1}, \ldots, S_{p_{k+1}}$. Following this route, we choose these $k+1$ sentences as the *Multi-Hop Path*. Given the discovery in §2 that most instances only needs 3 sentences, we restrict k to be at most 2, i.e., with only 1 or 2 bridge entities. It is possible to have several multi-hop paths for a certain pair with different lists of bridge entities.

Default Paths If neither of the aforementioned rules applies, we consider a rough estimate for the evidence with the most relevant sentences. We collect all pairs of sentences where one contains the head entity and the other contains the tail entity as *Default Paths*. Formally, let $\{S_{h_1}, \ldots, S_{h_p}\}$ and $\{S_{t_1}, \ldots, S_{t_q}\}$ denote the sets of sentences that contain the head entity e_h and the tail entity e_t, respectively. For this entity pair, we will have $p \times q$ Default Paths $\{S_{h_1}, S_{t_1}\}, \ldots, \{S_{h_p}, S_{t_q}\}$. Note that this type of paths is extracted only when no paths are found with the previous two patterns.

4 Comparing with Annotated Evidence

To demonstrate the effectiveness of our heuristic rules, we check the size of our path set on DocRED

	Path Recall	#Sent	#Path
C	71.7%	2.31	1.71
M	31.5%	3.14	2.35
C+M	80.5%	2.73	2.37
C+M+D	87.5%	2.69	2.27
document	-	8.00	-

Table 2: C, M and D stand for Consecutive Paths, Multi-hop Paths, and Default Paths, respectively. #Path and #Sent are the average path numbers and average sentence numbers in the union of all paths.

and their consistency with the gold supporting evidence. As mentioned in §2, the gold annotation acts as a collection of all related evidence, while each of our extracted paths represents one possible and minimal sentence set. Ideally, if the path set is sufficient, all connecting sentences between the entity pair should be successfully captured. In other words, they would be presented via various paths in our path set. Therefore, the union of paths is expected to be a superset of the supporting evidence. We use the **Coverage** of the supporting evidence to measure the *sufficiency* of our path set, which stands for the percentage of instances whose supporting evidence is fully covered by the union of our paths. Meanwhile, the total number of paths ($\#Path$) and union size of the paths ($\#Sent$) should also remain at a low standard, so as to avoid *redundancy*.

Table 2 shows the statistics of the path sets extracted via our rules. The Consecutive Paths form a strong baseline that covers 71.7% of instances. Combining the three types, up to 87.5% of instances from the supporting evidence are fully covered by our path sets. The main reason that C+M+D can not cover all the instances is that the supporting evidence annotated in DocRED includes all associated sentences, while C+M+D only find a sufficient set to identify the relation.

Meanwhile, notice that the union of the three types contains only 2.69 different sentences on average, which means that our methods can filter out up to 2/3 of the original text. Also, our method is computationally efficient since only 2.27 paths need to be modeled on average. This demonstrates that our methods form a sufficient and non-redundant estimate for the gold supporting evidence, drastically alleviating the negative impact of irrelevant information.

Table 3: Model performance on DocRED.

5 Experiments

To further validate the sufficiency of our selected paths, we perform evaluation on DocRED by feeding the paths to an RE model. While previous works take entire documents as input, we replace the document with our selected paths regarding a given entity pair. Intuitively, if the paths can cover all crucial information in the document, we would expect comparable or better performance with identical model architecture, as our paths contain little irrelevant information and may help focus on a few key sentences.

Setup Given a pair of entities, all paths are first extracted as described in §3. Since each path corresponds to one possible connection of the head and tail entities, we predict the relations with each path independently and aggregate the results afterwards.

For every single path c, we concatenate all sentences in it as one segment $[\mathbf{w_1^c}, ..., \mathbf{w_m^c}]$, where the order of sentences is the same as in the original document. The segment is fed to a BiLSTM to obtain the contextual embeddings $[\mathbf{h_1^c}, ..., \mathbf{h_m^c}]$. The representation of an entity mention, which spans from the s-th word to the t-th word, is defined as $\mathbf{m_k^c} = \frac{1}{t-s+1}\sum_{j=s}^{t}\mathbf{h_j^c}$. The representation of an entity e_i^c with K mentions is computed as the average of the representations of its mentions: $\mathbf{e_i^c} = \frac{1}{K}\sum_k \mathbf{m_k^c}$. Then, we use a two-layer perceptron to calculate the probability of each relation r based on the current path c: $P_{ij}^c(r) = \sigma(F([e_i^c; e_j^c; |e_i^c - e_j^c|; e_i^c * e_j^c]))$, where $\sigma(\cdot)$ is the Sigmoid function and $F(\cdot)$ stands for the two-layer perceptron.

After obtaining the prediction of every path between a given entity pair, we aggregate the predicted results by selecting the most likely predictions: $P_{ij}(r) = \max_c P_{ij}^c(r)$.

We use the Glove-100 (Pennington et al., 2014)

embedding for the BiLSTM encoder with hidden size 256. Following previous works (Nan et al., 2020b), we report the F1 for intra- and inter-sentence entity pairs along with the overall F1 score as evaluation metrics.

Results We compare our methods with previous sequence-based models and graph-based models. All these models take the entire document as input. As shown in Table 3, our selected path with BiLSTM achieves 56.23% F1 on the test set, which outperforms the sequence-based models. Compared with the baseline BiLSTM, our model brings 5.68% and 5.62% improvement on intra- and inter-sentence entity pairs on the dev set, respectively.

Surprisingly, our simple method achieves a higher performance compared with graph-based models, which are more complex and also possess the ability to filter out irrelevant information. Combined with our path-selection scheme, a BiLSTM can perform 1.25% and 1.15% better on the dev and test set, respectively, compared to the SOTA graph-based model in the same situation. This may indicate that, while graph-based models have shown excellent abilities to focus on important information in a self-adaptive manner, it is more helpful to explicitly select from the document than to fully rely on graph-based models. With a simple filtering scheme inspired by human annotations, we can better explore the potentials of existing models and produce better results.

6 Discussion

So far we have shown from experiments the limited number of sentences required to deduce a relation instance. While the interesting results seem unconventional for Document RE, which features complex inter-sentence relations, it is worth mentioning that possible explanations exist in current works in related fields. The interdisciplinary outlooks may provide helpful insights for community members to understand the causes of the *three-sentences* phenomenon and revisit the problem of Document-level Relation Extraction.

Linguistic Perspective One likely cause of the discussed phenomenon is that the seemingly distant relations are not so difficult given their linguistic form. Stevenson (2006) mentions that a majority of inter-sentence relation instances are in fact due to *co-references* (anaphoric expressions or alternative descriptions). In these cases, relations could be considered to be described entirely within one sentence but with head or tail entities being referred to indirectly. Considering anaphoric expressions are likely to appear in surrounding sentences for the candidate mentions (Chowdhury and Zweigenbaum, 2013), these findings are directly in line with our observation that consecutive paths could support more than 70% relation instances, and provide evidence for *three-sentences* phenomenon.

Cognitive Perspective Another possible explanation is that the RE task is naturally defined within a limited amount of entities and context, given the nature of the human brain. It is widely believed that *Working Memory* (WM) (Baddeley, 1992) plays a vital role to store and manipulate information in inference tasks (Barreyro et al., 2012), but the capacity of separate information chunks in WM are often limited to 4 (Cowan, 2001). As we need to memorize all the separate entities in the inference chain along with their relations, it is natural that we tend to describe a relation within a limited number of sentences, since rendering a relationship with more sentences may cause our WM to exceed its capacity. Daneman and Carpenter (1980) show that the success rate of completing a reading task drastically drops if too much information, exceeding the subject's WM capacity, is required for the task. Therefore, as the datasets are constructed from natural language, the *three-sentences* phenomenon in the data may be a common pattern that we (unconsciously) follow for mutual understanding.

7 Conclusion

In this paper, we perform an analysis over 3 document RE benchmark datasets, and find that human annotators often use a small number of sentences to extract entity relations in document level. This motivates us to think over which sentences are critical for document RE. We carefully design heuristic rules to select informative *path* sets from entire documents, which can be further combined with a simple BiLSTM to achieve competitive performance on a benchmark dataset, even better than complex graph-based methods.

Unsupervised Cross-Domain Prerequisite Chain Learning using Variational Graph Autoencoders

Irene Li, Vanessa Yan, Tianxiao Li, Rihao Qu and **Dragomir Radev**
Yale University, USA
{irene.li,vanessa.yan,tianxiao.li,rihao.qu,dragomir.radev}@yale.edu

Abstract

Learning prerequisite chains is an essential task for efficiently acquiring knowledge in both known and unknown domains. For example, one may be an expert in the natural language processing (NLP) domain but want to determine the best order to learn new concepts in an unfamiliar Computer Vision domain (CV). Both domains share some common concepts, such as machine learning basics and deep learning models. In this paper, we propose unsupervised cross-domain concept prerequisite chain learning using an optimized variational graph autoencoder. Our model learns to transfer concept prerequisite relations from an information-rich domain (source domain) to an information-poor domain (target domain), substantially surpassing other baseline models. Also, we expand an existing dataset by introducing two new domains—CV and Bioinformatics (BIO). The annotated data and resources, as well as the code, will be made publicly available.

1 Introduction

With the rapid growth of online educational resources in diverse fields, people need an efficient way to acquire new knowledge. Building a concept graph can help people design a correct and efficient study path (ALSaad et al., 2018; Yu et al., 2020). There are mainly two approaches to learning prerequisite relations between concepts: one is to extract the relations directly from course content, video sequences, textbooks, or Wikipedia articles (Yang et al., 2015b; Pan et al., 2017; Alzetta et al., 2019), but this approach requires extra work on feature engineering and keyword extraction. Our method follows a different approach of inferring the relations within a concept graph (Liang et al., 2018; Li et al., 2019, 2020).

In a concept graph, we define $p \rightarrow q$ as the notion that learning concept p is a prerequisite to learning concept q. Existing methods formulate this question as a classification task. A typical method is to encode concept pairs and train a classifier to predict if there is a prerequisite relation (Alzetta et al., 2019; Yu et al., 2020). However, this method requires annotated prerequisite pairs during training. Alternatively, others have used graph-based models to predict prerequisite relations. Gordon et al. (2016) proposed information-theoretic approaches to infer concept dependencies. Li et al. (2019) modeled a concept graph using Variational Graph Autoencoders (VGAE) (Kipf and Welling, 2016), training their model to infer unseen prerequisite relations in a semi-supervised way. While most of the previous methods were supervised or semi-supervised, Li et al. (2020) introduced Relational-VGAE, which enabled unsupervised learning on prerequisite relations.

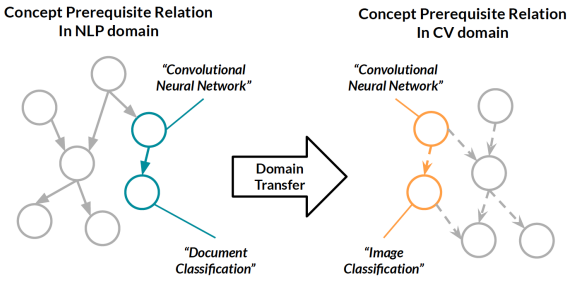

Figure 1: Cross-domain prerequisite chains.

Existing work mainly focuses on prerequisite relations within a single domain. In this paper, we tackle the task of cross-domain prerequisite chain learning, by transferring prerequisite relations between concepts from a relatively information-rich domain (source domain) to an information-poor domain (target domain). As an example, we illustrate in Figure 1, a partial concept graph from the Natural Language Processing (NLP) domain and a partial concept graph from the Computer Vision (CV) domain. Prerequisite relations among concepts in the NLP domain are known, and we seek to infer prerequisite relations among concepts in

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1005–1011
August 1–6, 2021. ©2021 Association for Computational Linguistics

the CV domain. These two domains share some concepts, such as *Convolutional Neural Network*. We assume that being aware of prerequisite relations among concepts in the source domain helps infer potential relations in the target domain. More specifically, in the figure, knowing that *Convolutional Neural Network→Document Classification* helps us determine that *Convolutional Neural Network→Image Classification*.

Our contributions are two-fold. First, we propose cross-domain variational graph autoencoders to perform unsupervised prerequisite chain learning in a heterogeneous graph. Our model is the first to do domain transfer within a single graph, to the best of our knowledge. Second, we extend an existing dataset by collecting and annotating resources and concepts in two new target domains. Data and code will be made public in https://github.com/Yale-LILY/LectureBank/tree/master/LectureBankCD.

2 Dataset

LectureBank2.0 (Li et al., 2020) dataset contains 1,717 lecture slides (hereon called **resources**) and 322 concepts with annotated prerequisite relations, largely from NLP. We treat this dataset as our information-rich source domain (NLP). Also, we propose an expansion dataset, LectureBankCD, by introducing two new target domains in the same data format: CV and Bioinformatics (BIO). We report statistics on the dataset in Table 1. For each domain, we identify high-quality lecture slides from the top university courses, collected by domain experts, and we choose concepts by crowd-sourcing. We end up with 201 CV concepts and 100 BIO concepts. In each domain, we ask two graduate-level annotators with deep domain knowledge to add prerequisite chain annotations for every possible pair of concepts. The Cohen's kappa agreement scores (McHugh, 2012) are 0.6396 for CV and 0.8038 for BIO. Cohen's kappa between 0.61–0.80 is considered substantial, so our annotations are reliable.

Domain	Files	Pages	Tks/pg	Con.	PosRel
NLP	1,717	65,028	47	322	1,551
CV	1,041	58,32	43	201	871
BIO	148	7,13	135	100	234

Table 1: LectureBankCD statistics on NLP, CV and BIO domain: Tks/pg (Tokens per slide page), Con. (Number of concepts), PosRel (Positive Relations).

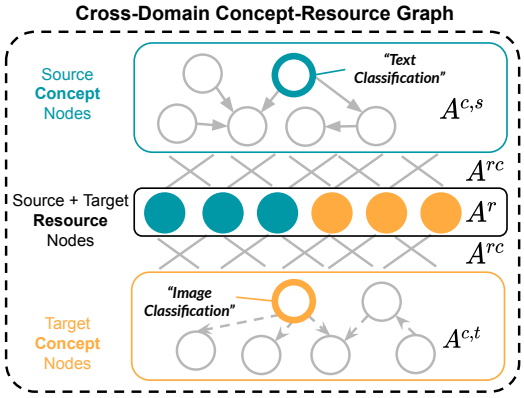

Figure 2: Cross-Domain Concept-Resource Graph: we model the resource nodes (solid nodes) and concept nodes (hollow nodes) from two domains (in blue and orange) in a heterogeneous graph. We show a subset of nodes and edges.

We take the union of the positive annotations for our experiments: 871 positive relations for CV and 234 positive relations for BIO.

3 Methodology

Inspired by Li et al. (2020), we build a cross-domain concept-resource graph $G = (X, A)$ that includes resource nodes and concept nodes from both the source and target domains (Figure 2). To obtain the node feature matrix X, we use either BERT (Devlin et al., 2019) or Phrase2Vec (Artetxe et al., 2018) embeddings. We consider four edge types to build the adjacency matrix A: $A^{c,s}$: edges between source concept nodes; A^{rc}: edges between all resource nodes and concept nodes; A^{r}: edges between resource nodes only; and $A^{c,t}$: edges between target concept nodes. In unsupervised prerequisite chain learning, $A^{c,s}$—concept relations of the source domain—are known, and the task is to predict $A^{c,t}$—concept relations of the target domain. For A^{rc} and A^{r}, we calculate cosine similarities based on node embeddings, consistent with previous works (Li et al., 2019; Chiu et al., 2020).

Cross-Domain Graph Encoder VGAE (Kipf and Welling, 2016) contains a graph neural network (GCN) encoder (Kipf and Welling, 2017) and an inner product decoder. In a GCN, the hidden representation of a node i in the next layer is computed using only the information of direct neighbours and the node itself. To account for cross-domain knowledge, we additionally consider the *domain neighbours* for each node i. These domain neighbours are a set of common or semantically similar

concepts from the other domain.[1] We define the cross-domain graph encoder as:

$$h_i^{(l+1)} = \sigma\Bigg(\sum_{j \in N_i} W^{(l)} h_j^{(l)} + W^{(l)} h_i^{(l)} + \sum_{k \in N_i^D} W_D^{(l)} h_k^{(l)}\Bigg)$$

where N_i denotes the set of direct neighbours of node i, N_i^D is the set of domain neighbours, and W_D and W are trainable weight matrices. To determine the domain neighbors, we compute cosine similarities and match the concept nodes only from source domain to target domain: $cosine(h_s, h_t)$. The values are then normalized into the range of [0,1], and we keep the top 10% of domain neighbors.[2]

DistMult Decoder We optimize the original inner product decoder from VGAE. To predict the link between a concept pair (c_i, c_j), we apply the DistMult (Yang et al., 2015a) method: we take the output node features from the last layer, $\hat{X}$, and define the following score function to recover the adjacency matrix $\hat{A}$ by learning a trainable weight matrix R: $\hat{A} = \hat{X}R\hat{X}$. A Sigmoid function is used to predict positive/negative labels from $\hat{A}$.

4 Evaluation

We evaluate on our new corpus LectureBankCD, treating the NLP domain as the source domain and transferring to the two new target domains: NLP→CV and NLP→BIO. Consistent with Kipf and Welling (2017); Li et al. (2019), we randomly split the positive relations into 85% training, 5% validation, and 10% testing. To account for imbalanced data, we randomly select negative relations such that the training set has the same number of positive and negative relations. We do the same for the validation and test sets. We report average scores over five different randomly seeded splits.

To encode concepts and resources, we test BERT and P2V embeddings. For BERT, we applied a pre-trained version from Google[3]. We trained P2V using all the resource data. Both methods only require free-text for training and encoding.

Baseline Models We concatenate the BERT/P2V embeddings of each pair of concepts and feed the result into a classifier (CLS + BERT and CLS + P2V). We train the classifier on the source domain only, then evaluate on the target domain. We report the best performance among Support Vector Machine, Logistic Regression, Gaussian Naïve Bayes, and Random Forest. In addition, we train the VGAE model Li et al. (2019) on the source domain and test on the target domain, initializing the VGAE input with BERT and P2V embeddings separately (VGAE + BERT and VGAE + P2V). Given that GAE is structurally similar to VGAE, we leave this for future work. Other graph-based methods including DeepWalk (Perozzi et al., 2014) and Node2vec (Grover and Leskovec, 2016) are not applicable in this setting as both models require training edges from the target domain in order to generate node embeddings for target concepts.

Proposed Method We report results of our proposed model, CD-VGAE, initialized with BERT and P2V node embeddings separately. Consistent with the work from Li et al. (2019) and Li et al. (2020), P2V embeddings yield better results than BERT embeddings in general. One possible reason for this difference is that BERT embeddings have a large number of dimensions, making it very easy to overfit. The two CLS models yield a negative result, with F1 worse than random guess. A possible reason is that treating concept pairs independently from the source domain may not be beneficial for the target domains. The VGAE models have a better performance when considering the concepts in a large graph. As shown in the table, our method performs better than the chosen baselines on both accuracy and F1 score, by incorporating information from domain neighbors. In particular, it yields much higher recall than all the baseline models. We provide further analysis in a later section.

Upper Bound Performance Finally, we conduct in-domain experiments on CV and BIO (supervised training and testing in the target domain), to show an upper bound for cross-domain performance. We test a variety of methods including traditional classifiers as well as graph-based approaches, including DeepWalk, Node2vec, and GraphSAGE (Hamilton et al., 2017).

5 Analysis

Next, we conduct quantitative analysis and case studies on the target domain concept graphs recovered by our model (CD-VGAE+P2V) and two

baseline models (CLS + P2V, VGAE + P2V), to take a closer look at the results.

Quantitative Analysis We first apply the three trained models to recover the concept graph in the CV domain. Compared to the ground truth with 871 positive relations, the baseline model predicts 527, VGAE predicts 963, and our model predicts 1,209. Similarly, in the BIO domain with 234 positive relations, the baseline model predicts only 128 positive edges, VGAE predicts 261, and our model predicts 303. Since our model tends to predict more positive edges, it has a higher recall. A higher recall is preferred in real-world applications as a system should not miss any relevant concepts when designing a user's study path.

Concept Graph Recovery We now provide case studies of the recovered concept graphs. In Table 3, we show successors of the concept *Image Processing* from the CV domain, i.e. concepts for which *Image Processing* is a prerequisite. Both the baseline model and VGAE miss many successor concepts, whereas our model can recover a correct list without any missing concepts.

We illustrate another case study from the BIO domain in Figure 3 using the concept *BLAST* (short for "basic local alignment search tool "), an algorithm for comparing primary biological sequence information. In the ground truth, BLAST has three prerequisite concepts (*Dynamic Programming*, *DNA* and *Sequence Alignment*), and one successor concept (*Homology Model*). We observe that VGAE predicts only one prerequisite, *DNA*, and misses all the others. In contrast, our model successfully includes all the ground truth relations, although it predicts some extra ones compared to VGAE. A closer look at the extra predictions reveals that these are still relevant topics, even though they are not direct prerequisites. For example, *Sequence Alignment*, *BLAST* and *Graph Theory* are all associated with sequence analysis and share some common algorithms (i.e. De Bruijn Graph).

We provide a case study in the CV domain, shown in Figure 4, by selecting concept node *Object Localization*. The ground truth shows that it has 14 direct neighbors. The VGAE model only predicts five neighbors, while our model predicts more. Our model has two wrong predictions, but it gets 12 correct ones. In contrast, the VGAE model misses up to 10 neighbors, which is not acceptable in an application scenario of an educational platform leading students to miss very useful information.

6 Conclusion

In this paper, we proposed the CD-VGAE model to solve the task of cross-domain prerequisite chain

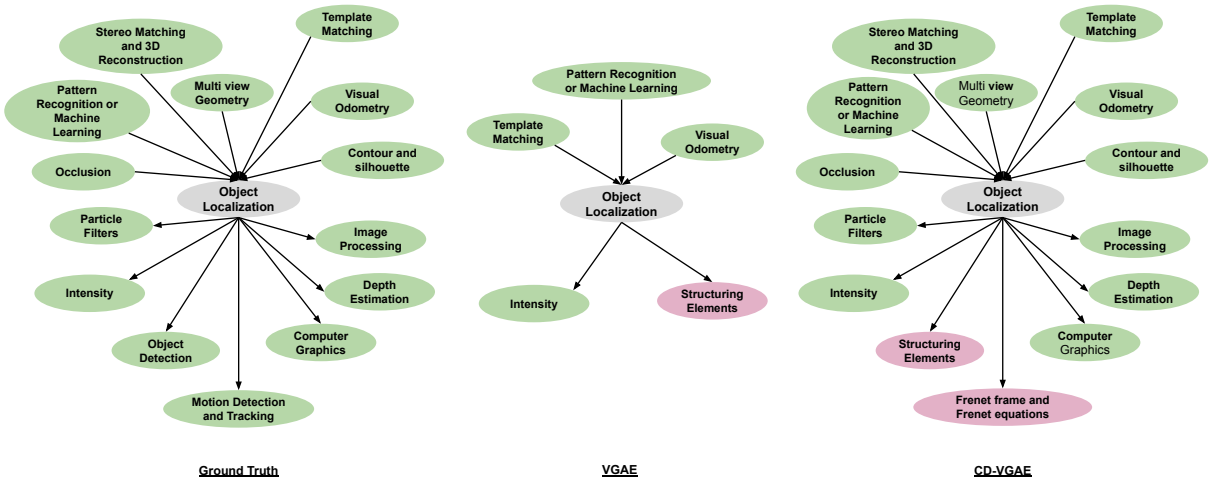

Figure 4: Case Study in CV: direct neighbors of *Object Localization*.

learning. Results show that our model outperforms previous unsupervised graph-based models by a large margin, especially with respect to the F1 and recall scores. In addition, we created a new dataset that contains resources and concepts from two domains along with annotated prerequisite relations.

Node2vec	**0.7956**	**0.8060**	0.7547	0.8727

Table 5: Supervised evaluation results: BIO→BIO. GS:GraphSAGE.

As a supplementary experiment, we present in-domain results in Table 4, 5: CV→CV and BIO→BIO respectively. While we show in the main paper that CLS + Node2vec yields the best result, which serves as an upper bound on cross-domain performance, we additionally show our experimental results for other supervised methods:

CLS + P2V/BERT We encode concept pairs with P2V/BERT, concatenate the embeddings of both concepts within each possible pair, and then train a binary classifier. We report the best performance among Support Vector Machine, Logistic Regression, Gaussian Naïve Bayes, and Random Forest.

DeepWalk, Node2vec DeepWalk (Perozzi et al., 2014) randomly samples a node and traverses to a neighbor node until it reaches a maximum length, updating the latent representation of each node after each "walk "to maximize the probability of each node's neighbors given a node's representation. Node2Vec (Grover and Leskovec, 2016) improves DeepWalk by providing the additional flexibility of placing weights on random walks. For both methods, we input the training prerequisite relations and obtain concept node embeddings. After generating embeddings for each concept in the target domain, we concatenate the embeddings of both concepts in each concept pair and pass the concatenated representation into a classifier to predict the relation. Again, we report the best performance from the same four classifiers.

GraphSAGE + P2V/BERT GraphSAGE (Hamilton et al., 2017) is an inductive framework to generate node embeddings for unseen data by leveraging existing node features. We first treat it as a node embedding method, as done with DeepWalk and Node2vec. After generating concept node embeddings, we train a classifier to predict concept relations and report in-domain results. In addition, we investigate GraphSAGE for the out-of-domain setting. We assume that, because there are unseen topics when transferring to new domains, such an inductive method like GraphSAGE may fit in our scenario. However, we end up with negative results as the original GraphSAGE may not fit in to this specific application. We leave further investigation for future work.

Attentive Multiview Text Representation for Differential Diagnosis

Abstract

We present a text representation approach that can combine different views (representations) of the same input through effective data fusion and attention strategies for ranking purposes. We apply our model to the problem of *differential diagnosis*, which aims to find the most probable diseases that match with clinical descriptions of patients, using data from the Undiagnosed Diseases Network. Our model outperforms several ranking approaches (including a commercially-supported system) by effectively prioritizing and combining representations obtained from traditional and recent text representation techniques. We elaborate on several aspects of our model and shed light on its improved performance.

1 Introduction

Electronic Health Records (EHRs) (Dick et al., 1997) contain a wealth of documented information and insights about patients health and well-being. However, it is difficult to effectively process such data due to complex terminology, missing information, and imprecise clinical descriptions (Friedman et al., 2013; Rajkomar et al., 2019). In addition, an especially challenging class of diseases are orphan or rare diseases (Kodra et al., 2012; Walley et al., 2018), which are diverse in symptoms and affect a smaller percentage of the population.

In this paper, we investigate how well Natural Language Processing (NLP) algorithms could reproduce the performance of clinical experts in the task of *differential diagnosis*–the process of distinguishing a particular disease from others that present similar clinical features, given medical histories (descriptions) of individual patients. We formulate this task as a ranking problem where the aim is to find the most probable diseases given medical histories of patients (Dragusin et al., 2013).

We develop a novel *pairwise* ranking algorithm that combines different views of patient and disease descriptions, and prioritizes effective views through an **A**ttentive **M**ultiview **N**eural **M**odel (AMNM). We research this problem using data from the Undiagnosed Diseases Network (UDN) (Gahl et al., 2015; Ramoni et al., 2017)[1], which includes concise medical history of patients and their corresponding diseases in the Online Mendelian Inheritance in Man (OMIM) dataset (Amberger et al., 2015).[2] All diagnoses–mappings between each patient and corresponding diseases–are provided by a team of expert clinicians from the UDN.

The contributions of this paper are as follows:

- illustrating the impact of NLP in detecting the nature of illness (diagnosis) in patients with rare diseases in a real-world setting, and
- a novel neural approach that effectively combines and prioritizes different views (representations) of inputs for ranking purposes.

Our Attentive Multiview Neural Model employs traditional and recent representation learning techniques and outperforms current pairwise neural ranking approaches through effective data fusion and attention strategies. We conduct several experiments to illustrate the utility of different fusion techniques for combining patient (query) and disease (document) representations.[3]

2 Method

In many domains, entities can be represented from multiple views. For example, a patient can be represented by demographic data, medical history, diagnosis codes, radiology images, etc. We propose a neural model to effectively prioritize important views and combine them for ranking purposes.

Figure 1 shows our model, which comprises of three major components: (a): an attention network that estimates and weights the contribution of each view in the ranking process, (b): a fusion network the utilizes intra-view feature interactions to effectively combine query-document representations, and (c): a `softmax` layer at the end that estimates the query-document relevance scores given their combined representations. We first formulate the problem and then explain these components.

2.1 Problem Statement

Let $(\mathbf{q}', \mathbf{d}')$ and $(\mathbf{q}'', \mathbf{d}'')$ denote two different views of the same query and document (throughout the paper, we think of queries and documents as clinical descriptions of patients and diseases respectively).[4] These views can be obtained using traditional (Robertson and Walker, 1994) or recent (Devlin et al., 2019) representation learning techniques applied to textual descriptions or codified data of queries and documents. For example, $\mathbf{q}'$ and $\mathbf{d}'$ can indicate representations of the *texts* of a query and a document, and $\mathbf{q}''$ and $\mathbf{d}''$ can indicate representations of the *medical concepts and codes* associated with the same query and document. Our task is to determine a relevance score between each given query and document. Toward this goal, we effectively prioritize and combine these representations through Attention and Fusion neural networks, which are described blow.

2.2 Attention Model

We develop an attention sub-network to explicitly capture the varying importance of views by assigning attentive weights to them. Specifically, given the embedding vectors of a query $\mathbf{q}^i \in \mathbb{R}^l$ and a document $\mathbf{d}^i \in \mathbb{R}^m$ in the ith view, we use a Feed-forward network, i.e. function $f(.)$ in Figure 1, to estimate the vector $\mathbf{a}$ that captures attention weights across views as follows:

$$f(\mathbf{q}^i, \mathbf{d}^i) = \varphi(\mathbf{W}^q \mathbf{q}^i + \mathbf{b}^q)^\top \cdot \varphi(\mathbf{W}^d \mathbf{d}^i + \mathbf{b}^d),$$
$$\mathbf{a} = \texttt{softmax}([f(\mathbf{q}^i, \mathbf{d}^i), \forall i]), \tag{1}$$

where $\mathbf{W}^q \in \mathbb{R}^{n \times l}$ and $\mathbf{W}^d \in \mathbb{R}^{n \times m}$ are weight matrices to transform the query and document representations into the same underlying space of dimension n, $\mathbf{b}^q \in \mathbb{R}^n$ and $\mathbf{b}^d \in \mathbb{R}^n$ are the trainable bias vectors for the query and document respectively and $\varphi(.)$ is the ReLU function. The

[4] Our model can incorporate any number of views; we only illustrate two views here for simplicity.

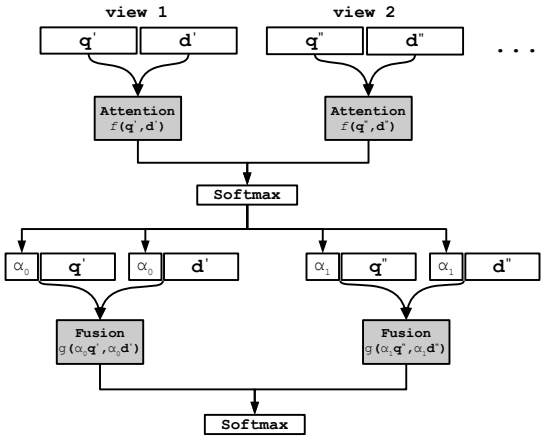

Figure 1: The architecture of our Attentive Multiview Neural Model (AMNM). For simplicity, we illustrate two views only, e.g. $(\mathbf{q}', \mathbf{d}')$ indicates representations of the texts of a query and a document, and $(\mathbf{q}'', \mathbf{d}'')$ indicates representations of the medical codes and concepts associated with the same query and document. $f(.)$ and $g(.)$ indicate attention and fusion functions respectively, and $\mathbf{a}_i$ indicates the attentive weight of the ith view estimated by the attention sub-network.

`softmax` activation function transforms the attention weights to $[0, 1]$ range. Assuming that the query-document pair of the more influential view are more similar in the underlying shared space (estimated by dot product in (1)), $\mathbf{a}$ captures attention weights of different views.

2.3 Fusion Model

Previous learning to rank approaches often concatenate query and document representations to combine their corresponding features (dos Santos et al., 2015; Amiri et al., 2016). There are a few approaches that explicitly capture feature interactions between queries and documents (Severyn and Moschitti, 2015; Echihabi and Marcu, 2003). We extend these fusion techniques and compare them.

Given the attention weights from (1), we develop a fusion sub-network, function $g(.)$ in Figure 1, to capture the intra-view feature interactions for query and document representations of each view. Our fusion network takes as input the *attentive embeddings* of each view, i.e. $(\alpha \times \mathbf{q}, \alpha \times \mathbf{d})$, and combines them through *one* of the following tensor fusion operations:

$$\begin{aligned} g^{dot}(\alpha\mathbf{q}, \alpha\mathbf{d}) &= \alpha^2 \times \varphi(\mathbf{W}^q\mathbf{q} + \mathbf{b}^q)^\top \cdot \\ &\quad \varphi(\mathbf{W}^d\mathbf{d} + \mathbf{b}^d), \\ g^{outer}(\alpha\mathbf{q}, \alpha\mathbf{d}) &= \alpha^2 \times \mathbf{q} \otimes \mathbf{d}, \\ g^{conv}(\alpha\mathbf{q}, \alpha\mathbf{d}) &= \alpha^2 \times \texttt{Conv1d}(\mathbf{q} \otimes \mathbf{d}), \end{aligned} \tag{2}$$

where g^{dot}, g^{outer}, and g^{conv} denote the dot product, outer product, and one-dimensional (1D) convolution with average pooling. In contrast to g^{dot}, g^{outer} and g^{conv} are considerably more expensive operations but may better encode feature interactions. The output of function g is flattened and considered as the *intra-view embedding*.

Finally, we obtain the overall fused representation for each view by concatenating its intra-view and attentive embeddings. The representations of all views are then fed into a `softmax` to estimate the relevance between queries and documents.

3 Experiments

Data: Our data includes medical histories of 257 patients provided by the the Undiagnosed Diseases Network (UDN[5]) (Gahl et al., 2015; Ramoni et al., 2017), as well as general descriptions (including clinical features) of more than 9K diseases available in the Online Mendelian Inheritance in Man (OMIM) dataset (Amberger et al., 2015). The UDN is a nationwide program that improves the level of diagnosis for individual patients (with severe clinical conditions) whose signs and symptoms have been intractable to diagnosis (Kobren et al., 2021; Amiri et al., 2021). To the best of our knowledge, this dataset is the largest available dataset for investigation on rare disease patients. The relevance judgment between patients and diseases is provided by a team of expert clinicians at the UDN. The total number of positive patient-disease pairs is $4,746$, where the number of unique diseases among these pairs is $1,131$; note that different patients can match with the same disease. We split the patients into training (80%), validation (10%), and test (10%) sets. In addition, for each positive pair in the training set, we create a negative pair for the same patient through random sampling of diseases. At test time, we create all the possible patient-disease pair combinations (more than 218K pairs) and use the estimated confidence scores of the classifier to rank all diseases against each test patient. In terms of views, we consider the texts of medical histories and diseases as the first view, and medical concepts and codes extracted from histories by QuickUMLS (Soldaini and Goharian, 2016) as the second view.

We note the concept and code view provides a higher level and more general semantic distinctions by grouping semantically-similar terms, while text view encodes other elements of semantics such as negation, hedging, etc.

Baselines: We consider the following baselines:

• **BM25** (Robertson et al., 1995): An unsupervised approach that effectively predicts relevance based on term frequency, inverse document frequency, and document length.

• **SVMs** (Cortes and Vapnik, 1995): We develop TF/IDF weighted ngrams (n=[1–2]) as features for the text and code/concept views, and conduct exhaustive search over hyperparameters for best performance on validation data. Such features were found effective on clinical texts by previous work (Howes et al., 2012; Reuber et al., 2009).

• **BERT** (Devlin et al., 2019): An attentive bidirectional language model that estimates the relevance between queries and documents by generating contextual representations, jointly conditioned on left and right contexts. We use BERT models developed for clinical text (Alsentzer et al., 2019).[6]

• **SVM**^{rank} (Joachims, 2002): An extension of SVMs to ranking problems which adaptively sorts documents based on their relevance to each query through empirical risk minimization. As features, we use relevance scores or probability predictions generated by the above baselines as well as additional features (unigram overlap and IDF-weighted unigram overlap) (Yu et al., 2014) to better establish the relevance between queries and documents.

• **PhenoTips** (Girdea et al., 2013): This *commercial* tool is currently used at the UDN to assist diagnostic efforts. It utilizes external sources such as the Human Phenotype Ontology (Köhler et al., 2017) and Orphanet data[7] to rank candidate diseases according to their ontology-based similarity to phenotypic descriptions of patients. PhenoTips employs advanced statistical modeling to differentiate candidate diseases, accounts for disorder frequencies in the general population according to Orphanet, supports negative phenotypes–symptoms that were not observed in the patient–and utilizes both code and text views.

[5]Access to phenotypic and genomic UDN data can be granted by submitting an online access request at dbGaP: https://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs001232.v1.p1.

[6]We input medical concepts to BERT by replacing them with their "preferred" concept, determined by UMLS (Lindberg, 1990; Bodenreider, 2004), across all patient and disease descriptions. For example, "diabetes mellitus type 1," "type 1 diabetes," "juvenile diabetes" and "IDDM" are all converted to "juvenile diabetes" (as the preferred concept).

[7]http://www.orpha.net

Settings: Initial representations for patient and disease descriptions are obtained from clinical BERT (Devlin et al., 2019; Alsentzer et al., 2019), i.e. $d_1, d_2 = 768$. In (1) and (2), we set the dimension of the shared space between query and document representations to $n = 100$. In addition, for the CNN fusion model, see (2), we use 250 filters and kernel size of 3. Further details are provided in the supplementary materials.

Evaluation Metrics: We employ Mean Average Precision (MAP), Precision at rank K (P@K), and Precision-Recall curve implemented in `trec_eval`[8] to compare competing systems. We use t-test for significance testing and asterisk mark (*) to indicate significant difference at $\rho = 0.01$.

3.1 Experimental Results

We report the performance of single and multiview models separately to ease comparison between views. The overall MAP and P@K, $\forall$K $\in \{5, 10\}$, performance of baselines for each view are reported in Table 1. The results show that BERT outperforms the other baselines across almost all measures. We attribute the poor performance of BM25 and SVMs to considerable difference in the underlying word/concept distribution in query and document spaces which can't be effectively addressed through lexical features (Burgun and Bodenreider, 2001; Pedersen et al., 2007).[9] In addition, BERT (code view) shows lower performance than BERT (text view). We conjecture that this results could be explained through the following points: (a): BERT is a strong language model and is robust in retrieving noun hypernyms or in completions involving shared category or role reversal (Ettinger, 2020), and (b): replacing medical concepts in text with their preferred concepts (see footnote 6) makes the original text less coherent, which can adversely affect the performance of BERT.

Table 2 shows the performance of SVM^{rank} with combined features across views, PhenoTips, and our Attentive Multiview Neural Model (AMNM) with different fusion functions. AMNM combines traditional and recent representation learning techniques by using BERT representations for text view, and BERT and SVMs representations for code view. All model combinations except for AMNM$_{bert\text{-}svms}$ (g^{conv}) lead to significant improvement against the best performing baseline–BERT (text view) in Table 1. AMNM$_{bert\text{-}bert}$ (g^{dot}) improves the best baseline by 3.4, 1.7 and 5.8 points in MAP, P@5 and P@10 respectively; the corresponding improvement for AMNM$_{bert\text{-}svms}$ (g^{dot}) is 2.9, 5.8 and 6.2 points respectively. We note that AMNM$_{bert\text{-}svms}$ (g^{dot}) leads to considerably higher P@{5,10}, metrics that have a pivotal role in practical use of search systems. In addition, PhenoTips shows comparable MAP to BERT but has considerably lower P@{5,10}.[10]

The fusion functions g^{dot} (dot product) and g^{outer} (outer product) outperform the more expensive fusion function g^{conv} (one-dimensional convolution). The lower performance of g^{conv} could be attributed to average pooling, which assumes different input dimensions equally contribute to the final representation and relevance. As a result, it may fail to eliminate noisy features or prioritize important ones.

	Text View			Code View		
Model	**MAP**	**P@5**	**P@10**	**MAP**	**P@5**	**P@10**
BM25	4.1	5.0	3.8	6.5	8.3	6.3

AMNM$_{bert\text{-}svms}$	g^{outer}	17.1*	17.5	17.1
AMNM$_{bert\text{-}svms}$	g^{conv}	11.4	14.2	13.9

Table 2: Model performance across different fusion functions. The Model column shows the source of representations for text and code views respectively. * indicates significant improvement against best-performing baseline reported in Table 1.

[8] https://trec.nist.gov/trec_eval/

[9] For example, these models can't effectively match a query containing "congestive heart failure" to relevant documents containing "cardiac decompensation," "pulmonary edema," and "ischemic cardiomyopathy."

[10] We note that, in case of rare and undiagnosed diseases, any small improvement is crucial as it can lead to better diagnostic clues. Clinicians often look at the top K results for clues and potential matches for each patient. Therefore, compared to standard evaluation metrics, a more practical evaluation metric for our task is Hit@K, which measures the likelihood of observing "at least one" relevant disease in the ranked list of top K diseases. The Hit@K ($K = 20$) performance of our model is 0.49, while the corresponding value for our best performing baseline is 0.37.

3.2 Model Analysis

We discuss how and why AMNM achieves its improved performance through the following experiments; see supplementary materials for details:

Prediction Variance Across Views: The Pearson correlation between the Average Precision of BERT (text view) and BERT (code view) on individual test queries (patients) is 0.87, which indicates less performance variation across views at query level. This is while the corresponding correlation between BERT (text view) and SVMs (code view) is only 0.34. The lack of diversity in the performance of BERT across these views could be a source of improvement in AMNM$_{bert\text{-}svms}$.

Attention Function: Given test examples (more than 218K patient-disease pairs), our attention sub-network is expected to assign a higher attentive weight to the view that better estimates the corresponding relevance score. To estimate the accuracy of this sub-network, we separately apply the trained BERT (text view) and SVMs (code view) models to generate their corresponding ranked lists of diseases for test patients. Then, for each *relevant* patient-disease pair, we evaluate our attention function in AMNM$_{bert\text{-}svms}$ by measuring whether it assigns a higher attentive weight to the better view–the view that positions the relevant disease at a higher rank compared to the other view. The results show that (a): our attention sub-network is 57.7% accurate in prioritizing better views, (b): BERT (text view) outperforms SVMs (code view) on 64.7% of relevant patient-disease pairs in terms of relative ranks, and our attention network accurately assigns higher weight to BERT on 88.6% of these examples, and (c): on the remaining 35.3% of examples that SVMs (code view) outperforms BERT (text view) in terms of relative ranks, our attention network assigns higher weight to SVMs in only 0.9% of these examples. Improving this percentage could boost the performance of our model and is the subject of our future work.

4 Related Work

The National Institutes of Health established the Undiagnosed Diseases Network (UDN) (Gahl et al., 2015; Ramoni et al., 2017) to facilitate research on undiagnosed and rare diseases. The UDN is a network of 12 clinical sites, and application to the UDN is open to all individuals who complete the application form and submit a referral letter from a health care professional (Kobren et al., 2021). A committee of experts in a review session reviews each UDN application and makes admission decisions. Walley et al. (2018) investigated major factors that may determine application outcomes of the UDN, which has been found effective in developing computational models for predicting admission outcomes (Amiri et al., 2021). In (Dragusin et al., 2013), authors developed a search engine for rare diseases, named FindZebra[11], which was based on information retrieval techniques available in Indri search engine (Strohman et al., 2005). In addition, previous work developed experimental setup to evaluate and compare search engines such as Google or Bing in predicting relevant diseases to given phenotypes (Shenker, 2014), employed medical anthologies and information content techniques (Köhler et al., 2009), leveraged collaborative filtering (Shen et al., 2017) and ensemble techniques (Jia et al., 2018) for this purpose.

Our work departs from previous research by investigating a multiview approach to undiagnosed patients, where we show effective attention and fusion techniques lead to better pairwise ranking for differential diagnosis.

5 Conclusion and Future Work

Given electronic health records of patients, we develop an attentive multiview text representation model to assist clinical experts by ranking the most probable and relevant diseases. Accurate and timely diagnosis is especially important for critically ill patients as it assists specialists to distinguish, prioritize, and accelerate treatment for such patients. Our work can be improved by (a): enriching the feature space through patient- and disease-specific information such patient demographic information and clinical synopsis of diseases, (b): improving model's attention mechanism, and (c): tackling differences in word distributions across patients (queries) and diseases (documents).

Ethics and Broader Impact Statement

This investigation included a small cohort of diagnosed patients in the Undiagnosed Diseases Network (UDN). The UDN is a network of 12 clinical sites, and application to the UDN is open to all individuals who complete the application form and submit a referral letter from a health care professional; a committee of experts in a review session reviews each UDN application and makes admission decisions. We included all data with no exclusions during the data analysis and manual review, except for cases with missing data or formatting issues. The population will therefore reflect the gender, race, ethnicity, age, and health status of the participating patients. In addition, all results have been presented in aggregate and no attempt have been made to identify individuals or facilities. However, during the course of this research and beyond that, there is a potential risk of loss of patient privacy and confidentiality. We have made and will make every effort to protect human subject information and minimize the likelihood of this risk (all authors with access to the data have successfully completed an education program in the protection of human subjects and privacy protection). In addition, our work is transformational in nature and its broader impacts are first and foremost the potential to improve the well-being of individual patients in the society (individuals who often find themselves on a protracted journey from one specialist to another without diagnosis even in this era of genomic sequencing), and support clinicians in their diagnostic efforts.

Abstract

Crowdworker-constructed natural language inference (NLI) datasets have been found to contain statistical artifacts associated with the annotation process that allow hypothesis-only classifiers to achieve better-than-random performance (Poliak et al., 2018; Gururangan et al., 2018; Tsuchiya, 2018). We investigate whether MedNLI, a physician-annotated dataset with premises extracted from clinical notes, contains such artifacts (Romanov and Shivade, 2018).

We find that entailed hypotheses contain generic versions of specific concepts in the premise, as well as modifiers related to responsiveness, duration, and probability. Neutral hypotheses feature conditions and behaviors that co-occur with, or cause, the condition(s) in the premise. Contradiction hypotheses feature explicit negation of the premise and implicit negation via assertion of good health. Adversarial filtering demonstrates that performance degrades when evaluated on the *difficult* subset. We provide partition information and recommendations for alternative dataset construction strategies for knowledge-intensive domains.

1 Introduction

In the clinical domain, the ability to conduct natural language inference (NLI) on unstructured, domain-specific texts such as patient notes, pathology reports, and scientific papers, plays a critical role in the development of predictive models and clinical decision support (CDS) systems.

Considerable progress in domain-agnostic NLI has been facilitated by the development of large-scale, crowdworker-constructed datasets, including the Stanford Natural Language Inference corpus (SNLI), and the Multi-Genre Natural Language Inference (MultiNLI) corpus (Bowman et al., 2015; Williams et al., 2017). MedNLI is a similarly-motivated, healthcare-specific dataset created by a small team of physician-annotators in lieu of crowdworkers, due to the extensive domain expertise required (Romanov and Shivade, 2018).

Poliak et al. (2018), Gururangan et al. (2018), Tsuchiya (2018), and McCoy et al. (2019) empirically demonstrate that SNLI and MultiNLI contain lexical and syntactic annotation artifacts that are disproportionately associated with specific classes, allowing a hypothesis-only classifier to significantly outperform a majority-class baseline model. The presence of such artifacts is hypothesized to be partially attributable to the priming effect of the example hypotheses provided to crowdworkers at annotation-time. Romanov and Shivade (2018) note that a hypothesis-only baseline is able to outperform a majority class baseline in MedNLI, but they do not identify specific artifacts.

We confirm the presence of annotation artifacts in MedNLI and proceed to identify their lexical and semantic characteristics. We then conduct adversarial filtering to partition MedNLI into *easy* and *difficult* subsets (Sakaguchi et al., 2020). We find that performance of off-the-shelf `fastText`-based hypothesis-only and hypothesis-plus-premise classifiers is lower on the *difficult* subset than on the *full* and *easy* subsets (Joulin et al., 2016). We provide partition information for downstream use, and conclude by advocating alternative dataset construction strategies for knowledge-intensive domains.[1]

2 The MedNLI Dataset

MedNLI is domain-specific evaluation dataset inspired by general-purpose NLI datasets, including SNLI and MultiNLI (Romanov and Shivade, 2018; Bowman et al., 2015; Williams et al., 2017). Much like its predecessors, MedNLI consists of premise-hypothesis pairs, in which the premises are drawn

[1] See https://github.com/crherlihy/clinical_nli_artifacts for code and partition ids.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1020–1027
August 1–6, 2021. ©2021 Association for Computational Linguistics

from the `Past Medical History` sections of a randomly selected subset of de-identified clinical notes contained in MIMIC-III (Johnson et al., 2016; Goldberger et al., 2000 (June 13). MIMIC-III was created from the records of adult and neonatal intensive care unit (ICU) patients. As such, complex and clinically severe cases are disproportionately represented, relative to their frequency of occurrence in the general population.

Physician-annotators were asked to write a *definitely true*, *maybe true*, and *definitely false* set of hypotheses for each premise, corresponding to *entailment*, *neutral* and *contradiction* labels, respectively. The resulting dataset has cardinality: $n_{\text{train}} = 11232$; $n_{\text{dev}} = 1395$; $n_{\text{test}} = 1422$.

3 MedNLI Contains Artifacts

To determine whether MedNLI contains annotation artifacts that may artificially inflate the performance of models trained on this dataset, we train a simple, premise-unaware, `fastText` classifier to predict the label of each premise-hypothesis pair, and compare the performance of this classifier to a majority-class baseline, in which all training examples are mapped to the most commonly occurring class label (Joulin et al., 2016; Poliak et al., 2018; Gururangan et al., 2018). Note that since annotators were asked to create an entailed, contradictory, and neutral hypothesis for each premise, MedNLI is class-balanced. Thus, in this setting, a majority class baseline is equivalent to choosing a label uniformly at random for each training example.

The micro F1-score achieved by the `fastText` classifier significantly exceeds that of the majority class baseline, confirming the findings of Romanov and Shivade (2018), who report a micro-F1 score of 61.9 but do not identify or analyze artifacts:

	dev	test
majority class	33.3	33.3
`fastText`	**64.8**	**62.6**

Table 1: Performance (micro F1-score) of the `fastText` hypothesis-only classifier.

As the confusion matrix for the test set shown in Table 2 indicates, the `fastText` model is most likely to misclassify entailment as neutral, and neutral and contradiction as entailment. Per-class precision and recall on the test set are highest for contradiction (73.2; 72.8) and lowest for entailment (56.7; 53.8).

	entailment	neutral	contradiction
entailment	**255**	151	68
neutral	126	**290**	58
contradiction	69	60	**345**

Table 2: Confusion matrix for `fastText` classifier.

4 Characteristics of Clinical Artifacts

In this section, we conduct class-specific lexical analysis to identify the clinical and domain-agnostic characteristics of annotation artifacts associated with each set of hypotheses in MedNLI.

4.1 Preprocessing

We cast each hypothesis string in the MedNLI training dataset to lowercase. We then use a `scispaCy` model pre-trained on the `en_core_sci_lg` corpus for tokenization and clinical named entity recognition (CNER) (Neumann et al., 2019a). One challenge associated with clinical text, and scientific text more generally, is that semantically meaningful entities often consist of spans rather than single tokens. To mitigate this issue during lexical analysis, we map each multi-token entity to a single-token representation, where sub-tokens are separated by underscores.

4.2 Lexical Artifacts

Following Gururangan et al. (2018), to identify tokens that occur disproportionately in hypotheses associated with a specific class, we compute token-class pointwise mutual information (PMI) with add-50 smoothing applied to raw counts, and a filter to exclude tokens appearing less than five times in the overall training dataset. Table 3 reports the top 15 tokens for each class.

$$\texttt{PMI}(\text{token}, \text{class}) = log_2 \frac{p(\text{token}, \text{class})}{p(\text{token}, \cdot)p(\cdot, \text{class})}$$

Entailment Entailment hypotheses are characterized by tokens about: (1) patient status and response to treatment (e.g., *responsive*; *failed*; *longer* as in *no longer intubated*); (2) medications and procedures which are common among ICU patients (e.g., *broad_spectrum*; *antibiotics*; *pressors*; *steroid_medication*; *underwent*; *removal*); (3) generalized versions of specific words in the premise (e.g., *comorbidities*; *multiple_medical_problems*), which Gururangan et al. (2018) also observe in SNLI; and (4) modifiers related to duration, frequency, or probability (e.g., *frequent*, *possible*, *high_risk*).

entailment	%	neutral	%	contradiction	%
just	0.25%	cardiogenic_shock	0.33%	no_history_of_cancer	0.27%
high_risk	0.26%	pelvic_pain	0.30%	no_treatment	0.27%
pressors	0.25%	joint_pain	0.30%	normal_breathing	0.27%
possible	0.26%	brain_injury	0.32%	no_history_of_falls	0.27%
elevated_blood_pressure	0.26%	delerium	0.30%	normal_heart_rhythm	0.28%
responsive	0.25%	intracranial_pressure	0.30%	health	0.26%
comorbidities	0.26%	smoking	0.42%	normal_head_ct	0.26%
spectrum	0.27%	obesity	0.41%	normal_vision	0.26%
steroid_medication	0.25%	tia	0.32%	normal_aortic_valve	0.27%
longer	0.26%	acquired	0.31%	bradycardic	0.26%
history_of_cancer	0.26%	head_injury	0.31%	normal_blood_sugars	0.27%
broad	0.26%	twins	0.30%	normal_creatinine	0.28%
frequent	0.25%	fertility	0.30%	cancer_history	0.26%
failed	0.26%	statin	0.30%	cardiac	0.33%
medical	0.29%	acute_stroke	0.30%	normal_chest	0.28%

Table 3: Top 15 tokens by `PMI`(token, class); % of *class* training examples that contain the token.

Neutral Neutral hypotheses feature tokens related to: (1) chronic and acute clinical conditions (e.g., *obesity*; *joint_pain*; *brain_injury*); (2) clinically relevant behaviors (e.g., *smoking*; *alcoholic*; *drug_overdose*); and (3) gender and reproductive status (e.g., *fertility*; *pre_menopausal*). Notably, the most discriminative conditions tend to be commonly occurring within the general population and generically stated, rather than rare and specific. This presumably contributes to the relative difficulty that the hypothesis-only `fastText` model has distinguishing between the entailment and neutral classes.

Contradiction Contradiction hypotheses are characterized by tokens that convey normalcy and good health. Lexically, such sentiment manifests as: (1) explicit negation of clinical severity, medical history, or in-patient status (e.g., *denies_pain*; *no_treatment*; *discharged_home*), or (2) affirmation of clinically unremarkable findings (e.g., *normal_heart_rhythm*; *normal_blood_sugars*), which would generally be rare among ICU patients. This suggests a heuristic of inserting negation token(s) to contradict the premise, which Gururangan et al. (2018) also observe in SNLI.

4.3 Syntactic Artifacts

Hypothesis Length In contrast to Gururangan et al. (2018)'s finding that entailed hypotheses in SNLI tend to be shorter while neutral hypotheses tend to be longer, hypothesis sentence length does not appear to play a discriminatory role in MedNLI, regardless of whether we consider merged- or separated-token representations of multi-word entities, as illustrated by Table 4:

	entailment		**neutral**		**contradiction**	
	mean	median	mean	median	mean	median
separate	5.6	5.0	5.2	5.0	5.6	5.0
merged	5.3	5.0	4.9	5.0	5.3	5.0

Table 4: Average and median hypothesis length by class and entity representation.

5 Physician-Annotator Heuristics

In this section, we re-introduce premises to our analysis to evaluate a set of hypotheses regarding latent, class-specific annotator heuristics. If annotators *do* employ class-specific heuristics, we should expect the semantic contents, φ, of a given hypothesis, $h \in \mathcal{H}$, to be influenced not only by the semantic contents of its associated premise, $p \in \mathcal{P}$, but also by the target class, $c \in \mathcal{C}$.

To investigate, we identify a set of heuristics parameterized by $\varphi(p)$ and c, and characterized by the presence of a set of heuristic-specific Medical Subject Headings (MeSH) linked entities in the premise and hypothesis of each heuristic-satisfying example. These heuristics are described below; specific MeSH features are detailed in the Appendix.

Hypernym Heuristic This heuristic applies when the premise contains clinical condition(s), medication(s), finding(s), procedure(s) or event(s), the target class is *entailment*, and the generated hypothesis contains term(s) that can be interpreted as super-types for a subset of elements in the premise (e.g., clindamycin <: antibiotic).

Probable Cause Heuristic This heuristic applies when the premise contains clinical condition(s), the target class is *neutral*, and the generated hypothesis provides a plausible, often subjective

or behavioral, causal explanation for the condition, finding, or event described in the premise (e.g., associating altered mental status with drug overdose).

Everything Is Fine Heuristic This heuristic applies when the premise contains condition(s) or finding(s), the target class is *contradiction*, and the generated hypothesis negates the premise or asserts unremarkable finding(s). This can take two forms: repetition of premise content plus negation, or inclusion of modifiers that convey good health.

Analysis We conduct a χ^2 test for each heuristic to determine whether we are able to reject the null hypothesis that pattern-satisfying premise-hypothesis pairs are uniformly distributed over classes.

heuristic	χ^2	p-value	top class
hypernym	59.15	1.4e-13‡	entail. (45.2%)
probable cause	111.05	7.7e-25‡	neutral (57.8%)
everything fine	874.71	1.1e-190‡	contradict. (83.8%)

Table 5: Results of χ^2 test statistic by heuristic, computed using the combined MedNLI dataset (‡ $p < 0.001$, † $p < 0.01$, * $p < 0.5$). Top class presented with % of heuristic-satisfying pairs.

The results support our hypotheses regarding each of the three heuristics. Notably, the percentage of heuristic-satisfying pairs accounted for by the top class is lowest for the HYPERNYM hypothesis, which we attribute to the high degree of semantic overlap between entailed and neutral hypotheses.

6 Adversarial Filtering

To mitigate the effect of clinical annotation artifacts, we employ `AFLite`, an adversarial filtering algorithm introduced by Sakaguchi et al. (2020) and analyzed by Bras et al. (2020), to create *easy* and *difficult* partitions of MedNLI.

`AFLite` requires distributed representations of the full dataset as input, and proceeds in an iterative fashion. At each iteration, an ensemble of n linear classifiers are trained and evaluated on different random subsets of the data. A score is then computed for each premise-hypothesis instance, reflecting the number of times the instance is correctly labeled by a classifier, divided by the number of times the instance appears in any classifier's evaluation set. The top-k instances with scores above a threshold, τ, are filtered out and added to the *easy* partition; the remaining instances are retained. This process continues until the size of the filtered subset is $< k$, or the number of retained instances is $< m$; retained instances constitute the *difficult* partition.

To represent the full dataset, we use $\texttt{fastText}_{\text{MIMIC-III}}$ embeddings, which have been pretrained on deidentified patient notes from MIMIC-III (Romanov and Shivade, 2018; Johnson et al., 2016). We represent each example as the average of its component token vectors. We proportionally adjust a subset of the hyperparameters used by Sakaguchi et al. (2020) to account for the fact that MedNLI contains far fewer examples than WINOGRANDE[2]: specifically, we set the training size for each ensemble, m, to 5620, which represents $\approx \frac{2}{5}$ of the MedNLI combined dataset. The remaining hyperparameters are unchanged: the ensemble consists of $n = 64$ logistic regression models, the filtering cutoff, k = 500, and the filtering threshold $\tau = 0.75$.

We apply `AFLite` to two different versions of MedNLI: (1) $\mathcal{X}_{h,m}$: hypothesis-only, multi-token entities merged, and (2) $\mathcal{X}_{ph,m}$: premise and hypothesis concatenated, multi-token entities merged. `AFLIte` maps each version to an *easy* and *difficult* partition, which can in turn be split into training, dev, and test subsets. We report results for the `fastText` classifier trained on the original, hypothesis-only (hypothesis + premise) MedNLI training set, and evaluated on the *full*, *easy* and *difficult* dev and test subsets of $\mathcal{X}_{h,m}$ ($\mathcal{X}_{ph,m}$), and observe that performance decreases on the *difficult* partition:

	model	eval dataset	full	easy (Δ)	difficult (Δ)
no premise	majority class	dev	0.33	0.34 (+0.01)	0.35 (+0.02)
no premise	majority class	test	0.33	0.35 (+0.02)	0.37 (+0.04)
no premise	`fastText`	dev	0.65	0.67 (+0.02)	0.46 (-0.19)
no premise	`fastText`	test	0.63	0.65 (+0.02)	0.4 (-0.23)
with premise	majority class	dev	0.33	0.45 (+0.12)	0.36 (+0.03)
with premise	majority class	test	0.33	0.48 (+0.15)	0.37 (+0.04)
with premise	`fastText`	dev	0.53	0.6 (+0.07)	0.43 (-0.1)
with premise	`fastText`	test	0.51	0.55 (+0.04)	0.4 (-0.11)

Table 6: Performance (micro F1-score) for the majority class baseline and `fastText` classifiers, with and without premise, by partition (e.g., *full, easy, difficult*).

7 Discussion

7.1 MedNLI is Not Immune from Artifacts

In this paper, we demonstrate that MedNLI suffers from the same challenge associated with annotation artifacts that its domain-agnostic predecessors have

[2]MedNLI's training dataset contains 14049 examples when the training, dev, and test sets are combined, while WINOGRANDE contains 47K after excluding the 6K used for fine-tuning.

encountered: namely, NLI models trained on {Med, S, Multi}NLI can perform well even without access to the training examples' premises, indicating that they often exploit shallow heuristics, with negative implications for out-of-sample generalization.

Interestingly, many of the high-level lexical characteristics identified in MedNLI can be considered domain-specific variants of the more generic, class-specific patterns identified in SNLI. This observation suggests that a set of abstract design patterns for inference example generation exists across domains, and may be reinforced by the prompts provided to annotators. Creative or randomized priming, such as Sakaguchi et al. (2020) 's use of anchor words from WikiHow articles, may help to decrease reliance on such design patterns, but it appears unlikely that they can be systematically sidestepped without introducing new, "corrective" artifacts.

7.2 A Prescription for Dataset Construction

To mitigate the risk of performance overestimation associated with annotation artifacts, Zellers et al. (2019) advocate adversarial dataset construction, such that benchmarks will co-evolve with language models. This may be difficult to scale in knowledge-intensive domains, as expert validation of adversarially generated benchmarks is typically required. Additionally, in high-stakes domains such as medicine, information-rich inferences should be preferred over correct but trivial inferences that time-constrained expert annotators may be rationally incentivized to produce, because entropy-reducing inferences are more useful for downstream tasks.

We advocate the adoption of a mechanism design perspective, so as to develop modified annotation tasks that reduce the cognitive load placed on expert annotators while incentivizing the production of domain-specific NLI datasets with high downstream utility (Ho et al., 2015; Liu and Chen, 2017). An additional option is to narrow the generative scope by defining a set of inferences deemed to be useful for a specific task. Annotators can then map (premise, relation) tuples to relation-satisfying, potentially fuzzy subsets of this pool of useful inferences, or return partial functions when more information is needed.

8 Ethical Considerations

When working with clinical data, two key ethical objectives include: (1) the preservation of patient privacy, and (2) the development of language and predictive models that benefit patients and providers to the extent possible, without causing undue harm. With respect to the former, MedNLI's premises are sampled from de-identified clinical notes contained in MIMIC-III (Goldberger et al., 2000 (June 13; Johnson et al., 2016), and the hypotheses generated by annotators do not refer to specific patients, providers, or locations by name. MedNLI requires users to complete Health Insurance Portability and Accountability Act (HIPAA) training and sign a data use agreement prior to being granted access, which we have complied with.

Per MedNLI's data use agreement requirements, we do not attempt to identify any patient, provider, or institution mentioned in the de-identified corpus. Additionally, while we provide AFLite *easy* and *difficult* partition information for community use in the form of split-example ids and a checksum, we do not share the premise or hypothesis text associated with any example. Interested readers are encouraged to complete the necessary training and obtain credentials so that they can access the complete dataset (Romanov and Shivade, 2018; Goldberger et al., 2000 (June 13).

With respect to benefiting patients, the discussion of natural language artifacts we have presented is intended to encourage clinical researchers who rely on (or construct) expert-annotated clinical corpora to train domain-specific language models, or consume such models to perform downstream tasks, to be aware of the presence of annotation artifacts, and adjust their assessments of model performance accordingly. It is our hope that these findings can be used to inform error analysis and improve predictive models that inform patient care.

A Appendix

A.1 Hypothesis-only Baseline Analysis

To conduct the analysis presented in Section 3, we take the MedNLI training dataset as input, and exclude the premise text for each training example. We cast the text of each training hypothesis to lowercase, but do not perform any additional preprocessing. We use an off-the-shelf `fastText` classifier, with all model hyperparameters set to their default values with the exception of `wordNgrams`, which we set equal to 2 to allow the model to use bigrams in addition to unigrams (Joulin et al., 2016). We evaluate the trained classifier on the hypotheses contained in the MedNLI dev and test datasets, and report results for each split.

A.2 Lexical Artifact Analysis

To perform the analysis presented in Section 4, we cast each hypothesis string in the MedNLI training dataset to lowercase. We then use a `scispaCy` model pre-trained on the `en_core_sci_lg` corpus for tokenization and clinical named entity recognition (CNER) (Neumann et al., 2019a). Next, we merge multi-token entities, using underscores as delimiters—e.g., "brain injury" → "brain_injury".

When computing token-class pointwise mutual information (PMI), we exclude tokens that appear less than five times in the overall training dataset's hypotheses. Then, following Gururangan et al. (2018), who apply add-100 smoothing to raw counts to highlight particularly discriminative token-class co-occurrence patterns, we apply add-50 smoothing to raw counts. Our approach is similarly motivated; our choice of 50 reflects the smaller state space associated with a focus on the clinical domain.

A.3 Semantic Analysis of Heuristics

To perform the statistical analysis presented in Section 5, we take the premise-hypothesis pairs from the MedNLI training, dev, and test splits, and combine them to produce a single corpus. We use a `scispaCy` model pre-trained on the `en_core_sci_lg` corpus for tokenization and entity linking (Neumann et al., 2019b), and link against the Medical Subject Headings (MeSH) knowledge base. We take the top-ranked knowledge base entry for each linked entity. Linking against MeSH provides a unique concept id, canonical name, alias(es), a definition, and one or more MeSH tree numbers for each recovered entity. Tree numbers convey semantic type information by embedding each concept into the broader MeSH hierarchy [3]. We operationalize each of our heuristics with a set of MeSH-informed semantic properties, which are defined as follows:

1. **Hypernym Heuristic:** a premise-hypothesis pair satisfies this heuristic if specific clinical concept(s) appearing in the premise appear in a more general form in the hypothesis. Formally: $\{(p,h)|\varphi(p) \subsetneq \varphi(h)\}$. MeSH tree numbers are organized hierarchically, and increase in length with specificity. Thus, when a premise entity and hypothesis entity are left-aligned, the hypothesis entity is a hypernym for the premise entity if the hypothesis entity is a substring of the premise entity. To provide a concrete example: *diabetes mellitus* is an *endocrine system disease*; the associated MeSH tree numbers are C19.246 and C19, respectively.

2. **Probable Cause Heuristic:** a premise-hypothesis pair satisfies this heuristic if: (1) the premise contains one or more MeSH entities belonging to high-level categories C (diseases), D (chemicals and drugs), E (analytical, diagnostic and therapeutic techniques, and equipment) or F (psychiatry and psychology); and (2) the hypothesis contains one or more MeSH entities that can be interpreted as providing a plausible causal or behavioral explanation for the condition, finding, or event described in the premise (e.g., smoking, substance-related disorders, mental disorders, alcoholism, homelessness, obesity).

3. **Everything Is Fine Heuristic:** a premise-hypothesis pair satisfies this heuristic if the hypothesis contains one or more of the same MeSH entities as the premise (excluding the *patient* entity, which appears in almost all notes) and also contains: (1) a negation word or phrase (e.g., *does not have*, *no finding*, *no*, *denies*); or (2) a word or phrase that affirms the patient's health (e.g., *normal*, *healthy*, *discharged*).

For each heuristic, we subset the complete dataset to find pattern-satisfying premise-heuristic pairs. We use this subset when performing the χ^2 tests.

A.4 Adversarial Filtering

When implementing `AFLite`, we follow Sakaguchi et al. (2020). We use a smaller training set size of $m = 5620$, but keep the remaining hyperparameters unchanged, such that the ensemble consists of $n = 64$ logistic regression models, the filtering cutoff, $k = 500$, and the filtering threshold $\tau = 0.75$.

Towards a more Robust Evaluation for Conversational Question Answering

Abstract

With the explosion of chatbot applications, Conversational Question Answering (CQA) has generated a lot of interest in recent years. Among proposals, reading comprehension models which take advantage of the conversation history (previous QA) seem to answer better than those which only consider the current question. Nevertheless, we note that the CQA evaluation protocol has a major limitation. In particular, models are allowed, at each turn of the conversation, to access the ground truth answers of the previous turns. Not only does this severely prevent their applications in fully autonomous chatbots, it also leads to unsuspected biases in their behavior. In this paper, we highlight this effect and propose new tools for evaluation and training in order to guard against the noted issues. The new results that we bring come to reinforce methods of the current state of the art.

1 Introduction

The ability to automatically answer questions from a set of raw text paragraphs has long been coveted by computer scientists (Woods, 1977). For applications in search engines, one could consider an isolated task where a user formulates a single question (Croft et al., 2010; Siblini et al., 2020). But recently, with usage in conversational agents (e.g. chatbots), a more contextualized variant referred to as Conversational Question Answering (CQA) has attracted a great deal of attention (Reddy et al., 2019; Choi et al., 2018). CQA differs from traditional (extractive) Question Answering (Rajpurkar et al., 2016) because Question-Answer (QA) pairs are not single but come in sequences within conversations. Therefore, models can use previous turns as context to extract the answer of the current question (Zhu et al., 2018; Huang et al., 2018; Qu et al., 2019a). In some cases, the history is even crucial to disambiguate pronouns in the question.

Similarly to other NLP tasks, the state-of-the-art approaches for CQA are variants of the Transformer Encoder (Vaswani et al., 2017), a deep neural network with several self-attention layers that produce contextualized representations of the "tokens" (words, subwords) that compose a text. For instance, models like BERT (Devlin et al., 2019; Lan et al., 2019; Sanh et al., 2019) obtain a more than decent performance on CQA datasets like QuAC (Choi et al., 2018) or CoQA (Reddy et al., 2019). However, they miss the context to fully understand the questions. Proposals have been made to integrate the history in several manners: using a recursive strategy (Huang et al., 2018), appending previous QAs to the current question as input (Zhu et al., 2018), and contextualizing the question-paragraph pair with respect to the history. We can mention in particular BERT-HAE and BERT-PHAE (Qu et al., 2019a,b) which improve BERT in a simple yet efficient way by encoding, in addition to segment and position, the fact that parts of the paragraph's words belonged to previous answers.

2 Motivation and main contributions

Our objective here is not to propose yet another model to try to obtain the best predictive score on CQA leaderboards. Instead, we focus our thinking around the current evaluation/training protocols with regards to the possible application cases. The starting point of our reflection is that currently, when evaluated on CQA datasets, models like BERT-HAE use the ground-truth answers of previous turns as context to answer the current question. This limits the scope of applicability to only a "semi-automatic" bot that would require a human providing supervision at each turn. We also show how it biases the selection of models towards those with an undesired filter behavior.

To make approaches from the literature usable

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1028–1034
August 1–6, 2021. ©2021 Association for Computational Linguistics

in more difficult/realistic scenarios like standalone chatbots (in which they can only access the previous questions and their predictions of the answers), we make the following contributions: **(1)** We implement new evaluation tools to first highlight the current unnoticed and undesirable behavior: in ground-truth free conditions, CQA approaches can become even less accurate than baselines like BERT which do not exploit the history at all. **(2)** We develop the analog training protocol to make approaches robust to the observed issues. In particular, this gives back state-of-the-art models the strength to outperform the baseline but this time in a scenario that connects better to real-world conversational agents. Our work comes with an implementation of conversational QA tools, based on the most widely used transformers library (Wolf et al., 2019).

3 Conversational Question Answering

Conversational Question Answering (CQA) is a Natural Language Processing task related to Machine Comprehension (MC) (Zhang et al., 2019; Gupta et al., 2020). MC has grown significantly over the last decade, particularly thanks to (1) large scale datasets such as SQuAD (Rajpurkar et al., 2016) or Natural Questions (Kwiatkowski et al., 2019), (2) the improvement of representation learning models (Joulin et al., 2017), (3) powerful mechanisms such as attention (Yang et al., 2016; Vaswani et al., 2017), and (4) the emergence of several related topics like multi-lingual modeling (Pires et al., 2019; Siblini et al., 2019) or Conversational Question Answering (Choi et al., 2018; Reddy et al., 2019).

In CQA, questions are grouped in conversations and often require the context, i.e. previous QA turns, to be fully understandable. QuAC (Choi et al., 2018) and CoQA (Reddy et al., 2019) are two examples of CQA datasets. They were both generated by humans (a "student" and a "teacher") through conversations where the student asks a series of questions, complementary or not, on a given paragraph and the teacher answers them. In this paper, we focus on QuAC (Question Answering in Context) which is more recent and described as more challenging than CoQA (Choi et al., 2018). It contains 14k conversations and around 100k question-paragraph pairs, split into a training set (11,567 conversations / 83,568 questions), a validation set (1,000 conversations / 7,354 questions) and a test set. It evaluates models with several metrics, the main one being the F1-score (Flach, 2003).

Models proposed for QuAC are similar to those developed for SQuAD (e.g. BiDAF (Seo et al., 2016) or BERT (Devlin et al., 2019)) but they additionally integrate the history. A popular example is BERT-HAE (Qu et al., 2019a). It uses BERT's architecture but modifies the input embedding layer to add a novel component: the History Answer Embedding (HAE). As usual, the input question-paragraph pair is tokenized and marked with positions and segments. Then, an additional History Answer marker is added to indicate whether the tokens belonged to answers of previous questions or not, and the resulting embedding is simply added to the other embedding vectors (token, position, segment) before the self-attention blocks. BERT-HAE was enhanced, in a later publication (Qu et al., 2019b) by BERT-PHAE (Positional HAE) which additionally encodes the turn position of the answers in the history. Although very promising, we note that BERT-HAE and BERT-PHAE, as well as other state of the art models for QuAC, access the ground-truth answers of previous turns during evaluation. Therefore, reported results only reflect the performance within a reduced scope of applicability. In the following, we detail this limitation and propose to complement the current protocol in order to improve both evaluation and training.

4 A more Robust Protocol

Consider a standalone chatbot that successively answers questions from documents. At each turn, it cannot know for sure the ground truth (GT) answers of the previous turns except if the user or another human provides supervision. This could happen in scenarios where the role of the algorithm is only to provide answer suggestions (semi-automatic) to a human agent (e.g. in customer support). However, applications often seek bots where the question-answer loop is automated (standalone). Here we investigate this second setting. We start by reproducing the literature results on the semi-automatic scenario, then we exhibit the limits and propose solutions for our target scenario.

4.1 Reproducing the Regular Evaluation in the Semi-automatic Scenario

To evaluate the baseline performance (semi-automatic), we train BERT-HAE and BERT-PHAE on QuAC using the protocol described by the authors (Qu et al., 2019a) and the same hyperparame-

ters: history markers from up to 6 turns, and specific optimization parameters (12 as batch size, 3e-5 as learning rate with a linear decrease to 0 over 24k training steps). We implement our own training script on the basis of codes pieces from the transformers library (Wolf et al., 2019) and BERT-HAE's authors[1]. Experiments are run with a Nvidia Tesla V100 GPU.

Model	F1	Uses history
BiDAF++ (Choi et al., 2018)	51.8	No
BERT (Qu et al., 2019a)	54.4 (54.8)	No
BERT-HAE (Qu et al., 2019a)	63.1 (63.4)	Yes
BERT-PHAE (Qu et al., 2019b)	64.7 (64.4)	Yes

Table 1: F1-score of BERT, BERT-HAE, BERT-PHAE and a previous baseline on QuAC using the regular evaluation protocol. We display the original results published by the authors and the ones we reproduced (in parentheses).

Our results are roughly equal to those previously reported (Table 1). BERT's F1 score is 54.8, which compares favorably to previous baselines such as BiDAF. By adjusting the representation of the tokens based on the history of answers, BERT-HAE allows a significant improvement to 63.4 (+15.7 %). The position of the turns in the history also has its importance allowing BERT-PHAE to further improve the F1-score to 64.4. This is probably because questions are often related to the answers that directly precede them. To improve the results even further, one can also select a specific subset of turns in the history (Qu et al., 2019b).

4.2 Critical Analysis: The Filtering Behavior

Although promising, the aforementioned results need to be considered with caution. A hasty conclusion is that adding the history allows the model to benefit from a context and hence to better process the current question. However the improvement could also be explained by a bias in the dataset at hand. Indeed, this question answering task is extractive, i.e. answers are selected from a paragraph. In the course of a conversation in QuAC, an average of 7 questions are successively asked on the same rather small paragraph. Thus simply filtering the paragraph tokens with the answer history provides the advantage of reducing considerably the list of possible remaining answers. Note however that such a filtering could also have a negative effect, in the presence of overlap between answers.

[1] https://github.com/prdwb/bert_hae

To get better insights of the impact of a filtering behavior in practice, we run three experiments.

Model	F1	F1 w/ post filtering
BEST	**95.6**	92.7
BERT	54.8	**56.9**
BERT-HAE	**63.4**	62.5

Table 2: Evaluation of the impact of post-filtering on BEST, BERT and BERT-HAE.

Experiment 1: The negative impact of filtering due to overlap We first compute the best reachable F1-score (that we refer to as BEST) as if we had a model that always predicts the expected answer. Then we compute "BEST w/ post filtering" with the same predictions except that we post-filter all tokens that belong the 6 previous turns' answers, except for the "Cannot Answer" tokens (reserved for unanswerable questions). BEST F1 score is 95.6[2] while "BEST F1 w/ post filtering" is lower but very close: 92.7 (Table 2). This tells us that the maximal negative impact of a filtering strategy on QuAC is weak. We find an explanation by doing proportion measurements in QuAC's eval set: in particular, the percentage of overlapping tokens (resp. non overlapping tokens) between answers is low (resp. high): 5.7% (resp. 74.1%), the other 20.2% being the "Cannot Answer" tokens.

Experiment 2: Global impact of a post filtering on the models After 6 turns, sometimes almost half of the paragraph tokens belong to the history of answers. Even if experiment 1 suggests a negative impact of filtering due to overlap, the positive impact on our baselines (due to the significant reduction of the number of candidate answers) could counterbalance. We therefore re-evaluate the models trained in section 4.1, but this time we apply a post processing of their predictions: the start/end logits of tokens that belong to the answers of previous turns are set to $-\infty$, except for the "Cannot Answer" tokens. This forces previous answers to be excluded from the final predicted span text. This simple strategy to integrate the history in BERT allows an improvement to an F1-score of 56.9 (Table 2). On the contrary, it globally reduces the score

[2] Intuitively, it should be 100. But this value is unreachable in practice. The reason is that questions in QuAC have several acceptable answers (span texts of various length) and we select one randomly as BEST prediction. And, QuAC's official evaluation script computes, for each sample, the average F1 between the prediction and all possible answers.

of BERT-HAE to 62.5 (a reduction factor slightly lower than with BEST). These results suggest that access to ground-truth answers of previous turns allows in QuAC, in which the overlap is weak, a filtering mechanism to be a positive way of integrating history. Results also suggest that BERT-HAE might already implicitly integrate a filtering behavior. Unquestionably, it does it in a more expressive manner than our hard post-processing, since the history markers are passed as inputs to the model.

Experiment 3: Does BERT-HAE exhibit a filter behavior? Although suggested by the previous experiment, we want to answer this question more clearly. We consider an experiment aligned with the philosophy of adversarial attacks (Akhtar and Mian, 2018; Morris et al., 2020). During evaluation, we systematically modify the history answer markers so that the tokens of the current expected answer are marked as if they belonged to the history. The results obtained from this evaluation protocol are displayed under the column "F1 w/ Adv" in Table 3. F1 w/ Adv allows to measure, with the F1 metric, the ability of the models to answer a question when its answer has already appeared in the conversation before. In this condition, we observe a dramatic drop in BERT-HAE's performance (from 63.4 to 41.7), and an even worse for BERT-PHAE. This confirms that these models tend to output lower probabilities for tokens that are in the history, which suggests a filtering behavior and makes their usage potentially counter productive.

4.3 Proposed Evaluation for the Standalone Scenario

The current evaluation protocol on QuAC's validation set can bias model selection towards those able to implement a filtering behavior, which seems to be the case for BERT-(P)HAE. Thus, it does not guarantee a robust behavior in a fully autonomous bot. Here we propose an extension.

Inspired by the literature of recurrent models, we refer to the regular evaluation protocol, which access to ground truth answers of previous turns, as the **"Teacher Forcing" (w/ TF) protocol**. Analogically, we consider a mode **"without Teacher Forcing" (w/o TF)** where models process a conversation in the natural order and only use their predictions as history. The latter is outlined in Algorithm 1, where "build_mark" refers to a function that computes the new HAE markers given the previous ones and the new answer. Note that the algorithm for evaluation w/ TF simply replaces "build_mark(HAE,$\text{answer}_{\text{pred}}$)" with "build_mark(HAE,$\text{answer}_{\text{GT}}$)".

Algorithm 1 Evaluation w/o TF

```
s ← 0
for conversation ∈ valid set do
    HAE ← None
    for turn ∈ conversation do
        question ← turn['question']
        answer_GT ← turn['answer']
        answer_pred ← model(question, HAE)
        HAE ← build_mark(HAE,answer_pred)
        s ← s + F1(answer_pred,answer_GT)
    end for
end for
return s / card(valid set)
```

When we take the models trained in section 4.1 (w/ TF) and evaluate them with the new standalone protocol (w/o TF), Table 3 shows that the performance drops from 63.4 to 53.5 with BERT-HAE and from 64.4 to 54.2 with BERT-PHAE. Concretely, although unsuspected with the original protocol, the approaches do not necessarily seem advantageous compared to BERT here. This in no way detracts the interest of these proposals, which implement clever architectures to integrate the history. It only prevents their application, as is, in the standalone scenario. Nevertheless, now that this issue is identified, we can try to design an appropriate strategy to avoid it from the start, by taking measures at the training phase.

4.4 Training for the Standalone Scenario

To complement the proposed evaluation protocol with a training one, we propose to apply a recipe inspired by the most popular defense mechanism against adversarial attacks called adversarial training (Ren et al., 2020), i.e. we introduce the disruptive element (here the mode without Teacher Forcing) at training time. We consider three heuristics: (1) we disable TF during all the training steps (Robust), (2) we disable TF randomly based on a Coin Flip (Robust-CF), (3) we progressively disable TF from 0% of the steps to 100% of the steps over the training iterations (Robust-P). The new training process is detailed in Algorithm 2, where "update" refers to the optimization algorithm that updates the model based on the loss and "heuristic.condition" is a condition that depends on the

heuristic (e.g. always true for heuristic (1)). Note that both heuristics (2) and (3) are inspired from scheduled sampling methods (Bengio et al., 2015) adapted to the context of CQA.

Algorithm 2 Robust Training

```
for conversation ∈ train set do
    HAE ← None
    for turn ∈ conversation do
        question ← turn['question']
        answer_GT ← turn['answer']
        answer_pred ← model(question, HAE)
        l ← loss(answer_pred,answer_GT)
        update(model,l)
        if heuristic.condition then
            answer_add ← answer_pred
        else
            answer_add ← answer_GT
        end if
        HAE ← build_mark(HAE,answer_add)
    end for
end for
return model
```

We obtain encouraging results (Table 3). In particular, BERT-PHAE Robust-P reaches a F1-score of 58.1 in the standalone scenario which is better than BERT's F1. Besides, "F1 /w Adv" for BERT-(P)HAE Robust seems to indicate that, the less we apply TF, the less the entailed model exhibits a filtering behavior. In fact, all the robust variants exhibit a weaker filtering behaviour than the original methods.

Model	F1 w/ TF	F1 w/o TF	F1 w/ Adv
BERT	-	54.4	-
BERT-HAE	**63.4**	53.5	41.7
BERT-HAE Robust	59.5	56.6	**51.7**
BERT-HAE Robust-CF	61.6	55.9	47.4
BERT-HAE Robust-P	60.7	**56.7**	50.7
BERT-PHAE	**64.4**	54.2	40.7
BERT-PHAE Robust	60.5	57.4	**53.3**
BERT-PHAE Robust-CF	62.2	56.4	47.7
BERT-PHAE Robust-P	62.4	**58.1**	51.6
BERT-AH	-	**58.3**	-

Table 3: Evaluation of BERT, BERT-HAE, BERT-PHAE, BERT-AH and the robust variants with different validation protocols.

Our experiment and results leave room for improvement with additional considerations on protocols/parameters/models. For instance, contrary to answers, standalone models can have access to the exact history of questions. What if we integrated the latter instead of the answer history in the model's input? We tested this by implementing a simple model that we refer to as BERT-AH (Appended History) in which previous questions are added to the regular BERT's inputs, and marked with a special embedding. BERT-AH obtains an F1-score of 58.3 (whatever the evaluation protocol, since answer history is not used). Thus, our guess is that the best direction for standalone CQA lies towards both the integration of previous questions and the robust integration of previous answers.

5 Conclusion

The work presented in this paper comes to complement the current training and evaluation protocols for CQA. It allows (1) highlighting unnoticed and undesirable behavior in existing approaches from the literature and (2) more robustness for their application in autonomous chatbots. We hope that this will encourage additional proposals in the same direction. Several improvements could be made in the future. First, because without Teacher Forcing the history is now predicted and not fixed, we could explore the impact of updating the model by back-propagating an answer's error through all previous turns and not only the current one. This would be analog to backpropagation through time. Second, we could augment the current CQA datasets or propose new ones to prevent the biases we observed: for example, QuAC could have conversations including wrong answers, since this occurs in real-life, so that models could be properly trained for. The associated turns would of course only be used as a part of histories. Finally, we should perform user tests to evaluate the robustness of models in real-life, because when a model's answer is wrong, we expect it to impact the next user's question(s). And this cannot be taken into account with the current protocol since the datasets are static.

Abstract

Existing models on Machine Reading Comprehension (MRC) require complex model architecture for effectively modeling long texts with paragraph representation and classification, thereby making inference computationally inefficient for production use. In this work, we propose VAULT: a light-weight and parallel-efficient paragraph representation for MRC based on contextualized representation from long document input, trained using a new Gaussian distribution-based objective that pays close attention to the partially correct instances that are close to the ground-truth. We validate our VAULT architecture showing experimental results on two benchmark MRC datasets that require long context modeling; one Wikipedia-based (Natural Questions (NQ)) and the other on TechNotes (TechQA). VAULT can achieve comparable performance on NQ with a state-of-the-art (SOTA) complex document modeling approach while being 16 times faster, demonstrating the efficiency of our proposed model. We also demonstrate that our model can also be effectively adapted to a completely different domain – TechQA – with large improvement over a model fine-tuned on a previously published large PLM.

1 Introduction

Machine Reading Comprehension (MRC) has seen great advances in recent years with the rise of pre-trained language models (PLM) (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2019) and public leaderboards (Rajpurkar et al., 2016, 2018; Yang et al., 2018; Joshi et al., 2017; Welbl et al., 2018; Kwiatkowski et al., 2019). While some challenges (Rajpurkar et al., 2016, 2018) focus on reading comprehension with shorter contexts, many others (Welbl et al., 2018; Joshi et al., 2017; Kwiatkowski et al., 2019; Tanaka et al., 2021) focus on longer contexts that cannot fit into a typical 512 sub-token transformer window. Motivated by this, we focus on reading comprehension with long contexts.

One newer approach to this task (Zheng et al., 2020) focuses on modeling document hierarchy to represent multi-grained information for answer extraction. Although this approach creates a strong representation of the text, it suffers from a significant drawback. The graph-based methods (Veličković et al., 2018) are inefficient on parallel hardware, such as GPUs, resulting in slow inference speed (Zhou et al., 2018; Zheng et al., 2020). Motivated by this, in this paper, we propose a reading comprehension model that addresses the above issue and uses a more light-weight, parallel-efficient (i.e. efficient on parallel hardware) paragraph representation based on long contextual representations for providing paragraph answers to questions. Instead of modeling document hierarchy from tokens to document pieces, we first introduce a base model that builds on top of a large "long-context" PLM (we use Longformer, Beltagy et al., 2020) to model longer contexts with lightweight representations of each paragraph. We note that while our approach could work with any PLM, we expect it to perform better with models that can support long contexts and therefore see more paragraph representations at once (Gong et al., 2020). To provide our model a notion of paragraph position relative to a text we also introduce position-aware paragraph representations (PAPR) utilizing special markup tokens and provide them as input for efficient paragraph classification. This approach allows us to encode paragraph-level position in the text and teach the model to impute information on each paragraph into the hidden outputs for these tokens that we can exploit to determine in which paragraph the answer resides. We then predict the

answer span from this identified paragraph.

While previous MRC methods (Chen et al., 2017; Devlin et al., 2019) use ground-truth start and end span positions exclusively as training objectives when extracting answer spans from the context and consider all other positions as incorrect instances equally. However, spans that overlap with the ground-truth should be considered as partially correct. Motivated by Li et al. (2020) which proposes a new optimization criteria based on constructing prior distribution over synonyms for machine translation, we further propose to improve the above base model by considering the start and end positions of ground-truth answer spans as Gaussian-like distributions, instead of single points, and optimize our model using statistical distance.

We call this final model, VAULT (**VA**riable **U**nified **L**ong **T**ext representation) as it can handle a variable number and lengths of paragraphs at any position with the same unified model structure to handle long texts.

To evaluate the performance of VAULT, we select the new Natural Questions (NQ, Kwiatkowski et al., 2019) and TechQA (Castelli et al., 2020) datasets. NQ attempts to make Machine Reading Comprehension (MRC) more realistic by providing longer Wikipedia documents as contexts and real user search-engine queries as questions, and aims at avoiding *observation bias*: high lexical overlap between the question and the answer context which can happen frequently if the question is created after the user sees the paragraph (Rajpurkar et al., 2016, 2018; Yang et al., 2018; Chakravarti et al., 2020; Karpukhin et al., 2020; Lee et al., 2019; Murdock et al., 2018). The task introduces the extraction of long answers (henceforth LA; typically paragraphs) besides also requiring short answers (henceforth SA) similar to SQuAD (Rajpurkar et al., 2016). In Figure 1 we examine an example from NQ along with the answers of VAULT and (Zheng et al., 2020). We see that while VAULT can extract answers from the very bottom of a page – if relevant – the existing system suffers from positional bias. It often predicts answers from the first paragraph of Wikipedia (a region which often contains the most relevant information). We evaluate our model for domain adaptation on TechQA, a recently introduced challenging dataset for QA on technical support articles where answers are typically 3-5 times longer than standard MRC datasets (Rajpurkar et al., 2016, 2018).

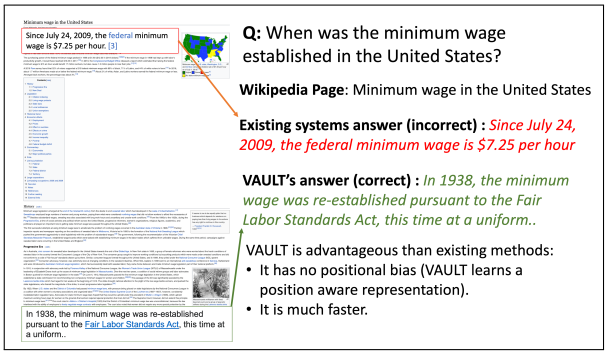

Figure 1: Example from the NQ dataset with answers from VAULT and (Zheng et al., 2020).

Empirically we first show that VAULT achieves comparable performance on NQ with (Zheng et al., 2020)'s document modeling architecture based on graph neural networks while being 16 times faster, demonstrating the efficiency of our proposed model. Secondly, we show the generalization of our model architecture for domain adaptation on TechQA. Our experiments show that our model pre-trained on NQ can be effectively adapted to TechQA outperforming a standard fine-tuned model trained on a large PLM such as RoBERTa. To summarize, our contributions include:

1. We introduce a novel and effective yet simple paragraph representation.
2. We introduce soft labels to leverage information from local contexts near ground-truth during training which is novel for MRC.
3. Our model provides similar performance to a SOTA system on NQ while being 16 times faster and also effectively adapts to a new domain: TechQA.

2 Related Work

Machine reading comprehension has been widely modeled as cloze-type span extraction (Chen et al., 2017; Cui et al., 2017; Devlin et al., 2019). In NQ, we need to identify answers in two levels, long and short answers. (Alberti et al., 2019a) adapt a span extraction model for short answer extraction. (Zheng et al., 2020; Liu et al., 2020) construct complex networks for paragraph-level representation to enhance long answer classification along with span extraction for short answers. In this work, we propose a more light-weight and parallel-efficient way for constructing paragraph-level representation and classification by using longer context and

modeling the negative instance through Gaussian prior optimization.

Using the hierarchical nature of a long document for question answering has been previously studied by (Choi et al., 2017), where they use a hierarchical approach to select candidate sentences and extract answers in those candidates. However, due to the limit of input length for large PLMs, existing methods (Alberti et al., 2019b; Zheng et al., 2020; Chakravarti et al., 2020) slice long documents into document pieces and perform prediction for each piece separately. In our work, we show that by modeling longer input with position-aware paragraph representation coupled with Gaussian prior optimization (which is novel for MRC), we can achieve comparable performance using much simpler architecture compared to previous models, which coincide with recent new PLM for long inputs on question answering (Ainslie et al., 2020)[1].

3 Model Architecture

In this section, we introduce VAULT, our proposed model that uses a simple yet effective paragraph representation based on a longer context. VAULT starts from a base classifier that utilizes position-aware paragraph representations trained on top of a large PLM: Longformer (Beltagy et al., 2020). Next, we further introduce our Gaussian Prior-based training objective that considers partial credits for positions near the ground-truth, instead of only focusing on one ground-truth position. We show an overview of VAULT on the example from Figure 1 in Figure 2.

3.1 A Base "Paragraph" Predictor Model

SOTA methods for paragraph prediction (Zheng et al., 2020; Liu et al., 2020) represent paragraphs through expensive graph modeling, making it inefficient for "large-scale" production MRC systems. On the other hand, simply selecting the first paragraph performs poorly (Kwiatkowski et al., 2019). We hypothesize that by modeling a much longer context even simple paragraph representation can be effective for paragraph (i.e., long answers) classification. For this purpose, we employ a large-window PLM: Longformer (Beltagy et al., 2020), which has shown effectiveness in modeling long contexts for QA (Yang et al., 2018; Welbl et al., 2018; Joshi et al., 2017). Compared to conventional Transformer-based PLMs e.g. RoBERTa (Liu et al., 2019) that can only take up to 512 subword tokens, Longformer provides a much larger maximum input length of 4,096.

Position-aware Paragraph Representation (PAPR): To address the fact that many popular *unstructured* texts such as Wikipedia pages have relatively standard ways of displaying certain relevant information (e.g. birthdays are usually in the first paragraph vs. spouse names are in the "Personal Life" paragraph), we provide the base model with a representation of which part of the text it is reading by marking the paragraphs with special atomic markup tokens (`[paragraph=i]`) at the beginning of each paragraph, indicating the position of the paragraph within the text[2]. With this input representation, we then directly perform long answer classification using the special paragraph token output embedding. Formally, for every paragraph $l_i \in P$, where P are all paragraphs in a text and the representation for the corresponding markup token $\boldsymbol{h}_i^p$, the logit of a paragraph answer a it computes is as $a_i^p = \boldsymbol{W}\boldsymbol{h}_i^p + \boldsymbol{b}$.

We obtain additional document-piece representation from the standard `[CLS]` (Devlin et al., 2019) token to model document pieces that do not contain paragraph answers. The probability of choosing the paragraph given context $\boldsymbol{c}$, is computed as the softmax over paragraph candidate (with an answer span) logits and not containing answer logit:

$$p_l(l_i \mid \boldsymbol{c}) = \text{softmax}(a_i^p).$$

We pad the paragraph representations to ensure a rectangular tensor in a batch. Our final prediction strategy is similar to Zheng et al. (2020) as we first choose the paragraph candidate with the highest logit among all candidates. We then extract span answers within the selected paragraph answer candidate using a standard pointer network.

3.2 Gaussian Prior Optimization (GPO)

Conventional span extraction models (Chen et al., 2017; Glass et al., 2020; Liu et al., 2020) optimize the probability of predicted start and end positions of the answer spans with ground-truth spans via maximum likelihood estimation (MLE,Wilks et al., 1938). MLE methods promote the probability for the ground-truth positions while suppressing the probability for all other positions. However we hypothesize that, for all those negative instances, the positions that are near the ground-truth should

[1]The code and model weights of ETC has not been released at the time of writing of the paper for us to have an accurate comparison.

[2]Similar tags are added for lists and tables.

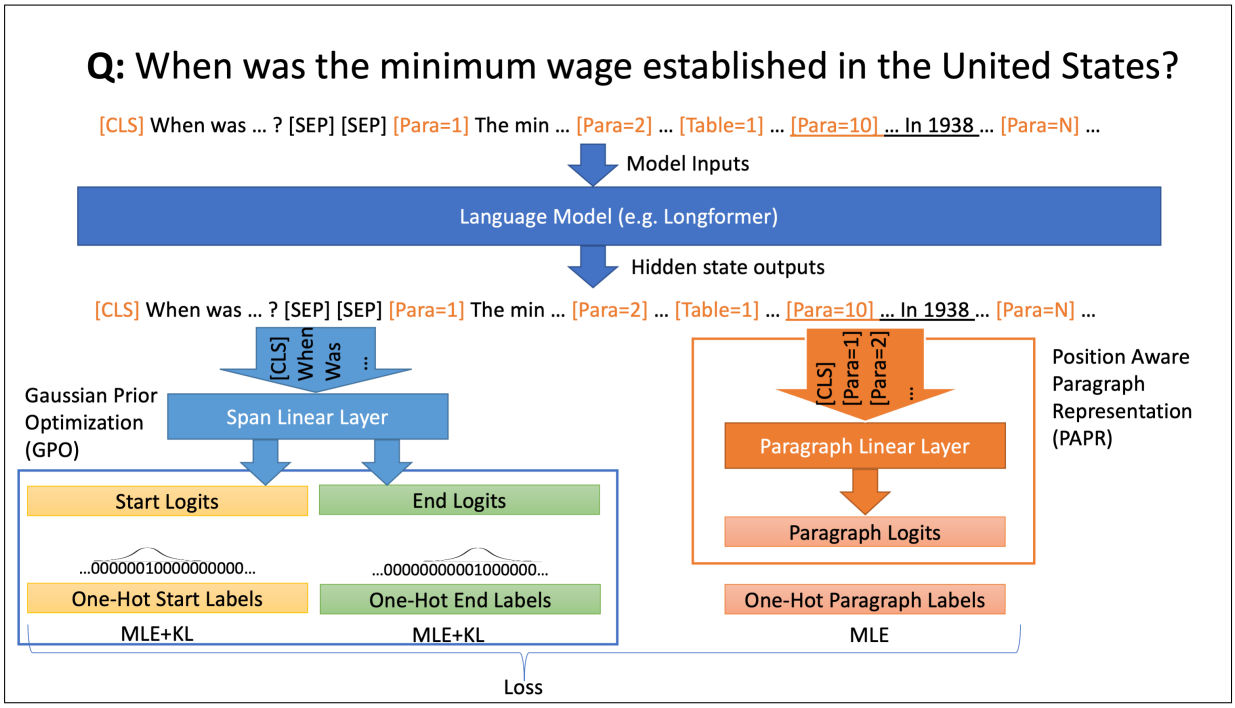

Figure 2: Overview of VAULT answering the example from Figure 1. The 10th paragraph containing the correct answer is underlined. The span linear layer receives hidden state outputs from all 4096 tokens in the window to create the start and end logits. The paragraph linear layer receives the orange-highlighted [CLS] and markup tokens (e.g. [Para=10]) to predict in which paragraph the answer resides. These logits are then used together to first select the best paragraph (LA) and finally select the best answer within said paragraph (SA).

be given higher credit than farther distant positions, since the extracted answers will be partially overlapping with the ground-truth.

To tackle this problem, we follow the intuition from Li et al. (2020) which proposes to promote the probability of generating synonyms using a Gaussian-like distribution for machine translation. We construct the distribution where it has the highest probability at ground-truth positions, and drop the probability exponentially as computed by the distance to the corresponding ground-truth positions. Specifically, for a groundtruth start or end position at y_s, where $s \in \{\text{start}, \text{end}\}$, we use a Gaussian distribution $\mathcal{N}(y_s, \sigma)$, where the mean is the position y_s and variance σ is a hyperparameter. We consider the probability density $\varphi(y \mid y_s, \sigma)$ of the Gaussian distribution at each position y as the logit for the corresponding position. We then use the softmax function with temperature T to rescale the logits to get the Gaussian-like distribution $q(y \mid \hat{y}_s)$ for ground-truth distribution at position y_s,

$$q(y \mid y_s) = \text{softmax}(\varphi(y \mid y_s, \sigma)/T).$$

We augment our MLE objective with an additional KL divergence (Kullback and Leibler, 1951) term between constructed distribution $q(y \mid y_s)$ and model prediction $p_s(y \mid \boldsymbol{c}), s \in \{\text{start}, \text{end}\}$, so that we can guide our model to follow the Gaussian-like distribution for partial credit.

$$\begin{aligned} L_D &= KL\left(q(y \mid y_s) \parallel p_s(y \mid \boldsymbol{c})\right) \\ &= \sum_y q(y \mid y_s) \log p_s(y \mid \boldsymbol{c}) \\ &\quad - \sum_y q(y \mid y_s) \log q(y \mid y_s). \end{aligned}$$

We refer to this final model as VAULT.

4 Experiments

Datasets: We experiment with two challenging "natural" MRC datasets: NQ (Kwiatkowski et al., 2019) and TechQA (Castelli et al., 2020). We provide a brief summary of the datasets and direct interested readers to the corresponding papers. NQ consists of crowdsourced-annotated *full* Wikipedia pages which appear in Google search logs with two tasks: the start and end offsets for the short answer (SA) and long answer (LA, eg. paragraph) – if they exist. TechQA is developed from real user questions in the customer support domain where each question is accompanied by 50 documents –

at most one of which has an answer – with answers significantly longer (~3-5x) than standard MRC datasets like SQuAD. We report official F1 scores for each dataset.

Results on NQ: We train VAULT on NQ – predicting the paragraph and span answers as NQ's LA and SA respectively – and compare against ROBERTA$_{DM}$: a RoBERTa (Liu et al., 2019) variant of the SOTA document model (DM) (Zheng et al., 2020) using the base variants for a more systematic comparison. Although it may seem fair to include a Longformer DM baseline in our table, doing so would be infeasible (and unwise) due to production resource constraints. We further show the impact of VAULT by providing ablation experiments where its components (GPO and PAPR) are removed. The base LM (Longformer in our experiments) without GPO and PAPR, is implemented in the style of (Alberti et al., 2019b; Chakravarti et al., 2020) where we first predict the SA and then select the enclosing LA. We aim to show that our proposed method provides comparable results to ROBERTA$_{DM}$ while being considerably faster while decoding and displaying improved performance over experiments just using the language model. To do this we consider development set SA and LA F1 (the F1 metrics with respect to the span and paragraph answers respectively) as well as decoding time t_{decode} (on a V100) as metrics.

Table 1 shows the results on the NQ dev set. We see VAULT and ROBERTA$_{DM}$ provide comparable F1 performance (precision and recall are shown in the Appendix). However, when it comes to decoding time, we can find VAULT decodes over 16 times faster than ROBERTA$_{DM}$. We additionally see in the ablation experiments that our enhancements increase both F1 metrics by multiple points, at the expense of some decoding time. In particular we note that the F1 performance of Longformer is not competitive with VAULT. We conclude that VAULT provides the best balance of F1 and decoding time as it is effectively tied on F1 (with ROBERTA$_{DM}$) and is only around 20 minutes slower to decode than the quickest model.

Domain Adaptation: Results on TechQA: Since VAULT has shown to be effective on NQ, we evaluate it on a new domain, TechQA. We compare it against a RoBERTa base model trained with the same hyper-parameters as (Castelli et al., 2020) – except we use 11 epochs instead of 20. We chose base instead of large (as is used for the TechQA baseline) to give a fair comparison since we are using a base PLM for our experiments with VAULT. Similarly, we use RoBERTa rather than BERT as it is closer to Longformer. Having already established the run-time effectiveness of VAULT on NQ, we focus on F1 metrics here, including "has answer" (HA) F1. We consider HA F1 our primary metric as we are exploring paragraph answer extraction in this work and (as previously mentioned) answers in TechQA are much longer than other datasets. We believe that the improvements in HA F1, at least partially, come from GPO.

Model	SA F1	LA F1	t_{decode}
ROBERTA$_{DM}$	**52.2**	70.1	11h
VAULT	51.6	**70.4**	40m
- GPO	49.1	67.6	41m
- PAPR (Longformer)	49.5	65.6	**22m**

Table 1: Comparison of VAULT vs. ROBERTA$_{DM}$ on NQ. We achieve comparable performance while being 16 times faster.

Model	F1	HA F1
RoBERTa	48.6	7.6
VAULT	**49.3**	**16.1**

Table 2: Results on TechQA dev set. VAULT clearly outperforms RoBERTa on both F1 and Has Answer F1.

Results on TechQA are reported in Table 2. We see that our VAULT model provides an improvement of 0.7 F1 and 8.5 HA F1 (denotes Has Answer); thus showing the effectiveness of our approach. In particular, we see that this approach of imputing a paragraph structure to classify provides a large boost to performance when a non-null answer exists (HA F1).

5 Conclusions

In this work we introduce and examine a powerful yet simple model for reading comprehension on long texts which we call VAULT, based on the hypothesis that with a large sequence length long answers can be classified effectively without computationally heavy graph-based models. We validate our approach by showing it yields F1 scores competitive with heavier methods at a fraction of the decoding cost on two very different domain benchmark datasets that require reading long texts.

A Additional Experimental Results

For interested readers we further show precision and recall numbers for the NQ experiments in Table 3.

B Implementation Details

B.1 NQ

All models for this work are implemented in (Wolf et al., 2020). We use the following hyperparameters for VAULT when finetuning on NQ: sequence length 4096, doc stride 2048 (Ainslie et al., 2020), negative instance subsampling rates (has answer/no answer) 0.02/0.08, learning rate 5e-5, and 4 epochs of training.

B.2 TechQA

While TechQA does provide full HTML for its Technotes, the answers are annotated with respect to the cleaned plaintext. Therefore to determine paragraph breaks for VAULT we split on the "\n\n" token "ĊĊ" in the vocabulary. By imputing paragraph answers in this way, we are then able to predict the paragraph answer and then a contained span answer.

C Example Analysis

We examine additional examples in Figure 3 to provide insight on the improvements of VAULT. We

Model	SA F1	SA P	SA R	LA F1	LA P	LA R
RoBERTa$_{DM}$	**52.2**	57.2	**48.0**	70.1	69.4	70.9
Vault	51.6	**61.5**	44.4	**70.4**	**69.5**	**71.4**
- GPO	49.1	57.6	42.7	67.6	67.0	68.1
- PAPR (Longformer)	49.5	56.4	44.2	65.6	62.4	69.3

Table 3: Comparison of Vault vs. RoBERTa$_{DM}$ on NQ with precision (P) and recall (R) statistics.

compare the correct answers produced by Vault with the incorrect answers produced by the ablated model from the last row of Table 3 (NQ) and Roberta baseline from the first row of Table 2 (TechQA).

In the first example the gold SA is null, however there is a gold LA. This indicates that there is no short span which answers the question: the correct answer here is an entire paragraph. This does not confuse Vault which is able to identify the correct answer directly. However the ablated model which attempts to predict SA first struggles here – predicting the incorrect LA – as there is no gold SA.

In the second example we see that in this Technote both the correct and incorrect answers are single sentence paragraphs surrounded by paragraph breaks. Our Vault is able to identify the correct paragraph using our imputed structure and select the correct answer – whereas the Roberta baseline selects a nearby but incorrect answer.

Example A1 (NQ)
Question: why did government sponsored surveys and land acts encourage migration to the west
Wikipedia Page: Homestead Acts
Text: ...
An extension of the Homestead Principle in law, the Homestead Acts were an expression of the " Free Soil " policy of Northerners who wanted individual farmers to own and operate their own farms, as opposed to Southern slave-owners who wanted to buy up large tracts of land and use slave labor, thereby shutting out free white men.

The first of the acts, the Homestead Act of 1862 , opened up millions of acres. Any adult who had never taken up arms against the U.S. government could apply. Women and immigrants who had applied for citizenship were eligible. The 1866 Act explicitly included black Americans and encouraged them to participate, but rampant discrimination slowed black gains. Historian Michael Lanza argues that while the 1866 law pack was not as beneficial as it might have been, it was part of the reason that by 1900 one fourth of all Southern black farmers owned their own farms. Figure 3: Additional Examples of questions in the NQ and TechQA datasets. Vault's correct answer is shown in green, incorrect baseline in red. (A1) The correct answer is a paragraph LA; only Vault identifies the correct LA directly even though the gold SA is null. (A2) Vault identifies the correct "paragraph" answer.

Avoiding Overlap in Data Augmentation for AMR-to-Text Generation

Wenchao Du

Abstract

Leveraging additional unlabeled data to boost model performance is common practice in machine learning and natural language processing. For generation tasks, if there is overlap between the additional data and the target text evaluation data, then training on the additional data is training on answers of the test set. This leads to overly-inflated scores with the additional data compared to real-world testing scenarios and problems when comparing models. We study the AMR dataset and Gigaword, which is popularly used for improving AMR-to-text generators, and find significant overlap between Gigaword and a subset of the AMR dataset. We propose methods for excluding parts of Gigaword to remove this overlap, and show that our approach leads to a more realistic evaluation of the task of AMR-to-text generation. Going forward, we give simple best-practice recommendations for leveraging additional data in AMR-to-text generation.[1]

1 Introduction

Deep learning has made remarkable progress in many areas of natural language processing, including language generation (Sutskever et al., 2014; Luong et al., 2015) and semantic parsing (Dong and Lapata, 2016). Nevertheless, neural models are usually data-hungry, and sophisticated use of data augmentation can often go a long way (Konstas et al., 2017; Wang et al., 2018; Du and Black, 2019; Wei and Zou, 2019). One common method of data augmentation is to leverage large amounts of out-of-domain data for semi-supervised learning. However, without proper examination of the data being used, the external data may contain significant overlap with the test set, leading to unfair gains as a result. This issue is a unique problem for natural language generation (NLG) tasks with data augmentation, because training with data that overlaps with the test set is akin to training on the answers. In this work, we study the task of AMR-to-text generation and scrutinize the datasets used for training and evaluation. Our contributions are two-fold: (1) we develop an examination procedure to confirm that there are serious overlaps between one of the AMR datasets and Gigaword (Parker et al., 2011), and conduct experiments showing that some of the performance gains are indeed "unfair"; (2) we propose several strategies to apply when collecting external data for training, and empirically show that these strategies can mitigate the aforementioned unfair gains. For best practice, we suggest future work on AMR-to-text generation exclude Gigaword articles that are written in the nearby months of those covering Proxy to be on the safer side (strategy `no-3Months` described in Section 5).

2 Related Work

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) has gained growing interest as a semantic formalism. The first AMR-to-text generator was developed using tree transducers (Flanigan et al., 2016). More recent work heavily adopted neural models, explored different architectures, and commonly employed Gigaword data to boost results (Konstas et al., 2017; Song et al., 2018; Wang et al., 2020). The most common approach is to use JAMR (Flanigan et al., 2014) to bootstrap labels for the additional data and then add them to the training data.

Prior work on AMR generation has used automatic metrics such as BLEU (Papineni et al., 2002) and human evaluations (May and Priyadarshi, 2017). Currently, there is increased research on evaluation metrics for NLG (Zhang et al., 2019;

[1] Our code for these best practices is available at https://github.com/jlab-nlp/amr-clean.

Table 1: The number of test sentences and domain of each AMR dataset. Note that LDC2015E86 and LDC2017T10 have identical test sentences.

Sellam et al., 2020, inter alia). However, we are not aware of prior work investigating the problem of test set overlap when using data-augmentation methods for generation. Closest to our work is prior practice in machine translation evaluation of excluding articles from the same time period as the test set (NIST, 2012).

3 Origin of AMR and Gigaword Overlap

In this section, we describe the reason for the overlap between the AMR dataset and Gigaword. In standard LDC releases of AMR, for example LDC2015E86 and LDC2017T10, the dev and test set consist of 5 datasets from different sources. Information about these datasets are listed in Table 1. Each sentence in the dev and test set is associated with an ID. The sentences of the Proxy dataset, in particular, have IDs that can be traced back to Gigaword articles. Upon inspection, these sentences appear to originate as close edits of sentences in Gigaword. For example, the sentence with ID "PROXY_LTW_ENG_20070831_0072.1" is originated from the Gigaword article with ID "LTW_ENG_20070831". The date on which a Gigaword news article was written is included in the ID. Since Proxy takes up more than half of the test sentences, such overlap could have a high impact on the evaluation of AMR-to-text generators. In the next section, we describe our procedure to empirically examine the effect of overlap between Proxy and Gigaword.

4 Measuring Overlap

We use the following procedure to quantitatively examine the overlap between Proxy and Gigaword dataset. For each Proxy sentence in the validation and test split, we find the Gigaword article whose ID is associated with the Proxy sentence ID. Then we tokenize and split the article into sentences. We measure the overlap between the Proxy sentence and each of the Gigaword sentences with 3 different metrics: (1) absolute count of common words, which is the number of distinct words that appear in both sentences, (2) BLEU score, and (3) ROUGE-L score.

	Mean	Median
Count 1st	13.85	13.0
Count 2nd	7.87	8.0
Count 3rd	7.16	7.0
ROUGE 1st	0.64	0.68
ROUGE 2nd	0.33	0.35
ROUGE 3rd	0.29	0.32
BLEU 1st	0.39	0.36
BLEU 2nd	0.07	0.05
BLEU 3rd	0.04	0.01

Table 2: The mean and median of the 3 highest scores for word count, BLEU, and ROUGE.

5 Exclusion Strategies

We propose and investigate 3 sampling strategies for constructing semi-supervised training datasets from Gigaword, and these strategies differ by how to exclude certain Gigaword articles: `no-ID` excludes articles whose id appeared in the proxy dataset; `no-Month` excludes articles that are written in the same month as those excluded by `no-ID` ; `no-3Months` excludes articles that are written in the same month or neighboring months from those excluded by `no-ID` . We use reservoir sampling (Vitter, 1985) to sample sentences from Gigaword. We first collect a set with 200k sentences without any exclusion as a baseline. We then filter out sentences that are from articles excluded by `no-ID` , and sample same number of sentences as those being filtered from articles that are included by `no-ID` . This yields a set of 200k sentences representing `no-ID` . We collect the sample sets for `no-Month` and `no-3Months` based on the baseline set in a similar fashion.[2]

We use the GGNN-dual-encoder model by (Ribeiro et al., 2019) as our model to study the effects of different exclusion strategies. For each exclusion strategy, we obtain 3 different samples using different random seeds and repeat experiments. We keep most of the hyperparameters from the original paper. We adjusted the learning rate schedule to accommodate larger sets of training

[2]Our code for doing this filtering is available on our GitHub repository.

	Sentence	Score
Count 1st	At least one of those bands appears to be splitting into at least two different groups.	13
Count 2nd	Even though the Bush White House has generally entrusted government agencies to officials ...	7
Count 3rd	The rentals violated U-Haul's rule requiring the tow vehicle to be at least 750 pounds heavier than the one being towed.	7
Bleu 1st	At least one of those bands appears to be splitting into at least two different groups.	0.70
Bleu 2nd	At least one of those inspections would have come at a particularly delicate time ...	0.20
Bleu 3rd	... as well as other outside organizations, at least one of which then sold tickets to its own members.	0.19
Rouge 1st	At least one of those bands appears to be splitting into at least two different groups.	0.91
Rouge 2nd	For at least a few of those percentage points, we have to thank Sheehan.	0.44
Rouge 3rd	At least one Democratic member of the group questioned Giuliani's decision to quit.	0.4

data. With sample sets of 200k sentences, each experiment takes 3 days to finish on a Tesla V100.

6 Results

6.1 Overlap between Proxy and Gigaword

In this section, we measure the overlap between Proxy and Gigaword using word and n-gram overlap evaluation measures, and study the effect of the overlap on the final trained system. We list the mean and median of the 3 sentences with highest overlap scores for each overlap measure in Table 2. It is clear that sentences with the top overlap score overlap significantly more than those sentences at the 2nd and 3rd place. Examples for illustration are given in Table 3. All three metrics tend to find the same top matching sentence. Most of the time, the test sentence in Proxy is an extractive summarization or rephrase of the top match in Gigaword, indicating a concerning overlap between Proxy and Gigaword.

To investigate the impact of semi-supervised training with these Gigaword sentences that are close duplicates of the test set, we create various sets for semi-supervised training. We create a cheat set using sentences with highest matching ROUGE scores, called Top 1 (Cheat). We are also interested in the impact of sentences from the same article as these duplicates, but with less overlap. We create additional sets with those that have top 2-4 overlap scores, top 5-7 overlap scores, etc. We trained the model with these sample sets for semi-supervised training, and the results on LDC2017T10 are listed in Table 4. The cheat set helped the evaluation on Proxy by more than 7 points, but only helped other datasets by about 1 point, if not hurting. As the matching scores decrease, the improvement on Proxy also went down. This indicates that the overlap sentences between Proxy and Gigaword give a significant unfair advantage, especially for the sentences with highest overlap.

6.2 Exclusion Strategies for Gigaword

To find a good exclusion strategy for constructing semi-supervised datasets from Gigaword, we sample semi-supervised training sets as described in Section 5 and ran experiments. The results on LDC2015E86 and LDC2017T10 are presented in Table 5 and 6, respectively. The results on LDC2017T10 is generally better than LDC2015E86, since the size of training of the former is larger than that of the later. Without excluding (i.e. baseline strategy), the results on Proxy are significantly better than no additional semi-supervised data (by about 8 points on LDC2017T10 and 10 points on LDC2015E86). It is also slightly better than being trained with the cheat set. This is because training on sample sets of size 200k yields much better language model than the small cheat set. On the other hand, training on the cheat set is almost as good as training on 200k additional data, since neural models are good at memorization. For LDC2017T10, filtering out articles covering Proxy test sentences decreases performance on Proxy by 1 point; excluding articles written in the same month and nearby months further decreases results on Proxy by more than 0.5 points. For LDC2015E86, excluding articles written in the same month decreases results on proxy by more than 1 point.

	Proxy	All Other
LDC2015/no-ID	0.400	0.379
LDC2015/no-Month	**0.045**	0.200
LDC2015/no-3Months	0.387	0.192
LDC2017/no-ID	0.202	0.357
LDC2017/no-Month	**0.002**	0.129
LDC2017/no-3Months	**0.047**	0.100

Table 7: P-values from statistical tests comparing system performance against baseline sampling. Significant results at $p = .05$ are highlighted.

Finally, we perform statistical tests with a paired t-test for comparing performance of systems trained on different sample sets against the baseline (no filtering). See Table 7. For LDC2015E86, `no-Month` resulted in lower BLEU scores on proxy dataset that are statistically significant; for LDC2017T10, both `no-Month` and `no-3Months` resulted in lower BLEU scores on proxy and the differences are statistically significant. All strategies performed similarly on all other datasets. This shows that the exclusion of certain overlapping articles in Gigaword has significant impact on the evaluation on Proxy dataset, but less so on the rest.

7 Conclusion and Recommendation

In this paper, we examined Gigaword, the commonly used dataset for improving AMR-to-text generation, and found sentences that almost duplicate the test set of Proxy, one of the AMR datasets. We developed a procedure that utilizes a word overlap measure to find overlapping sentences, and

found several metrics that may be good at finding duplicating sentences. We proposed 3 different strategies for excluding overlapping data from Gigaword, and validated the idea that without filtering certain articles, the evaluation results may be unfair. For best practice, we suggest future work on AMR-to-text generation exclude Gigaword articles that are written in the nearby months of those covering Proxy to be on the safer side (`no-3Months`). Additionally, we suggest future work report results on each AMR dataset separately so that techniques favoring one dataset can be detected.

Weakly-Supervised Methods for Suicide Risk Assessment: Role of Related Domains

Chenghao Yang[1], **Yudong Zhang**[1], **Smaranda Muresan**[1,2]

Data Science Institute, Columbia University[2]
yangalan1996@gmail.com
{zhang.yudong, smara}@columbia.edu

Abstract

Social media has become a valuable resource for the study of suicidal ideation and the assessment of suicide risk. Among social media platforms, Reddit has emerged as the most promising one due to its anonymity and its focus on topic-based communities (subreddits) that can be indicative of someone's state of mind or interest regarding mental health disorders such as r/SuicideWatch, r/Anxiety, r/depression. A challenge for previous work on suicide risk assessment has been the small amount of labeled data. We propose an empirical investigation into several classes of weakly-supervised approaches, and show that using pseudo-labeling based on related issues around mental health (e.g., anxiety, depression) helps improve model performance for suicide risk assessment.

1 Introduction

Suicide has been identified as one of the leading causes of deaths and approximately 1.5% of people die by suicide every year (WHO et al., 2016; Fazel and Runeson, 2020). Despite years o clinical research on suicide, researoners have concluded that suicide cannot be predicted using the standard clinical practice of asking patients about their suicidal thoughts (McHugh et al., 2019). Recently, Coppersmith et al. (2018) and Nock et al. (2019) discuss the opportunities of using social media combined with natural language processing (NLP) techniques to complement traditional clinical records and help in suicide risk analysis and early suicide intervention.

To facilitate further research on automatic suicide risk assessment, Zirikly et al. (2019) proposed a shared task, where they collected user data from r/SuicideWatch subreddit and annotated it with user-level suicide risk: no-risk, low-risk, medium-risk and high-risk. By comparing the results of the participating teams in this shared task, Zirikly et al. (2019) conclude that one of the major challenges comes from the insufficient data for intermediate suicide risk levels (i.e., low risk and medium risk) rather than extreme risk levels (i.e., no risk and high risk). Matero et al. (2019) find that using a dual BERT-LSTM-Attention model to separately extract information from both SuicideWatch and Non-SuicideWatch posts together with feature engineering that includes emotion features, personality scores, user's anxiety and depression scores are important for model performance.

In this paper, instead of feature engineering or complex model architectures, we explore whether weakly supervised methods and data augmentation techniques based on clinical psychology research can help improve model performance. We explore several weakly-supervised methods, and show that a simple approach based on insights from clinical psychology research (O'Connor and Nock, 2014) obtains the best performance. This model uses pseudo-labeling (PL) on data from the subreddits r/Anxiety and r/depression, which are considered important risk factors for suicide. We also present a potential application of our model for studying the suicide risk among people who use drugs, opening the door for using NLP methods to deepen our understanding between opioid use disorder (OUD) and mental health. The code for this paper can be found at https://github.com/yangalan123/WM-SRA.

2 Methods

We focus on Task A from the CLPsych 2019 shared task "Predicting the Degree of Suicide Risk in Reddit Posts" (Zirikly et al., 2019). The goal of the task is to predict the user-level suicide risk category based on their posts in the r/SuicideWatch subreddit. Specifically, a user u_i is associated with a col-

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1049–1057
August 1–6, 2021. ©2021 Association for Computational Linguistics

lection of $n(i)$ posts $C_i = \{x_{i,1}, x_{i,2}, \ldots, x_{i,n(i)}\}$, where each post $x_{i,k}(1 \leq k \leq n)$ has $m(i,k)$ sentences $x_{i,k} = [s_{ik,1}, s_{ik,2}, \ldots, s_{ik,m(i,k)}]$. We need to predict $y_i \in \{a, b, c, d\}$ using C_i, where a, b, c, d represent no-risk, low-risk, medium-risk and high-risk, respectively. In the original dataset, there are 496 users in the training set and 125 users in the test sets. We further split 100 users from the training set to create the validation set. The sizes for the train/valid/test sets are 746, 173, and 186 respectively.

Data Pre-processing Following the advice in (Zirikly et al., 2019), we replace all human names and URLs in the Reddit posts with special tokens "_PERSON_" and "_URL_", respectively. We also remove punctuation and stop words besides lowercasing. Due to the limitation of GPU memory, we split those large posts to be passages with no more than 128 words[1] and make sure that the split point is not in the middle of the sentence[2]. Such passages are treated as separate posts.

Model Architecture Our architecture is a BERT (Devlin et al., 2019) model. We also experimented with other state-of-the-art pre-trained language models (PLMs), including RoBERTa (Liu et al., 2019) and XLNET (Yang et al., 2019), but found BERT to work the best and thus consider it as our baseline architecture (more details can be found in Appendix A). Each post $x_{i,k}$ is fed into BERT (Devlin et al., 2019) and we get post embedding $\vec{e}_{i,k} = \text{BERT}(x_{i,k})$. Then we do simple mean-pooling to obtain the user embedding $\vec{u}_i = \frac{\sum_{k=1}^{n(i)} \vec{e}_{i,k}}{n(i)}$. Finally, we feed $\vec{u}_i$ to a fully-connected layer and use the Softmax layer to predict the risk level probability $\tilde{P}(y_i|C_i)$. The label with the largest probability is picked as the final prediction $\hat{y}_i$. For training, the cross entropy loss $\mathcal{L}_{\text{clf}}$ is applied to optimize our model.

2.1 Weakly-supervised Methods

Task-Adaptive Pre-training Recent works (Lee et al., 2020; Gururangan et al., 2020) point out that task-adaptive pre-training (TAP) can help pre-trained language models better adapt to the target domains and can bring improvement, especially in data-poor scenarios. Specifically, we continue pre-training (e.g., masked language modeling for BERT) on a task-relevant *unlabeled corpus* and then do normal fine-tuning on the task. Our unlabeled corpus consists of all r/SuicideWatch posts (aggregated per user) from the training sets of all the tasks (A, B, C) in the shared task (Zirikly et al., 2019). There are 621 users and 138,057 posts in this unlabeled corpus. We do continued pre-training for 2 to 3 epochs and do early stopping.

Multi-view Learning Multi-view learning (Xu et al., 2013) (MVL) is one of the widely recognized semi-supervised methods. Clark et al. (2018) provides a successful example of utilizing MVL in sequential labeling tasks. The idea is to create perturbations by masking words in certain positions and requiring the model to learn the similar distribution over the complete labeled examples and the corresponding masked examples besides normal classification training. However, since ours is a user-level classification task, we cannot directly borrow the same strategy from (Clark et al., 2018) as it mainly works on sequence labeling. We propose to create perturbations $\tilde{C}_i$ based on four strategies.[3] First, for each sentence, we will randomly mask 10% of tokens (**Word-Mask**). Second, considering that users may have posts of many words, we also propose a sentence-level masking strategy (**Sent-Mask**). For each post of a single user in the training set, we would randomly mask 10% of tokens. Third, we only keep the beginning and ending sentences in each passage (**BegEd**). Usually these sentences convey the main purpose of the posts and should preserve important semantics. Forth, we use Bert-extractive-summarizer (Miller, 2019) to extract the summary for each passage (**K-Sum**). It works mainly by first encoding each sentence $s_{ik,j}$ using a PLM to a continuous-valued representation $\vec{s}_{ik,j}$ and then training a K-means clustering over $\vec{s}_{ik,j}$. Finally it will pick K sentences for each passage that are closest to the center. Empirically, we set $K = 5$.

In training, we use KL-divergence to enforce the constraint that the predicted probability on perturbed examples $\tilde{P}(y_i|\tilde{C}_i)$ should be close to the one on complete examples (i.e., $\tilde{P}(y_i|C_i)$). The

[1] The 128 maximum passage length is tuned based on the validation set for both GPU memory and better computational efficiency for large posts. We do not observe a significant performance drop without a larger passage length.

[2] We use a limited-size stack and greedily add each sentence into the stack. If adding a new sentence will make the sum of lengths of all sentences in the stack exceed 128, we pop out all sentences, concatenate them to a new passage and then add this new sentence to the stack. For sentences having more than 128 words, we treat them as individual posts.

[3] The masking proportions for **Word-mask** and **Sent-Mask** are tuned empirically on the validation set.

loss incurred by KL-divergence is simply added to the classification loss and these two losses are optimized together for each training instance.

Clinical Psychology Inspired Pseudo-labeling According to the analysis of the shared task report (Zirikly et al., 2019), the main challenge for the 4-way classification comes from insufficient data for the intermediate classes (i.e., low-risk and medium-risk). A straightforward solution is to collect data for these two classes. Recent clinical psychological research (O'Connor and Nock, 2014) points out that mental health issues such as depression and anxiety can be important risk factors for suicide. Inspired by this study, we collect data from r/Anxiety and r/depression from Reddit. The time range of all collected data is from December 1, 2008 to September 30, 2020. We sample a small proportion of the collected data from both subreddits and after manual verification, we decided to assign *low-risk* labels to all r/Anxiety users in the sample and *medium-risk* labels to all r/depression users in the sample. Since we do not have experts to label these posts, adding too much pseudo-labeling data might introduce too much noise. Based on preliminary experiments on the *validation set*, the number of added pseudo-labeling data is 8% of the suicide risk assessment training data. The only difference between these experiments and the main experiments is that we only train the model for 10 epochs rather than full 20 epochs. Table 1 show results for different sizes of added pseudo-labeled data from r/depression on the validation set. All pseudo-labeling data follows roughly the same pattern with the best proportion being 8%.

$\frac{\#(\text{r/depression})}{\#(\text{Training})}$	Macro-F1 on Validation set
2%	0.408
8%	0.471
16%	0.442
32%	0.408

Table 1: Results of different proportions of added pseudo-labeling data from r/depression.

3 Experiments and Results

We implement our BERT model based on huggingface Transformer (Wolf et al., 2020). Due to the limitation of GPU memory, we only use the *base* version.We split 20% of original training data to be the validation set and fix the split for all models. The model selection is made by early stopping and we train all models for 20 epochs with the batch size 32. For users with too many posts and words, we only sample 100 passages for them. Table 2 shows our results on Macro-F1.

No.	Approach	Setup	Macro (P/R/F1)
1	Baseline	BERT	0.436 / 0.424 / 0.427
2	TAP	BERT	0.439 / 0.445 / 0.432
3	MVL	Word-Mask	0.464 / 0.466 / 0.463
4	MVL	Sent-Mask	0.380 / 0.409 / 0.383
5	MVL	BegEd	0.384 / 0.422 / 0.401
6	MVL	K-Sum	0.384 / 0.422 / 0.401
7	PL	Depression (medium-risk)	**0.535 / 0.480 / 0.498**
8	PL	Anxiety (low-risk)	0.495 / 0.469 / 0.478
9	PL	Depression + Anxiety	0.473 / 0.456 / 0.463
10	PL	Task C (low-risk)	0.475 / 0.462 / 0.460
11	-	Task C (crowd-labeled)	0.418 / 0.406 / 0.408

Table 2: Results Task A test set. For each of tasks 7-11, the size of added data is 8% of training data. Metrics are all reported on macro-average.

Task-Adaptive Pre-training After applying task-adaptive pre-training on BERT, we see small performance gains over BERT (i.e., from 0.427 to 0.432). That might be because even we use the whole corpus provided by the shared task, it is still not large enough.

Multi-view Learning Word-Mask strategy improves over the BERT baseline. Compared with the adaptive pre-training results on BERT, which also do word-level masking but only trained on language modeling, we can see that MVL provides a more efficient way to utilize a small training corpus and bring 3.1% gain on Macro-F1. However, all the other MVL approaches hurt the performance when compared to the BERT baseline. This might be because the proposed sentence-level perturbation strategy can seriously break the semantics of each post and thus influence the overall performance, and random sampling over sentences hurts most.

Clinical Psychology Inspired Pseudo-labeling Exp 7, 8 and 9 in Table 2 achieve the Top-3 Macro-F1 scores. This indicates that although our psychology-inspired pseudo-labeling technique is simpler than other weakly-supervised methods, adding meaningful pseudo-label data from relevant domains helps mitigate the problem of insufficient data in the intermediate classes (b and c). To verify this point, we show the class-wise classification results for PL-based models in Table 3 where we can

Setup	a	b	c	d
Baseline	0.730	0.077	0.333	0.566
Depression (medium-risk)	0.764	0.273	0.327	0.627
Anxiety (low-risk)	0.724	0.160	0.415	0.614
Depression + Anxiety	0.767	0.143	0.370	0.574
Task C (low-risk)	0.762	0.080	0.318	0.678
Task C (crowd-labeled)	0.667	0	0.357	0.609

Table 3: Class-wise performance (F1) for PL-based methods (a=no-risk; b=low-risk; c=medium-risk; d=high-risk).

see improvements on b and c classes. Due to space constraints, we present the class-wise performance for all models in Appendix C.

The investigation over the confusion matrix of the best model (shown in Section 4) further supports our hypothesis. However, when we try to combine different pseudo-labeling data together (see Exp 9, where we add users from r/depression and r/Anxiety following the proportion of $1:2$[4] and still keep the added user number the same), we observe a slight performance drop. The reason might be that users in these two PL datasets might be at the boundary of the low-risk and medium-risk and simply mixing them together will make the model confuse between these two classes (see Supplemental material D for all confusion matrices).

Furthermore, we wanted to test the role of the *clinical psychology* aspect of our pseudo-labeling approach. Does the gain come from the meaningful domains (anxiety and depression) or just by adding additional data? To answer this, we use additional data provided by Task C of the shared task that contains posts from random subreddits (e.g., sports). We do two experiments: 1) assign low-risk to all such users and 2) assign the gold labels provided by the task via crowdsourcing. We add the same size as for the other pseudo-label experiment (8% of training data). The results (Exp 10 & 11 in Table 2) show that the clinical psychology inspired PL outperforms these models by meaningfully addressing the intermediate classes insufficient data problem.

4 Error Analysis

In this section, we take a closer look at the prediction results of our best model (clinical psychology inspired pseudo labeling using r/depression as medium risk) by looking at the confusion matrix and sampled error cases. We plot the confusion matrices for the baseline model (Exp 1 in Table 2) and the best model (Exp 7 in Table 2) in Figure 1. We can see that, the best model achieves the improvement mainly by fixing error cases wrongly predicted as no-risk (where the true labels are "b", "c" and "d", with greater error reduction for "d") and low-risk (where the true labels are "c" and "d"). As O'Connor and Nock (2014) point out, depression is a serious mental issue and has become one of the most important risk factors of suicide. Adding posts from r/depression can help the model understand better what is "medium-risk" and "high-risk" and thus raise the alert for the signals of similar or related mental issues.

We can also see that the main problem of our best model, is still the confusion between "b" (low-risk) and "c" (medium-risk). In addition, the problem of wrongly predicting the examples belonging to intermediate classes to high-risk ones still exists. By manual investigation, we find that both problems require expertise in mental health to make the subtle distinctions. For example, the following text comes from a low-risk example[5] that is wrongly predicted as high-risk by our best model:

> " *sadness has taken me. . . i am sad , lonely , and i have no interest in living anymore. . . i didnt want to die. . . my mind is diseased , unable to take happiness. . . i have no interest in forming any more.* . . . i dont think ill do it. . . "

It can be seen that there are many negative or even desperate expressions (marked as red) in this examples, mixed with some short signals (marked as blue) possibly indicating a person considered at low-risk. The model can be fooled by the massive negative expressions and make the wrong predictions if the model is not aware of the true intent of the person. Therefore, reliable intent identification that could consider user posts across time and other information would be a powerful tool to help the model prevent mistakes like this.

5 Application: Predicting Suicide Risk of People Who Use Drugs

In order to further verify the effectiveness of our model in real-world applications, we create a sim-

[4] See Supplemental material B for detailed experiments over different mixing proportions

[5] Based on ethical consideration, we drop out many sensitive and private content of this example.

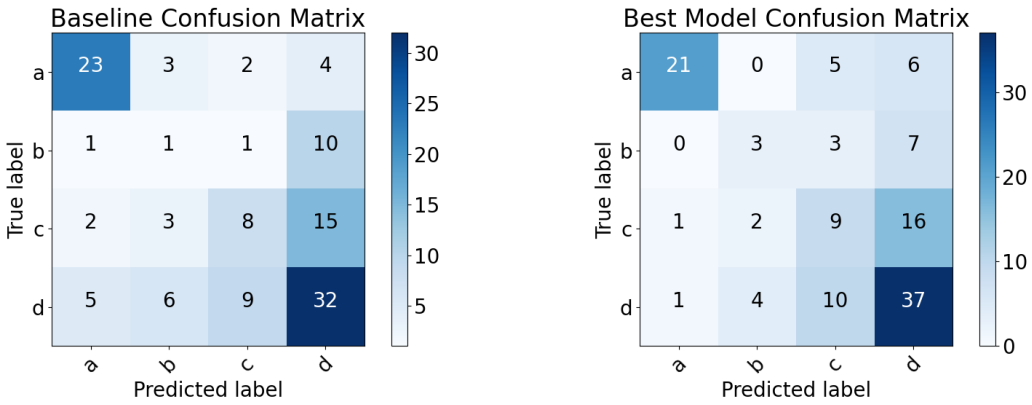

Figure 1: Visualization of the confusion matrices for the baseline model (Exp 1) and the best model (Exp 7) .

ulation scenario: we apply our best model (Exp 7) over the data that is collected for 612 users who post on both r/opiates and r/SuicideWatch. r/opiates is a subreddit where people discuss topics around opioid usage (e.g., drug doses, withdrawal anguish, daily experiences, harm reduction). This community members could often be at a high suicide risk (Aladağ et al., 2018; Yao et al., 2020). We apply our model over their $1,176$ posts on r/SuicideWatch and find that our model predicts that 15.52% of them are no-risk, while 84.48% of them are of low-risk, medium-risk and high-risk. The results on sampled $2,863$ r/opiate posts are 30.56% for no-risk and 69.44% for at least some risk. The predicted outputs are highly aligned with reported results using crowdsourcing annotation of suicidal or not-suicidal by Yao et al. (2020) and show the effectiveness of our model in this simulated scenario.[6] We hope this will open the door of using NLP methods to investigate the link between suicidal ideation and fatal overdoses among people who use drugs.

6 Conclusions

We investigated a series of weakly-supervised methods and find that pseudo-labeling on data related to risk factors for suicide (depression, anxiety) can help improve model performance. This provides an alternative way to use theoretically-grounded models (e.g., compared to feature engineering). We also show a potential use case of this work for understanding suicidal ideation among users who use drugs (e.g., opiates).

[6]The original Mturk annotation dataset is not open-sourced and thus we can only do rough trend matching on our own collected data.

Ethical Considerations

The dataset for suicide risk assessment was obtained from the organizers of the 2019 Clinical Psychology Shared Task on Suicide Risk Assessment, by filling in a participant application where we affirmed that we would follow the shared task's rules. We have obtained IRB approval (exempt) from Columbia University to use the data as it consists of publicly available and anonymous posts extracted from Reddit. For the application part, we also obtained Columbia IRB approval (exempt) for the data publicly available and anonymous data from r/opiates. All data is kept secure and online userIDs are not associated to the posts.

Our intention of developing and improving suicide risk assessment models is to help health professionals and/or social workers identify people that might be at risk of committing suicide. We emphasize our intention that suicide risk assessment models such as the ones developed here to be used responsibly, with a human in the loop — for example a medical professional, a mental health specialist, who can look at the predicted labels and offer explanations and decide whether or not they seem sensible. We would urge any user of suicide risk assessment technology to carefully control who may use the system. Currently, the presented models may fail in two ways: they may either mislabel an at-risk user as no-risk (our current models are particularly designed to minimize this risk), or classify a no-risk user with some level of risk. Obviously, there is some potential harm to a person who is truly in need if a system based on this work fails to detect their suicidal ideation, and it is possible that a person who is not truly in need may be irritated or offended if someone reaches out to them because

of a mistake. That is why, this system needs only to be used as additional help for health professionals.

We note that because most of our data were collected from Reddit, a website with a known overall demographic skew (towards young, white, American men[7]), our conclusions about what expressions of different suicide risk levels look like and how to detect them cannot necessarily be applied to broader groups of people. This might be particularly acute for vulnerable populations such as people with opioid use disorder (OUD). We hope that this research stimulates more work by the research community to consider and model ways in which different groups express suicidal ideation.

A Comparison of Different Pre-trained Language Models

Given that there has been significant progress on the architecture designs after BERT, we have experimented with different PLMs, such as RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019). From Table 4, we can see that on the Test set, the Macro-F1 scores for BERT and RoBERTa are almost the same and XLNet performs worse than BERT. Therefore, we hypothesis that the architecture of PLMs will not influence substantially the results on this task so we chose BERT model.

PLM	TAP?	PL?	MVL?	Macro-F1
BERT	No	No	No	0.427
XLNET	No	No	No	0.422
RoBERTa	No	No	No	0.408

Table 4: Experiment results for different PLMs. Here we only show the macro-F1 for the baseline model built on different PLMs.

B Results for Different Mixing Proportions

Table 5 shows the results for different mixing proportions of pseudo-labeling data from r/Anxiety and r/depression. Due to the limitation of space, in the main paper, we only show the results achieved by the best mixing proportions.

Mixing Proportion	Macro-F1
1: 5	0.398
1: 2	0.463
1: 1	0.434
2: 1	0.441
5: 1	0.442

Can Transformer Models Measure Coherence In Text? Re-Thinking the Shuffle Test

Philippe Laban , Luke Dai , Lucas Bandarkar , and Marti A. Hearst

UC Berkeley
{phillab, luke.dai, lucasbandarkar, hearst}@berkeley.edu

Abstract

The *Shuffle Test* is the most common task to evaluate whether NLP models can measure coherence in text. Most recent work uses direct supervision on the task; we show that by simply finetuning a RoBERTa model, we can achieve a near perfect accuracy of 97.8%, a state-of-the-art. We argue that this outstanding performance is unlikely to lead to a good model of text coherence, and suggest that the Shuffle Test should be approached in a Zero-Shot setting: models should be evaluated without being trained on the task itself. We evaluate common models in this setting, such as Generative and Bi-directional Transformers, and find that larger architectures achieve high-performance out-of-the-box. Finally, we suggest the k-Block Shuffle Test, a modification of the original by increasing the size of blocks shuffled. Even though human reader performance remains high (around 95% accuracy), model performance drops from 94% to 78% as block size increases, creating a conceptually simple challenge to benchmark NLP models.

1 Introduction

In recent years, text generation applications, fueled by Transformer models pre-trained on large datasets, have achieved dramatic results on a wide range of NLP tasks. These include GPT2 applied to story completion of fan fiction (Radford et al., 2019), the PEGASUS model (Zhang et al., 2020) improving state-of-the-art on ten summarization datasets in widely varying domains, and more recently GPT3 (Brown et al., 2020) doing well on a diversity of tasks in a zero-shot setting. However, it is not clear how *coherent* the text generated by these models is.

The computational linguistics literature holds many competing definitions of *coherence* in text; Wang and Guo (2014) provide a useful brief summary of key competing theories. This work attempts to identify the *absence* of coherence, noting that a text might be composed of valid sentences when viewed independently, but when read sequentially, semantic relations are not well-supported.

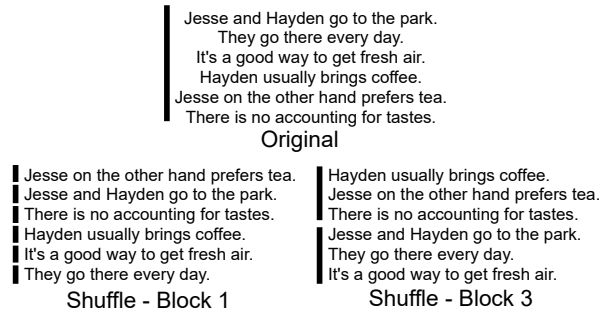

Figure 1: **Can modern NLP models recognize shuffled, incoherent text without supervision?** Yes (mostly) when all sentences are shuffled (left), but less so when shuffling k blocks at a time (right).

The NLP community has proposed models to *measure* coherence, as well as repeatable tasks to evaluate these models. In this paper, we outline these common tasks, and describe what we believe is a limitation in the framework of the most common task: the Shuffle Test. The Shuffle Test is a conceptually simple and reproducible task, in which a model must differentiate between an original text and a sentence-order shuffled version. Because of its simplicity, we make the argument that the Shuffle Test should be viewed as a *probe*: a task on which models should be evaluated without directed supervision. Prior work (Paulus et al., 2018) has shown that directly optimizing evaluation metrics such as ROUGE or BLEU leads to inadequate models, exploiting weaknesses in the evaluation metrics.

We show that this phenomenon occurs with the current application of the Shuffle Test in related work. To demonstrate the pitfalls, we finetune a RoBERTa-large model – an architecture several or-

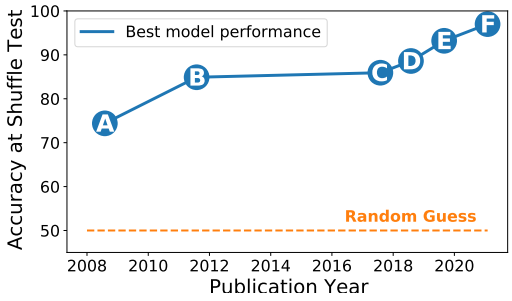

Figure 2: Timeline of incremental accuracy improvements on the *Shuffle Test* on the WSJ corpus. Letters are for models described in Section 2.2.

ders of magnitude larger than previously used models – on the Shuffle Test and show the results outperform previous models, with an accuracy of 97.8%. We argue this model has most likely learned features specific to recognizing shuffled-ness, which is probably a conflated signal for the underlying goal of learning a strong coherence model.

We first outline prior work on tasks and models to measure textual coherence, then describe the framework for the Zero-Shot Shuffle Test, showing how to adapt common models to the setting, and finally propose a variation to the Shuffle Test that significantly increases the challenge for models, while not affecting human performance at the task.[1]

2 Tasks and Models for Coherence

2.1 Tasks for Coherence Evaluation

The Shuffle Test, introduced by Barzilay and Lapata (2008), is the most common task for coherence model evaluation. The task is a binary classification, in which a model must discriminate between a document and a *shuffled document*, obtained by randomly shuffling the order of sentences in the document. The most common dataset for evaluation is a set of articles from the Wall Street Journal (Elsner and Charniak, 2011).

In **the Insertion Test**, a single sentence from a document is removed, and the model must predict the sentence position. Typically, models assign a score to each possible position, and predict the one with highest score. One limitation of the Insertion Test is that model accuracies are low, often in the 10-20% range (Elsner and Charniak, 2011). To our knowledge, there is no evaluation of human performance on this test; with the possibility that the task can have more than one plausible solution. Computational cost is another limitation, often growing linearly with the number of sentences.

In **the Sentence Ordering Task**, a model is given an randomly ordered sentence set, and must produce the correct ordering of sentences. The task is often restricted to generative models, as it is prohibitively expensive to score all combinations to extract a best-scoring order (Logeswaran et al., 2018).

2.2 Models for the Shuffle Test

Figure 2 is a timeline of models that have led to progress on the Shuffle Test since its introduction.

The Entity Grid (model A in Fig. 2) was introduced by Barzilay and Lapata (2008). A text is transformed into an entity grid, a matrix (#sentences x #entities) indicating presence of an entity in a sentence. The entity grid is featurized and used to train a predictor on coherence tasks.

Elsner and Charniak (2011) (model B) extended the entity grid by adding linguistic features such as named-entity type. Nguyen and Joty (2017) (model C) introduce the first neural approach, using a convolutional neural network (CNN) to operate over the entity grid, and Joty et al. (2018) (model D) added word embeddings to entity-grid features. Most recently, Moon et al. (2019) (model E) replaced traditional word vectors with ELMO (Peters et al., 2018) contextual word vectors.

Crucially, all these models are directly trained on the Shuffle Test, and with each iteration of improvement, model capacity (i.e., the number of trainable parameters) has increased. We finetune a RoBERTa-large (Liu et al., 2019) (model F), a still larger model, on the Shuffle Test, and achieve a 97.8% accuracy on the WSJ test set, a new state-of-the-art.

Training details. We finetune the RoBERTa-large on the training portion of the WSJ dataset, and setup the task as a sequence classification. We trained using the ADAM optimizer, using a learning rate of $1e^{-5}$ and a batch-size of 16. The model was trained on a single GPU, an Nvidia V-100, and training converged within 10 minutes. Model checkpoint was selected based on a validation set accuracy, and tested once on the standard WSJ test set.

This stellar performance leads us to believe that there are two conflated factors that cause good performance on the Shuffle Test: a model that can

[1]The code and model checkpoints are available at: https://github.com/tingofurro/shuffle_test.

truly recognize the lack of coherence in shuffled text, and a model specialized at the Shuffle Test, recognizing shuffle-specific features in text, without assessing textual coherence. This resonates with findings from Mohiuddin et al. (2020), who show that increased model performance at the Shuffle Test in supervised models does not necessarily lead to improvements in downstream tasks, such as ranking of generated summaries. Ideally, the Shuffle Test would be used to assess coherence models that work independently of the test itself.

We propose a simple solution: coherence models should be evaluated on the Shuffle Test in a Zero-Shot setting; without being supervised on the test, preventing the learning of shuffle-specific features, and more directly evaluating coherence aptitudes.

3 Zero-Shot Shuffle Test

We now define specifically what factors need to be respected to satisfy the zero-shot setting.

> In the Zero-Shot Shuffle Test, the evaluated model must not be pre-trained, fine-tuned or modified using shuffled text.

More specifically, this restricts the use of the Shuffle Test as supervision (as a binary classification task), as well as other tasks that involve shuffling text, such as the sentence ordering task.

Next, we adapt common architectures to the Zero-Shot Shuffle Test and assess performance in diverse textual domains.

3.1 Zero-Shot Coherence Models

We adapt the two common classes of Transformer models to the Zero-Shot Shuffle Test: Generative and Bi-directional Transformers.

Generative Transformers are compatible with language modeling, in which a model assigns a likelihood to a sequence of words ($S = [W_1, ...W_n]$). Transformers estimate the likelihood of a sequence by factoring on sequence order:

$$P(S) = \prod_{i=1}^{N} P(W_i|W_1...W_{i-1}) \quad (1)$$

Taking the log of the likelihood ($log(P(S))$) is often preferred as it allows for numerical stability.

To perform a Zero-Shot Shuffle Test, we compute log-likelihoods of the original and shuffled documents and predict the lower-scoring one as shuffled.

We experiment with GPT2 models of varying sizes (**GPT2-base**, **GPT2-medium**, **GPT2-large**), and finetune an In-Domain GPT2-medium using a language modeling loss in each domain to evaluate whether in-domain specialization improves performance (**GPT2-med-ID**).

When texts exceed sequence-length limits of models (e.g., 512 words), we implement a sliding window mechanism. The sequence is split into successive windows with 50% overlap. Window log-likelihoods are averaged into a document log-likelihood.

Bi-Directional Transformers, exemplified by BERT (Devlin et al., 2019), are the second class of models we adapt to the test. Unlike Generative Transformers, bi-directional Transformers do not impose strict sequence order, rendering sequence likelihood estimation less straightforward.

Salazar et al. (2020) propose a solution, with Masked Language Model Scoring (MLMS), in which a likelihood is estimated by masking each word in the sequence, predicting its identity, and averaging all word-likelihoods into a score:

$$\text{MLMS}(S) = \frac{1}{N}\sum_{i=1}^{N} \log P_{MLM}(W_i|W_{\setminus i}) \quad (2)$$

where $W_{\setminus i} = S - \{W_i\}$. Unlike generative models, each word's likelihood is conditioned on all others, an advantage of Bi-directional models. For the Zero-Shot Shuffle Test, the document with lower MLMS is predicted as shuffled.

One key disadvantage of MLMS is its computational cost: scoring requires a forward-pass for each word in the sequence; by contrast, generative models usually require a single forward pass. This limits our ability to test large models, and therefore test only base models: **BERT-base** and **RoBERTa-base**.

3.2 Datasets

To examine whether there are significant differences in performance across domains, we evaluate with the Shuffle Test using three distinct domains. We performed a manual check to determine that the datasets we selected do not overlap with the dataset used to pre-train BERT, RoBERTa and GPT2. The three domains are:

News domain. We use the standard Wall Street Journal (WSJ) test-set introduced by Elsner and Charniak (2011) in the supervised Shuffle Test. The dataset contains 1006 documents.

	Domain (%)			
Model	**WSJ**	**Legal**	**Reddit**	**Overall**
GPT2-base	47.2	92.0	74.8	71.3
GPT2-medium	91.2	98.6	88.9	92.9
GPT2-large	73.2	**99.3**	90.6	87.7
BERT-base	73.2	96.1	86.1	85.1
RoBERTa-base	82.3	94.8	**96.7**	91.3
GPT2-med-id	**93.1**	98.8	90.0	**94.0**

Table 1: Accuracy of Zero-Shot Shuffle Tests of models on three domains: Wall Street Journal (WSJ), Billsum documents (Legal), and Reddit. We report an overall, averaged performance across domains.

	Block Size				
Model	**1**	**2**	**3**	**4**	**5**
Human Perf. - WSJ	97.5	94.5	93.0	96.0	94.0
GPT2-med - WSJ	95.3	91.4	89.5	87.4	85.3
GPT2-med - Legal	98.7	98.0	96.9	95.9	94.5
GPT2-med - Reddit	89.5	76.9	66.1	59.1	53.8
GPT2-med - Avg.	94.5	88.8	84.2	80.8	77.9

Table 2: **Results of Zero-Shot KBST varying the block size from one to five.** The GPT2-medium model was tested on all three domains, and human performance was measured on WSJ.

Legal domain. We use the full document released in the BillSum dataset (Kornilova and Eidelman, 2019) which consists of US Congressional and California state bills. We use the first 1,000 documents in the standard test set.

Blog domain. We use posts of the Reddit TIFU dataset (Kim et al., 2019), consisting of stories written by members of the Reddit community. We use the first 1,000 documents of the corpus.

We choose these datasets as they are publicly available, can easily be accessed through the HuggingFace datasets package (Wolf et al., 2020) and represent a diversity of textual domains.

We note that document length affects the amount of displacement that occurs from shuffling, with more displacement in longer texts. To take this effect into account, we truncate documents at 20 sentences before administering the Shuffle Test.

3.3 Results

Overall, all models significantly outperform random chance, with the GPT2-medium achieving 91.2% on the WSJ test-set out of the box where the previous supervised state-of-the-art was 93%. Bi-directional models achieve better results than generative models at Transformer-base size (e.g., GPT2-base vs. RoBERTa-base).

Increasing model size leads to large performance improvement for GPT2, confirming that according to the Shuffle Test, larger Transformer models improve at modeling coherence. In-domain finetuning leads to an improvement on all domains (GPT2-med-id outperforming GPT2-medium), confirming the strength of in-domain finetuning (Howard and Ruder, 2018).

Finally, models achieved stronger performance on the Legal domain, with models all scoring 92.0 or above. Overall, three of the six models we test achieve compound performance over 90%.

There is a potential question about the zero-shot nature of the BERT training method. The original BERT model is trained with two objectives, one of which is Next Sentence Prediction (NSP). In NSP, the model is exposed to two blocks of text, and must predict whether they are adjacent in a document or not. It can be argued that NSP is an indirect supervision signal for the Shuffle Test. However, we find that the BERT model performs worse than RoBERTa, a similar model in architecture trained without the NSP objective. This difference in performance suggests that the NSP objective is not the cause of the superior performance of these models, thus preserving the claim that they act in a zero-shot manner for the purposes of the Shuffle Test.

We next propose a modification to the Shuffle Test that challenges models significantly more.

4 The k-Block Shuffle Test

Results in Section 3 can be interpreted to mean that with large enough Transformer models, the Shuffle Test with no supervision is essentially a solved task. We find that a simple modification of the Shuffle Test can significantly reduce model performance, without affecting human annotator performance.

The modification we propose, k-Block Shuffle Test (KBST), is illustrated in Figure 1. In the standard Shuffle Test, text is divided into sentences and shuffled, with a unit of one sentence. In the k-Block Shuffle Test, sentences are grouped in contiguous blocks of k sentences (resembling paragraphs), and the blocks are shuffled, maintaining sentence order in each block. Within a block, sentences remain locally coherent, and as block size increases, the fraction of correct sentence transitions increases, while potentially incoherent transitions decrease.

To establish the feasibility of the KBST with differing block-sizes, we performed a human evaluation completed by authors of the paper as well as a

third annotator recruited on the Upwork[2] platform. This annotator is a native English speaker with experience in proofreading, and was remunerated at $15/hour USD.

The human evaluation consisted of performing KBST on 500 documents randomly sampled from the WSJ dataset, with 100 tests for each block-size from one to five. Each Shuffle test was performed by at least two annotators. We find that there is high inter-annotator agreement (Cohen's Kappa $\kappa = 0.86$), which does not significantly vary with block-size (ranging from 0.76-0.94).

KBST results for human and computational models are shown in Table 2. Human performance is very high on WSJ, averaging above 95%, and is not significantly affected by block-size.

Timings logged during human annotation show that Shuffle Tests took on average 40% more time for larger (3-5) than smaller blocks (1-2), showing the task requires more attention from annotators as block size increases.

In all three domains, increased block size leads to a decrease in model performance. The magnitude of decrease in performance from block-size 1 to 5 is sensitive to the domain, with a drop of 4% in the legal domain, and 36% for Reddit, on which the 5-block performance of 53.8% narrowly outperforms random performance.

Aggregate model performance drops from 94.5% for block-size 1 to 77.9% for block-size 5, leaving significant room in larger block-size to measure future model improvements.

Although increasing the block size leads to a more challenging task for current models, we argue models should not be evaluated on a single block size, but on several block sizes, with each block size giving a perspective on the model's performance at a specific point between local and global coherence (Van Dijk, 1985).

5 Limitations and Future Work

Shuffling vs. Coherence. In this work, we propose an improved setting for the Shuffle Test, the most popular probe to measure textual coherence. However, many linguistic phenomena necessary for coherence of text cannot be measured by shuffling sentence order. In the long-run, the community should build more elaborate coherence measures, to build a more complete picture of model capabilities and limitations.

[2]https://www.upwork.com

Coherence in Long Text. We limited our analysis to texts with up to 512 words, a common constraint in pre-trained Transformers. Recent progress in model architectures open the possibility to process longer text, with models such as the Reformer (Kitaev et al., 2019), Longformer (Beltagy et al., 2020) and Big Bird (Zaheer et al., 2020) processing sequences of several thousand words. With longer sequences, one can further increase the block-size of the k-Blocked Shuffle Test (i.e., k=20) to gain understanding of model's ability to discern global coherence (Van Dijk, 1985), or main topics and subtopics (Hearst, 1997).

Specialized Coherence Models. In this work, we limit our analysis to popular models out-of-the-box, establishing baseline performances for the Zero-Shot KBST. Future work should establish whether performance can be further improved, for instance using word-level likelihood signals and surprisal profiles.

6 Conclusion

In this work, we discuss a potential limitation in the framing of the Shuffle Test, the most commonly used task to evaluate models for textual coherence. We show that a RoBERTa model can be finetuned to achieve near-perfect performance without necessarily measuring coherence, and propose a new framework: the Zero-Shot Shuffle Test, in which direct supervision is disallowed. Modern NLP architectures can achieve high performance out-of-the-box in this Zero-Shot setting on a variety of textual domains. We find however that models struggle when we introduce a simple modification, k-Blocking, to the shuffling strategy, with accuracy dropping from around 94% to around 78%. The k-Block Shuffle Test in a Zero-Shot setting is a straightforward, reproducible task that can be used to benchmark future NLP architectures to measure coherence capabilities.

Acknowledgments

We would like to thank Katie Stasaski, Dongyeop Kang, and the ACL reviewers for their helpful comments. This work was supported by a Microsoft BAIR Commons grant as well as a Microsoft Azure Sponsorship.

Ethical Considerations

We present a method to evaluate models on their ability to measure textual coherence. We have ex-

clusively run experiments in the English language, and even though we expect the method to be adaptable to other languages, we have not verified this assumption experimentally and limit our claims to the English language.

For the human evaluation, we paid the annotator above the minimum wage, and do not release any personal identifiable information. We did not collect payment information and relied on a third party (Upwork.com) for remuneration.

SimCLS: A Simple Framework for Contrastive Learning of Abstractive Summarization

Yixin Liu
Carnegie Mellon University
yixinl2@cs.cmu.edu

Pengfei Liu *
Carnegie Mellon University
pliu3@cs.cmu.edu

Abstract

In this paper, we present a conceptually simple while empirically powerful framework for abstractive summarization, SIMCLS, which can bridge the gap between the *learning objective* and *evaluation metrics* resulting from the currently dominated sequence-to-sequence learning framework by **formulating text generation as a reference-free evaluation problem** (i.e., quality estimation) assisted by *contrastive learning*. Experimental results show that, with minor modification over existing top-scoring systems, SimCLS can improve the performance of existing top-performing models by a large margin. Particularly, 2.51 absolute improvement against BART (Lewis et al., 2020) and 2.50 over PEGASUS (Zhang et al., 2020a) w.r.t ROUGE-1 on the CNN/DailyMail dataset, driving the state-of-the-art performance to a new level. We have open-sourced our codes and results: https://github.com/yixinL7/SimCLS. Results of our proposed models have been deployed into EXPLAINABOARD (Liu et al., 2021a) platform, which allows researchers to understand our systems in a more fine-grained way.

1 Introduction

Sequence-to-sequence (Seq2Seq) neural models (Sutskever et al., 2014) have been widely used for language generation tasks, such as abstractive summarization (Nallapati et al., 2016) and neural machine translation (Wu et al., 2016). While abstractive models (Lewis et al., 2020; Zhang et al., 2020a) have shown promising potentials in the summarization task, they share the widely acknowledged challenges of Seq2Seq model training. Specifically, Seq2Seq models are usually trained under the framework of Maximum Likelihood Estimation (MLE) and in practice they are commonly trained with the *teacher-forcing* (Williams and Zipser, 1989) algorithm. This introduces a gap between the *objective function* and the *evaluation metrics*, as the objective function is based on local, token-level predictions while the evaluation metrics (e.g. ROUGE (Lin, 2004)) would compare the holistic similarity between the gold references and system outputs. Furthermore, during the test stage the model needs to generate outputs autoregressivelly, which means the errors made in the previous steps will accumulate. This gap between the *training* and *test* has been referred to as the *exposure bias* in the previous work (Bengio et al., 2015; Ranzato et al., 2016).

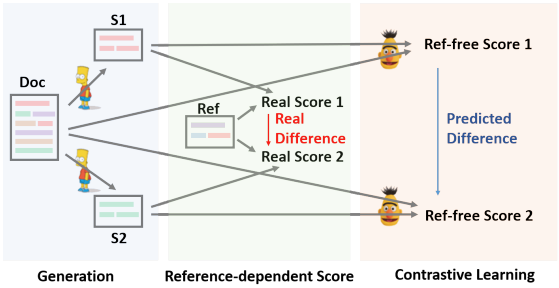

Figure 1: SimCLS framework for two-stage abstractive summarization, where Doc, S, Ref represent the document, generated summary and reference respectively. At the first stage, a Seq2Seq generator (BART) is used to generate candidate summaries. At the second stage, a scoring model (RoBERTa) is used to predict the performance of the candidate summaries based on the source document. The scoring model is trained with contrastive learning, where the training examples are provided by the Seq2Seq model.

A main line of approaches (Paulus et al., 2018; Li et al., 2019) proposes to use the paradigm of Reinforcement Learning (RL) to mitigate the aforementioned gaps. While RL training makes it possible to train the model with rewards based on global predictions and closely related to the evaluation metrics, it introduces the common challenges of deep RL. Specifically, RL-based training suffers from the noise gradient estimation (Greensmith et al., 2004) problem, which often makes the training un-

stable and sensitive to hyper-parameters. Minimum risk training, as an alternative, has also been used in the language generation tasks (Shen et al., 2016; Wieting et al., 2019). However, the accuracy of the estimated loss is restricted by the number of sampled outputs. Other methods (Wiseman and Rush, 2016; Norouzi et al., 2016; Edunov et al., 2018) aim to extend the framework of MLE to incorporate sentence-level scores into the objective functions. While these methods can mitigate the limitations of MLE training, the relation between the evaluation metrics and the objective functions used in their methods can be indirect and implicit.

Among this background, in this work we generalize the paradigm of contrastive learning (Chopra et al., 2005) to introduce an approach for abstractive summarization which achieves the goal of directly optimizing the model with the corresponding evaluation metrics, thereby mitigating the gaps between training and test stages in MLE training. While some related work (Lee et al., 2021; Pan et al., 2021) have proposed to introduce a contrastive loss as an augmentation of MLE training for conditional text generation tasks, we instead choose to disentangle the functions of contrastive loss and MLE loss by introducing them at different stages in our proposed framework.

Specifically, inspired by the recent work of Zhong et al. (2020); Liu et al. (2021b) on text summarization, we propose to use a two-stage model for abstractive summarization, where a Seq2Seq model is first trained to generate candidate summaries with MLE loss, and then a parameterized evaluation model is trained to rank the generated candidates with contrastive learning. By optimizing the generation model and evaluation model at separate stages, we are able to train these two modules with supervised learning, bypassing the challenging and intricate optimization process of the RL-based methods.

Our main contribution in this work is to approach metric-oriented training for abstractive summarization by proposing a generate-then-evaluate two-stage framework with contrastive learning, which not only put the state-of-the-art performance on CNN/DailyMail to a new level (2.2 ROUGE-1 improvement against the baseline model), also demonstrates the great potentials of this two-stage framework, calling for future efforts on optimizing Seq2Seq models using methods beyond maximum likelihood estimation.

2 Contrastive Learning Framework for Abstractive Summarization

Given a source document D and a reference summary $\hat{S}$, the goal of an abstractive summarization model f is to generate the candidate summary $S = f(D)$ such that it receives the highest score $m = M(S, \hat{S})$ assigned by an evaluation metric M. In this work, we break down the holistic generation process into two stages which consist of a *generation model* g for generating candidate summaries and a *evaluation model* h for scoring and selecting the best candidate. Fig 1 illustrates the general framework.

Stage I: Candidate Generation The generation model $g(\cdot)$ is a Seq2Seq model trained to maximize the likelihood of reference summary $\hat{S}$ given the source document D. The pre-trained $g(\cdot)$ is then used to produce multiple candidate summaries $S_1, \cdots, S_n$ with a sampling strategy such as Beam Search, where n is the number of sampled candidates.

Stage II: Reference-free Evaluation The high-level idea is that a better candidate summary S_i should obtain a higher quality score w.r.t the source document D. We approach the above idea by contrastive learning and define an *evaluation function* $h(\cdot)$ that aims to assign different scores $r_1, \cdots, r_n$ to the generated candidates solely based on the similarity between the source document and the candidate S_i, i.e., $r_i = h(S_i, D)$. The final output summary S is the candidate with the highest score:

$$S = \underset{S_i}{\operatorname{argmax}}\, h(S_i, D). \tag{1}$$

Here, we instantiate $h(\cdot)$ as a large pre-trained self-attention model, RoBERTa (Liu et al., 2019). It is used to encode S_i and D separately, and the cosine similarity between the encoding of the first tokens is used as the similarity score r_i.

Contrastive Training Instead of explicitly constructing a positive or negative example as most existing work with contrastive learning have adopted (Chen et al., 2020; Wu et al., 2020), here the "*contrastiveness*" is reflect in the diverse qualities of naturally generated summaries evaluated by a parameterized model $h(\cdot)$. Specifically, we introduce a ranking loss to $h(\cdot)$:

$$\begin{aligned} L = &\sum_i \max(0, h(D, \tilde{S}_i) - h(D, \hat{S})) \\ &+ \sum_i \sum_{j>i} \max(0, h(D, \tilde{S}_j) - h(D, \tilde{S}_i) + \lambda_{ij}), \end{aligned} \tag{2}$$

where $\tilde{S}_1, \cdots, \tilde{S}_n$ is descendingly sorted by $M(\tilde{S}_i, \hat{S})$. Here, $\lambda_{ij} = (j-i)*\lambda$ is the corresponding margin that we defined following Zhong et al. (2020), and λ is a hyper-parameter.[1] M can be any automated evaluation metrics or human judgments and here we use ROUGE (Lin, 2004).

3 Experiments

3.1 Datasets

We use two datasets for our experiments. The dataset statistics are listed in Appendix A.

`CNNDM` CNN/DailyMail[2] (Hermann et al., 2015; Nallapati et al., 2016) dataset is a large scale news articles dataset.

`XSum` XSum[3] (Narayan et al., 2018) dataset is a highly abstractive dataset containing online articles from the British Broadcasting Corporation (BBC).

3.2 Evaluation Metrics

We use ROUGE-1/2/L (R-1/2/L) as the main evaluation metrics for our experiments. We also evaluate our model on the recently developed semantic similarity metrics, namely, BERTScore (Zhang et al., 2020b) and MoverScore (Zhao et al., 2019).

3.3 Base Systems

As the generation model and the evaluation model in our two-stage framework are trained separately, we use pre-trained state-of-the-art abstractive summarization systems as our generation model. Specifically, we use **BART** (Lewis et al., 2020) and **Pegasus** (Zhang et al., 2020a) as they are popular and have been comprehensively evaluated.

3.4 Training Details

For baseline systems, we use the checkpoints provided by the *Transformers*[4] (Wolf et al., 2020) library. We use diverse beam search (Vijayakumar et al., 2016) as the sampling strategy to generate candidate summaries. We use 16 groups for diversity sampling, which results in 16 candidates. To train the evaluation model, we use Adam optimizer (Kingma and Ba, 2015) with learning rate scheduling. The model performance on the validation set is used to select the checkpoint. More details are described in Appendix B.

[1] As it is insensitive, we fix it to 0.01 in our experiments.

Table 1: Results on `CNNDM`. **BS** denotes BERTScore, **MS** denotes MoverScore. **Origin** denotes the original performance of the baseline model. **Min**, **Max**, **Random** are the oracles that select candidates based on their ROUGE scores. †: significantly better than the baseline model (Origin) ($p < 0.01$). *: results reported in the original papers.

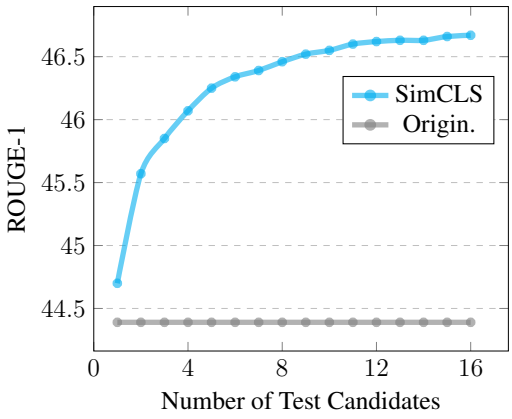

Figure 2: Test performance with different numbers of candidate summaries on `CNNDM`. **Origin** denotes the original performance of the baseline model.

3.5 Results on CNNDM dataset

The results on `CNNDM` dataset are shown in Tab. 1. We use the pretrained BART[5] as the base generation model (**Origin**). We use **BART**, **Pegasus**, **GSum** (Dou et al., 2021) and **ProphetNet** (Qi et al., 2020) for comparison. Notably, the Max oracle which always selects the best candidate has much better performance than the original outputs, suggesting that using a diverse sampling strategy can further exploit the potential power of the pretrained abstractive system. Apart from ROUGE, we also present the evaluation results on semantic similarity metrics. Our method is able to outperform the baseline model on all metrics, demonstrating its improvement is beyond exploiting the potential artifacts of ROUGE. While the scale of improvement is harder to interpret with these metrics, we note that the improvement is able to pass the significance test.

Table 2: Sentence alignments between source articles and summaries on CNNDM dataset. The aligned sentences for reference and our summaries are **bolded** (they are the same in this example). The aligned sentences for baseline summaries are *italicized*. **Origin** denotes the original performance of the baseline model.

Level	System	Precision	Recall	F-Score
Entity	Origin	40.70	59.13	48.22
	SimCLS	**43.36**	**59.79**	**50.27**
Sentence	Origin	38.11	38.65	37.18
	SimCLS	**42.58**	**40.22**	**40.12**

Table 3: Performance analysis on CNNDM dataset. **Origin** denotes the original performance of the baseline model.

With the constraints of computation power, we try to use as many candidates as possible for the evaluation model training. However, we also notice that our method is robust to the specific number of candidates, as during test we found that our model is still able to outperform the baseline model with fewer candidates, which is illustrated in Fig. 2.

3.6 Fine-grained Analysis

To demonstrate that our method is able to make meaningful improvement w.r.t the summary quality, here we compare our method with the baseline model at different semantic levels on CNNDM.

3.6.1 Entity-level

Inspired by the work of Gekhman et al. (2020) and Jain et al. (2020), we compare the model performance w.r.t the *salient entities*, which are entities in source documents that appear in the reference summaries. Specifically, (1) we extract the entities from the source documents,[6] (2) select the *salient entities* based on the entities in reference summaries, (3) compare the *salient entities* with entities in candidate summaries. Results in Tab. 3 demonstrate that our method can better capture the important semantic information of the source documents.

3.6.2 Sentence-level

Sentence Alignments Here we investigate if our method makes sentence-level differences compared to the baseline model. Specifically, (1) we match each sentence in the summaries to a sentence in the source documents based on their similarity (indicated by ROUGE scores),[7] (2) compute the sentence-level similarity between the reference and system-generated summaries based on the overlaps of their matched sentences in the source documents. The results in Tab. 3 demonstrate that the generated summaries of our method is more similar to the reference summaries at the sentence level.

Positional Bias In Tab. 2, we present a case study of the sentence alignment. We use the same matching approach to map the summary sentences to the sentences in source articles. In this example, the output of our method focuses on the same sentences as the reference summary does, while the baseline summary focuses on some different sentences.

Interestingly, the reference summary focuses on the very last sentence in the article, and our method can follow this pattern. Upon examining this pattern, we notice a positional bias of abstractive models when handling long source articles (more than

[6] We use a pre-trained NER model provided by spaCy to extract the entities: https://spacy.io/

[7] Notably, this matching approach formulates an extractive oracle when reference summaries are used for matching, which achieves 54.54/30.73/50.35 ROUGE-1/2/L scores.

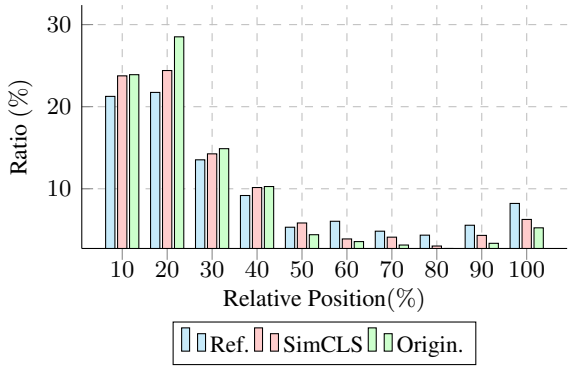

Figure 3: Positional Bias. X-asis: the relative position of the matched sentence in source documents. Y-axis: the ratio of the matched sentences. For fair comparison, articles are first truncated to the generator's maximum input length. **Origin** denotes the original performance of the baseline model.

System	R-1	R-2	R-L	BS	MS
BART*	45.14	22.27	37.25	-	-
Pegasus*	47.21	24.56	39.25	-	-
GSum*	45.40	21.89	36.67	-	-
Origin	47.10	24.53	39.23	69.48	61.34
Min	40.97	19.18	33.68	66.01	59.58
Max	52.45	28.28	43.36	72.56	62.98
Random	46.72	23.64	38.55	69.30	61.23
SimCLS	**47.61**†	**24.57**	**39.44**†	**69.81**†	**61.48**†

Table 4: Results on XSum dataset. **BS** denotes BERTScore, **MS** denotes MoverScore. **Origin** denotes the original performance of the baseline model. **Min**, **Max**, **Random** are the oracles that select candidates based on their ROUGE scores. †: significantly better than the baseline model (Origin) ($p < 0.05$). *: results reported in the original papers.

30 sentences). Fig. 3 shows that the baseline summaries are more likely to focus on the head sentences compared to the references, which may result from the autoregressive generation process of the Seq2Seq models. Our method is able to mitigate this bias, as the candidate sampling process (diverse beam search) generates candidates different from the original outputs, and our evaluation model can assess the holistic quality of the candidates.

3.7 Results on XSum dataset

To evaluate our method's performance beyond CNNDM dataset, we also test our method on XSum dataset, and the results are shown in Tab. 4. Here, we use Pegasus[8] as the base system since it achieves better performance than BART on XSum. We follow the same sampling strategy to generate the training data. However, as this strategy generally results in lower ROUGE-2 score on XSum dataset, we use a different strategy to generate the validation and test data (4 candidates generated by 4 diverse groups). Our method is still able to outperform the baseline, but with a smaller margin compared to CNNDM. Summaries in XSum are shorter (one-sentence) and more abstractive, which restricts the semantic diversity of candidates and makes it harder to make meaningful improvement.

4 Conclusion

In this work, we present a contrastive summarization framework that aims to optimize the quality of generated summaries at summary-level, which mitigates the discrepancy between the training and test stages in the MLE framework. Apart from the significant improvement over the baseline model on CNNDM dataset, we present a comprehensive evaluation at different semantic levels, explaining the sources of the improvement made by our method. Notably, our experimental results also indicate that the existing abstractive systems have the potential of generating candidate summaries much better than the original outputs. Therefore, our work opens up the possibility for future directions including (1) extending this two-stage strategy to other datasets for abstractive models; (2) improving the training algorithms for abstractive models towards a more holistic optimization process.

A Dataset Statistics

Datasets	# Num			Avg. Len	
	Train	Valid	Test	Doc.	Sum.
CNNDM	287K	13K	11K	768.6	55.7
XSum	203K	11K	11K	429.2	23.3

Table 5: Datasets Statistics. Len is the length of tokens.

The source documents and reference summaries are lower-cased. Due to the input length limitation, some source documents are truncated during training.

B Experiment Details

Candidate Generation We use diverse beam search to generate the candidate summaries. We use the same beam search configuration as the original work except those related to diverse beam search. In particular, the diversity penalty is set to 1, and we use 16 diversity groups with 16 beams, which results in 16 candidates.

Model We use the pretrained RoBERTa with 'roberta-base' version provided by the *Transformers* library as our evaluation model, which contains 125M parameters.

Optimizer We use Adam optimizer with learning rate scheduling:

$$lr = 0.002 \cdot \min(\text{step\_num}^{-0.5}, \text{step\_num} \cdot \text{warmup\_steps}^{-1.5}), \quad (3)$$

where the warmup_steps is 10000.

Training details The batch size in our experiments is 32. We evaluate the model performance on the validation set at every 1000 steps, using the averaged ROUGE-1/2/L score as the selecting criteria. The training is converged in 5 epochs, which takes around 40 hours on 4 GTX-1080-Ti GPUs on CNN/DailyMail dataset and 20 hours on XSum dataset.

SaRoCo: Detecting Satire in a Novel Romanian Corpus of News Articles

Ana-Cristina Rogoz, Mihaela Găman, Radu Tudor Ionescu*
University of Bucharest
14 Academiei Street, Bucharest, Romania
*raducu.ionescu@gmail.com

Abstract

In this work, we introduce a corpus for satire detection in Romanian news. We gathered 55,608 public news articles from multiple real and satirical news sources, composing one of the largest corpora for satire detection regardless of language and the only one for the Romanian language. We provide an official split of the text samples, such that training news articles belong to different sources than test news articles, thus ensuring that models do not achieve high performance simply due to overfitting. We conduct experiments with two state-of-the-art deep neural models, resulting in a set of strong baselines for our novel corpus. Our results show that the machine-level accuracy for satire detection in Romanian is quite low (under 73% on the test set) compared to the human-level accuracy (87%), leaving enough room for improvement in future research.

1 Introduction

According to its definition in the Cambridge Dictionary, satire is "a humorous way of criticizing people or ideas"[1]. News satire employs this mechanism in the form of seemingly legitimate journalistic reporting, with the intention of ridiculing public figures, politics or contemporary events (McClennen and Maisel, 2014; Peters and Broersma, 2013; Rubin et al., 2016). Although the articles pertaining to this genre contain fictionalized stories, the intent is not to mislead the public into thinking that the discussed subjects are real. On the contrary, satirical news articles are supposed to reveal their nature by the writing style and comedic devices employed, such as irony, parody or exaggeration. Thus, the intention behind the writing differentiates satirical news (Rubin et al., 2016) from fake news (Meel and Vishwakarma, 2019; Pérez-Rosas et al., 2018; Sharma et al., 2019). However, in some rare cases, the real intent might be deeply buried in the complex irony and subtleties of news satire (Barbieri et al., 2015a), which has the effect of fiction being deemed as factual (Zhang et al., 2020). Even so, there is a clear distinction between satirical and fake news. In fake news, the intent is to deceive the readers in thinking that the news is real, while presenting fake facts to influence the readers' opinion. Since our study is focused on satire detection, we consider discussing research on fake news detection as being out of our scope. At the same time, we acknowledge the growing importance of detecting fake news and the fact that an accurate differentiation of satirical from legitimate journalistic reports might be seen as a starting point in controlling the spread of deceptive news (De Sarkar et al., 2018).

Satire detection is an important task that could be addressed prior to the development of conversational systems and robots that interact with humans. Certainly, the importance of understanding satirical (funny, ridiculous or ironical) text becomes obvious when we consider a scenario in which a robot performs a dangerous action because it takes a satirical comment of the user too literally. Given the relevance of the task for the natural language processing community, satire detection has already been investigated in several well-studied languages such as Arabic (Saadany et al., 2020), English (Burfoot and Baldwin, 2009; De Sarkar et al., 2018; Goldwasser and Zhang, 2016; Yang et al., 2017), French (Ionescu and Chifu, 2021; Liu et al., 2019), German (McHardy et al., 2019), Spanish (Barbieri et al., 2015b) and Turkish (Toçoğlu and Onan, 2019). Through the definition of satire, the satire detection task is tightly connected to irony and sarcasm detection. These tasks strengthen or broaden the language variety with languages such as Ara-

bic (Karoui et al., 2017), Chinese (Jia et al., 2019), Dutch (Liebrecht et al., 2013) and Italian (Giudice, 2018).

In this work, we introduce SaRoCo[2], the **Sa**tire detection **Ro**manian **Co**rpus, which comprises 55,608 news articles collected from various sources. To the best of our knowledge, this is the first and only data set for the study of Romanian satirical news. Furthermore, SaRoCo is also one of the largest data sets for satirical news detection, being surpassed only two corpora, one for English (Yang et al., 2017) and one for German (McHardy et al., 2019). However, our corpus contains the largest collection of satirical news articles (over 27,000). These facts are confirmed by the comparative statistics presented in Table 1.

Along with the novel data set, we include two strong deep learning methods to be used as baselines in future works. The first method is based on low-level features learned by a character-level convolutional neural network (Zhang et al., 2015), while the second method employs high-level semantic features learned by the Romanian version of BERT (Dumitrescu et al., 2020). The gap between the human-level performance and that of the deep learning baselines indicates that there is enough room for improvement left for future studies. We make our corpus and baselines available online for nonprofit educational and research purposes, under an open-source noncommercial license agreement.

2 Corpus

SaRoCo gathers both satirical and non-satirical news from some of the most popular Romanian news websites. The collected news samples were found in the public web domain, i.e. access is provided for free without requiring any subscription to the publication sources. The entire corpus consists of 55,608 samples (27,628 satirical samples and 27,980 non-satirical samples), having more than 28 million tokens in total, as illustrated in Table 2. Each sample is composed of a title (headline), a body and a corresponding label (satirical or non-satirical). As shown in Table 3, an article has around 515.24 tokens on average, with an average of 24.97 tokens for the headline. We underline that the labels are automatically determined, based on the fact that a publication source publishes either regular or satirical news, but not both.

We provide an official split for our corpus, such that all future studies will use the same training, val-

Table 4: Examples of news headlines from SaRoCo.

idation and test sets, easing the direct comparison with prior results. Following McHardy et al. (2019), we use disjoint sources for training, validation and test, ensuring that models do not achieve high performance by learning author styles or topic biases particular to certain news websites. While crawling the public news articles, we selected the same topics (culture, economy, politics, social, sports, tech) and the same time frame (between 2011 and 2020) for all news sources to control for potential biases induced by uneven topic or time distributions across the satirical and non-satirical genres.

After crawling satirical and non-satirical news samples, our first aim was to prevent discrimination based on named entities. The satirical character of an article should be inferred from the language use rather than specific clues, such as named entities. For example, certain sources of news satire show preference towards mocking politicians from a specific political party, and an automated system might erroneously label a news article about a member of the respective party as satirical simply based on the presence of the named entity. Furthermore, we even noticed that some Romanian politicians have certain mocking nicknames assigned in satirical news. In order to eliminate named entities, we followed a similar approach as the one used for the MOROCO (Butnaru and Ionescu, 2019) data set. Thus, all the identified named entities are replaced with the special token NE. Besides eliminating named entities, we also substituted all whitespace characters with space and replaced multiple consecutive spaces with a single space. A set of processed satirical and regular headlines are shown in Table 4.

3 Baselines

Fine-tuned Ro-BERT. Our first baseline consists of a fine-tuned Romanian BERT (Dumitrescu et al., 2020), which follows the same transformer-based model architecture as the original BERT (Devlin et al., 2019). According to Dumitrescu et al. (2020), the Romanian BERT (Ro-BERT) attains better results than the multilingual BERT on a range of tasks. We therefore assume that the Romanian BERT should represent a stronger baseline for our Romanian corpus.

We use the Ro-BERT encoder to encode each text sequence into a list of token IDs. The tokens are further processed by the model, obtaining the corresponding 768-dimensional embeddings. At this point, we add a global average pooling layer to obtain a Continuous Bag-of-Words (CBOW) representation for each sequence of text, followed by a Softmax output layer with two neural units, each predicting the probability for one category, either non-satirical or satirical. To obtain the final class label for a text sample, we apply *argmax* on the two probabilities. We fine-tune the whole model for 10 epochs on mini-batches of 32 samples, using the Adam with decoupled weight decay (AdamW) optimizer (Loshchilov and Hutter, 2019), with a learning rate of 10^{-7} and the default value for ϵ.

Character-level CNN. The second baseline model considered in the experiments is a Convolutional Neural Network (CNN) that operates at the character level (Zhang et al., 2015). We set the input size to 1,000 characters. After the input layer, we add an embedding layer to encode each character into a vector of 128 components. The optimal architecture for the task at hand proved to be composed of three convolutional (conv) blocks, each having a conv layer with 64 filters applied at stride 1, followed by Scaled Exponential Linear Unit (SELU) activation. From the first block to the third block, the convolutional kernel sizes are 5, 3 and 1, respectively. Max-pooling with a filter size of 3 is applied after each conv layer. After each conv block, we insert a Squeeze-and-Excitation block

Table 5: Validation and test results of the character-level CNN and the fine-tuned Ro-BERT applied on SaRoCo.

with the reduction ratio set to $r = 64$, following Butnaru and Ionescu (2019). To prevent overfitting, we use batch normalization and Alpha Dropout (Klambauer et al., 2017) with a dropout rate of 0.5. The final prediction layer is composed of two neural units, one for each class (i.e. legitimate and satirical), with Softmax activation. We use the Nesterov-accelerated Adaptive Moment Estimation (Nadam) optimizer (Dozat, 2016) with a learning rate of $2 \cdot 10^{-4}$, training the network for 50 epochs on mini-batches of 128 samples.

4 Experiments

Evaluation. We conducted binary classification experiments on SaRoCo, predicting if a given piece of text is either satirical or non-satirical. As evaluation metrics, we employ the precision and recall for each of the two classes. We also combine these scores through the macro F_1 and micro F_1 (accuracy) measures.

Results. In Table 5, we present the results of the two baselines on the SaRoCo validation and test sets. We observe that both models tend to have higher precision scores in detecting satire than in detecting regular news. The trade-off between precision and recall is skewed towards higher recall for the non-satirical news class. Since both models share the same behavior, we conjecture that the behavior is rather caused by the particularities of the satire detection task.

Discriminative feature analysis. We analyze the discriminative features learned by the character-level CNN, which is one of the proposed baseline systems for satire detection. We opted for the character-level CNN in favor of the fine-tuned BERT, as the former method allows us to visualize discriminative features using Grad-CAM (Selvaraju et al., 2017), a technique that was initially used to explain decisions of CNNs applied on images. We adapted this technique for the character-level CNN, then extracted and analyzed the most predictive patterns in SaRoCo. The motivation behind this was to validate that the network's decisions are not based on some biases that escaped our data collection and cleaning process.

Humans	0.8735	0.8711	0.9416	0.7970	0.8332	0.9500

Table 8: Averaged performance of ten human annotators versus deep learning baselines on 200 news headlines from SaRoCo.

via Grad-CAM in the satirical news samples. The network seems to pick up obvious clues such as slang, insults and popular sayings rather than more subtle indicatives of satire, including irony or exaggeration. At the same time, for the real news in SaRoCo, there are fewer categories of predictive patterns. In general, the CNN deems formal, standard news expressions as relevant for regular news. These patterns vary across topics and domains. The CNN also finds that the presence of numbers and statistical clues is indicative for non-satirical content, which is consistent with the observations of Yang et al. (2017). Our analysis reveals that the discriminative features are appropriate for satire detection, showing that our corpus is indeed suitable for the considered task.

Deep models versus humans. Given 100 satirical and 100 non-satirical news headlines (titles) randomly sampled from the SaRoCo test set, we asked ten Romanian human annotators to label each sample as satirical or non-satirical. We evaluated the deep learning methods on the same subset of 200 samples, reporting the results in Table 8. First, we observe that humans have a similar bias as the deep learning models. Indeed, for both humans and models, the trade-off between precision and recall is skewed towards higher precision for the satirical class and higher recall for the non-satirical class. We believe this is linked to the way people and machines make a decision. Humans look for patterns of satire in order to label a sample as satire. If a satire-specific pattern is not identified, the respective sample is labeled as regular, increasing the recall for the non-satirical class. Although humans and machine seem to share the same way of thinking, there is a considerable performance gap in satire detection between humans and machines. Indeed, the average accuracy of our ten human annotators is around 87%, while the state-of-the-art deep learning models do not surpass 68% on the same news headlines. Even on full news articles (see Table 5), the models barely reach an accuracy of 73% on the test set. Hence, we conclude there is a significant performance gap between humans and machines, leaving enough room for exploration in future work on Romanian satire detection.

We would like to emphasize that our human evaluation was performed by casual news readers, and the samples were shown after named entity removal, thus having a fair comparison with the AI models. We underline that named entity removal makes the task more challenging, even for humans.

5 Conclusion

In this work, we presented SaRoCo, a novel data set containing satirical and non-satirical news samples. To the best of our knowledge, SaRoCo is the only corpus for Romanian satire detection and one of the largest corpora regardless of language. We trained two state-of-the-art neural models as baselines for future research on our novel corpus. We also compared the performance of the neural models with the averaged performance of ten human annotators, showing that the neural models lag far behind the human-level performance. Our discriminative feature analysis confirms the limitations of state-of-the-art neural models in detecting satire. Although we selected a set of strong models from the recent literature as baselines for SaRoCo, significant future research is necessary to close the gap with respect to the human-level satire detection performance. Designing models to pick up irony or exaggerations could pave the way towards closing this gap in future work.

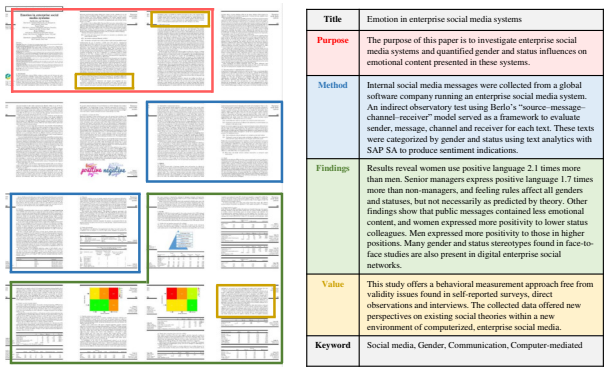
Abstract

Faceted summarization provides briefings of a document from different perspectives. Readers can quickly comprehend the main points of a long document with the help of a structured outline. However, little research has been conducted on this subject, partially due to the lack of large-scale faceted summarization datasets. In this study, we present FacetSum, a faceted summarization benchmark built on Emerald journal articles, covering a diverse range of domains. Different from traditional document-summary pairs, FacetSum provides *multiple summaries*, each targeted at specific sections of a long document, including the purpose, method, findings, and value. Analyses and empirical results on our dataset reveal the importance of bringing structure into summaries. We believe FacetSum will spur further advances in summarization research and foster the development of NLP systems that can leverage the structured information in both long texts and summaries.

1 Introduction

Text summarization is the task of condensing a long piece of text into a short summary without losing salient information. Research has shown that a well-structured summary can effectively facilitate comprehension (Hartley et al., 1996; Hartley and Sydes, 1997). A case in point is the *structured abstract*, which consists of multiple segments, each focusing on a specific facet of a scientific publication (Hartley, 2014), such as background, method, conclusions, etc. The structure therein can provide much additional clarity for improved comprehension and has long been adopted by databases and publishers such as MEDLINE and Emerald.

Despite these evident benefits of structure, summaries are often framed as a linear, structure-less sequence of sentences in the flourishing array of summarization studies (Nallapati et al., 2017; See et al., 2017; Paulus et al., 2018; Grusky et al., 2018; Narayan et al., 2018; Sharma et al., 2019; Lu et al., 2020; Cachola et al., 2020). We postulate that a primary reason for this absence of structure lies in the lack of a high-quality, large-scale dataset with structured summaries. In fact, existing studies in faceted summarization (Huang et al., 2020; Tauchmann et al., 2018; Jaidka et al., 2016; Contractor et al., 2012; Kim et al., 2011; Jaidka et al., 2018; Stead et al., 2019) are often conducted with rather limited amount of data that are grossly insufficient to meet today's ever-growing model capacity.



Title	Emotion in enterprise social media systems
Purpose	The purpose of this paper is to investigate enterprise social media systems and quantified gender and status influences on emotional content presented in these systems.
Method	Internal social media messages were collected from a global software company running an enterprise social media system. An indirect observatory test using Berlo's "source–message–channel–receiver" model served as a framework to evaluate sender, message, channel and receiver for each text. These texts were categorized by gender and status using text analytics with SAP SA to produce sentiment indications.
Findings	Results reveal women use positive language 2.1 times more than men. Senior managers express positive language 1.7 times more than non-managers, and feeling rules affect all genders and statuses, but not necessarily as predicted by theory. Other findings show that public messages contained less emotional content, and women expressed more positivity to lower status colleagues. Men expressed more positivity to those in higher positions. Many gender and status stereotypes found in face-to-face studies are also present in digital enterprise social networks.
Value	This study offers a behavioral measurement approach free from validity issues found in self-reported surveys, direct observations and interviews. The collected data offered new perspectives on existing social theories within a new environment of computerized, enterprise social media.
Keyword	Social media, Gender, Communication, Computer-mediated

Figure 1: An example of the proposed FacetSum dataset. Each facet of the structured abstract summarizes different sections of the paper.

We aim to address this issue by proposing the FacetSum dataset. It consists of 60,024 scientific articles collected from Emerald journals, each associated with a *structured* abstract that summarizes the article from distinct aspects including purpose, method, findings, and value. Scale-wise, we empirically show that the dataset is sufficient for training large-scale neural generation models such as BART (Lewis et al., 2020) for adequate generalization. In terms of quality, each structured abstract in FacetSum is provided by the original author(s) of the article, who are arguably in the best position to summarize their own work. We also provide

2 FacetSum for Faceted Summarization

The FacetSum dataset is sourced from journal articles published by Emerald Publishing[1] (Figure 1). Unlike many publishers, Emerald imposes explicit requirements that authors summarize their work from multiple aspects (Emerald, 2021): **Purpose** describes the motivation, objective, and relevance of the research; **Method** enumerates specific measures taken to reach the objective, such as experiment design, tools, methods, protocols, and datasets used in the study; **Findings** present major results such as answers to the research questions and confirmation of hypotheses; and **Value** highlights the work's value and originality[2]. Together, these facets give rise to a comprehensive and informative structure in the abstracts of the Emerald articles, and by extension, to FacetSum's unique ability to support faceted summarization.

2.1 General Statistics

We collect 60,532 publications from Emerald Publishing spanning 25 domains. Table 1 lists some descriptive statistics of the dataset. Since FacetSum is sourced from journal articles, texts therein are naturally expected to be longer compared to other formats of scientific publications. In addition, although each facet is more succinct than the traditional, structure-less abstracts, a full length abstract containing all facets can be considerably longer. Empirically, we compare the source and the target lengths with some existing summarization datasets in similar domains including CLPubSum (Collins et al., 2017), PubMed (Cohan et al., 2018), ArXiv (Cohan et al., 2018), SciSummNet (Yasunaga et al., 2019), and SciTldr (Cachola et al., 2020). On average, the source length in FacetSum is 58.9% longer (6,827 vs 4,297), and the target length is 37.0% longer (290.4 vs 212.0).

From a summarization perspective, these differences imply that FacetSum may pose significantly increased modeling and computation challenges due to the increased lengths in both the source and the target. Moreover, the wide range of research domains (Figure 3, Appendix D) may also introduce much linguistic diversity w.r.t. vocabulary, style, and discourse. Therefore, compared to existing scientific publication datasets that only focus on specific academic disciplines (Cohan et al., 2018; Cachola et al., 2020), FacetSum can also be used to assess a model's robustness in domain shift and systematic generalization.

To facilitate assessment of generalization, we reserve a dev and a test set each consisting of 6,000 randomly sampled data points; the remaining data are intended as the training set. We ensure that the domain distribution is consistent across all three subsets. Besides, we intentionally leave out Open-Access papers as another test set, to facilitate researchers who do not have full Emerald access[3].

2.2 Structural Alignment

In this section, we focus our analysis on one of the defining features of FacetSum — its potential to support faceted summarization. Specifically, we investigate how the abstract structure (i.e., facets) aligns with the article structure. Given an abstract facet A and its corresponding article S, we quantify this alignment by:

$$S_A = \{\arg\max_{s_i \in S}(\texttt{Rouge-1}(s_i, a_j)) : a_j \in A\} \quad (1)$$

Semantically, S_A consists of sentence indices in S that best align with each sentence in A.

Sentence-level Alignment We first plot the tuples $\{(s_i, i/|S|) : i \in S_A\}$, where s_i is the i-th sentence in S, and $|S|$ is the number of sentences in S. Intuitively, the plot density around position $i/|S|$ entails the degree of alignment between the facet

[1]The data has been licensed to researchers at subscribing institutions to use (including data mining) for non-commercial purposes. See detailed policies at https://www.emerald.com/

[2]There are three optional facets (about research, practical and social implications) that are missing from a large number of articles and hence omitted in this study.

[3]Both the split information of FacetSum and the code for scraping and parsing the data are available at https://github.com/hfthair/emerald_crawler

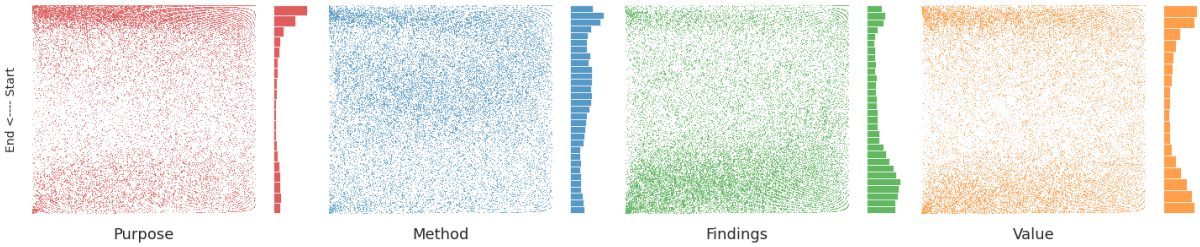

Figure 2: Oracle sentence distribution over a paper. X-axis: 10,000 papers sampled from FacetSum, sorted by full text length from long to short; y-axis: normalized position in a paper. We provide each sub-figure's density histogram on their right.

Abstract \ Paper Section	Full	I+C	Introduction	Method	Result	Conclusion

Purpose	49.76	47.06	44.23	30.12	33.87	36.23
Method	45.36	34.23	30.82	37.53	29.07	28.46
Findings	52.09	45.28	33.65	29.49	42.80	42.35
Value	45.98	42.37	35.29	26.68	32.52	36.85

Table 2: Scores of sentence aligning in Rouge-L.

A and the article S at that position[4]. With 10,000 articles randomly sampled from FacetSum, Figure 2 exhibits distinct differences in the density distribution among the facets in FacetSum. For example, with $A =$ Purpose, resemblance is clearly skewed towards the beginning of the articles, while Findings are mostly positioned towards the end; the Method distribution is noticeably more uniform than the others. These patterns align well with intuition, and are further exemplified by the accompanying density histograms.

Section-level Alignment We now demonstrate how different abstract facets align with different sections in an article. Following conventional structure of scientific publications (Suppe, 1998; Rosenfeldt et al., 2000), we first classify sections into *Introduction*, *Method*, *Result* and *Conclusion* using keyword matching in the section titles.[5]

Given a section $S^i \subseteq S$ and an abstract $A_j \subseteq A$, we define the section-level alignment $g(S^i, A_j)$ as $\texttt{Rouge-1}(\texttt{cat}(S^i_{A_j}), \texttt{cat}(A_j))$, where $\texttt{cat}(\cdot)$ denotes sentences concatenation, and $S^i_{A_j}$ is defined by Equation (1). Table 2 is populated by varying A_j and S^i across the rows and columns, respectively. **Full** denotes the full paper or abstract (concatenation of all facets). We also include the concatenation of introduction and conclusion (denoted I+C) as a possible value for S^i, due to its demonstrated effectiveness as summaries in prior work (Cachola et al., 2020).

The larger numbers on the diagonal (in red) empirically confirm a strong alignment between FacetSum facets and their sectional counterparts in articles. We also observe a significant performance gap between using I+C and the full paper as S^i. One possible reason is that the summaries in FacetSum (particularly Method and Findings) may contain more detailed information beyond introduction and conclusion. This suggests that for some facets in FacetSum, simple tricks to condense full articles do not always work; models need to instead comprehend and retrieve relevant texts from full articles in a more sophisticated manner.

3 Experiments and Results

We use FacetSum to benchmark a variety of summarization models from state-of-the-art supervised models to unsupervised and heuristics-based models. We also provide the scores of a sentence-level extractive oracle system (Nallapati et al., 2017). We report Rouge-L in this section and include Rouge-1/2 results in Appendix E.

Unsupervised Models vs Heuristics We report performances of unsupervised and heuristics summarization methods (see Table 3). Tailoring to the unique task of generating summaries for a specific facet, we only use the section (defined in Section 2.2) corresponding to a facet as model input. Evaluation is also performed on the concatenation

[4]We use the relative position $i/|S|$ so that all positions are commensurate across multiple documents.

[5]To ensure close-to-perfect precision, we choose keywords that are as specific and prototypical to each section as possible (listed in Appendix A). The resulting recall is around 0.7, i.e. about 70% of sections can be correctly retrieved with the title-keyword matching method. And we find 2,751 (out of 6,000) test samples that all four sections are matched successfully. Though far from perfect, we believe this size is sufficient for the significance of subsequent analyses.

	Model	Source Text	Full	Purpose	Method	Findings	Value

Table 3: Model performance on FacetSum (Rouge-L). See Table 6 and 7 in Appendix E for full results. **Bold** text indicates the best scores on FacetSum test split in each column.

of all facets (column **Full**), which resembles the traditional research abstract. **Lead-K/Tail-K** are two heuristic-based models that extract the first/last k sentences from the source text.

We observe that heuristic models do not perform well on **Full**, where the unsupervised models can achieve decent performance. Nevertheless, all models perform poorly on summarizing individual facets, and unsupervised models fail to perform better than simple heuristics consistently. The inductive biases of those models may not be good indicators of summary sentences on specific facets. A possible reason is that they are good at locating overall important sentences of a document, but they cannot differentiate sentences of each facet, even we try to alleviate this by using the corresponding section as input.

Supervised Models As for the supervised baseline, we adopt the BART model (Lewis et al., 2020), which has recently achieved SOTA performance on abstractive summarization tasks with scientific articles (Cachola et al., 2020). We propose two training strategies for the BART model, adapting it to handle the unique challenge of faceted summarization in FacetSum. In **BART**, we train the model to generate the concatenation of all facets, joined by special tokens that indicate the start of a specific facet (e.g., |PURPOSE| to indicate the start of Purpose summary). During evaluation, the generated text is split into multiple facets based on the special tokens, and each facet is compared against the corresponding ground-truth summary. In **BART-Facet**, we train the model to generate one specific facet given the source text and an indicator specifies which facet to generate. Inspired by CATTS (Cachola et al., 2020), we prepend section tags at the beginning of each training input to generate summaries for a particular facet (see implementation details in Appendix C).

Empirically, supervised models outperform unsupervised baselines by a large margin (Table 3). Comparing between the two training strategies, BART-Facet outperforms BART significantly. While BART performs comparably on Purpose, performance decreases drastically for subsequent facets, possibly due to current models' inadequacy with long targets. Thus it can perform decently at the beginning of generation (≈40 on Purpose), where the dependency is relatively easy-to-handle. However, the output quality degrades quickly towards the end (≈5 on Value).

With I+C as source text, both training strategies exhibit much better results than using full paper. This is opposite to the observation in Table 2, potentially due to the limitation of the current NLG systems, i.e., the length of source text has crucial impacts to the model performance. With the much extended positional embeddings in our models (10,000 tokens), we suspect some other issues such as long term dependencies may lead to this discrepancy, which warrants further investigation.

4 Conclusion & Future Work

We introduce FacetSum to support the research of faceted summarization, which targets summarizing scientific documents from multiple facets. We provide extensive analyses and results to investigate the characteristics of FacetSum. Our observations call for the development of models capable of handling very long documents and outputting controlled text. Specifically, we will consider exploring the following topics in future work: (1) incorporating methods for long-document processing, such as reducing input length by extracting key sentences (Pilault et al., 2020) or segments (Zhao et al., 2020); (2) examining the possibility of building a benchmark for systematic generalization (Bahdanau et al., 2018) with the domain categories; (3) automatically structuring traditional abstracts (Huang et al., 2020) with FacetSum.

	explor	manag	differ
	develop	research	public
Method	base	studi	structur
	conduct	data	qualit
	collect	analysi	differ
	test	model	empir
	develop	paper	social
Findings	found	result	signific
	indic	studi	posit
	suggest	manag	social
	provid	effect	differ
	identifi	relationship	higher
Value	provid	studi	new
	contribut	paper	social
	develop	research	differ
	base	manag	empir
	examin	literatur	import

Table 5: Top five frequent verbs/nouns/adjectives in each facet of structured abstract. We preprocess the text with lowercasing, stemming and stopword removal and extract part-of-speech tags using Spacy (Honnibal et al., 2020).

C Implementation Details

To make BART take full text as input, we extend the positional embedding to 10,000 tokens. This was required to leverage long text of papers in `FacetSum` with average length of 6000 words.

Experiments of unsupervised baselines are implemented with Sumy (Belica, 2021) and official code of HipoRank. We tune the hyperparameters of HipoRank with the validation set. The BART experiments are finetuned using Fairseq (Ott et al., 2019), with learning rate of $3e^{-5}$, batch size of 1, max tokens per batch of 10,000 and update frequency of 4. We finetune all models for 20,000 steps with single NVIDIA Tesla V100 16GB and we report the results of the last checkpoint. The small batch size is the consequence of the large input size. For inference, we use beam size of 4 and maximum length of 500/200 tokens for BART/BART-Facet respectively.

D Domains Covered by `FacetSum`

In Figure 3, we show the distribution of domain categories in `FacetSum`.

E Full Results

In this section, we provide additional experiment results. In Table 6, we show the full results of the extractive oracle system (first row in Table 3). In Table 7, we provide full results of all other models (heuristic models, unsupervised models, and supervised models in Table 3).

F Example of Outputs by BART and BART-Facet

In Table 8, we show an example of the generated faceted summaries by BART and BART-Facet of the same paper, compared against the ground-truth faceted abstract.

Facet	Ground Truth	BART	BART-Facet
Purpose	The purpose of this paper is to advance the information society research by examining and better understanding the impact of the adoption information and communication technologies (ICT) within households on improving sustainability.	The purpose of this paper is to answer the question: Does the adoption of information and communication technologies (ICT) within households contribute to sustainability? For this purpose, the study focuses on addressing the following specific questions: What criteria clearly and deeply describe the ICT adoption within households? What are the criteria that clearly describe sustainability within households, and are there statistically significant correlations between ICT and sustainability?	The purpose of this paper is to answer the question: Does the adoption of information and communication technologies (ICT) within households contribute to sustainability?
Method	The survey questionnaire was used and data collected from 679 Polish households were statistically analyzed to understand the phenomena of ICT adoption and sustainability as well as identify correlations between them.	A survey was carried out in Poland. The data were collected through a structured questionnaire and analyzed using structural equation modeling (SEM).	The study is based on a quantitative research design. The data were collected through a questionnaire survey among the households in Poland. The survey was carried out in two phases. In the first phase, the ICT adoption within households was measured using a structured questionnaire, and in the second phase the data were analyzed using structural equation modeling (SEM) to test the hypothesized relationships.
Findings	The research findings reveal that the ICT adoption is well described by the ICT outlay, information culture, ICT management and ICT quality, whereas sustainability is composed of ecological, economic, socio-cultural and political sustainability. Furthermore, the ICT quality, ICT management and information culture have a significant impact on sustainability, whereas the ICT outlay does not have such an impact.	Results show that ICT is a key enabler of sustainability in households. The results also show that there are statistically significant correlation between the IIT adoption within the households and sustainability.	The results show that the adoption of ICT within households is positively related to sustainability. The results also show that there are statistically significant correlations between the ICT adoption within households and sustainability.
Value	The paper provides and verifies a new theoretical model of sustainable information society to depict various dimensions shaping the ICT adoption and their impact on different types of sustainability in the context of households.	This study is the first to empirically investigate the impact of ICT on sustainability. The findings of this study will be complementary with findings concerning the contribution of IIT to sustainability in enterprises and allow for the advancement in the sustainable information society (SIS) research.	This study contributes to the literature by providing a deeper understanding of the ICT adoption within households and the contribution of ICT to sustainability in transition economies, i.e. the former European Eastern Bloc countries.

Table 8: Outputs by **BART** and **BART-Facet** on different facets. Both models are able to generate reasonable summaries given the specified facet. BART-Facet provides more information of Method and less errors than BART (e.g. "IIT" is a typo of "ICT"). However both models tend to directly copy text from the source, for example both outputs of Purpose can be found in the introduction of the paper.

Replicating and Extending "*Because Their Treebanks Leak*": Graph Isomorphism, Covariants, and Parser Performance

Abstract

Søgaard (2020) obtained results suggesting the fraction of trees occurring in the test data isomorphic to trees in the training set accounts for a non-trivial variation in parser performance. Similar to other statistical analyses in NLP, the results were based on evaluating linear regressions. However, the study had methodological issues and was undertaken using a small sample size leading to unreliable results. We present a replication study in which we also bin sentences by length and find that only a small subset of sentences vary in performance with respect to graph isomorphism. Further, the correlation observed between parser performance and graph isomorphism in the wild disappears when controlling for covariants. However, in a controlled experiment, where covariants are kept fixed, we do observe a strong correlation. We suggest that conclusions drawn from statistical analyses like this need to be tempered and that controlled experiments can complement them by more readily teasing factors apart.

1 Introduction

We undertake a replication study of Søgaard (2020) which introduced graph isomorphism (DUG - directed unlabelled graph isomorphism) as a means of explaining differences in parser performance across different treebanks. It measures the ratio of graphs[1] in the test set that were also observed in the training data. It is intuitive that this would likely be related to parser performance.

However, DUG has two important covariants. The size of the training data impacts DUG because the smaller a treebank is, the less likely there will be many crossovers between training and test data. DUG is also tied to the mean sentence length in the test data: smaller sentences are much more likely to have a tree structure already seen in the training, as there are fewer possible trees and the reverse is true for longer sentences, e.g. the number of possible trees for a sentence with 20 tokens is 12,826,228.

[1]Note that in the treebanks used in this paper, namely Universal Dependencies, well-formed trees are enforced.

2 Related Work

There is a long history of investigating the causes of variance in parser performance. The effect of training data size on parser performance is well attested (Sagae et al., 2008; Falenska and Çetinoğlu, 2017; Strzyz et al., 2019; Dehouck et al., 2020). Sentence length has also been observed to impact performance (McDonald and Nivre, 2011). One likely factor behind this is different sentence lengths having difference dependency distance distributions (Ferrer-i-Cancho and Liu, 2014) which in turn affects parsing as longer dependencies are typically harder to parse (Anderson and Gómez-Rodríguez, 2020; Falenska et al., 2020). Others have offered explanations based on linguistic characteristics such as morphological complexity (Dehouck and Denis, 2018; Çöltekin, 2020), part-of-speech bigram perplexity (Berdicevskis et al., 2018), and word order freedom (Gulordava and Merlo, 2016).

The history of reproduction and replication in NLP is not so well established, with only a few studies in recent years, e.g. on Universal Dependency (UD) parsing (Çöltekin, 2020) and on automatic essay scoring systems (Huber and Çöltekin, 2020).

Linear techniques, linear regression models or evaluating correlation coefficients are commonly used for statistical analyses of NLP systems. They have been used to model constituency parser performance (Ravi et al., 2008), to evaluate what affects annotation agreement (Bayerl and Paul, 2011), to investigate what impacts statistical MT systems (Guzman and Vogel, 2012), what impacts performance on span identifying tasks (Papay et al., 2020), and many other examples. Therefore, it is likely that lessons drawn from this replication

Table 1: Issues with using multivariable linear model and cross-validation (CV) to evaluate explained variance. The first set of columns (Original) uses the exact same settings as the original paper (namely one CV split and the original seed) on the original data (CoNLL18) and the predictions from UDPipe 1.2 and UDPipe 2.0 for the extended data. The DUG explained variance is much smaller for the new data. The second set of columns show the same analysis but averaged over 10 different seeds used for the CV splits. The explained variances are almost all negative, which means the linear fit failed.

analysis will be impactful in a broader sense as the conclusions here can be applied in many subareas of NLP, namely the sensitive handling of covariants by using partial coefficients, controlled experiments, or signal subtraction; a strong adherence to visualising data; and considering whether the phenomena under consideration are likely to be sensitive to sentence length, as is often the case in NLP, and if so undertaking a sentence-length binning analysis to complement coarser analyses.

2.1 Original paper

Søgaard (2020) attempted to explain the difference of parser performance across treebanks by using DUG and also undirected unlabelled graph isomorphism (UUG). Two graphs are isomorphic if there is a renaming of vertices that makes them equal. The first process in calculating DUG (or UUG) is to collect the set of unique graphs that occur in the training data. In the original paper, this set of graphs is referred to as the isomorphisms. Once the training isomorphisms are obtained for a given treebank, the number of graphs in the test data that are members of one of these equivalence classes is counted. The final value is then the proportion of test instances that are isomorphic to the training data. This then gives a value between 0 (all test instances are unique) and 1 (no unique test instances).

The analysis was undertaken using a small sample of treebanks that were used at the CoNLL 2018 shared task, using the LAS of the top performing system for each treebank to measure parser performance (Zeman et al., 2018). The impact DUG (or UUG) has on parsing performance was evaluated by fitting a linear regression to the data with DUG as the control variable. A number of other potential measurements that could explain parser performance were also taken into consideration, but only as alternative explanation and not covariants. The exception to this was using the size of the training data as a covariant. The explained variance and absolute error for each linear regression fit was reported using a three-fold cross-validation. The results suggested that DUG was the most strongly correlated measurement evaluated. We show that this result does not hold up when accounting for covariants, that using cross-validation method with the linear regression is not a robust method for an analysis like this, and that by controlling the main covariants of DUG, we can observe a more trustworthy correlation to parser performance.

3 Analysis and results

We evaluate directed graph isomorphism (DUG) as it was more strongly related to parser performance in the original paper.

Main covariants We focus on the two main covariants of DUG: training data size (in sentences) and mean sentence length of the test data, $\langle L_{\text{test}} \rangle$.

Data and parsers The data from the original paper consists of 33 UD treebanks, with LAS taken from the respective top performing parser from the CoNLL 2018 shared task (Zeman et al., 2018). Note that these systems are all variations of the biaffine graph-based parser of Dozat and Manning (2017). For replication, we also use a neural transition-based system UDPipe 1.2 (Straka et al., 2016), using UD models 2.4 and UD v2.5 (Zeman et al., 2019), and a neural graph-based system UDPipe 2.0 (Straka, 2018), using UD models 2.6 and UD v2.7 (Zeman et al., 2020). This results in 94 treebanks for UDPipe 1.2 and 90 for UDPipe 2.0. The difference is due to issues running the web-based UDPipe 2.0 on larger files.

3.1 Reproduction and replication

In the original paper, the analysis focuses on fitting a multi-variable linear regression to the data to control for covariants. However, the models only used training size plus one other variable as features. Further, cross-validation is used so as to avoid over-fitting. While over-fitting isn't directly an issue, the metrics that are typically reported overestimate the variance explained by a linear model, e.g. explained variance, η^2, or R^2 (Lane et al., 2007). Averaging η^2 over different splits can potentially offset this positive bias but it requires a certain amount of data to be reliable. In Table 1, we show the results using the original data from Søgaard (2020). The values shown in the left-most column are exact reproductions of the original values. Only the value for $\langle L_{\text{test}} \rangle$ is different as the original paper appears to have used a normalised value. We also show η^2 for the linear model using all variables, which is negative, i.e. the fit failed.

We next show the results using UDPipe 1.2 and 2.0. While the values for training size on its own and with $\langle L_{\text{test}} \rangle$ are similar, the high η^2 for training size with DUG is no longer observed. This seems to be due to specious results born out of serendipitous splits for the smaller sample from CoNLL 2018.

We then tested this same procedure using different seeds to shuffle the cross-validation splits. The results are almost exclusively negative, i.e. the linear models failed to fit to the data at all. This further highlights an issue of using this methodology when sample size is small, as the random split can have large impact on the statistical metrics.

3.2 Extending the analysis

As the linear models performed so poorly, we measured the correlation coefficients (Spearman's ρ) for each of the variables with respect to LAS and also the potential covariants with respect to DUG. These are reported in Table 2 and we include visualisations of these in Figures 5 and 6 in the Appendix

	CoNLL18	UDPipe 1.2	UDPipe 2.0
size	0.46 (p=0.007)	0.54 (p<0.001)	0.37 (p<0.001)
DUG	-0.13 (p=0.458)	-0.13 (p=0.213)	-0.18 (p=0.083)
$\langle L_{\textbf{test}} \rangle$	0.20 (p=0.272)	0.35 (p=0.001)	0.33 (p=0.001)
size	0.44 (p=0.011)	0.42 (p<0.001)	0.46 (p<0.001)
$\langle L_{\textbf{test}} \rangle$	-0.96 (p<0.001)	-0.91 (p<0.001)	-0.92 (p<0.001)

Table 2: Spearman's ρ for variables with respect to LAS (top) and DUG (bottom).

	CoNLL18	UDPipe 1.2	UDPipe 2.0
log-size	0.055	0.319	0.126
+DUG	0.132	0.410	0.277
+$\langle L_{\textbf{test}} \rangle$	0.106	0.452	0.294
All	-0.184	0.412	0.229

Table 3: Using multivariable linear model and CV to evaluate explained variance with random shuffling (10 splits) and logarithmic transformation of treebank size.

for the CoNLL 2018 data and the UDPipe 2.0 data. Interestingly, DUG has the highest p-value for all systems, far from statistical significance. However, DUG appears to be strongly correlated to both covariants, especially $\langle L_{\text{test}} \rangle$ with $\rho > 0.9$ and $p < 0.001$ for all datasets and systems. Also of note is that training data size is convincingly correlated to LAS, but based on the linear models it doesn't appear to be predictive of parser performance. Based on this and on the visualisation of the data in Figures 5 and 6 in the Appendix (as well as visualisations of training size vs. LAS in the literature, see §2), it seems clear that the relation between these variables is not linear but logarithmic. We show LAS against training data size with a logarithmic scale in Figure 4 in the Appendix.

Table 3 shows the results of the limited linear model and cross-validation technique using 10 different seeds as above and using log training size. For these results, the explained variance of the models are all positive and relatively high, that is, the models manage to fit the data unlike in the original setup. This one change offsets the failure of the linear model technique, which is not surprising. However, it seems to suggest that DUG is not a useful feature, as training size with $\langle L_{\text{test}} \rangle$ outperforms training size with DUG for all datasets except CoNLL18. And the models which use all features are worse than just using training data size and $\langle L_{\text{test}} \rangle$, with the CoNLL18 model resulting in a negative explained variance, again meaning the fit failed. For CoNLL18, training data size and DUG does outperform the model using $\langle L_{\text{test}} \rangle$.

3.3 Sentence length binning

We analyse the relation between test sentence lengths and DUG by binning the data with respect to sentence length. This entails taking each sentence of length l for each treebank, in both the training and test data, and calculating DUG and the corresponding LAS based on these subsets. Figure 1 shows some of these bins (for sentences of

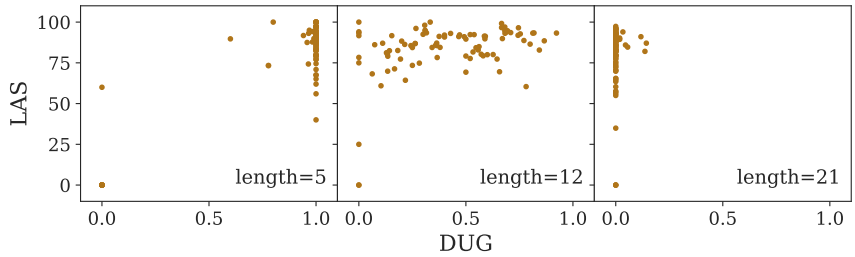

Figure 1: DUG binned wrt sentence length. Values are for UDPipe 2.0 with UD v2.7 for 90 treebanks.

length of 5, 12, and 21 tokens) for UDPipe 2.0. A full visualisation of each bin ranging from length 3 tokens to 30 is shown in Figure 7 in the Appendix.

DUG is almost exclusively 1.0 for shorter sentences, as can be seen in Figure 1 for sentence length 5. The number of possible directed trees for sentences with less tokens is too small for there not to be crossover: there are only 9 possible unlabelled trees for sentences of length 5 (Sloane, 1996). Conversely, for longer sentences, DUG is almost exclusively 0.0 as the number of possible tree structures is considerable (35,221,832 for sentences of length 21).

For a small subset of sentence lengths, ranging from length 9 to 14, there is meaningful spread of values for DUG, with a broadly-speaking linear relation with respect to LAS. Based on this result, i.e. that only certain sentence lengths are suitable for using DUG, we considered using a *focused* version of DUG, i.e. a variant calculated considering only sentences between length 9 and 14 in the training and test data. We then analysed how this measurement correlated with parser performance. Table 4 shows the correlations for focused DUG with respect to LAS, training size, and $\langle L_{\text{test}} \rangle$. While the correlation between focused DUG and LAS is much higher than for DUG and LAS, this is due to the focused version being much more strongly correlated to training size ($\rho = 0.91$ with a p-value less than 0.001 for both datasets) and the correlation with $\langle L_{\text{test}} \rangle$ is much diminished. Also, this focused version of DUG improves performance for the linear model when used only with training data size, but $\langle L_{\text{test}} \rangle$ improves it much more. Using all 3 is again worse than just using training data size with $\langle L_{\text{test}} \rangle$, however, focused DUG doesn't lower the performance as much as the full variant does.

	UDPipe 1.2	UDPipe 2.0
LAS	0.47 (p<0.001)	0.31 (p=0.003)
size	0.91 (p<0.001)	0.91 (p<0.001)
$\langle L_{\textbf{test}} \rangle$	0.32 (p=0.002)	-0.34 (p=0.001)
log-size	0.319	0.126
+DUG	0.331	0.147
+$\langle L_{\textbf{test}} \rangle$	0.452	0.294
All	0.406	0.265

Table 4: Correlations wrt focused DUG (top) and explained variance (bottom) for focused DUG (sentence lengths 9 to 14) with shuffling for CV (10 seeds).

3.4 Controlling covariants

Having established that DUG does not improve linear models predicting LAS and that DUG is strongly correlated to training treebank size and $\langle L_{\text{test}} \rangle$, we attempted to find a signal by removing the background signals associated with these variables. We applied a linear fit to the training data size and LAS and then divided the LAS scores by the predicted values of that fit. Then we applied a linear fit to $\langle L_{\text{test}} \rangle$ and these *normalised* values and again divided these values out. Finally, we evaluated these *doubly normalised* values against DUG. This process is shown in Figure 2 for UDPipe 2.0 and the resulting coefficients for UDPipe 1.2 and 2.0 are in Table 7 of the Appendix. Removing the signals of the covariants results in a linear fit against DUG with a zero gradient and with a coefficient of 0.01 (p=0.926). Removing the variance associated with these covariants effectively removes any signal associated with DUG.

To corroborate this background subtraction analysis, we also report the partial coefficients in Table 5. When controlling for both covariants, correlations are small, and p-values very high, for both

	CoNLL18	UDPipe 1.2	UDPipe 2.0
DUG	-0.13 (p=0.458)	-0.13 (p=0.213)	-0.18 (p=0.083)
size	-0.44 (p=0.010)	-0.50 (p<0.001)	-0.46 (p<0.001)
$\langle L_{\textbf{test}} \rangle$	0.18 (p=0.329)	-0.13 (p=0.213)	0.21 (p=0.049)
both	-0.27 (p=0.126)	0.01 (p=0.915)	-0.12 (p=0.245)

Table 5: Partial Spearman's ρ for DUG with covariants.

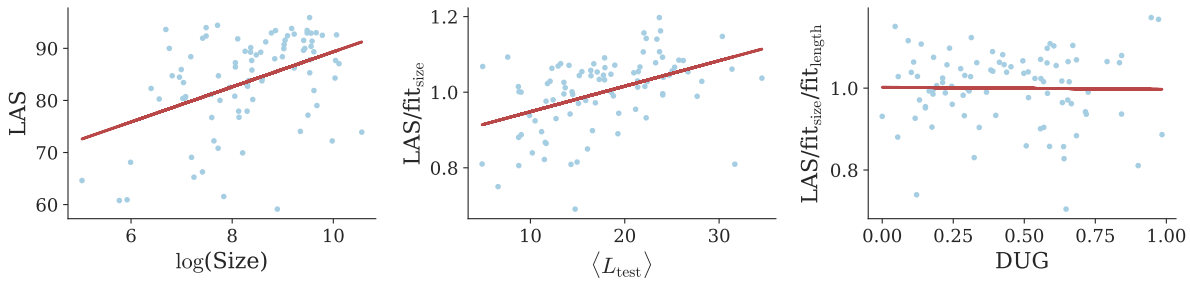

Figure 2: Visualisation of removing background signal associated with covariants of the log of training size (log(Size)) and mean test length $\langle L_{test} \rangle$. The spearman's ρ for DUG and LAS is -0.18 (p=0.083), for DUG and LAS/bcg$_{size}$ is -0.40 (p<0.001) compared to $\langle L_{test} \rangle$and LAS/bcg$_{size}$ of 0.465 (p<0.001), and finally DUG and LAS/bcg$_{size}$bcg$_{Ltest}$ is 0.01 (p=0.926).

UDPipe systems. CoNLL18 has a stronger signal, but it is negative (which is the opposite relation one would expect) and has a large p-value.

3.5 Controlled experiment - fixing covariants

We also evaluated DUG's relation to LAS in a controlled experiment where we sampled subsets of treebanks keeping training data size constant and also the sentence length of both training and test data. We trained UDPipe 1.2 models (UDPipe 2.0 is not available beyond using pre-existing models), using standard settings. We were limited to 9 treebanks, as we required a reasonable amount of data and using only one sentence length reduces the number of usable treebanks. We combined all of the data for treebanks which had over 1200 sentences of length 12. We then created splits such that a single 1000-sentence training set was created by randomly sampling sentences. Then a number of 200-sentence test sets were created, generating as many splits as the data allowed for a given treebank.

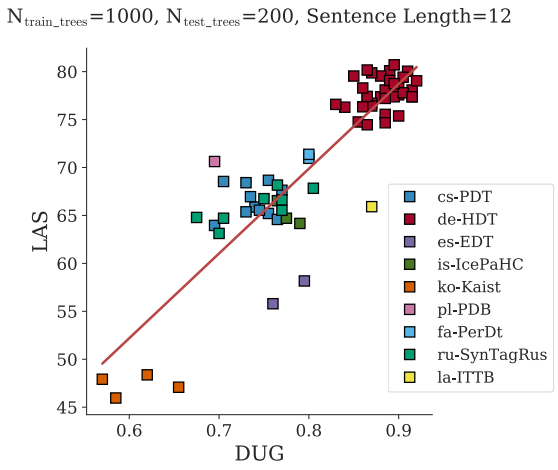

Figure 3: DUG vs LAS for controlled experiment. ρ = 0.82 (p< 0.001).

In this way we varied DUG indirectly, but by using different treebanks to sample from we obtained values spanning a reasonable range (0.6 - 0.9). This results in a Spearman's ρ of 0.82 (p<0.001) and is visualised in Figure 3 in the Appendix. So in this rigid context, we do observe a very strong correlation between DUG and LAS, echoing the analysis from the sentence-length binning procedure.

4 Conclusion

With this case study we have shown the value of replicating analyses in NLP. Our analysis has shown that the original results were unreliable and it has highlighted methodological issues the original analysis had. Also, the results regarding the methodology presented here (i.e. the need to visualise and evaluate correlations before considering linear regression techniques, the potential sensitivity to sentence length of measurements used in NLP statistical analyses, the need to control for all covariants and evaluate their impact using partial coefficients at the very least, and finally that using controlled experiments can help better evaluate the impact of specific measurements and can complement statistical analyses) will likely be useful for other statistical analyses in different areas of NLP.

A Appendix

The appendix mainly consists of visualisations corresponding to the statistical analyses described in the main body. Some additional information is given to supplement the main analyses in Tables 6 and 7 which give the correlations for the focused DUG analysis and the background removal process, respectively.

Figure 4 shows the logarithmic relation between LAS and the training data size for UDPipe 2.0 and UD v2.7. Figure 5 gives the visualisations for the data used in the original paper and Figure 6 gives the corresponding visualisation for UDPipe 2.0 and UD v2.7.

Figure 7 expands the example plots shown in Figure 1 which only showed extreme cases. This shows LAS versus DUG for every sentence length bin from length 3 to 30. This clearly shows the issue with DUG as discussed in the main body.

All the data used for the analyses presented in this paper can be found in the supplementary material associated with the paper.

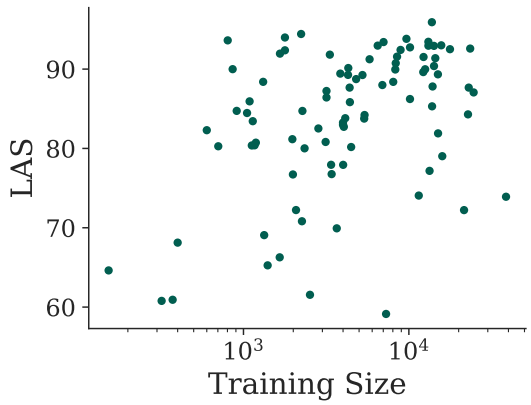

Figure 4: LAS with respect to training set size, in logarithmic scale, for UDPipe 2.0 and UD v2.7.

	UDPipe 1.2	UDPipe 2.0
DUG	0.47 (p<0.001)	0.31 (p=0.003)
size	-0.15 (p=0.153)	-0.10 (p=0.335)
$\langle L_{\textbf{test}} \rangle$	0.64 (p<0.001)	0.48 (p<0.001)
both	0.17 (p=0.110)	0.04 (p=0.683)

Table 6: Partial Spearman's ρ for focused DUG (i.e. using only the measurement for sentences of length 9 to 14) with covariants.

	Spearman's ρ	p-value
DUG LAS	-0.184	0.083
DUG LAS-bcg$_{\textbf{size}}$	-0.400	0.000
DUG LAS-bcg$_{\textbf{size,Ltest}}$	0.010	0.926
$\langle L_{\text{Test}} \rangle$ **LAS-bcg$_{\textbf{size}}$**	0.465	0.000

Table 7: Correlation of DUG with LAS and then with LAS with the background associated with size and length (L) removed. Isolated row shows correlation of LAS without size background and mean sentence length in test data.

Don't Rule Out Monolingual Speakers: A Method For Crowdsourcing Machine Translation Data

Rajat Bhatnagar, Ananya Ganesh and **Katharina Kann**
University of Colorado Boulder
{rajat.bhatnagar, ananya.ganesh, katharina.kann}@colorado.edu

Abstract

High-performing machine translation (MT) systems can help overcome language barriers while making it possible for everyone to communicate and use language technologies in the language of their choice. However, such systems require large amounts of parallel sentences for training, and translators can be difficult to find and expensive. Here, we present a data collection strategy for MT which, in contrast, is cheap and simple, as it does not require bilingual speakers. Based on the insight that humans pay specific attention to movements, we use graphics interchange formats (GIFs) as a pivot to collect parallel sentences from monolingual annotators. We use our strategy to collect data in Hindi, Tamil and English. As a baseline, we also collect data using images as a pivot. We perform an intrinsic evaluation by manually evaluating a subset of the sentence pairs and an extrinsic evaluation by finetuning mBART (Liu et al., 2020) on the collected data. We find that sentences collected via GIFs are indeed of higher quality.

1 Introduction

Machine translation (MT) – automatic translation of text from one natural language into another – provides access to information written in foreign languages and enables communication between speakers of different languages. However, developing high performing MT systems requires large amounts of training data in the form of parallel sentences – a resource which is often difficult and expensive to obtain, especially for languages less frequently studied in natural language processing (NLP), endangered languages, or dialects.

For some languages, it is possible to scrape data from the web (Resnik and Smith, 2003), or to leverage existing translations, e.g., of movie subtitles (Zhang et al., 2014) or religious texts (Resnik et al., 1999). However, such sources of data are only available for a limited number of languages, and it is impossible to collect large MT corpora for a diverse set of languages using these methods. Professional translators, which are a straightforward alternative, are often rare or expensive.

	Sentence for GIFs	Showing only image 2 to annotators
English Annotator	A dog is running around in a circle.	A woman is sitting on a lawn chair while a dog runs nearby.
Hindi Annotator	एक कुत्ता गोल गोल भाग रहा है (A dog is running around in a circle)	काला कुत्ता खेल रहा है। (A black dog is playing)

Figure 1: Sentences written by English and Hindi annotators using GIFs or images as a pivot.

In this paper, we propose a new data collection strategy which is cheap, simple, effective and, importantly, does not require professional translators or even bilingual speakers. It is based on two assumptions: (1) **non-textual modalities can serve as a pivot for the annotation process** (Madaan et al., 2020); and (2) **annotators subconsciously pay increased attention to moving objects**, since humans are extremely good at detecting motion, a crucial skill for survival (Albright and Stoner, 1995). Thus, we propose to leverage graphics interchange formats (GIFs) as a pivot to collect parallel data in two or more languages.

We prefer GIFs over videos as they are short in duration, do not require audio for understanding and describe a comprehensive story visually. Furthermore, we hypothesize that GIFs are better pivots than images – which are suggested by Madaan et al. (2020) for MT data collection – based on our second assumption. We expect that people who

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1099–1106
August 1–6, 2021. ©2021 Association for Computational Linguistics

are looking at the same GIF tend to focus on the main action and characters within the GIF and, thus, tend to write more similar sentences. This is in contrast to using images as a pivot, where people are more likely to focus on different parts of the image and, hence, to write different sentences, cf. Figure 1.

We experiment with collecting Hindi, Tamil and English sentences via Amazon Mechanical Turk (MTurk), using both GIFs and images as pivots. As an additional baseline, we compare to data collected in previous work (Madaan et al., 2020). We perform both intrinsic and extrinsic evaluations – by manually evaluating the collected sentences and by training MT systems on the collected data, respectively – and find that leveraging GIFs indeed results in parallel sentences of higher quality as compared to our baselines.[1]

2 Related Work

In recent years, especially with the success of transfer learning (Wang et al., 2018) and pretraining in NLP (Devlin et al., 2019), several techniques for improving neural MT for low-resource languages have been proposed (Sennrich et al., 2016; Fadaee et al., 2017; Xia et al., 2019; Lample et al., 2017; Lewis et al., 2019; Liu et al., 2020).

However, supervised methods still outperform their unsupervised and semi-supervised counterparts, which makes collecting training data for MT important. Prior work scrapes data from the web (Lai et al., 2020; Resnik and Smith, 2003), or uses movie subtitles (Zhang et al., 2014), religious texts (Resnik et al., 1999), or multilingual parliament proceedings (Koehn, 2005). However, those and similar resources are only available for a limited set of languages. A large amount of data for a diverse set of low-resource languages cannot be collected using these methods.

For low-resource languages, Hasan et al. (2020) propose a method to convert noisy parallel documents into parallel sentences. Zhang et al. (2020) filter noisy sentence pairs from MT training data.

The closest work to ours is Madaan et al. (2020). The authors collect (pseudo-)parallel sentences with images from the Flickr8k dataset (Hodosh et al., 2013) as a pivot, filtering to obtain images which are simplistic and do not contain culture-specific references. Since Flickr8k already contains 5 English captions per image, they select images whose captions are short and of high similarity to each other. Culture-specific images are manually discarded. We compare to the data from Madaan et al. (2020) in Section 4, denoting it as M20.

3 Experiments

3.1 Pivot Selection

We propose to use GIFs as a pivot to collect parallel sentences in two or more languages. As a baseline, we further collect parallel data via images as similar to our GIFs as possible. In this subsection, we describe our selection of both mediums.

GIFs We take our GIFs from a dataset presented in Li et al. (2016), which consists of 100k GIFs with descriptions. Out of these, 10k GIFs have three English one-sentence descriptions each, which makes them a suitable starting point for our experiments. We compute the word overlap in F1 between each possible combination of the three sentences, take the average per GIF, and choose the highest scoring 2.5k GIFs for our experiments. This criterion filters for GIFs for which all annotators focus on the same main characters and story, and it eliminates GIFs which are overly complex. We thus expect speakers of non-English languages to focus on similar content.

Images Finding images which are comparable to our GIFs is non-trivial. While we could compare our GIFs' descriptions to image captions, we hypothesize that the similarity between the images obtained thereby and the GIFs would be too low for a clean comparison. Thus, we consider two alternatives: (1) using the *first* frame of all GIFs, and (2) using the *middle* frame of all GIFs.

In a preliminary study, we obtain two Hindi one-sentence descriptions from two different annotators for both the first and the middle frame for a subset of 100 GIFs. We then compare the BLEU (Papineni et al., 2002) scores of all sentence pairs. We find that, on average, sentences for the middle frame have a BLEU score of 7.66 as compared to 4.58 for the first frame. Since a higher BLEU score indicates higher similarity and, thus, higher potential suitability as MT training data, we use the middle frames for the image-as-pivot condition in our final experiments.

[1] All data collected for our experiments is available at https://nala-cub.github.io/resources.

Rating	Sentences from the GIF-as-Pivot Setting
1	A child flips on a trampoline. A girl enjoyed while playing.
3	A man in a hat is walking up the stairs holding a bottle of water. A man is walking with a plastic bottle.
5	A man is laughing while holding a gun. A man is laughing while holding a gun.
	Sentences from the Image-as-Pivot Setting
1	A woman makes a gesture in front of a group of other women. This woman is laughing.
3	An older woman with bright lip stick lights a cigarette in her mouth. This woman is lighting a cigarette.
5	A woman wearing leopard print dress and a white jacket is walking forward. A woman is walking with a leopard print dress and white coat.

Table 1: Sentences obtained in English and Hindi for each setting where both annotators agree on the rating. The first sentence is the sentence written in English and the second sentence is the corresponding English translation of the Hindi sentence, translated by the authors.

3.2 Data Collection

We use MTurk for all of our data collection. We collect the following datasets: (1) one single-sentence description in Hindi for each of our 2,500 GIFs; (2) one single-sentence description in Hindi for each of our 2,500 images, i.e., the GIFs' middle frames; (3) one single-sentence description in Tamil for each of the 2,500 GIFs; (4) one single-sentence description in Tamil for each of the 2,500 images; and (5) one single-sentence description in English for each of our 2,500 images. To build parallel data for the GIF-as-pivot condition, we randomly choose one of the available 3 English descriptions for each GIF.

For the collection of Hindi and Tamil sentences, we restrict the workers to be located in India and, for the English sentences, we restrict the workers to be located in the US. We use the instructions from Li et al. (2016) with minor changes for all settings, translating them for Indian workers.[2]

Each MTurk human intelligence task (HIT) consists of annotating five GIFs or images, and we expect each task to take a maximum of 6 minutes. We pay annotators in India \$0.12 per HIT (or \$1.2 per hour), which is above the minimum wage of \$1 per hour in the capital Delhi.[3] Annotators in the US are paid \$1.2 per HIT (or \$12 per hour). We have obtained IRB approval for the experiments reported in this paper (protocol #: 20-0499).

[2]Our instructions can be found in the appendix.

	GIF-as-Pivot	Image-as-Pivot	M20
Hindi–English	**2.92**	2.20	2.63
Tamil–English	**3.03**	2.33	-

Table 2: Manual evaluation of a subset of our collected sentences; scores from 1 to 5; higher is better.

3.3 Test Set Collection

For the extrinsic evaluation of our data collection strategy we train and test an MT system. For this, we additionally collect in-domain development and test examples for both the GIF-as-pivot and the image-as-pivot setting.

Specifically, we first collect 250 English sentences for 250 images which are the middle frames of previously unused GIFs. We then combine them with the English descriptions of 250 additional unused GIFs from Li et al. (2016). For the resulting set of 500 sentences, we ask Indian MTurk workers to provide a translation into Hindi and Tamil. We manually verify the quality of a randomly chosen subset of these sentences. Workers are paid \$1.2 per hour for this task. We use 100 sentence pairs from each setting as our development set and the remaining 300 for testing.

4 Evaluation

4.1 Intrinsic Evaluation

In order to compare the quality of the parallel sentences obtained under different experimental conditions, we first perform a manual evaluation of a subset of the collected data. For each lan-

	Rating	GIF-as-pivot	Image-as-pivot	M20
Hi-En	5	**13.08**	2.5	10.0
Ta-En		**6.0**	3.5	-
Hi-En	>= 4	**35.77**	15.5	26.43
Ta-En		**37.0**	14.0	-
Hi-En	>= 3	**61.15**	39.0	51.43
Ta-En		**67.5**	42.5	-
Hi-En	>= 2	**82.69**	63.0	75.0
Ta-En		**92.5**	72.5	-
Hi-En	>= 1	**100.0**	**100.0**	**100.0**
Ta-En		**100.0**	**100.0**	-

Table 3: Cumulative percentages with respect to each setting; GIF-as-pivot shows the best results;

guage pair, we select the same random 100 sentence pairs from the GIF-as-pivot and image-as-pivot settings. We further choose 100 random sentence pairs from M20. We randomly shuffle all sentence pairs and ask MTurk workers to evaluate the translation quality. Each sentence pair is evaluated independently by two workers, i.e., we collect two ratings for each pair. Sentence pairs are rated on a scale from 1 to 5, with 1 being the worst and 5 being the best possible score.[4]

Each evaluation HIT consists of 11 sentence pairs. For quality control purposes, each HIT contains one manually selected example with a perfect (for Hindi–English) or almost perfect (for Tamil–English) translation. Annotators who do not give a rating of 5 (for Hindi–English) or a rating of at least 4 (for Tamil–English) do not pass this check. Their tasks are rejected and republished.

Results The average ratings given by the annotators are shown in Table 2. Sentence pairs collected via GIF-as-pivot obtain an average rating of 2.92 and 3.03 for Hindi–English and Tamil–English, respectively. Sentences from the image-as-pivot setting only obtain an average rating of 2.20 and 2.33 for Hindi–English and, respectively, Tamil–English. The rating obtained for M20 (Hindi only) is 2.63. As we can see, for both language pairs the GIF-as-pivot setting is rated consistently higher than the other two settings, thus showing the effectiveness of our data collection strategy. This is in line with our hypothesis that the movement displayed in GIFs is able to guide the sentence writer's attention.

We now explicitly investigate how many of the translations obtained via different strategies are acceptable or good translations; this corresponds to a score of 3 or higher. Table 3 shows that 61.15% of the examples are rated 3 or above in the GIF-as-pivot setting for Hindi as compared to 39.0% and 51.43% for the image-as-pivot setting and M20, respectively. For Tamil, 67.5% of the sentences collected via GIFs are at least acceptable translations. The same is true for only 42.5% of the sentences obtained via images.

We show example sentence pairs with their ratings from the GIF-as-pivot and image-as-pivot settings for Hindi–English in Table 1.

[4]The definitions of each score as given to the annotators can be found in the appendix.

4.2 Extrinsic Evaluation

We further extrinsically evaluate our data by training an MT model on it. Since, for reasons of practicality, we collect only 2,500 examples, we leverage a pretrained model instead of training from scratch. Specifically, we finetune an mBART model (Liu et al., 2020) on increasing amounts of data from all setting in both directions. mBART is

a transformer-based sequence-to-sequence model which is pretrained on 25 monolingual raw text corpora. We finetune it with a learning rate of 3e-5 and a dropout of 0.3 for up to 100 epochs with a patience of 15.

Results The BLEU scores for all settings are shown in Tables 4 and 5 for Hindi–English and Tamil–English, respectively. We observe that increasing the dataset size mostly increases the performance for all data collection settings, which indicates that the obtained data is useful for training. Further, we observe that each model performs best on its own in-domain test set.

Looking at Hindi-to-English translation, we see that, on average, models trained on sentences collected via GIFs outperform sentences from images or M20 for all training set sizes, except for the 500-examples setting, where image-as-pivot is best. However, results are mixed for Tamil-to-English translation.

Considering English-to-Hindi translation, models trained on M20 data outperform models trained on sentences collected via GIFs or our images in nearly all settings. However, since the BLEU scores are low, we manually inspect the obtained outputs. We find that the translations into Hindi are poor and differences in BLEU scores are often due to shared individual words, even though the overall meaning of the translation is incorrect. Similarly, for English-to-Tamil translation, all BLEU scores are below or equal to 1. We thus conclude that 2,500 examples are not enough to train an MT system for these directions, and, while we report all results here for completeness, we believe that the intrinsic evaluation paints a more complete picture.[5] We leave a scaling of our extrinsic evaluation to future work.

5 Conclusion

In this work, we made two assumptions: (1) that a non-textual modality can serve as a pivot for MT data collection, and (2) that humans tend to focus on moving objects. Based on this, we proposed to collect parallel sentences for MT using GIFs as pivots, eliminating the need for bilingual speakers and reducing annotation costs. We collected parallel sentences in English, Hindi and Tamil using our approach and conducted intrinsic and extrinsic evaluations of the obtained data, comparing our strategy to two baseline approaches which used images as pivots. According to the intrinsic evaluation, our approach resulted in parallel sentences of higher quality than either baseline.

Acknowledgments

We would like to thank the anonymous reviewers, whose feedback helped us improve this paper. We are also grateful to Aman Madaan, the first author of the M20 paper, for providing the data splits and insights from his work. Finally, we thank the members of CU Boulder's NALA Group for their feedback on this research.

A Sentence Rating Instructions

Score	Title	Description
1	Not a translation	There is no relation whatsoever between the source and the target sentence
2	Bad	Some word overlap, but the meaning isn't the same
3	Acceptable	The translation conveys the meaning to some degree but is a bad translation
4	Good	The translation is missing a few words but conveys most of the meaning adequately
5	Perfect	The translation is perfect or close to perfect

Table 6: Description of the ratings for the manual evaluation of translations.

B MTurk Instructions

Instructions for English image task

Below you will see five images. Your task is to describe each image in one English sentence. You should focus solely on the visual content presented in the image. Each sentence should be grammatically correct. It should describe the main characters and their actions, but NOT your opinions, guesses or interpretations.

- DOs
  - Please use only English words. No digits allowed (spell them out, e.g., three).
  - Sentences should neither be too short nor too long. Try to be concise.
  - Each sentence must contain a verb.
  - If possible, include adjectives that describe colors, size, emotions, or quantity.
  - Please pay attention to grammar and spelling.
  - Each sentence must express a complete idea, and make sense by itself.
  - The sentence should describe the main characters, actions, setting, and relationship between the objects.
- DONTs
  - The sentence should NOT contain any digits.
  - The sentence should NOT mention the name of a movie, film, and character.
  - The sentence should NOT mention invisible objects and actions.
  - The sentence should NOT make subjective judgments about the image.

Remember, please describe only the visual content presented in the images. Focus on the main characters and their actions.

निर्देश **(Instructions for GIF Task in Hindi)**

नीचे आपको पांच गिफ (GIF) दिखाई देंगे। आपको हर गिफ को एक वाक्य में हिंदी में समझाना है। आपको सिर्फ गिफ में जो हो रहा है उसपर ध्यान देना है। आपके वाक्य की व्याकरण सही होनी चाहिए। आपको मुख्य पात्रों और उनके कार्यों का वर्णन करना है और आपको अपनी राय नहीं देनी है।

- क्या करें -
  - कृपया केवल हिंदी शब्दों और हिंदी लिपि (देवनागरी) का उपयोग करें। किसी भी अंक को पूरी तरह लिखे (उदहारण - तीन लिखे नाकि ३)।
  - वाक्य न तो बहुत छोटे होने चाहिए और न ही बहुत लंबे। संक्षिप्त होने का प्रयास करें। वाक्य कम से कम चार शब्दों का होना चाहिए।
  - प्रत्येक वाक्य में एक क्रिया होनी चाहिए।
  - यदि संभव हो तो विशेषणों का इस्तिमाल करें जो की रंगो, आकार व भावनाओं को अच्छे से समझा सके।
  - कृपया व्याकरण और स्पेलिंग पर ध्यान दें।
  - प्रत्येक वाक्य को एक पूर्ण विचार व्यक्त करना चाहिए, और खुद से समझ में आना चाहिए।
  - आपके वाक्य को मुख्य अतिथिओ, वस्तुओ और उनके साथ हो रही चीज़ो को समझाना है।
- क्या न करें -
  - वाक्य में कोई अंक नहीं होना चाहिए।
  - वाक्य में किसी फिल्म या एक्टर का नाम नहीं होना चाहिए।
  - वाक्य में अदृश्य वस्तुओं और कार्यों का उल्लेख नहीं होना चाहिए।
  - वाक्य में अपने व्यक्तिगत राय न डालें।

याद रखें, गिफ में जो दिख रहा है उसी के बारे में लिखे। मुख्य पात्रों और उनके कार्यों पर ध्यान दें।

வழிமுறைகள் **(Instructions for GIF task in Tamil)**

கீழே ஐந்து அனிமேஷன் செய்யப்பட்ட கிப் (GIF) காட்டப்பட்டுள்ளன. ஒவ்வொரு GIF ஐ ஒரு தமிழ் வாக்கியத்தில் விவரிப்பதே உங்கள் பணி. GIF இல் உள்ள காட்சியில் மட்டுமே நீங்கள் கவனம் செலுத்த வேண்டும். GIF இல் உள்ள முக்கிய கதாபாத்திரங்களையும் அவற்றின் செயல்களையும் வர்ணிக்க வேண்டும், ஆனால் உங்கள் கருத்துக்கள், யூகங்கள் அல்லது விளக்கங்கள் அல்ல. ஒவ்வொரு வாக்கியமும் இலக்கணப்படி சரியாக இருக்க வேண்டும்.

- செய்க:
  - தமிழ் வார்தைகளை மட்டும் பயன்படுத்தவும். எண்களை வார்த்தையில் எழுதவும் (3 -> மூன்று)
  - வாக்கியங்கள் மிகக் குறுகியதாகவோ அல்லது நீண்டதாகவோ இருக்கக்கூடாது.
  - ஒவ்வொரு வாக்கியத்திலும் ஒரு வினை (செயலை குறிக்கும் வார்த்தை) இருக்க வேண்டும்.
  - முடிந்தால், வண்ணங்கள், அளவு, உணர்ச்சிகளை விவரிக்கும் வார்த்தைகளை சேர்க்கவும்.
  - இலக்கணம் மற்றும் எழுத்துப்பிழைகள் இல்லாதப்படி எழுதவும்.
  - ஒவ்வொரு வாக்கியமும் முழுமையாக இருக்க வேண்டும், மேலும் வாக்கியத்தை தனியாகப் படித்தால் அர்த்தம் புரிய வேண்டும்.।
  - வாக்கியம் GIFஇல் உள்ள முக்கிய கதாபாத்திரங்கள், செயல்கள், அமைப்பு, மற்றும் பொருள்களுக்கு இடையிலான உறவை விவரிக்க வேண்டும்.
- செய்யாதீர்:
  - வாக்கியத்தில் எந்த எண்களும் இருக்கக்கூடாது.
  - வாக்கியத்தில் எந்த திரைப்படம், மற்றும் நடிகர் அல்லது கதாபாத்திரத்தின் பெயரைக் குறிப்பிடக்கூடாது.
  - வாக்கியத்தில் கண்ணுக்கு தெரியாத பொருள்கள் மற்றும் செயல்களைக் குறிப்பிடக்கூடாது.
  - வாக்கியத்தில் தங்களின் எண்ணங்களோ தீர்மானங்களோ இருக்கக்கூடாது.

கவனிக்கவும்: அனிமேஷன் செய்யப்பட்ட GIF இல் காணும் காட்சியை மட்டும் வர்ணிக்கவும். அதில் இருக்கும் முக்கிய கதாப்பாத்திரங்கள் மற்றும் செயல்களில் கவனம் செலுத்தவும்.

Figure 2: Instructions for the data collection via images in English, via GIFs in Hindi and Tamil.
