Message from the General Chair

I am delighted to welcome you to the Joint Conference of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (ACL-IJCNLP 2021)!

We are very grateful for many people. Fei Xia, Wenjie Li (Maggie) and Roberto Navigli, as the Program Chairs, have admirably guided the work of main conference organization and management. The calm and experienced Priscilla Rasmussen has done a lot of work for the signing of contracts with virtual platform company, Underline.io, calculation of registration fees and managing the entire registration process, and communication with sponsors and exhibitors. The amazing 68-person organizing committee, who all contributed so much to make the conference successful: Local Chairs (Priscilla Rasmussen, Thepchai Supnithi, Thanaruk Theeramunkong), Tutorial Chairs (David Chiang, Min Zhang), Workshop Chairs (Kentaro Inui, Michael Strube), Student Research Workshop Chairs (Jad Kabbara, Haitao Lin, Amandalynne Paullada, Jannis Vamvas), Faculty Advisors to the Student Workshop (Jing Jiang, Rico Sennrich, Derek F. Wong, Nianwen Xue), Audio-Video Chairs (Suchathit Boonnag, Rachasak Somyanonthanakul), Conference Handbook Chair (Krit Kosawat), Demonstration Chairs (Heng Ji, Jong C. Park, Rui Xia), Diversity and Inclusion Committee Chairs (Academic Inclusion Chairs: Avirup Sil, Kayathi Chandu, Lifu Huang, Sara Rosenthal; Accessibility Chairs: Minlie Huang, Vivian Chen, Yang Feng; Financial Access Chairs: Martha Yifiru Tachbelie, Alexis Palmer, Ignatius Eziani, Manuel Mager, Nafise Moosavi; Socio-cultural Inclusion Chairs: Alvin Grissom, Xanda Schofield, Pedro Rodriguez), Local Sponsorship Chairs (Rachada Kongkrachantra, Jing Li, Kobkrit Viriyayudhakorn, Zhongyu Wei), Publications Chairs (Yuki Arase, Jing-Shin Chang, Yvette Graham), Publicity Chair (Kai-Fam Wong), Remote Presentation Chairs (Zhongjun He, Nattapol Kritsuthikul, Yadollah Yaghoobzadeh), Sustainability Chairs (Angeliki Lazaridou, Qi Zhang), Reviewer Mentoring Committe Chairs (Jing Huang, Antoine Bosselut, Christophe Gravier), Website and Conference App Chairs (Chutima Beokhaimook, Witchaworn Mankhong), Student Volunteer Coordinator (Dongyan Zhao), Ethic Advisory Committee Chairs (Malvina Nissim, Min-Yen Kan, Xanda Schofield), Social Media Committee Chairs (Luciana Benotti, Lidong Bing, Zhumin Chen, Rachele Sprugnoli, Mark Seligman), Virtual Infrastructure Committee Advisor (Hao Fang), Virtual Infrastructure Committee Chairs (Wei Lu, Krich Nasingkun, Alessandro Raganato, Shaonan Wang, Liang-Chih Yu, Jianfei Yu).

The success of the conference is inseparable from the guidance and advice of ACL Officers. Special thanks to Hinrich Schütze, Rada Mihalcea, David Yarowsky, Shiqi Zhao and Yusuke Miyao. The general chair of NAACL'2021, Dr. Kristina Toutanova provided me much advice based on her experience with NAACL'2021 organization. The friendly cooperation with NAACL'2021 and EACL'2021 workshop chairs and tutorial chairs is very important and is of mutual benefit to each other.

Sponsors and exhibitors are always very important. We are extremely grateful to all sponsors for their continuing support to help our conferences be very successful.

And finally, I would like to thank every one of you for making ACL-IJCNLP'2021 such a success by submitting papers and demos, serving as area chairs and reviewers, session chairs, invited speakers and volunteers, and by joining us in virtual environment.

Welcome and hope you all enjoy the conference!

Chengqing Zong

ACL-IJCNLP'2021 General Chair
June 28, 2021

Message from the Program Chairs

Welcome to the Joint Conference of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (ACL-IJCNLP 2021)! ACL-IJCNLP 2021 has a special historical significance as this is a particularly exciting period: our field has grown dramatically, NLP research is now ubiquitous in products, and the barrier to entry to the field has lowered considerably. Like ACL 2020, ACL-IJCNLP 2021 is held as a virtual conference again due to the worldwide COVID-19 pandemic which has lasted for more than one year. We are very grateful for all of your support and contributions during this difficult time, which make this conference special and memorable.

Abstract and Full-paper Submissions: To synchronize with NAACL 2021, our conference's review cycle was about three weeks shorter than that of ACL 2020. To make the short review cycle work, we introduced an abstract submission step, which required authors to submit an abstract by Jan 25, 2021, one week before the full-paper submission deadline on Feb 1, 2021. This extra step gave NAACL 2021 authors an opportunity to withdraw their papers from NAACL 2021 and submit them to ACL-IJCNLP 2021 based on feedback from NAACL 2021's rebuttal period. In total, we received $4,266$ abstract submissions and $3,350$ full paper submissions.

Tracks: The submissions were assigned to one of 24 topic tracks. The tracks were similar to those used in previous conferences but with a few changes:

1. Based on the number of submissions in previous conferences, we followed NAACL 2021 and combined two tracks ("Semantics: Sentence Level" and "Semantics: Textual Inference and Other Areas of Semantics") into a single track "Semantics: Sentence-level Semantics, Textual Inference and Other areas".

2. To accommodate a wider and more diverse area, we changed the name of the "Computational Social Science and Social Media" track to "Computational Social Science and Cultural Analytics".

3. Following NAACL 2021, we combined the "Theory and Formalism" with the "Cognitive Modeling and Psycholinguistics" areas into "Linguistic theories, Cognitive Modeling and Psycholinguistics". This track is designed to encourage submissions targeted to theoretical underpinning of NLP models which had little/small presence in the past ACL conferences.

4. We introduced a new theme: "NLP for Social Good (NLP4SG)". The application of AI to provide positive social impact has been an important topic in recent years. However, to date, this has not been a topic highlighted at the ACL main conference. This track is designed to invite submissions that can provide insights for the ACL-IJCNLP community on the topic of NLP for Social Good as well as how NLP could potentially cause or be used for social harm.

Program Committee: To meet the reviewer demands of a growing conference without compromising review quality, we started recruiting Senior Area Chairs (SACs) and Area Chairs in early fall 2020. Then we initiated a large-scale reviewer recruiting effort in Nov 2020. We compiled a big list of reviewers from previous conferences, and sent out invitations to more than $9,000$ candidates, asking the ones who were willing to serve to fill out a Microsoft reviewer form. About $4,400$ of the invitees filled out the form. We then worked with SACs and ACs in selecting reviewers and assigning them to appropriate tracks. The whole process of forming the program committee was very complex and took several months to complete and, at the end, we have the largest ever program committee in the history of ACL with 60 SACs, 323 ACs, and $3,685$ primary reviewers.

Reviewer Mentoring Program: Review quality is crucial for the success of a large conference like ACL. Thus, it is of central importance for our community to mentor and train new reviewers in order to keep up with the community's rapid growth, both in terms of submissions and in terms of new members of the community. Therefore, this year we continued the reviewer mentoring program launched with ACL 2020. Ultimately, the goal of this program is to provide long-needed mentoring to new reviewers. We formed a reviewer mentoring committee. Collaborating with them and SACs, we paired Area Chairs (mentors) with first-time ACL reviewers (mentees, often Ph.D. students or junior researchers) during the paper assignment process. The mentees would submit reviews early for the mentors to provide feedback, and the mentees would then revise their reviews based on the feedback. In addition, to help all the reviewers, the reviewer mentoring committee created several videos including the presentation of the mentoring program, a general reviewing tutorial, information about the review form used for this conference, and guidelines on how to consider ethical issues reproducibility in submissions.

Ethical review: The ethical impact and potential applications of our research should be an important consideration for research design, and as artificial intelligence is becoming more mainstream, these issues are increasingly pertinent. To address the potential ethical concerns, we allowed authors to include a broader impact statement or other discussion of ethics in the paper, which does not count towards the page limit. We formed an Ethics Advisory Committee (EAC) with three co-chairs and 57 EAC reviewers. During the review process, reviewers were asked to flag submissions with ethical concerns. The EAC then reviewed all the flagged papers to determine whether the papers should be (a) accepted as is, (b) conditional accepted (with specification of what must be addressed in the camera-ready version in order for the condition to be removed), or (c) rejected on ethical grounds (with explanation of the reject decision). Based on their decisions and the SAC recommendations, we made the accept/reject decisions and sent out acceptance notifications on May 6, 2021. The whole process was explained in a blog posted to the conference website on May 10, 2021. The camera-ready version of the conditionally accepted papers were checked by the EAC again. The EAC informed us that all these papers had made satisfactory revisions and thus we removed the condition on the papers. The whole process was very complex, and we were grateful for the hard work of the EAC and the authors.

Acceptance to Main Conference: After the review process, out of the $3,350$ full submissions, 710 papers (139 short, 571 long) were accepted into the main conference. With an acceptance rate of 21.2%, ACL-IJCNLP 2021 continues to be a highly competitive conference. Based on the nominations from Senior Area Chairs, we selected 28 papers as candidates for the Best Paper awards. We formed a Best Paper Award Committee, who went over all the candidates and selected one best paper, one best theme paper and six outstanding papers.

Findings: To continue the success of Findings at EMNLP 2020, we decided to introduce Findings papers, which are papers that are not accepted for publication in the main conference, but nonetheless have been assessed by the Program Committee as solid work with sufficient substance, quality and novelty. Out of the $3,350$ full submissions, 493 papers were invited to be included in the Findings. Thirty-six papers declined the offer, leading to 457 papers (118 short and 339 long) to be published in the Findings of ACL: ACL-IJCNLP 2021. To increase the visibility of the Finding papers, the authors of such papers can choose to make a 3-minute video to be included in the virtual conference site. Our workshop chairs also helped to pair Findings papers with ACL-IJCNLP 2021 workshops for the possibility of Finding papers to be presented at those workshops.

TACL and CL papers: Continuing the tradition, ACL-IJCNLP 2021 will also feature 27 papers that were published at Transactions of the Association for Computational Linguistics (TACL) and 5 papers from the journal of Computational Linguistics (CL).

Keynote speakers: Another highlight of our program is three exciting keynote talks, given by Prof. Christopher Potts (Stanford University), Prof. Helen Meng (Chinese University of Hong Kong), and Dr. Alejandrina Cristia (École Normale Supérieure).

ACL-IJCNLP 2021 would not be possible without the support from the community. There are many people we would like to thank for their significant contributions! First, we would like to thank our Program Committee, whose names are included in the Program Committee pages in the proceedings:

- Our awesome 60 **Senior Area Chairs** who were instrumental in every aspect of the review process (e.g., AC/reviewer selection, paper assignment, recommendation for paper acceptance, nomination of best papers and outstanding reviewers). For many of them, the scope of their responsibilities was equivalent to chairing a small conference. The 323 **Area Chairs** who led paper review discussions, wrote meta-reviews, and mentored junior reviewers. In addition, they have helped SACs with reviewer selection, paper assignment, and many other tasks.
- Our 3,685 **primary reviewers** and 262 **secondary reviewers** who provided valuable feedback to the authors. Special thanks to those who stepped in at the last minute to serve as emergency reviewers.

Second, we would like to thank many ACL-IJCNLP 2021 committees that we have worked with, including:

- Our **Best Paper Selection Committee**, Bonnie Webber, Tim Baldwin and Ellen Riloff for selecting best papers and outstanding papers under a very tight schedule.
- Our **Ethics Advisory Committee**, chaired by Min-Yen Kan, Malvina Nissim, and Xanda Schofield, for their hard work to ensure that all the accepted papers have addressed the ethical issues appropriately.
- Our **Reviewer Mentoring Committee**, Jing Huang, Antoine Bosselut and Christophe Gravier, for preparing mentoring materials and providing review support to first-time reviewers.
- Our **Publication Co-Chairs**, Jing-Shin Chang, Yuki Arase, and Yvette Graham, for their tremendous effort in making the proceedings.
- Our **Social Media Committee**, chaired by Luciana Benotti, Lidong Bing, Zhumin Chen, Mark Seligman, and Rachele Sprugnoli, for effectively communicating conference updates and other urgent information on social media platforms.
- The **Workshop Chairs**, Kentaro Inui and Michael Strube, for connecting Findings paper authors with individual workshops for possible presentations.
- The **Website & Conference App Chairs**, Chutima Beokhaimook and Witchaworn Mankhong, for making numerous updates to the conference website.

Third, we would like to thank many people who help us with various software used for the conference:

- Rich Gerber at **SoftConf**, who is always quick to respond to our emails and resolve difficulties we encountered with the START system.
- C. M. Downey at the University of Washington, who helped us to extend and run the external paper assignment system developed by Graham Neubig.
- Caterina Lacerra and Rocco Tripodi at the Sapienza University of Rome, who helped us in the creation of internal spreadsheets and processing scripts.
- The whole **Underline** team (Sol Rosenberg, Fun Lee, Jordan Young, Daniel Luise) who created a virtual site for the conference.

As Program chairs, we were in charge of several dozen tasks and many of them were new to us. We would not be able to complete the tasks without the advice from our colleagues, including:

- Our **General Chair** Chengqing Zong, who has been very supportive throughout the whole process, giving us the flexibility to innovate while providing an invaluable sounding board.
- The **Program Co-Chairs of ACL 2020**, Joyce Chai, Natalie Schluter and Joel Tetreault; the **Program Co-Chairs of EMNLP 2020**, Trevor Cohn, Yulan He and Yang Liu; the **Program Co-Chairs of NAACL 2021**, Anna Rumshisky, Luke Zettlemoyer and Dilek Hakkani-Tur, for generously sharing their experience, documentation, and advice in organizing ACL conferences and for answering our questions, often on short notice.
- **ACL Executive Committee**, especially Rada Mihalcea (the **ACL President**) and Hinrich Schütze (the **ACL Past President**), Shiqi Zhao (**Secretary**), Priscilla Rasmussen (**Business Manager**), Nitin Madnani (**Member-at-large**), to help us sort through various issues.
- **TACL Editors-in-Chief** Ani Nenkova and Brian Roark, **TACL Editorial Assistant** Cindy Robinson, and **CL Editor-in-Chief** Hwee Tou Ng for coordinating TACL and CL presentations at the conference.

We would also like to thank all the authors ($8,757$ in total) who submitted their work to the conference. Although we were only able to accept a small percentage of the submissions, your hard work makes this conference exciting and our community strong.

Last, but not least, we thank our students, interns, postdocs, colleagues, and families for being so understanding and supportive when we were swamped by countless conference deadlines and meetings.

Our deepest gratitude is to all of you. We hope you will enjoy the conference.

Fei Xia, University of Washington
Wenjie Li, The Hong Kong Polytechnic University
Roberto Navigli, Sapienza University of Rome

ACL-IJCNLP 2021 Program Committee Co-Chairs

Organizing Committee

General Chair:

Chengqing Zong, Institute of Automation, Chinese Academy of Sciences

Program Committee Co-Chairs:

Wenjie Li, The Hong Kong Polytechnic University
Roberto Navigli, Sapienza University of Rome
Fei Xia, University of Washington

Local Organization Committee Co-Chairs:

Priscilla Rasmussen, Association for Computational Linguistics (ACL)
Thepchai Supnithi, National Electronics and Computer Technology Center (NECTEC)
Thanaruk Theeramunkong, The Artificial Intelligence Association of Thailand and Sirindhorn International Institute of Technology (SIIT), Thammasat University

Tutorial Chairs:

David Chiang, University of Notre Dame
Min Zhang, Soochow University

Workshop Chairs:

Kentaro Inui, Tohoku University
Michael Strube, GmbH Heidelberg

Student Research Workshop Chairs:

Jad Kabbara, McGill University and the Montreal Institute for Learning Algorithms (MILA)
Haitao Lin, Institute of Automation, Chinese Academy of Sciences
Amandalynne Paullada, University of Washington
Jannis Vamvas, Universität Zürich

Faculty Advisors to the Student Research Workshop:

Jing Jiang, Singapore Management University
Rico Sennrich, University of Edinburgh
Derek F. Wong, University of Macau
Nianwen Xue, Brandeis University

Demo Chairs:

Heng Ji, University of Illinois at Urbana-Champaign
Jong C. Park, Korea Advanced Institute of Science and Technology
Rui Xia, Nanjing University of Science and Technology

Publications Chairs:

Yuki Arase, Osaka University
Jing-Shin Chang, National Chi-Nan University
Yvette Graham, Trinity College Dublin

Publicity Chair:

Kai-Fam Wong, The Chinese University of Hong Kong

Sponsorship Co-Chairs:

Rachada Kongkrachantra, Thammasat University
Jing Li, The Hong Kong Polytechnic University
Kobkrit Viriyayudhakorn, iApp Technology Co., Ltd.
Zhongyu Wei, Fudan University

Diversity & Inclusion (D&I) Chairs:

Sub-Committee of Childcare ++ Accessibility:

Leader: Minlie Huang, Tsinghua University
Member: Vivian Chen, National Taiwan University
Member: Yang Feng, Institute of Computing Technology, Chinese Academy of Sciences

Sub-Committee of Academic Inclusion:

Leader: Avirup Sil, IBM
Member: Kayathi Chandu, Carnegie Mellon University
Member: Lifu Huang, Virginia Tech
Member: Sara Rosenthal, IBM Research AI

Sub-Committee of Financial Access:

Leader: Alexis Palmer, University of Colorado Boulder
Leader: Martha Yifiru Tachbelie, Addis Ababa University
Member: Ignatius Eziani, Lancaster University
Member: Manuel Mager, University of Stuttgart
Member: Nafise Moosavi, TU Darmstadt

Sub-Committee of Socio-cultural Inclusion:

Leader: Alvin Grissom, Haverford College
Member: Pedro Rodriguez, University of Maryland, College Park
Member: Xanda Schofield, Harvey Mudd College

Ethics Advisory Committee (EAC):

Min-Yen Kan, National University of Singapore
Malvina Nissim, University of Groningen
Xanda Schofield, Harvey Mudd College

Sustainability Chairs:

Angeliki Lazaridou, DeepMind
Qi Zhang, Fudan University

Audio-Video Chairs:

Suchathit Boonnag, AIAT
Rachasak Somyanonthanakul, Rangsit University

Remote Presentation Chairs:

Zhongjun He, Baidu Co.
Nattapol Kritsuthikul, NECTEC, NSTDA
Yadollah Yaghoobzadeh, University of Tehran

Virtual Infrastructure Committee (VIC):

Advisor:

Hao Fang, Microsoft Semantic Machines

Co-Chairs:

Wei Lu, Singapore University of Technology and Design
Krich Nasingkun, National Electronics and Computer Technology Center
Alessandro Raganato, University of Helsinki
Shaonan Wang, Institute of Automation, Chinese Academy of Sciences
Jianfei Yu, Nanjing University of Science and Technology
Liang-Chih Yu, Yuan Ze University

Reviewer Mentoring Committee Chairs:

Antoine Bosselut, Stanford University
Christophe Gravier, Universite de Saint-Etienne/Lyon
Jing Huang, JD AI Research

Social Media Committee Co-Chairs:

Luciana Benotti, National University of Cordoba
Lidong Bing, DAMO Academy, Alibaba Group
Zhumin Chen, Shandong University
Mark Seligman, Speechmorphing, Inc.
Rachele Sprugnoli, Università Cattolica del Sacro Cuore

Handbook Chair:

Krit Kosawat, NECTEC, NSTDA

Website & Conference App Chairs:

Chutima Beokhaimook, Rangsit University
Witchaworn Mankhong, NECTEC, NSTDA

Student Volunteer Coordinator:

Dongyan Zhao, Peking University

Technical Support:

C. M. Downey, University of Washington
Caterina Lacerra, Sapienza University of Rome
Rocco Tripodi, University of Bologna
Naoki Okada, Osaka University
Masato Yoshinaka, Osaka University

Program Committee

Program Chairs:

Fei Xia, University of Washington
Wenjie Li, The Hong Kong Polytechnic University
Roberto Navigli, Sapienza University of Rome

Senior Area Chairs and Area Chairs:

(Senior area chairs are in bold.)

Computational Social Science and Cultural Analytics:

David Jurgens, **Paolo Rosso**, **Noah Smith**, Timothy Baldwin, Cristina Bosco, Antoine Doucet, Manuel Montes, Alice Oh, Simone Paolo Ponzetto, Sara Rosenthal, Thamar Solorio, Chenhao Tan, Oren Tsur, Leo Wanner, Diyi Yang

Dialogue and Interactive Systems:

Minlie Huang, **Gina-Anne Levow**, **Jason Williams**, Luciana Benotti, Y-Lan Boureau, Yunbo Cao, Asli Celikyilmaz, Yun-Nung Chen, Heriberto Cuayahuitl, Emily Dinan, Maryam Fazel-Zarandi, Kallirroi Georgila, Alborz Geramifard, Matthew Henderson, Ryuichiro Higashinaka, Kentaro Inui, Casey Kennington, Kazunori Komatani, Sungjin Lee, Rebecca J. Passonneau, Giuseppe Riccardi, Ethan Selfridge, Gabriel Skantze, Ruihua Song, David Traum, Stefan Ultes, Tsung-Hsien Wen, Wei Wu, Rui Yan, Kai Yu, Zhou Yu, Wei-Nan Zhang

Discourse and Pragmatics:

Vera Demberg, **Michael Strube**, Jacob Andreas, Chloé Braud, Sadao Kurohashi, Sharid Loáiciga, Nafise Sadat Moosavi

Ethics in NLP:

Ryan Georgi, **Dirk Hovy**, Kai-Wei Chang, Karën Fort, Alvin Grissom II, Margot Mieskes, Vinodkumar Prabhakaran

Information Extraction:

Yunyao Li, **Hoifung Poon**, **Dan Roth**, Alan Akbik, Christos Christodoulopoulos, Leon Derczynski, Jacob Eisenstein, Luheng He, Parisa Kordjamshidi, Mausam, Stephen Mayhew, Makoto Miwa, Lluís Màrquez, Thien Huu Nguyen, Qiang Ning, Haoruo Peng, Roi Reichart, Xiang Ren, Alan Ritter, Alla Rozovskaya, Kevin Small, Yangqiu Song, Vivek Srikumar, Shashank Srivastava, Elior Sulem, Chen-Tse Tsai, William Yang Wang, Wenpeng Yin

Information Retrieval and Text Mining:

Hang Li, **Gabriella Pasi**, Sophia Ananiadou, Mohand Boughanem, Nicola Ferro, Nazli Goharian, Seung-won Hwang, Jing Jiang, Jian-Yun Nie, Raffaele Perego, Suzan Verberne, Quan Wang, Gerard de Melo

Interpretability and Analysis of Models for NLP:

Anna Rogers, **Sameer Singh**, **Xu Sun**, Afra Alishahi, Jasmijn Bastings, Yonatan Belinkov, Danushka Bollegala, Grzegorz Chrupala, Bhuwan Dhingra, Sebastian Gehrmann, Wei Lu, Marco Tulio Ribeiro, Anders Søgaard, Ian Tenney, Byron Wallace

Language Generation:

Michel Galley, **Michael White**, **Jiajun Zhang**, Anya Belz, Giuseppe Carenini, Nina Dethlefs, Mark Dras, Michael Elhadad, Angela Fan, Mary Ellen Foster, Liang Huang, Shujian Huang, Yangfeng Ji, Ioannis Konstas, Sujian Li, Lili Mou, Myle Ott, Ankur P. Parikh, Owen Rambow, Stephen Roller, Advaith Siddharthan, Jinsong Su, Duyu Tang, Zhiguo Wang, Yizhe Zhang

Language Grounding to Vision, Robotics and Beyond:

Mohit Bansal, **Hannaneh Hajishirzi**, Yoav Artzi, Joyce Chai, Nancy Chen, Desmond Elliott, Chuang Gan, Zhe Gan, Ani Kembhavi, Radu Soricut, Jesse Thomason, Mark Yatskar

Linguistic Theories, Cognitive Modeling and Psycholinguistics:

Roger Levy, **James Pustejovsky**, Alexander Clark, Afsaneh Fazly, Naomi Feldman, Tal Linzen, Kyle Mahowald

Machine Learning for NLP:

Ming-Wei Chang, **Kevin Duh**, **Tie-Yan Liu**, **Sebastian Ruder**, Waleed Ammar, Yuki Arase, Niranjan Balasubramanian, Loïc Barrault, Daniel Beck, Yonatan Bisk, Wray Buntine, Allyson Ettinger, Matthias Gallé, Marjan Ghazvininejad, Mohit Iyyer, Shafiq Joty, Sarvnaz Karimi, Hideto Kazawa, Junyi Jessy Li, Zachary Lipton, Yang Liu, Zhiyuan Liu, Daichi Mochihashi, Naoaki Okazaki, Jong Park, Nanyun Peng, Tao Qin, Sujith Ravi, Mrinmaya Sachan, Natalie Schluter, Pontus Stenetorp, Karl Stratos, Jun Suzuki, Lu Wang, Dani Yogatama, Koichiro Yoshino

Machine Translation and Multilinguality:

Philipp Koehn, **Qun Liu**, **François Yvon**, Wilker Aziz, Marine Carpuat, Boxing Chen, Colin Cherry, Marta R. Costa-jussà, Marcello Federico, Yang Feng, Andrew Finch, Mark Fishel, Jiatao Gu, Gholamreza Haffari, Zhongjun He, Mu Li, Liangyou Li, Junhui Li, Kenton Murray, Jan Niehues, Maja Popović, Artem Sokolov, Sara Stymne, Longyue Wang, Tong Xiao

Multidisciplinary and Area Chair COI:

Iryna Gurevych, **Andreas Vlachos**, Dan Goldwasser, Omer Levy, Diarmuid Ó Séaghdha

NLP Applications:

Jimmy Lin, **Vincent Ng**, **Min Zhang**, Beata Beigman Klebanov, Luigi Di Caro, Sanda Harabagiu, Mamoru Komachi, Juntao Li, Jing Li, Yang Liu, David Mimno, Preslav Nakov, Tristan Naumann, Emily Prud'hommeaux, David Smith, Lijun Wu, Jingjing Xu, Min Yang, Jing Yuan, Marcos Zampieri, Wei Zhang

Phonology, Morphology and Word Segmentation:

Yan Song, **Nianwen Xue**, Ryan Cotterell, Xipeng Qiu, Attapol Rutherford

Question Answering:

Jennifer Chu-Carroll, **Alessandro Moschitti**, **Furu Wei**, Roberto Basili, Jordan Boyd-Graber, Weiwei Cheng, Eunsol Choi, Danilo Croce, Li Dong, Yansong Feng, Simone Filice, Radu Florian, Zornitsa Kozareva, Jing Liu, Ramesh Nallapati, Cicero Nogueira dos Santos, Siddharth Patwardhan, Matthias Petri, Oleg Rokhlenko, Minjoon Seo, Avi Sil, Luca Soldaini, Anh Tuan Luu, Olga Uryupina, Thuy Vu, Fabio Massimo Zanzotto

Resources and Evaluation:

Samuel Bowman, **Nancy Ide**, Johan Bos, Tommaso Caselli, Jesse Dodge, Kyle Gorman, Daniel Khashabi, Jin-Dong Kim, Jonathan K. Kummerfeld, John P. McCrae, Joakim Nivre, Massimo Poesio, Saku Sugawara, Adina Williams

Semantics: Lexical:

Mona Diab, **Mohammad Taher Pilehvar**, Marianna Apidianaki, Eduardo Blanco, Jose Camacho-Collados, Manaal Faruqui, Tommaso Pasini, German Rigau, Vered Shwartz, Veselin Stoyanov, Aline Villavicencio, Ivan Vulić, Yadollah Yaghoobzadeh, Yi Zhang

Semantics: Sentence-level Semantics, Textual Inference and Other areas:

Doug Downey, **Raymond Mooney**, **Xiaodan Zhu**, Iz Beltagy, Jonathan Berant, Chandra Bhagavatula, Chris Callison-Burch, Danqi Chen, Greg Durrett, Katrin Erk, Francis Ferraro, Daniel Gildea, Edward Grefenstette, Robin Jia, Douwe Kiela, Mike Lewis, Quan Liu, Christopher Potts, Rachel Rudinger, Mo Yu

Sentiment Analysis, Stylistic Analysis, and Argument Mining:

Bing Liu, **Rada Mihalcea**, **Saif Mohammad**, Alexandra Balahur, Lidong Bing, Julian Brooke, Anna Feldman, Yulan He, Lun-Wei Ku, John Lawrence, Maria Liakata, Smaranda Muresan, Soujanya Poria, Bing Qin, Serena Villata, Xiaojun Wan

Speech and Multimodality:

Haizhou Li, **Florian Metze**, Julia Hockenmaier, Preethi Jyothi, Herman Kamper, Dorothea Kolossa, Hung-yi Lee, Lei Xie

Summarization:

Mirella Lapata, **Horacio Saggion**, Florian Boudin, Jackie Chi Kit Cheung, Katja Filippova, Peter Liu, Fei Liu, Shashi Narayan, Manabu Okumura, Laura Perez-Beltrachini, Maxime Peyrard, Laura Plaza, Xingxing Zhang

Syntax: Tagging, Chunking and Parsing:

Slav Petrov, **Emily Pitler**, Carlos Gómez-Rodríguez, Daniel Hershcovich, Marco Kuhlmann, Yuji Matsumoto, Reut Tsarfaty, Yannick Versley, Yue Zhang, Miryam de Lhoneux

Theme:

Jinho Choi, **Joel Tetreault**, Tim Althoff, Isabelle Augenstein, Steven Bethard, Courtney Napoles, Brendan O'Connor, Yulia Tsvetkov, Rob Voigt

Best Paper Selection Committee:

Timothy Baldwin, Ellen Riloff, Bonnie Webber

Primary Reviewers:

Asma Ben Abacha, Jade Abbott, Ahmed Abdelali, Muhammad Abdul-Mageed, Anne Abeille, Omri Abend, Ahmed AbuRa'ed, Abdalghani Abujabal, Pablo Accuosto, Manoj Acharya, Judit Ács, Heike Adel, Somak Aditya, Stergos Afantenos, Haithem Afli, Sachin Agarwal, Sanchit Agarwal, Shubham Agarwal, Sumeet Agarwal, Rodrigo Agerri, Karan Aggarwal, Piush Aggarwal, Manex Agirrezabal, Željko Agić, Ameeta Agrawal, Priyanka Agrawal, Sweta Agrawal, Gustavo Aguilar, Roee Aharoni, Wasi Ahmad, Natalie Ahn, Lars Ahrenberg, Aman Ahuja, Chaitanya Ahuja, Mohammad Ailannejadi, Akiko Aizawa, Reina Akama, Mohammad Akbari, Alan Akbik, Ahmet Aker, Farhad Akhbardeh, Md. Keynote Talk: Advancing Technological Equity in Speech and Language Processing

Helen Meng
The Chinese University of Hong Kong (CUHK)

Abstract: Accelerating advances in AI and deep neural networks have powered the proliferation of speech and language technologies in applications such as virtual assistants, smart speakers, reading machines, etc. The technologies have performed impressively well, achieving human parity in speech recognition accuracies and speech synthesis naturalness. As these technologies continue to permeate our daily lives, they need to support diverse users and usage contexts with inputs that deviate from the mainstream. Examples include non-native speakers, code-switching, speech carrying myriad emotions and styles, and speakers with impairments and disorders. Under such contexts, existing technologies often suffer performance degradations and fail to fulfill the needs of the users. The crux of the problem lies in data scarcity and data sparsity, which are exacerbated by high data variability.

This talk presents an overview of some of the approaches we have used to address the challenges of data shortage, positioned at various stages along the processing pipeline. They include: data augmentation based on speech signal perturbations, use of pre-trained representations, learning speech representation disentanglement, knowledge distillation architectures, meta-learned model re-initialization, as well as adversarially trained models. The effectiveness of these approaches are demonstrated through a variety of applications, including accented speech recognition, dysarthric speech recognition, code-switched speech synthesis, disordered speech reconstruction, one-shot voice conversion and exemplar-based emotive speech synthesis. These efforts strive to develop speech and language technologies that can gracefully adapt and accommodate a diversity of user needs and usage contexts, in order to achieve technological equity in our society.

Bio: Helen Meng is Patrick Huen Wing Ming Professor of Systems Engineering and Engineering Management at The Chinese University of Hong Kong (CUHK). Her research interests include speech and language technologies to support multilingual and multimodal human-computer interactions, eLearning and assistive technologies, as well as big data decision analytics using AI. She leads the interdisciplinary research team that received the first Theme-based Research Scheme Project in Artificial Intelligence in 2019 from the Hong Kong SAR Government's Research Grants Council. She is Chair of the Curriculum Development in the CUHK-JC AI4Future Project, which has developed the courseware for pre-tertiary AI education being taught in a growing number of participating secondary schools across Hong Kong.

Helen received all her degrees from MIT. She is the Founding Director of the CUHK Ministry of Education (MoE)-Microsoft Key Laboratory for Human-Centric Computing and Interface Technologies (since 2005), Tsinghua-CUHK Joint Research Center for Media Sciences, Technologies and Systems (since 2006), and Stanley Ho Big Data Decision Analytics Research Center (since 2013). Previously, she has served as CUHK Faculty of Engineering's Associate Dean (Research), Chairman of the Department of Systems Engineering and Engineering Management, Editor-in-Chief of the IEEE Transactions on Audio, Speech and Language Processing, Member of the IEEE Signal Processing Society Board of Governors, ISCA Board Member and presently member of the IEEE SPS Awards Board and ISCA International Advisory Council. She was elected APSIPA's inaugural Distinguished Lecturer 2012-2013 and ISCA Distinguished Lecturer 2015-2016. Her awards include the Ministry of Education Higher Education Outstanding Scientific Research Output Award 2009, Microsoft Research Outstanding Collaborator Award 2016 (1 in 32 worldwide), IBM Faculty Award 2016, HKPWE Outstanding Women Professionals and Entrepreneurs Award 2017 (1 in 20 since 1999), Hong Kong ICT Silver Award 2018 in Smart Inclusion, 2019 IEEE SPS Leo L. Beranek Meritorious Service Award and various best paper

awards. Helen has served in a number of government appointments, which include memberships in the Steering Committee of Hong Kong's Electronic Health Record Sharing, Social Welfare Department's Joint Committee on Information Technology for the Social Welfare Sector and Advisory Committee on financing social welfare services. She is also a member of the AI4SDGs AI for Children Working Group. Helen is a Fellow of IEEE, ISCA, HKIE and HKCS.

Keynote Talk: Learning and Processing Language from Wearables: Opportunities and Challenges

Alejandrina Cristia
Laboratoire de Sciences Cognitives et de Psycholinguistique,
Département d'études cognitives, ENS, EHESS, CNRS, PSL University

Abstract: Recent years have seen tremendous improvement in the ease with which we can collect naturalistic language samples via devices worn over long periods of time. These allow unprecedented access to ego-centered experiences in language perceived and produced, including by young children. For example, in a newly-formed consortium, we pulled together over 40k hours of audio, collected from 1,001 children growing up in industrialized or hunter-horticulturalist populations, located in one of 12 countries. Such data are interesting for many purposes, including as 1. fodder for unsupervised language learning models aimed at mimicking what the child does; 2. indices of early language development that can be used to assess the impact of behavioral and pharmacological interventions; and 3. samples of the natural use of language(s) in low-resource and multilingual settings. The technology allowing to carve out interesting information from these large datasets, however, is lagging behind – but this may not be such a bad thing after all, since the ethical, technical, and legal handling of such data also need some work to increase the chances that the net impact of research based on this technique is positive. In this talk, I draw from cutting-edge research building on long-form recordings from wearables and a framework for doing the most good we can (effective altruism) to highlight surprising findings in early language acquisition, and delineate key priorities for future work.

Bio: Alejandrina Cristia is a senior researcher at the Centre National de la Recherche Scientifique (CNRS), leader of the Language Acquisition Across Cultures team, and director of the Laboratoire de Sciences Cognitives et Psycholinguistique (LSCP) cohosted by the Ecole Normale Supérieure, EHESS, and PSL. In 2021, she is an invited researcher in the Foundations of Learning Program of the Abdul Latif Jameel Poverty Action Lab (J-PAL), and a guest researcher at the Max Planck Institute for Evolutionary Anthropology. Her long-term aim is to answer the following questions: What are the linguistic representations that infants and adults have? Why and how are they formed? How may learnability biases shape the world's languages? To answer these questions, she combines multiple methodologies including spoken corpora analyses, behavioral studies, neuroimaging (NIRS), and computational modeling. This interdisciplinary approach has resulted in over 100 publications in pscyhology, linguistics, and development journals as well as IEEE and similar conferences. With an interest in cumulative, collaborative, and transparent science, she contributed to the creation of the first meta-meta-analysis platform (metalab.stanford.edu) and several international networks, including saliently the LangVIEW consortium that is leading /L+/, the First truly global summer/winter school on language acquisition.[1] She received the 2017 John S. McDonnell Scholar Award in Understanding Human Cognition, the 2020 Médaille de Bronze CNRS Section Linguistique, and an ERC Consolidator Award (2021-2026) for the ExELang[2] project.

Keynote Talk: Reliable Characterizations of NLP Systems as a Social Responsibility

Christopher Potts
Stanford University

Abstract: This is an incredible moment for NLP. We all routinely work with models whose capabilities would have seemed like science fiction just two decades ago, powerful organizations eagerly await our latest results, and NLP technologies are playing an increasingly large role in shaping our society. As a result, all of us in the NLP community are likely to participate in research that will contribute (to varying degrees and perhaps only indirectly) to technologies that will impact many people's lives, with both positive and negative consequences – for example, technologies that broaden accessibility, enhance creative self-expression, heighten surveillance, and create propaganda. What can we do to fulfill the social responsibility that this brings? As a (very) partial answer to this question, I will review a number of important recent developments, spanning many research groups, concerning dataset creation, model introspection, and system assessment. Taken together, these ideas can help us more reliably characterize how NLP systems will behave, and more reliably communicate this information to a wider range of potential users. In this way, they can help us meet our obligations to the people whose lives are impacted by the results of our research.

Bio: Christopher Potts is Professor and Chair of Linguistics and Professor (by courtesy) of Computer Science at Stanford, and a faculty member in the Stanford NLP Group and the Stanford AI Lab. His group uses computational methods to explore how emotion is expressed in language and how linguistic production and interpretation are influenced by the context of utterance. This research combines methods from linguistics, cognitive psychology, and computer science, in the service of both scientific discovery and technology development. He was previously Chief Scientist at Roam Analytics, a start-up focused on applying NLP in healthcare and the life sciences (now Parexel AI Labs). He is a long-time Action Editor at TACL, a frequent Area Chair at ACL conferences, and currently an Ethics Committee co-chair for EMNLP 2021.

Table of Contents

Conference Program

Monday, August 2, 2021 (all times UTC+0)

08:15–08:35 ***Opening Session***

08:40–09:00 ***Presidential Address***

09:00–10:00 ***Keynote 1. Helen Meng: Advancing Technological Equity in Speech and Language Processing***

Session 1A: Computational Social Science and Cultural Analytics 1

10:00–10:10 *Investigating label suggestions for opinion mining in German Covid-19 social media*
Tilman Beck, Ji-Ung Lee, Christina Viehmann, Marcus Maurer, Oliver Quiring and Iryna Gurevych

10:10–10:20 *How Did This Get Funded?! Automatically Identifying Quirky Scientific Achievements*
Chen Shani, Nadav Borenstein and Dafna Shahaf

10:20–10:30 *Engage the Public: Poll Question Generation for Social Media Posts*
Zexin Lu, Keyang Ding, Yuji Zhang, Jing Li, Baolin Peng and Lemao Liu

10:30–10:40 *HateCheck: Functional Tests for Hate Speech Detection Models*
Paul Röttger, Bertie Vidgen, Dong Nguyen, Zeerak Waseem, Helen Margetts and Janet Pierrehumbert

10:40–10:50 *Unified Dual-view Cognitive Model for Interpretable Claim Verification*
Lianwei Wu, Yuan Rao, Yuqian Lan, Ling Sun and Zhaoyin Qi

10:50–10:57 *Catchphrase: Automatic Detection of Cultural References*
Nir Sweed and Dafna Shahaf

Session 1B: Language Generation 1

10:00–10:10 *DeepRapper: Neural Rap Generation with Rhyme and Rhythm Modeling*
Lanqing Xue, Kaitao Song, Duocai Wu, Xu Tan, Nevin L. Zhang, Tao Qin, Wei-Qiang Zhang and Tie-Yan Liu

10:10–10:20 *PENS: A Dataset and Generic Framework for Personalized News Headline Generation*
Xiang Ao, Xiting Wang, Ling Luo, Ying Qiao, Qing He and Xing Xie

10:20–10:30 *Enhancing Content Preservation in Text Style Transfer Using Reverse Attention and Conditional Layer Normalization*
Dongkyu Lee, Zhiliang Tian, Lanqing Xue and Nevin L. Zhang

10:30–10:40 *Mention Flags (MF): Constraining Transformer-based Text Generators*
Yufei Wang, Ian Wood, Stephen Wan, Mark Dras and Mark Johnson

10:40–10:50 *Generalising Multilingual Concept-to-Text NLG with Language Agnostic Delexicalisation*
Giulio Zhou and Gerasimos Lampouras

10:50–10:57 *On Training Instance Selection for Few-Shot Neural Text Generation*
Ernie Chang, Xiaoyu Shen, Hui-Syuan Yeh and Vera Demberg

Session 1C: Dialog and Interactive Systems 1

10:00–10:10 *Conversations Are Not Flat: Modeling the Dynamic Information Flow across Dialogue Utterances*
Zekang Li, Jinchao Zhang, Zhengcong Fei, Yang Feng and Jie Zhou

10:10–10:20 *Dual Slot Selector via Local Reliability Verification for Dialogue State Tracking*
Jinyu Guo, Kai Shuang, Jijie Li and Zihan Wang

10:20–10:30 *Transferable Dialogue Systems and User Simulators*
Bo-Hsiang Tseng, Yinpei Dai, Florian Kreyssig and Bill Byrne

10:30–10:40 *BoB: BERT Over BERT for Training Persona-based Dialogue Models from Limited Personalized Data*
Haoyu Song, Yan Wang, Kaiyan Zhang, Wei-Nan Zhang and Ting Liu

10:40–10:50 *GL-GIN: Fast and Accurate Non-Autoregressive Model for Joint Multiple Intent Detection and Slot Filling*
Libo Qin, Fuxuan Wei, Tianbao Xie, Xiao Xu, Wanxiang Che and Ting Liu

10:50–10:57 *Coreference Resolution without Span Representations*
Yuval Kirstain, Ori Ram and Omer Levy

Session 1D: Information Extraction 1

10:00–10:10 *Accelerating BERT Inference for Sequence Labeling via Early-Exit*
Xiaonan Li, Yunfan Shao, Tianxiang Sun, Hang Yan, Xipeng Qiu and Xuanjing Huang

10:10–10:20 *Modularized Interaction Network for Named Entity Recognition*
Fei Li, Zheng Wang, Siu Cheung Hui, Lejian Liao, Dandan Song, Jing Xu, Guoxiu He and meihuizi jia

10:20–10:30 *Capturing Event Argument Interaction via A Bi-Directional Entity-Level Recurrent Decoder*
Xi Xiangyu, Wei Ye, Shikun Zhang, Quanxiu Wang, Huixing Jiang and Wei Wu

10:30–10:40 *UniRE: A Unified Label Space for Entity Relation Extraction*
Yijun Wang, Changzhi Sun, Yuanbin Wu, Hao Zhou, Lei Li and Junchi Yan

10:40–10:50 *Refining Sample Embeddings with Relation Prototypes to Enhance Continual Relation Extraction*
Li Cui, Deqing Yang, Jiaxin Yu, Chengwei Hu, Jiayang Cheng, Jingjie Yi and Yanghua Xiao

10:50–10:57 *Enhancing Entity Boundary Detection for Better Chinese Named Entity Recognition*
Chun Chen and Fang Kong

Monday, August 2, 2021 (all times UTC+0) (continued)

Session 1E: Machine Translation and Multilinguality 1

10:00–10:10 *Contrastive Learning for Many-to-many Multilingual Neural Machine Translation*
Xiao Pan, Mingxuan Wang, Liwei Wu and Lei Li

10:10–10:20 *Understanding the Properties of Minimum Bayes Risk Decoding in Neural Machine Translation*
Mathias Müller and Rico Sennrich

10:20–10:30 *Multi-Head Highly Parallelized LSTM Decoder for Neural Machine Translation*
Hongfei Xu, Qiuhui Liu, Josef van Genabith, Deyi Xiong and Meng Zhang

10:30–10:40 *A Bidirectional Transformer Based Alignment Model for Unsupervised Word Alignment*
Jingyi Zhang and Josef van Genabith

10:40–10:50 *Learning Language Specific Sub-network for Multilingual Machine Translation*
Zehui Lin, Liwei Wu, Mingxuan Wang and Lei Li

10:50–10:57 *Difficulty-Aware Machine Translation Evaluation*
Runzhe Zhan, Xuebo Liu, Derek F. Wong and Lidia S. Chao

Session 2A: Sentiment Analysis, Stylistic Analysis, and Argument Mining 1

11:00–11:10 *Exploring the Efficacy of Automatically Generated Counterfactuals for Sentiment Analysis*
Linyi Yang, Jiazheng Li, Padraig Cunningham, Yue Zhang, Barry Smyth and Ruihai Dong

11:10–11:20 *Bridge-Based Active Domain Adaptation for Aspect Term Extraction*
Zhuang Chen and Tieyun Qian

11:20–11:30 *Multimodal Sentiment Detection Based on Multi-channel Graph Neural Networks*
Xiaocui Yang, Shi Feng, Yifei Zhang and Daling Wang

11:30–11:40 *Aspect-Category-Opinion-Sentiment Quadruple Extraction with Implicit Aspects and Opinions*
Hongjie Cai, Rui Xia and Jianfei Yu

11:40–11:47 *Uncertainty and Surprisal Jointly Deliver the Punchline: Exploiting Incongruity-Based Features for Humor Recognition*
Yubo Xie, Junze Li and Pearl Pu

11:47–11:54 *Counterfactuals to Control Latent Disentangled Text Representations for Style Transfer*
Sharmila Reddy Nangi, Niyati Chhaya, Sopan Khosla, Nikhil Kaushik and Harshit Nyati

Session 2B: Summarization 1

11:00–11:10 *PASS: Perturb-and-Select Summarizer for Product Reviews*
Nadav Oved and Ran Levy

11:10–11:20 *Deep Differential Amplifier for Extractive Summarization*
Ruipeng Jia, Yanan Cao, Fang Fang, Yuchen Zhou, Zheng Fang, Yanbing Liu and Shi Wang

11:20–11:30 *Multi-TimeLine Summarization (MTLS): Improving Timeline Summarization by Generating Multiple Summaries*
Yi Yu, Adam Jatowt, Antoine Doucet, Kazunari Sugiyama and Masatoshi Yoshikawa

11:30–11:40 *Self-Supervised Multimodal Opinion Summarization*
Jinbae Im, Moonki Kim, Hoyeop Lee, Hyunsouk Cho and Sehee Chung

11:40–11:50 *A Training-free and Reference-free Summarization Evaluation Metric via Centrality-weighted Relevance and Self-referenced Redundancy*
Wang Chen, Piji Li and Irwin King

11:50–12:00 *DESCGEN: A Distantly Supervised Datasetfor Generating Entity Descriptions*
Weijia Shi, Mandar Joshi and Luke Zettlemoyer

Session 2C: Interpretability and Analysis of Models for NLP 1

11:00–11:10 *Introducing Orthogonal Constraint in Structural Probes*
Tomasz Limisiewicz and David Mareček

11:10–11:20 *Hidden Killer: Invisible Textual Backdoor Attacks with Syntactic Trigger*
Fanchao Qi, Mukai Li, Yangyi Chen, Zhengyan Zhang, Zhiyuan Liu, Yasheng Wang and Maosong Sun

11:20–11:30 *Examining the Inductive Bias of Neural Language Models with Artificial Languages*
Jennifer C. White and Ryan Cotterell

11:30–11:40 *Explaining Contextualization in Language Models using Visual Analytics*
Rita Sevastjanova, Aikaterini-Lida Kalouli, Christin Beck, Hanna Schäfer and Mennatallah El-Assady

11:40–11:50 *Improving the Faithfulness of Attention-based Explanations with Task-specific Information for Text Classification*
George Chrysostomou and Nikolaos Aletras

11:50–11:57 *Attention Flows are Shapley Value Explanations*
Kawin Ethayarajh and Dan Jurafsky

Session 2D: Language Grounding to Vision, Robotics and Beyond 1

11:00–11:10 *Generating Landmark Navigation Instructions from Maps as a Graph-to-Text Problem*
Raphael Schumann and Stefan Riezler

11:10–11:20 *E2E-VLP: End-to-End Vision-Language Pre-training Enhanced by Visual Learning*
Haiyang Xu, Ming Yan, Chenliang Li, Bin Bi, Songfang Huang, Wenming Xiao and Fei Huang

11:20–11:30 *Learning Relation Alignment for Calibrated Cross-modal Retrieval*
Shuhuai Ren, Junyang Lin, Guangxiang Zhao, Rui Men, An Yang, Jingren Zhou, Xu Sun and Hongxia Yang

11:30–11:40 *KM-BART: Knowledge Enhanced Multimodal BART for Visual Commonsense Generation*
Yiran Xing, Zai Shi, Zhao Meng, Gerhard Lakemeyer, Yunpu Ma and Roger Wattenhofer

11:40–11:47 *Video Paragraph Captioning as a Text Summarization Task*
Hui Liu and Xiaojun Wan

11:47–11:54 *Are VQA Systems RAD? Measuring Robustness to Augmented Data with Focused Interventions*
Daniel Rosenberg, Itai Gat, Amir Feder and Roi Reichart

Session 2E: Machine Learning for NLP 1

11:00–11:10 *Cascaded Head-colliding Attention*
Lin Zheng, Zhiyong Wu and Lingpeng Kong

11:10–11:20 *Structural Knowledge Distillation: Tractably Distilling Information for Structured Predictor*
Xinyu Wang, Yong Jiang, Zhaohui Yan, Zixia Jia, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

11:20–11:30 *Parameter-efficient Multi-task Fine-tuning for Transformers via Shared Hypernetworks*
Rabeeh Karimi Mahabadi, Sebastian Ruder, Mostafa Dehghani and James Henderson

11:30–11:40 *COSY: COunterfactual SYntax for Cross-Lingual Understanding*
SICHENG YU, Hao Zhang, Yulei Niu, Qianru Sun and Jing Jiang

11:40–11:50 *OoMMix: Out-of-manifold Regularization in Contextual Embedding Space for Text Classification*
Seonghyeon Lee, Dongha Lee and Hwanjo Yu

11:50–11:57 *How Helpful is Inverse Reinforcement Learning for Table-to-Text Generation?*
Sayan Ghosh, Zheng Qi, Snigdha Chaturvedi and Shashank Srivastava

Session 3A: Computational Social Science and Cultural Analytics 2

14:00–14:10 *Understanding and Countering Stereotypes: A Computational Approach to the Stereotype Content Model*
Kathleen C. Fraser, Isar Nejadgholi and Svetlana Kiritchenko

14:10–14:20 *Structurizing Misinformation Stories via Rationalizing Fact-Checks*
Shan Jiang and Christo Wilson

14:20–14:30 *Modeling Language Usage and Listener Engagement in Podcasts*
Sravana Reddy, Mariya Lazarova, Yongze Yu and Rosie Jones

14:30–14:40 *Breaking Down the Invisible Wall of Informal Fallacies in Online Discussions*
Saumya Sahai, Oana Balalau and Roxana Horincar

14:40–14:50 *SocAoG: Incremental Graph Parsing for Social Relation Inference in Dialogues*
Liang Qiu, Yuan Liang, Yizhou Zhao, Pan Lu, Baolin Peng, Zhou Yu, Ying Nian Wu and Song-Chun Zhu

14:50–14:57 *Automatic Fake News Detection: Are Models Learning to Reason?*
Casper Hansen, Christian Hansen and Lucas Chaves Lima

Session 3B: Dialog and Interactive Systems 2

14:00–14:10 *TicketTalk: Toward human-level performance with end-to-end, transaction-based dialog systems*
Bill Byrne, Karthik Krishnamoorthi, Saravanan Ganesh and Mihir Kale

14:10–14:20 *Improving Dialog Systems for Negotiation with Personality Modeling*
Runzhe Yang, Jingxiao Chen and Karthik Narasimhan

14:20–14:30 *Learning from Perturbations: Diverse and Informative Dialogue Generation with Inverse Adversarial Training*
Wangchunshu Zhou, Qifei LI and Chenle Li

14:30–14:40 *Increasing Faithfulness in Knowledge-Grounded Dialogue with Controllable Features*
Hannah Rashkin, David Reitter, Gaurav Singh Tomar and Dipanjan Das

14:40–14:47 *Saying No is An Art: Contextualized Fallback Responses for Unanswerable Dialogue Queries*
Ashish Shrivastava, Kaustubh Dhole, Abhinav Bhatt and Sharvani Raghunath

14:47–14:54 *N-Best ASR Transformer: Enhancing SLU Performance using Multiple ASR Hypotheses*
Karthik Ganesan, Pakhi Bamdev, Jaivarsan B, Amresh Venugopal and Abhinav Tushar

Session 3C: Information Extraction 2

14:00–14:10 *CitationIE: Leveraging the Citation Graph for Scientific Information Extraction*
Vijay Viswanathan, Graham Neubig and Pengfei Liu

14:10–14:20 *From Discourse to Narrative: Knowledge Projection for Event Relation Extraction*
Jialong Tang, Hongyu Lin, Meng Liao, Yaojie Lu, Xianpei Han, Le Sun, Weijian Xie and Jin Xu

14:20–14:30 *AdvPicker: Effectively Leveraging Unlabeled Data via Adversarial Discriminator for Cross-Lingual NER*
Weile Chen, Huiqiang Jiang, Qianhui Wu, Börje Karlsson and Yi Guan

14:30–14:40 *Compare to The Knowledge: Graph Neural Fake News Detection with External Knowledge*
Linmei Hu, Tianchi Yang, Luhao Zhang, Wanjun Zhong, Duyu Tang, Chuan Shi, Nan Duan and Ming Zhou

14:40–14:50 *Discontinuous Named Entity Recognition as Maximal Clique Discovery*
Yucheng Wang, Bowen Yu, Hongsong Zhu, Tingwen Liu, Nan Yu and Limin Sun

14:50–15:00 *LNN-EL: A Neuro-Symbolic Approach to Short-text Entity Linking*
Hang Jiang, Sairam Gurajada, Qiuhao Lu, Sumit Neelam, Lucian Popa, Prithviraj Sen, Yunyao Li and Alexander Gray

Session 3D: Machine Translation and Multilinguality 2

14:00–14:10 *Do Context-Aware Translation Models Pay the Right Attention?*
Kayo Yin, Patrick Fernandes, Danish Pruthi, Aditi Chaudhary, André F. T. Martins and Graham Neubig

14:10–14:20 *Adapting High-resource NMT Models to Translate Low-resource Related Languages without Parallel Data*
Wei-Jen Ko, Ahmed El-Kishky, Adithya Renduchintala, Vishrav Chaudhary, Naman Goyal, Francisco Guzmán, Pascale Fung, Philipp Koehn and Mona Diab

14:20–14:30 *Bilingual Lexicon Induction via Unsupervised Bitext Construction and Word Alignment*
Haoyue Shi, Luke Zettlemoyer and Sida I. Wang

14:30–14:40 *Multilingual Speech Translation from Efficient Finetuning of Pretrained Models*
Xian Li, Changhan Wang, Yun Tang, Chau Tran, Yuqing Tang, Juan Pino, Alexei Baevski, Alexis Conneau and Michael Auli

14:40–14:47 *Gender bias amplification during Speed-Quality optimization in Neural Machine Translation*
Adithya Renduchintala, Denise Diaz, Kenneth Heafield, Xian Li and Mona Diab

14:47–14:54 *Machine Translation into Low-resource Language Varieties*
Sachin Kumar, Antonios Anastasopoulos, Shuly Wintner and Yulia Tsvetkov

Session 3E: Interpretability and Analysis of Models for NLP 2

14:00–14:10 *Learning Faithful Representations of Causal Graphs*
Ananth Balashankar and Lakshminarayanan Subramanian

14:10–14:20 *What Context Features Can Transformer Language Models Use?*
Joe O'Connor and Jacob Andreas

14:20–14:30 *Integrated Directional Gradients: Feature Interaction Attribution for Neural NLP Models*
Sandipan Sikdar, Parantapa Bhattacharya and Kieran Heese

14:30–14:37 *Is Sparse Attention more Interpretable?*
Clara Meister, Stefan Lazov, Isabelle Augenstein and Ryan Cotterell

Monday, August 2, 2021 (all times UTC+0) (continued)

14:37–14:44 *The Case for Translation-Invariant Self-Attention in Transformer-Based Language Models*
Ulme Wennberg and Gustav Eje Henter

14:44–14:51 *Relative Importance in Sentence Processing*
Nora Hollenstein and Lisa Beinborn

Poster 1A: Semantics: Sentence-level Semantics, Textual Inference and Other areas

15:00–17:00 *DeCLUTR: Deep Contrastive Learning for Unsupervised Textual Representations*
John Giorgi, Osvald Nitski, Bo Wang and Gary Bader

15:00–17:00 *Doing Good or Doing Right? Exploring the Weakness of Commonsense Causal Reasoning Models*
Mingyue Han and Yinglin Wang

15:00–17:00 *XLPT-AMR: Cross-Lingual Pre-Training via Multi-Task Learning for Zero-Shot AMR Parsing and Text Generation*
Dongqin Xu, Junhui Li, Muhua Zhu, Min Zhang and Guodong Zhou

15:00–17:00 *Span-based Semantic Parsing for Compositional Generalization*
Jonathan Herzig and Jonathan Berant

15:00–17:00 *AND does not mean OR: Using Formal Languages to Study Language Models' Representations*
Aaron Traylor, Roman Feiman and Ellie Pavlick

15:00–17:00 *Enforcing Consistency in Weakly Supervised Semantic Parsing*
Nitish Gupta, Sameer Singh and Matt Gardner

15:00–17:00 *Compositional Generalization and Natural Language Variation: Can a Semantic Parsing Approach Handle Both?*
Peter Shaw, Ming-Wei Chang, Panupong Pasupat and Kristina Toutanova

Poster 1B: Linguistic Theories, Cognitive Modeling and Psycholinguistics

15:00–17:00 *A Targeted Assessment of Incremental Processing in Neural Language Models and Humans*
Ethan Wilcox, Pranali Vani and Roger Levy

Poster 1C: Semantics: Lexical Semantics

15:00–17:00 *The Possible, the Plausible, and the Desirable: Event-Based Modality Detection for Language Processing*
Valentina Pyatkin, Shoval Sadde, Aynat Rubinstein, Paul Portner and Reut Tsarfaty

Poster 1D: Phonology, Morphology and Word Segmentation

15:00–17:00 *To POS Tag or Not to POS Tag: The Impact of POS Tags on Morphological Learning in Low-Resource Settings*
Sarah Moeller, Ling Liu and Mans Hulden

Poster 1E: Speech and Multimodality

15:00–17:00 *Prosodic segmentation for parsing spoken dialogue*
Elizabeth Nielsen, Mark Steedman and Sharon Goldwater

15:00–17:00 *VoxPopuli: A Large-Scale Multilingual Speech Corpus for Representation Learning, Semi-Supervised Learning and Interpretation*
Changhan Wang, Morgane Riviere, Ann Lee, Anne Wu, Chaitanya Talnikar, Daniel Haziza, Mary Williamson, Juan Pino and Emmanuel Dupoux

15:00–17:00 *An Improved Model for Voicing Silent Speech*
David Gaddy and Dan Klein

Poster 1F: Ethics in NLP

15:00–17:00 *What's in the Box? An Analysis of Undesirable Content in the Common Crawl Corpus*
Alexandra Luccioni and Joseph Viviano

15:00–17:00 *Stereotyping Norwegian Salmon: An Inventory of Pitfalls in Fairness Benchmark Datasets*
Su Lin Blodgett, Gilsinia Lopez, Alexandra Olteanu, Robert Sim and Hanna Wallach

Poster 1G: Information Retrieval and Text Mining

15:00–17:00 *Robust Knowledge Graph Completion with Stacked Convolutions and a Student Re-Ranking Network*
Justin Lovelace, Denis Newman-Griffis, Shikhar Vashishth, Jill Fain Lehman and Carolyn Rosé

15:00–17:00 *A DQN-based Approach to Finding Precise Evidences for Fact Verification*
Hai Wan, Haicheng Chen, Jianfeng Du, Weilin Luo and Rongzhen Ye

Poster 1H: Machine Learning for NLP

15:00–17:00 *The Art of Abstention: Selective Prediction and Error Regularization for Natural Language Processing*
Ji Xin, Raphael Tang, Yaoliang Yu and Jimmy Lin

15:00–17:00 *Unsupervised Out-of-Domain Detection via Pre-trained Transformers*
Keyang Xu, Tongzheng Ren, Shikun Zhang, Yihao Feng and Caiming Xiong

15:00–17:00 *Continual Quality Estimation with Online Bayesian Meta-Learning*
Abiola Obamuyide, Marina Fomicheva and Lucia Specia

15:00–17:00 *MATE-KD: Masked Adversarial TExt, a Companion to Knowledge Distillation*
Ahmad Rashid, Vasileios Lioutas and Mehdi Rezagholizadeh

15:00–17:00 *Selecting Informative Contexts Improves Language Model Fine-tuning*
Richard Antonello, Nicole Beckage, Javier Turek and Alexander Huth

15:00–17:00 *Explainable Prediction of Text Complexity: The Missing Preliminaries for Text Simplification*
Cristina Garbacea, Mengtian Guo, Samuel Carton and Qiaozhu Mei

15:00–17:00 *Multi-Task Retrieval for Knowledge-Intensive Tasks*
Jean Maillard, Vladimir Karpukhin, Fabio Petroni, Wen-tau Yih, Barlas Oguz, Veselin Stoyanov and Gargi Ghosh

Poster 1I: Interpretability and Analysis of Models for NLP

15:00–17:00 *When Do You Need Billions of Words of Pretraining Data?*
Yian Zhang, Alex Warstadt, Xiaocheng Li and Samuel R. Bowman

15:00–17:00 *Analyzing the Source and Target Contributions to Predictions in Neural Machine Translation*
Elena Voita, Rico Sennrich and Ivan Titov

15:00–17:00 *Comparing Test Sets with Item Response Theory*
Clara Vania, Phu Mon Htut, William Huang, Dhara Mungra, Richard Yuanzhe Pang, Jason Phang, Haokun Liu, Kyunghyun Cho and Samuel R. Bowman

15:00–17:00 *Uncovering Constraint-Based Behavior in Neural Models via Targeted Fine-Tuning*
Forrest Davis and Marten van Schijndel

15:00–17:00 *More Identifiable yet Equally Performant Transformers for Text Classification*
Rishabh Bhardwaj, Navonil Majumder, Soujanya Poria and Eduard Hovy

Poster 1J: Dialog and Interactive Systems

15:00–17:00 *AugNLG: Few-shot Natural Language Generation using Self-trained Data Augmentation*
Xinnuo Xu, Guoyin Wang, Young-Bum Kim and Sungjin Lee

15:00–17:00 *A Span-based Dynamic Local Attention Model for Sequential Sentence Classification*
Xichen Shang, Qianli Ma, Zhenxi Lin, Jiangyue Yan and Zipeng Chen

Poster 1K: Resources and Evaluation

15:00–17:00 *How effective is BERT without word ordering? Implications for language understanding and data privacy*
Jack Hessel and Alexandra Schofield

15:00–17:00 *Can vectors read minds better than experts? Comparing data augmentation strategies for the automated scoring of children's mindreading ability*
Venelin Kovatchev, Phillip Smith, Mark Lee and Rory Devine

15:00–17:00 *A Dataset and Baselines for Multilingual Reply Suggestion*
Mozhi Zhang, Wei Wang, Budhaditya Deb, Guoqing Zheng, Milad Shokouhi and Ahmed Hassan Awadallah

15:00–17:00 *WikiSum: Coherent Summarization Dataset for Efficient Human-Evaluation*
Nachshon Cohen, Oren Kalinsky, Yftah Ziser and Alessandro Moschitti

15:00–17:00 *What Ingredients Make for an Effective Crowdsourcing Protocol for Difficult NLU Data Collection Tasks?*
Nikita Nangia, Saku Sugawara, Harsh Trivedi, Alex Warstadt, Clara Vania and Samuel R. Bowman

15:00–17:00 *UMIC: An Unreferenced Metric for Image Captioning via Contrastive Learning*
Hwanhee Lee, Seunghyun Yoon, Franck Dernoncourt, Trung Bui and Kyomin Jung

15:00–17:00 *Neural OCR Post-Hoc Correction of Historical Corpora*
Lijun Lyu, Maria Koutraki, Martin Krikl and Besnik Fetahu

Poster 1L: Computational Social Science and Cultural Analytics

15:00–17:00 *Align Voting Behavior with Public Statements for Legislator Representation Learning*
Xinyi Mou, Zhongyu Wei, Lei Chen, Shangyi Ning, Yancheng He, Changjian Jiang and Xuanjing Huang

15:00–17:00 *Measure and Evaluation of Semantic Divergence across Two Languages*
Syrielle Montariol and Alexandre Allauzen

Poster 1M: Machine Translation and Multilinguality

15:00–17:00 *Improving Zero-Shot Translation by Disentangling Positional Information*
Danni Liu, Jan Niehues, James Cross, Francisco Guzmán and Xian Li

15:00–17:00 *Common Sense Beyond English: Evaluating and Improving Multilingual Language Models for Commonsense Reasoning*
Bill Yuchen Lin, Seyeon Lee, Xiaoyang Qiao and Xiang Ren

15:00–17:00 *Attention Calibration for Transformer in Neural Machine Translation*
Yu Lu, Jiali Zeng, Jiajun Zhang, Shuangzhi Wu and Mu Li

15:00–17:00 *Anchor-based Bilingual Word Embeddings for Low-Resource Languages*
Tobias Eder, Viktor Hangya and Alexander Fraser

15:00–17:00 *Diverse Pretrained Context Encodings Improve Document Translation*
Domenic Donato, Lei Yu and Chris Dyer

15:00–17:00 *Multilingual Agreement for Multilingual Neural Machine Translation*
Jian Yang, Yuwei Yin, Shuming Ma, Haoyang Huang, Dongdong Zhang, Zhoujun Li and Furu Wei

15:00–17:00 *Exploiting Language Relatedness for Low Web-Resource Language Model Adaptation: An Indic Languages Study*
Yash Khemchandani, Sarvesh Mehtani, Vaidehi Patil, Abhijeet Awasthi, Partha Talukdar and Sunita Sarawagi

Poster 1N: Syntax: Tagging, Chunking, and Parsing

15:00–17:00 *On Finding the K-best Non-projective Dependency Trees*
Ran Zmigrod, Tim Vieira and Ryan Cotterell

15:00–17:00 *Higher-order Derivatives of Weighted Finite-state Machines*
Ran Zmigrod, Tim Vieira and Ryan Cotterell

Poster 1O: Theme

15:00–17:00 *Towards Argument Mining for Social Good: A Survey*
Eva Maria Vecchi, Neele Falk, Iman Jundi and Gabriella Lapesa

15:00–17:00 *Automated Generation of Storytelling Vocabulary from Photographs for use in AAC*
Mauricio Fontana de Vargas and Karyn Moffatt

Poster 1P: NLP Applications

15:00–17:00 *CLIP: A Dataset for Extracting Action Items for Physicians from Hospital Discharge Notes*
James Mullenbach, Yada Pruksachatkun, Sean Adler, Jennifer Seale, Jordan Swartz, Greg McKelvey, Hui Dai, Yi Yang and David Sontag

15:00–17:00 *Assessing Emoji Use in Modern Text Processing Tools*
Abu Awal Md Shoeb and Gerard de Melo

15:00–17:00 *Select, Extract and Generate: Neural Keyphrase Generation with Layer-wise Coverage Attention*
Wasi Ahmad, Xiao Bai, Soomin Lee and Kai-Wei Chang

Poster 1Q: Language Generation

15:00–17:00 *Factorising Meaning and Form for Intent-Preserving Paraphrasing*
Tom Hosking and Mirella Lapata

15:00–17:00 *AggGen: Ordering and Aggregating while Generating*
Xinnuo Xu, Ondřej Dušek, Verena Rieser and Ioannis Konstas

15:00–17:00 *Reflective Decoding: Beyond Unidirectional Generation with Off-the-Shelf Language Models*
Peter West, Ximing Lu, Ari Holtzman, Chandra Bhagavatula, Jena D. Hwang and Yejin Choi

15:00–17:00 *Towards Table-to-Text Generation with Numerical Reasoning*
Lya Hulliyyatus Suadaa, Hidetaka Kamigaito, Kotaro Funakoshi, Manabu Okumura and Hiroya Takamura

15:00–17:00 *Data-to-text Generation with Macro Planning*
Ratish Puduppully and Mirella Lapata

Poster 1R: Summarization

15:00–17:00 *BACO: A Background Knowledge- and Content-Based Framework for Citing Sentence Generation*
Yubin Ge, Ly Dinh, Xiaofeng Liu, Jinsong Su, Ziyao Lu, Ante Wang and Jana Diesner

15:00–17:00 *Language Model as an Annotator: Exploring DialoGPT for Dialogue Summarization*
Xiachong Feng, Xiaocheng Feng, Libo Qin, Bing Qin and Ting Liu

15:00–17:00 *Reinforcement Learning for Abstractive Question Summarization with Question-aware Semantic Rewards*
Shweta Yadav, Deepak Gupta, Asma Ben Abacha and Dina Demner-Fushman

Poster 1S: Question Answering

15:00–17:00 *Challenges in Information-Seeking QA: Unanswerable Questions and Paragraph Retrieval*
Akari Asai and Eunsol Choi

15:00–17:00 *A Semantics-aware Transformer Model of Relation Linking for Knowledge Base Question Answering*
Tahira Naseem, Srinivas Ravishankar, Nandana Mihindukulasooriya, Ibrahim Abdelaziz, Young-Suk Lee, Pavan Kapanipathi, Salim Roukos, Alfio Gliozzo and Alexander Gray

15:00–17:00 *A Gradually Soft Multi-Task and Data-Augmented Approach to Medical Question Understanding*
Khalil Mrini, Franck Dernoncourt, Seunghyun Yoon, Trung Bui, Walter Chang, Emilia Farcas and Ndapa Nakashole

15:00–17:00 *Neural Retrieval for Question Answering with Cross-Attention Supervised Data Augmentation*
Yinfei Yang, Ning Jin, Kuo Lin, Mandy Guo and Daniel Cer

Poster 1T: Language Grounding to Vision, Robotics and Beyond

15:00–17:00 *Enhancing Descriptive Image Captioning with Natural Language Inference*
Zhan Shi, Hui Liu and Xiaodan Zhu

Poster 1U: Information Extraction

15:00–17:00 *Leveraging Type Descriptions for Zero-shot Named Entity Recognition and Classification*
Rami Aly, Andreas Vlachos and Ryan McDonald

15:00–17:00 *MECT: Multi-Metadata Embedding based Cross-Transformer for Chinese Named Entity Recognition*
Shuang Wu, Xiaoning Song and Zhenhua Feng

15:00–17:00 *MOLEMAN: Mention-Only Linking of Entities with a Mention Annotation Network*
Nicholas FitzGerald, Dan Bikel, Jan Botha, Daniel Gillick, Tom Kwiatkowski and Andrew McCallum

15:00–17:00 *Factuality Assessment as Modal Dependency Parsing*
Jiarui Yao, Haoling Qiu, Jin Zhao, Bonan Min and Nianwen Xue

Poster 1V: Sentiment Analysis, Stylistic Analysis, and Argument Mining

15:00–17:00 *Directed Acyclic Graph Network for Conversational Emotion Recognition*
Weizhou Shen, Siyue Wu, Yunyi Yang and Xiaojun Quan

15:00–17:00 *Improving Formality Style Transfer with Context-Aware Rule Injection*
Zonghai Yao and hong yu

15:00–17:00 *Topic-Driven and Knowledge-Aware Transformer for Dialogue Emotion Detection*
Lixing Zhu, Gabriele Pergola, Lin Gui, Deyu Zhou and Yulan He

15:00–17:00 *Syntopical Graphs for Computational Argumentation Tasks*
Joe Barrow, Rajiv Jain, Nedim Lipka, Franck Dernoncourt, Vlad Morariu, Varun Manjunatha, Douglas Oard, Philip Resnik and Henning Wachsmuth

15:00–17:00 *Stance Detection in COVID-19 Tweets*
Kyle Glandt, Sarthak Khanal, Yingjie Li, Doina Caragea and Cornelia Caragea

15:00–17:00 *eMLM: A New Pre-training Objective for Emotion Related Tasks*
Tiberiu Sosea and Cornelia Caragea

15:00–17:00 *Topic-Aware Evidence Reasoning and Stance-Aware Aggregation for Fact Verification*
Jiasheng Si, Deyu Zhou, Tongzhe Li, Xingyu Shi and Yulan He

17:00—18:00 ***Keynote 2. Alejandrina Cristia: Learning and Processing Language from Wearables: Opportunities and Challenges***

Session 4A: Computational Social Science and Cultural Analytics 3

23:00–23:10 *Changes in European Solidarity Before and During COVID-19: Evidence from a Large Crowd- and Expert-Annotated Twitter Dataset*
Alexandra Ils, Dan Liu, Daniela Grunow and Steffen Eger

23:10–23:20 *Measuring Conversational Uptake: A Case Study on Student-Teacher Interactions*
Dorottya Demszky, Jing Liu, Zid Mancenido, Julie Cohen, Heather Hill, Dan Jurafsky and Tatsunori Hashimoto

23:20–23:30 *A Survey of Code-switching: Linguistic and Social Perspectives for Language Technologies*
A. Seza Doğruöz, Sunayana Sitaram, Barbara E. Bullock and Almedia Jacqueline Toribio

23:30–23:40 *Learning from the Worst: Dynamically Generated Datasets to Improve Online Hate Detection*
Bertie Vidgen, Tristan Thrush, Zeerak Waseem and Douwe Kiela

23:40–23:50 *InfoSurgeon: Cross-Media Fine-grained Information Consistency Checking for Fake News Detection*
Yi Fung, Christopher Thomas, Revanth Gangi Reddy, Sandeep Polisetty, Heng Ji, Shih-Fu Chang, Kathleen McKeown, Mohit Bansal and Avi Sil

23:50–23:57 *On Positivity Bias in Negative Reviews*
Madhusudhan Aithal and Chenhao Tan

Session 4B: Dialog and Interactive Systems 3

23:00–23:10 *I like fish, especially dolphins: Addressing Contradictions in Dialogue Modeling*
Yixin Nie, Mary Williamson, Mohit Bansal, Douwe Kiela and Jason Weston

23:10–23:20 *A Sequence-to-Sequence Approach to Dialogue State Tracking*
Yue Feng, Yang Wang and Hang Li

23:20–23:30 *Discovering Dialog Structure Graph for Coherent Dialog Generation*
Jun Xu, Zeyang Lei, Haifeng Wang, Zheng-Yu Niu, Hua Wu and Wanxiang Che

23:30–23:40 *Dialogue Response Selection with Hierarchical Curriculum Learning*
Yixuan Su, Deng Cai, Qingyu Zhou, Zibo Lin, Simon Baker, Yunbo Cao, Shuming Shi, Nigel Collier and Yan Wang

Monday, August 2, 2021 (all times UTC+0) (continued)

23:40–23:50 *A Joint Model for Dropped Pronoun Recovery and Conversational Discourse Parsing in Chinese Conversational Speech*
Jingxuan Yang, Kerui Xu, Jun Xu, Si Li, Sheng Gao, Jun Guo, Nianwen Xue and Ji-Rong Wen

23:50–23:57 *PRAL: A Tailored Pre-Training Model for Task-Oriented Dialog Generation*
Jing Gu, Qingyang Wu, Chongruo Wu, Weiyan Shi and Zhou Yu

Session 4C: Information Extraction 3

23:00–23:10 *A Systematic Investigation of KB-Text Embedding Alignment at Scale*
Vardaan Pahuja, Yu Gu, Wenhu Chen, Mehdi Bahrami, Lei Liu, Wei-Peng Chen and Yu Su

23:10–23:20 *Named Entity Recognition with Small Strongly Labeled and Large Weakly Labeled Data*
Haoming Jiang, Danqing Zhang, Tianyu Cao, Bing Yin and Tuo Zhao

23:20–23:30 *Ultra-Fine Entity Typing with Weak Supervision from a Masked Language Model*
Hongliang Dai, Yangqiu Song and Haixun Wang

23:30–23:40 *Improving Named Entity Recognition by External Context Retrieving and Cooperative Learning*
Xinyu Wang, Yong Jiang, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

23:40–23:47 *ROPE: Reading Order Equivariant Positional Encoding for Graph-based Document Information Extraction*
Chen-Yu Lee, Chun-Liang Li, Chu Wang, Renshen Wang, Yasuhisa Fujii, Siyang Qin, Ashok Popat and Tomas Pfister

23:47–23:54 *Zero-shot Event Extraction via Transfer Learning: Challenges and Insights*
Qing Lyu, Hongming Zhang, Elior Sulem and Dan Roth

Session 4D: Interpretability and Analysis of Models for NLP 3

23:00–23:10 *Implicit Representations of Meaning in Neural Language Models*
Belinda Z. Li, Maxwell Nye and Jacob Andreas

23:10–23:20 *Causal Analysis of Syntactic Agreement Mechanisms in Neural Language Models*
Matthew Finlayson, Aaron Mueller, Sebastian Gehrmann, Stuart Shieber, Tal Linzen and Yonatan Belinkov

23:20–23:30 *Bird's Eye: Probing for Linguistic Graph Structures with a Simple Information-Theoretic Approach*
Yifan Hou and Mrinmaya Sachan

23:30–23:40 *Knowledgeable or Educated Guess? Revisiting Language Models as Knowledge Bases*
Boxi Cao, Hongyu Lin, Xianpei Han, Le Sun, Lingyong Yan, Meng Liao, Tong Xue and Jin Xu

23:40–23:50 *Poisoning Knowledge Graph Embeddings via Relation Inference Patterns*
Peru Bhardwaj, John Kelleher, Luca Costabello and Declan O'Sullivan

23:50–23:57 *Using Adversarial Attacks to Reveal the Statistical Bias in Machine Reading Comprehension Models*
Jieyu Lin, Jiajie Zou and Nai Ding

Session 4E: Ethics in NLP 1

23:00–23:10 *Bad Seeds: Evaluating Lexical Methods for Bias Measurement*
Maria Antoniak and David Mimno

23:10–23:20 *A Survey of Race, Racism, and Anti-Racism in NLP*
Anjalie Field, Su Lin Blodgett, Zeerak Waseem and Yulia Tsvetkov

23:20–23:30 *Intrinsic Bias Metrics Do Not Correlate with Application Bias*
Seraphina Goldfarb-Tarrant, Rebecca Marchant, Ricardo Muñoz Sánchez, Mugdha Pandya and Adam Lopez

23:30–23:40 *RedditBias: A Real-World Resource for Bias Evaluation and Debiasing of Conversational Language Models*
Soumya Barikeri, Anne Lauscher, Ivan Vulić and Goran Glavaš

Monday, August 2, 2021 (all times UTC+0) (continued)

23:40–23:47 *Quantifying and Avoiding Unfair Qualification Labour in Crowdsourcing*
Jonathan K. Kummerfeld

23:47–23:54 *Men Are Elected, Women Are Married: Events Gender Bias on Wikipedia*
Jiao Sun and Nanyun Peng

Tuesday, August 3, 2021 (all times UTC+0)

Session 5A: Machine Translation and Multilinguality 3

00:00–00:10 *Contributions of Transformer Attention Heads in Multi- and Cross-lingual Tasks*
Weicheng Ma, Kai Zhang, Renze Lou, Lili Wang and Soroush Vosoughi

00:10–00:20 *Crafting Adversarial Examples for Neural Machine Translation*
Xinze Zhang, Junzhe Zhang, Zhenhua Chen and Kun He

00:20–00:30 *UXLA: A Robust Unsupervised Data Augmentation Framework for Zero-Resource Cross-Lingual NLP*
M Saiful Bari, Tasnim Mohiuddin and Shafiq Joty

00:30–00:40 *Glancing Transformer for Non-Autoregressive Neural Machine Translation*
Lihua Qian, Hao Zhou, Yu Bao, Mingxuan Wang, Lin Qiu, Weinan Zhang, Yong Yu and Lei Li

00:40–00:47 *Modeling Task-Aware MIMO Cardinality for Efficient Multilingual Neural Machine Translation*
Hongfei Xu, Qiuhui Liu, Josef van Genabith and Deyi Xiong

00:47–00:54 *Adaptive Nearest Neighbor Machine Translation*
Xin Zheng, Zhirui Zhang, Junliang Guo, Shujian Huang, Boxing Chen, Weihua Luo and Jiajun CHEN

Session 5B: Language Grounding to Vision, Robotics and Beyond 2

00:00–00:10 *Hierarchical Context-aware Network for Dense Video Event Captioning*
Lei Ji, Xianglin Guo, Haoyang Huang and Xilin Chen

00:10–00:20 *Control Image Captioning Spatially and Temporally*
Kun Yan, Lei Ji, Huaishao Luo, Ming Zhou, Nan Duan and Shuai Ma

00:20–00:30 *Edited Media Understanding Frames: Reasoning About the Intent and Implications of Visual Misinformation*
Jeff Da, Maxwell Forbes, Rowan Zellers, Anthony Zheng, Jena D. Hwang, Antoine Bosselut and Yejin Choi

00:30–00:40 *PIGLeT: Language Grounding Through Neuro-Symbolic Interaction in a 3D World*
Rowan Zellers, Ari Holtzman, Matthew Peters, Roozbeh Mottaghi, Aniruddha Kembhavi, Ali Farhadi and Yejin Choi

00:40–00:50 *Neural Event Semantics for Grounded Language Understanding*
Shyamal Buch, Li Fei-Fei and Noah Goodman

Session 5C: Machine Learning for NLP 2

00:00–00:10 *Modeling Fine-Grained Entity Types with Box Embeddings*
Yasumasa Onoe, Michael Boratko, Andrew McCallum and Greg Durrett

00:10–00:20 *ChineseBERT: Chinese Pretraining Enhanced by Glyph and Pinyin Information*
zijun sun, Xiaoya Li, Xiaofei Sun, Yuxian Meng, Xiang Ao, Qing He, Fei Wu and Jiwei Li

00:20–00:30 *Weight Distillation: Transferring the Knowledge in Neural Network Parameters*
Ye Lin, Yanyang Li, Ziyang Wang, Bei Li, Quan Du, Tong Xiao and Jingbo Zhu

00:30–00:40 *Optimizing Deeper Transformers on Small Datasets*
Peng Xu, Dhruv Kumar, Wei Yang, Wenjie Zi, Keyi Tang, Chenyang Huang, Jackie Chi Kit Cheung, Simon J.D. Prince and Yanshuai Cao

00:40–00:50 *BERTAC: Enhancing Transformer-based Language Models with Adversarially Pretrained Convolutional Neural Networks*
Jong-Hoon Oh, Ryu Iida, Julien Kloetzer and Kentaro Torisawa

00:50–00:57 *On Orthogonality Constraints for Transformers*
Aston Zhang, Alvin Chan, Yi Tay, Jie Fu, Shuohang Wang, Shuai Zhang, Huajie Shao, Shuochao Yao and Roy Ka-Wei Lee

Session 5D: NLP Applications 1 and Ethics

00:00–00:10 *COVID-Fact: Fact Extraction and Verification of Real-World Claims on COVID-19 Pandemic*
Arkadiy Saakyan, Tuhin Chakrabarty and Smaranda Muresan

00:10–00:20 *Explaining Relationships Between Scientific Documents*
Kelvin Luu, Xinyi Wu, Rik Koncel-Kedziorski, Kyle Lo, Isabel Cachola and Noah A. Smith

00:20–00:30 *IrEne: Interpretable Energy Prediction for Transformers*
Qingqing Cao, Yash Kumar Lal, Harsh Trivedi, Aruna Balasubramanian and Niranjan Balasubramanian

00:30–00:40 *Mitigating Bias in Session-based Cyberbullying Detection: A Non-Compromising Approach*
Lu Cheng, Ahmadreza Mosallanezhad, Yasin Silva, Deborah Hall and Huan Liu

00:40–00:50 *PlotCoder: Hierarchical Decoding for Synthesizing Visualization Code in Programmatic Context*
Xinyun Chen, Linyuan Gong, Alvin Cheung and Dawn Song

00:50–01:00 *Changing the World by Changing the Data*
Anna Rogers

Session 6A: Machine Learning for NLP 3

01:00–01:10 *EarlyBERT: Efficient BERT Training via Early-bird Lottery Tickets*
Xiaohan Chen, Yu Cheng, Shuohang Wang, Zhe Gan, Zhangyang Wang and Jingjing Liu

01:10–01:20 *On the Effectiveness of Adapter-based Tuning for Pretrained Language Model Adaptation*
Ruidan He, Linlin Liu, Hai Ye, Qingyu Tan, BOSHENG DING, Liying Cheng, Jiawei Low, Lidong Bing and Luo Si

01:20–01:30 *Data Augmentation for Text Generation Without Any Augmented Data*
Wei Bi, Huayang Li and Jiacheng Huang

01:30–01:40 *KEPLER: A Unified Model for Knowledge Embedding and Pre-trained Language Representation*
Xiaozhi Wang, Tianyu Gao, Zhaocheng Zhu, Zhengyan Zhang, Zhiyuan Liu, Juanzi Li and Jian Tang

01:40–01:50 *Integrating Semantics and Neighborhood Information with Graph-Driven Generative Models for Document Retrieval*
Zijing Ou, Qinliang Su, Jianxing Yu, Bang Liu, Jingwen Wang, Ruihui Zhao, Changyou Chen and Yefeng Zheng

01:50–01:57 *Measuring and Improving BERT's Mathematical Abilities by Predicting the Order of Reasoning.*
Piotr Piękos, Mateusz Malinowski and Henryk Michalewski

Session 6B: Resources and Evaluation 1

01:00–01:10 *SMURF: SeMantic and linguistic UndeRstanding Fusion for Caption Evaluation via Typicality Analysis*
Joshua Feinglass and Yezhou Yang

01:10–01:20 *KaggleDBQA: Realistic Evaluation of Text-to-SQL Parsers*
Chia-Hsuan Lee, Oleksandr Polozov and Matthew Richardson

01:20–01:30 *QASR: QCRI Aljazeera Speech Resource A Large Scale Annotated Arabic Speech Corpus*
Hamdy Mubarak, Amir Hussein, Shammur Absar Chowdhury and Ahmed Ali

01:30–01:40 *An Empirical Study on Hyperparameter Optimization for Fine-Tuning Pre-trained Language Models*
Xueqing Liu and Chi Wang

01:40–01:50 *Better than Average: Paired Evaluation of NLP systems*
Maxime Peyrard, Wei Zhao, Steffen Eger and Robert West

01:50–01:57 *Happy Dance, Slow Clap: Using Reaction GIFs to Predict Induced Affect on Twitter*
Boaz Shmueli, Soumya Ray and Lun-Wei Ku

Session 6C: Semantics: Sentence-level Semantics, Textual Inference and Other areas 1

01:00–01:10 *Chase: A Large-Scale and Pragmatic Chinese Dataset for Cross-Database Context-Dependent Text-to-SQL*
Jiaqi Guo, Ziliang Si, Yu Wang, Qian Liu, Ming Fan, Jian-Guang LOU, Zijiang Yang and Ting Liu

01:10–01:20 *CLINE: Contrastive Learning with Semantic Negative Examples for Natural Language Understanding*
Dong Wang, Ning Ding, Piji Li and Haitao Zheng

01:20–01:30 *Tree-Structured Topic Modeling with Nonparametric Neural Variational Inference*
Ziye Chen, Cheng Ding, Zusheng Zhang, Yanghui Rao and Haoran Xie

01:30–01:40 *ExCAR: Event Graph Knowledge Enhanced Explainable Causal Reasoning*
Li Du, Xiao Ding, Kai Xiong, Ting Liu and Bing Qin

01:40–01:50 *Infusing Finetuning with Semantic Dependencies*
Zhaofeng Wu, Hao Peng and Noah Smith

01:50–01:57 *Exploring Listwise Evidence Reasoning with T5 for Fact Verification*
Kelvin Jiang, Ronak Pradeep and Jimmy Lin

Session 6D: Sentiment Analysis, Stylistic Analysis, and Argument Mining 2

01:00–01:10 *Distributed Representations of Emotion Categories in Emotion Space*
Xiangyu Wang and Chengqing Zong

01:10–01:20 *Style is NOT a single variable: Case Studies for Cross-Stylistic Language Understanding*
Dongyeop Kang and Eduard Hovy

01:20–01:30 *DynaSent: A Dynamic Benchmark for Sentiment Analysis*
Christopher Potts, Zhengxuan Wu, Atticus Geiger and Douwe Kiela

01:30–01:40 *A Hierarchical VAE for Calibrating Attributes while Generating Text using Normalizing Flow*
Bidisha Samanta, Mohit Agrawal and NIloy Ganguly

01:40–01:50 *A Unified Generative Framework for Aspect-based Sentiment Analysis*
Hang Yan, Junqi Dai, Tuo Ji, Xipeng Qiu and Zheng Zhang

01:50–02:00 *Classifying Argumentative Relations Using Logical Mechanisms and Argumentation Schemes*
Yohan Jo, Seojin Bang, Chris Reed and Eduard Hovy

Session 7A: Dialog and Interactive Systems 4

08:00–08:10 *Discovering Dialogue Slots with Weak Supervision*
Vojtěch Hudeček, Ondřej Dušek and Zhou Yu

08:10–08:20 *Enhancing the generalization for Intent Classification and Out-of-Domain Detection in SLU*
Yilin Shen, Yen-Chang Hsu, Avik Ray and Hongxia Jin

08:20–08:30 *ProtAugment: Intent Detection Meta-Learning through Unsupervised Diverse Paraphrasing*
Thomas Dopierre, Christophe Gravier and Wilfried Logerais

08:30–08:40 *Robustness Testing of Language Understanding in Task-Oriented Dialog*
Jiexi Liu, Ryuichi Takanobu, Jiaxin Wen, Dazhen Wan, hongguang li, weiran nie, Cheng LI, Wei Peng and Minlie Huang

08:40–08:50 *Comprehensive Study: How the Context Information of Different Granularity Affects Dialogue State Tracking?*
Puhai Yang, Heyan Huang and Xian-Ling Mao

08:50–09:00 *OTTers: One-turn Topic Transitions for Open-Domain Dialogue*
Karin Sevegnani, David M. Howcroft, Ioannis Konstas and Verena Rieser

Session 7B: Semantics: Sentence-level Semantics, Textual Inference and Other areas 2

08:00–08:10 *Towards Robustness of Text-to-SQL Models against Synonym Substitution*
Yujian Gan, Xinyun Chen, Qiuping Huang, Matthew Purver, John R. Woodward, Jinxia Xie and Pengsheng Huang

08:10–08:20 *KACE: Generating Knowledge Aware Contrastive Explanations for Natural Language Inference*
Qianglong Chen, Feng Ji, Xiangji Zeng, Feng-Lin Li, Ji Zhang, Haiqing Chen and Yin Zhang

08:20–08:30 *Self-Guided Contrastive Learning for BERT Sentence Representations*
Taeuk Kim, Kang Min Yoo and Sang-goo Lee

08:30–08:40 *LGESQL: Line Graph Enhanced Text-to-SQL Model with Mixed Local and Non-Local Relations*
Ruisheng Cao, Lu Chen, Zhi Chen, Yanbin Zhao, Su Zhu and Kai Yu

08:40–08:47 *DefSent: Sentence Embeddings using Definition Sentences*
Hayato Tsukagoshi, Ryohei Sasano and Koichi Takeda

08:47–08:54 *Discrete Cosine Transform as Universal Sentence Encoder*
Nada Almarwani and Mona Diab

Session 7C: Speech and Multimodality 1

08:00–08:10 *Multi-stage Pre-training over Simplified Multimodal Pre-training Models*
Tongtong Liu, Fangxiang Feng and Xiaojie WANG

08:10–08:20 *Beyond Sentence-Level End-to-End Speech Translation: Context Helps*
Biao Zhang, Ivan Titov, Barry Haddow and Rico Sennrich

08:20–08:30 *LayoutLMv2: Multi-modal Pre-training for Visually-rich Document Understanding*
Yang Xu, Yiheng Xu, Tengchao Lv, Lei Cui, Furu Wei, Guoxin Wang, Yijuan Lu, Dinei Florencio, Cha Zhang, Wanxiang Che, Min Zhang and Lidong Zhou

08:30–08:40 *UNIMO: Towards Unified-Modal Understanding and Generation via Cross-Modal Contrastive Learning*
Wei Li, Can Gao, Guocheng Niu, Xinyan Xiao, Hao Liu, Jiachen Liu, Hua Wu and Haifeng Wang

08:40–08:50 *Missing Modality Imagination Network for Emotion Recognition with Uncertain Missing Modalities*
Jinming Zhao, Ruichen Li and Qin Jin

08:50–09:00 *Stacked Acoustic-and-Textual Encoding: Integrating the Pre-trained Models into Speech Translation Encoders*
Chen Xu, Bojie Hu, Yanyang Li, Yuhao Zhang, shen huang, Qi Ju, Tong Xiao and Jingbo Zhu

Session 7D: Syntax: Tagging, Chunking, and Parsing 1

08:00–08:10 *N-ary Constituent Tree Parsing with Recursive Semi-Markov Model*
Xin Xin, Jinlong Li and Zeqi Tan

08:10–08:20 *Automated Concatenation of Embeddings for Structured Prediction*
Xinyu Wang, Yong Jiang, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

08:20–08:30 *Multi-View Cross-Lingual Structured Prediction with Minimum Supervision*
Zechuan Hu, Yong Jiang, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

08:30–08:40 *The Limitations of Limited Context for Constituency Parsing*
Yuchen Li and Andrej Risteski

Tuesday, August 3, 2021 (all times UTC+0) (continued)

08:40–08:50 *Neural Bi-Lexicalized PCFG Induction*
Songlin Yang, Yanpeng Zhao and Kewei Tu

Session 7E: Resources and Evaluation 2

08:00–08:10 *Ruddit: Norms of Offensiveness for English Reddit Comments*
Rishav Hada, Sohi Sudhir, Pushkar Mishra, Helen Yannakoudakis, Saif M. Mohammad and Ekaterina Shutova

08:10–08:20 *Towards Quantifiable Dialogue Coherence Evaluation*
Zheng Ye, Liucun Lu, Lishan Huang, Liang Lin and Xiaodan Liang

08:20–08:30 *Assessing the Representations of Idiomaticity in Vector Models with a Noun Compound Dataset Labeled at Type and Token Levels*
Marcos Garcia, Tiago Kramer Vieira, Carolina Scarton, Marco Idiart and Aline Villavicencio

08:30–08:40 *Factoring Statutory Reasoning as Language Understanding Challenges*
Nils Holzenberger and Benjamin Van Durme

08:40–08:50 *Evaluating Evaluation Measures for Ordinal Classification and Ordinal Quantification*
Tetsuya Sakai

08:50–08:57 *AligNarr: Aligning Narratives on Movies*
Paramita Mirza, Mostafa Abouhamra and Gerhard Weikum

Session 8A: Information Extraction 4

09:00–09:10 *Interpretable and Low-Resource Entity Matching via Decoupling Feature Learning from Decision Making*
Zijun Yao, Chengjiang Li, Tiansi Dong, Xin Lv, Jifan Yu, Lei Hou, Juanzi Li, YICHI ZHANG and zelin Dai

09:10–09:20 *Locate and Label: A Two-stage Identifier for Nested Named Entity Recognition*
Yongliang Shen, Xinyin Ma, Zeqi Tan, Shuai Zhang, Wen Wang and Weiming Lu

09:20–09:30 *Text2Event: Controllable Sequence-to-Structure Generation for End-to-end Event Extraction*
Yaojie Lu, Hongyu Lin, Jin Xu, Xianpei Han, Jialong Tang, Annan Li, Le Sun, Meng Liao and Shaoyi Chen

09:30–09:40 *A Large-Scale Chinese Multimodal NER Dataset with Speech Clues*
Dianbo Sui, Zhengkun Tian, Yubo Chen, Kang Liu and Jun Zhao

09:40–09:50 *A Neural Transition-based Joint Model for Disease Named Entity Recognition and Normalization*
Zongcheng Ji, Tian Xia, Mei Han and Jing Xiao

09:50–10:00 *OntoED: Low-resource Event Detection with Ontology Embedding*
Shumin Deng, Ningyu Zhang, Luoqiu Li, Chen Hui, tou huaixiao, Mosha Chen, Fei Huang and Huajun Chen

Session 8B: Machine Translation and Multilinguality 4

09:00–09:10 *Self-Training Sampling with Monolingual Data Uncertainty for Neural Machine Translation*
Wenxiang Jiao, Xing Wang, Zhaopeng Tu, Shuming Shi, Michael Lyu and Irwin King

09:10–09:20 *Breaking the Corpus Bottleneck for Context-Aware Neural Machine Translation with Cross-Task Pre-training*
Linqing Chen, Junhui Li, Zhengxian Gong, Boxing Chen, Weihua Luo, Min Zhang and Guodong Zhou

09:20–09:30 *Guiding Teacher Forcing with Seer Forcing for Neural Machine Translation*
Yang Feng, Shuhao Gu, Dengji Guo, Zhengxin Yang and Chenze Shao

09:30–09:40 *Cascade versus Direct Speech Translation: Do the Differences Still Make a Difference?*
Luisa Bentivogli, Mauro Cettolo, Marco Gaido, Alina Karakanta, Alberto Martinelli, Matteo Negri and Marco Turchi

Tuesday, August 3, 2021 (all times UTC+0) (continued)

09:40–09:50 *Unsupervised Neural Machine Translation for Low-Resource Domains via Meta-Learning*
Cheonbok Park, Yunwon Tae, TaeHee Kim, Soyoung Yang, Mohammad Azam Khan, Lucy Park and Jaegul Choo

09:50–09:57 *An Exploratory Analysis of Multilingual Word-Level Quality Estimation with Cross-Lingual Transformers*
Tharindu Ranasinghe, Constantin Orasan and Ruslan Mitkov

Session 8C: Machine Learning for NLP 4

09:00–09:10 *Lightweight Cross-Lingual Sentence Representation Learning*
Zhuoyuan Mao, Prakhar Gupta, Chenhui Chu, Martin Jaggi and Sadao Kurohashi

09:10–09:20 *ERNIE-Doc: A Retrospective Long-Document Modeling Transformer*
SiYu Ding, Junyuan Shang, Shuohuan Wang, Yu Sun, Hao Tian, Hua Wu and Haifeng Wang

09:20–09:30 *Marginal Utility Diminishes: Exploring the Minimum Knowledge for BERT Knowledge Distillation*
Yuanxin LIU, Fandong Meng, Zheng Lin, Weiping Wang and Jie Zhou

09:30–09:40 *Rational LAMOL: A Rationale-based Lifelong Learning Framework*
Kasidis Kanwatchara, Thanapapas Horsuwan, Piyawat Lertvittayakumjorn, Boonserm Kijsirikul and Peerapon Vateekul

09:40–09:50 *EnsLM: Ensemble Language Model for Data Diversity by Semantic Clustering*
Zhibin Duan, Hao Zhang, Chaojie Wang, Zhengjue Wang, Bo Chen and Mingyuan Zhou

09:50–10:00 *LeeBERT: Learned Early Exit for BERT with cross-level optimization*
Wei Zhu

Session 8D: NLP Applications 2

09:00–09:10 *Unsupervised Extractive Summarization-Based Representations for Accurate and Explainable Collaborative Filtering*
Reinald Adrian Pugoy and Hung-Yu Kao

09:10–09:20 *PLOME: Pre-training with Misspelled Knowledge for Chinese Spelling Correction*
Shulin Liu, Tao Yang, Tianchi Yue, Feng Zhang and Di Wang

09:20–09:30 *Competence-based Multimodal Curriculum Learning for Medical Report Generation*
Fenglin Liu, Shen Ge and Xian Wu

09:30–09:40 *Learning Syntactic Dense Embedding with Correlation Graph for Automatic Readability Assessment*
Xinying Qiu, Yuan Chen, Hanwu Chen, Jian-Yun Nie, Yuming Shen and Dawei Lu

09:40–09:50 *Meta-KD: A Meta Knowledge Distillation Framework for Language Model Compression across Domains*
Haojie Pan, Chengyu Wang, Minghui Qiu, Yichang Zhang, Yaliang Li and jun huang

09:50–09:57 *Exploration and Exploitation: Two Ways to Improve Chinese Spelling Correction Models*
Chong Li, Cenyuan Zhang, Xiaoqing Zheng and Xuanjing Huang

Session 8E: Question Answering 1

09:00–09:10 *A Semantic-based Method for Unsupervised Commonsense Question Answering*
Yilin Niu, Fei Huang, Jiaming Liang, Wenkai Chen, Xiaoyan Zhu and Minlie Huang

09:10–09:20 *Explanations for CommonsenseQA: New Dataset and Models*
Shourya Aggarwal, Divyanshu Mandowara, Vishwajeet Agrawal, Dinesh Khandelwal, Parag Singla and Dinesh Garg

09:20–09:30 *Few-Shot Question Answering by Pretraining Span Selection*
Ori Ram, Yuval Kirstain, Jonathan Berant, Amir Globerson and Omer Levy

09:30–09:40 *UnitedQA: A Hybrid Approach for Open Domain Question Answering*
Hao Cheng, Yelong Shen, Xiaodong Liu, Pengcheng He, Weizhu Chen and Jianfeng Gao

09:40–09:50 *Database reasoning over text*
James Thorne, Majid Yazdani, Marzieh Saeidi, Fabrizio Silvestri, Sebastian Riedel and Alon Halevy

09:50–09:57 *Training Adaptive Computation for Open-Domain Question Answering with Computational Constraints*
Yuxiang Wu, Pasquale Minervini, Pontus Stenetorp and Sebastian Riedel

Session 9A: Machine Translation and Multilinguality 5

10:00–10:10 *Online Learning Meets Machine Translation Evaluation: Finding the Best Systems with the Least Human Effort*
Vânia Mendonça, Ricardo Rei, Luisa Coheur, Alberto Sardinha and Ana Lúcia Santos

10:10–10:20 *How Good is Your Tokenizer? On the Monolingual Performance of Multilingual Language Models*
Phillip Rust, Jonas Pfeiffer, Ivan Vulić, Sebastian Ruder and Iryna Gurevych

10:20–10:30 *Evaluating morphological typology in zero-shot cross-lingual transfer*
Antonio Martínez-García, Toni Badia and Jeremy Barnes

10:30–10:40 *From Machine Translation to Code-Switching: Generating High-Quality Code-Switched Text*
Ishan Tarunesh, Syamantak Kumar and Preethi Jyothi

10:40–10:50 *Fast and Accurate Neural Machine Translation with Translation Memory*
Qiuxiang He, Guoping Huang, Qu Cui, Li Li and Lemao Liu

10:50–10:57 *An Empirical Study on Adversarial Attack on NMT: Languages and Positions Matter*
Zhiyuan Zeng and Deyi Xiong

Session 9B: Resources and Evaluation 3

10:00–10:10 *Annotating Online Misogyny*
Philine Zeinert, Nanna Inie and Leon Derczynski

10:10–10:20 *Few-NERD: A Few-shot Named Entity Recognition Dataset*
Ning Ding, Guangwei Xu, Yulin Chen, Xiaobin Wang, Xu Han, Pengjun Xie, Haitao Zheng and Zhiyuan Liu

10:20–10:30 *MultiMET: A Multimodal Dataset for Metaphor Understanding*
Dongyu Zhang, Minghao Zhang, Heting Zhang, Liang Yang and Hongfei LIN

10:30–10:40 *Human-in-the-Loop for Data Collection: a Multi-Target Counter Narrative Dataset to Fight Online Hate Speech*
Margherita Fanton, Helena Bonaldi, Serra Sinem Tekiroğlu and Marco Guerini

10:40–10:47 *OntoGUM: Evaluating Contextualized SOTA Coreference Resolution on 12 More Genres*
Yilun Zhu, Sameer Pradhan and Amir Zeldes

Session 9C: Question Answering 2

10:00–10:10 *Can Generative Pre-trained Language Models Serve As Knowledge Bases for Closed-book QA?*
Cunxiang Wang, Pai Liu and Yue Zhang

10:10–10:20 *Joint Models for Answer Verification in Question Answering Systems*
Zeyu Zhang, Thuy Vu and Alessandro Moschitti

10:20–10:30 *Answering Ambiguous Questions through Generative Evidence Fusion and Round-Trip Prediction*
Yifan Gao, Henghui Zhu, Patrick Ng, Cicero Nogueira dos Santos, Zhiguo Wang, Feng Nan, Dejiao Zhang, Ramesh Nallapati, Andrew O. Arnold and Bing Xiang

10:30–10:40 *TAT-QA: A Question Answering Benchmark on a Hybrid of Tabular and Textual Content in Finance*
Fengbin Zhu, Wenqiang Lei, Youcheng Huang, Chao Wang, Shuo Zhang, Jiancheng Lv, Fuli Feng and Tat-Seng Chua

10:40–10:50 *Modeling Transitions of Focal Entities for Conversational Knowledge Base Question Answering*
Yunshi Lan and Jing Jiang

10:50–10:57 *In Factuality: Efficient Integration of Relevant Facts for Visual Question Answering*
Peter Vickers, Nikolaos Aletras, Emilio Monti and Loïc Barrault

Session 9D: Semantics: Sentence-level Semantics, Textual Inference and Other areas 3

10:00–10:10 *Evidence-based Factual Error Correction*
James Thorne and Andreas Vlachos

10:10–10:20 *Probabilistic, Structure-Aware Algorithms for Improved Variety, Accuracy, and Coverage of AMR Alignments*
Austin Blodgett and Nathan Schneider

10:20–10:30 *Meta-Learning to Compositionally Generalize*
Henry Conklin, Bailin Wang, Kenny Smith and Ivan Titov

10:30–10:40 *Taming Pre-trained Language Models with N-gram Representations for Low-Resource Domain Adaptation*
Shizhe Diao, Ruijia Xu, Hongjin Su, Yilei Jiang, Yan Song and Tong Zhang

10:40–10:50 *ERICA: Improving Entity and Relation Understanding for Pre-trained Language Models via Contrastive Learning*
Yujia Qin, Yankai Lin, Ryuichi Takanobu, Zhiyuan Liu, Peng Li, Heng Ji, Minlie Huang, Maosong Sun and Jie Zhou

10:50–10:57 *Zero-shot Fact Verification by Claim Generation*
Liangming Pan, Wenhu Chen, Wenhan Xiong, Min-Yen Kan and William Yang Wang

Session 9E: Sentiment Analysis, Stylistic Analysis, and Argument Mining 3

10:00–10:10 *Position Bias Mitigation: A Knowledge-Aware Graph Model for Emotion Cause Extraction*
Hanqi Yan, Lin Gui, Gabriele Pergola and Yulan He

10:10–10:20 *Every Bite Is an Experience: Key Point Analysis of Business Reviews*
Roy Bar-Haim, Lilach Eden, Yoav Kantor, Roni Friedman and Noam Slonim

10:20–10:30 *Structured Sentiment Analysis as Dependency Graph Parsing*
Jeremy Barnes, Robin Kurtz, Stephan Oepen, Lilja Øvrelid and Erik Velldal

10:30–10:37 *Thank you BART! Rewarding Pre-Trained Models Improves Formality Style Transfer*
Huiyuan Lai, Antonio Toral and Malvina Nissim

10:37–10:44 *Deep Context- and Relation-Aware Learning for Aspect-based Sentiment Analysis*
Shinhyeok Oh, Dongyub Lee, Taesun Whang, IlNam Park, Seo Gaeun, EungGyun Kim and Harksoo Kim

10:44–10:51 *Towards Generative Aspect-Based Sentiment Analysis*
Wenxuan Zhang, Xin Li, Yang Deng, Lidong Bing and Wai Lam

Session 10A: Machine Translation and Multilinguality 6

11:00–11:10 *Consistency Regularization for Cross-Lingual Fine-Tuning*
Bo Zheng, Li Dong, Shaohan Huang, Wenhui Wang, Zewen Chi, Saksham Singhal, Wanxiang Che, Ting Liu, Xia Song and Furu Wei

11:10–11:20 *Improving Pretrained Cross-Lingual Language Models via Self-Labeled Word Alignment*
Zewen Chi, Li Dong, Bo Zheng, Shaohan Huang, Xian-Ling Mao, Heyan Huang and Furu Wei

11:20–11:30 *Rejuvenating Low-Frequency Words: Making the Most of Parallel Data in Non-Autoregressive Translation*
Liang Ding, Longyue Wang, Xuebo Liu, Derek F. Wong, Dacheng Tao and Zhaopeng Tu

11:30–11:40 *G-Transformer for Document-Level Machine Translation*
Guangsheng Bao, Yue Zhang, Zhiyang Teng, Boxing Chen and Weihua Luo

Tuesday, August 3, 2021 (all times UTC+0) (continued)

11:40–11:50 *Prevent the Language Model from being Overconfident in Neural Machine Translation*
Mengqi Miao, Fandong Meng, Yijin Liu, Xiao-Hua Zhou and Jie Zhou

11:50–11:57 *Bilingual Mutual Information Based Adaptive Training for Neural Machine Translation*
Yangyifan Xu, Yijin Liu, Fandong Meng, Jiajun Zhang, Jinan Xu and Jie Zhou

Session 10B: Dialog and Interactive Systems 5

11:00–11:10 *Towards Emotional Support Dialog Systems*
Siyang Liu, Chujie Zheng, Orianna Demasi, Sahand Sabour, Yu Li, Zhou Yu, Yong Jiang and Minlie Huang

11:10–11:20 *Novel Slot Detection: A Benchmark for Discovering Unknown Slot Types in the Task-Oriented Dialogue System*
Yanan Wu, Zhiyuan Zeng, Keqing He, Hong Xu, Yuanmeng Yan, Huixing Jiang and Weiran Xu

11:20–11:30 *GTM: A Generative Triple-wise Model for Conversational Question Generation*
Lei Shen, Fandong Meng, Jinchao Zhang, Yang Feng and Jie Zhou

11:30–11:40 *Diversifying Dialog Generation via Adaptive Label Smoothing*
Yida Wang, Yinhe Zheng, Yong Jiang and Minlie Huang

11:40–11:50 *Out-of-Scope Intent Detection with Self-Supervision and Discriminative Training*
Li-Ming Zhan, Haowen Liang, Bo LIU, Lu Fan, Xiao-Ming Wu and Albert Y.S. Lam

11:50–11:57 *Continual Learning for Task-oriented Dialogue System with Iterative Network Pruning, Expanding and Masking*
Binzong Geng, Fajie Yuan, Qiancheng Xu, Ying Shen, Ruifeng Xu and Min Yang

Session 10C: Information Extraction 5

11:00–11:10 *Document-level Event Extraction via Heterogeneous Graph-based Interaction Model with a Tracker*
Runxin Xu, Tianyu Liu, Lei Li and Baobao Chang

11:10–11:20 *Nested Named Entity Recognition via Explicitly Excluding the Influence of the Best Path*
Yiran Wang, Hiroyuki Shindo, Yuji Matsumoto and Taro Watanabe

11:20–11:30 *LearnDA: Learnable Knowledge-Guided Data Augmentation for Event Causality Identification*
Xinyu Zuo, Pengfei Cao, Yubo Chen, Kang Liu, Jun Zhao, Weihua Peng and Yuguang Chen

11:30–11:40 *Revisiting the Negative Data of Distantly Supervised Relation Extraction*
Chenhao Xie, Jiaqing Liang, Jingping Liu, Chengsong Huang, Wenhao Huang and Yanghua Xiao

11:40–11:50 *Knowing the No-match: Entity Alignment with Dangling Cases*
Zequn Sun, Muhao Chen and Wei Hu

11:50–11:57 *TIMERS: Document-level Temporal Relation Extraction*
Puneet Mathur, Rajiv Jain, Franck Dernoncourt, Vlad Morariu, Quan Hung Tran and Dinesh Manocha

Session 10D: Phonology, Morphology and Word Segmentation 1

11:00–11:10 *Superbizarre Is Not Superb: Derivational Morphology Improves BERT's Interpretation of Complex Words*
Valentin Hofmann, Janet Pierrehumbert and Hinrich Schütze

11:10–11:20 *Optimizing over Subsequences Generates Context-Sensitive Languages*
Andrew Lamont

11:20–11:30 *Morphology Matters: A Multilingual Language Modeling Analysis*
Hyunji Hayley Park, Katherine J. Zhang, Coleman Haley, Kenneth Steimel, Han Liu and Lane Schwartz

11:30–11:37 *Improving Arabic Diacritization with Regularized Decoding and Adversarial Training*
Han Qin, Guimin Chen, Yuanhe Tian and Yan Song

Tuesday, August 3, 2021 (all times UTC+0) (continued)

11:37–11:44 *When is Char Better Than Subword: A Systematic Study of Segmentation Algorithms for Neural Machine Translation*
Jiahuan Li, Yutong Shen, Shujian Huang, Xinyu Dai and Jiajun CHEN

11:44–11:51 *More than Text: Multi-modal Chinese Word Segmentation*
Dong Zhang, Zheng Hu, Shoushan Li, Hanqian Wu, Qiaoming Zhu and Guodong Zhou

Session 10E: Semantics: Lexical Semantics 1

11:00–11:10 *BERT is to NLP what AlexNet is to CV: Can Pre-Trained Language Models Identify Analogies?*
Asahi Ushio, Luis Espinosa Anke, Steven Schockaert and Jose Camacho-Collados

11:10–11:20 *Exploring the Representation of Word Meanings in Context: A Case Study on Homonymy and Synonymy*
Marcos Garcia

11:20–11:30 *Measuring Fine-Grained Domain Relevance of Terms: A Hierarchical Core-Fringe Approach*
Jie Huang, Kevin Chang, JinJun Xiong and Wen-mei Hwu

11:30–11:37 *A Mixture-of-Experts Model for Antonym-Synonym Discrimination*
Zhipeng Xie and Nan Zeng

11:37–11:44 *Learning Domain-Specialised Representations for Cross-Lingual Biomedical Entity Linking*
Fangyu Liu, Ivan Vulić, Anna Korhonen and Nigel Collier

11:44–11:51 *A Cluster-based Approach for Improving Isotropy in Contextual Embedding Space*
Sara Rajaee and Mohammad Taher Pilehvar

14:00–15:30 ***Business meeting and Green NLP panel***

15:30–16:30 ***Keynote 3. Christopher Potts: Reliable Characterizations of NLP Systems as a Social Responsibility***

Session 11A: Dialog and Interactive Systems 6

16:30–16:40 *HERALD: An Annotation Efficient Method to Detect User Disengagement in Social Conversations*
Weixin Liang, Kai-Hui Liang and Zhou Yu

16:40–16:50 *Value-Agnostic Conversational Semantic Parsing*
Emmanouil Antonios Platanios, Adam Pauls, Subhro Roy, Yuchen Zhang, Alexander Kyte, Alan Guo, Sam Thomson, Jayant Krishnamurthy, Jason Wolfe, Jacob Andreas and Dan Klein

16:50–17:00 *MPC-BERT: A Pre-Trained Language Model for Multi-Party Conversation Understanding*
Jia-Chen Gu, Chongyang Tao, Zhenhua Ling, Can Xu, Xiubo Geng and Daxin Jiang

17:00–17:10 *Best of Both Worlds: Making High Accuracy Non-incremental Transformer-based Disfluency Detection Incremental*
Morteza Rohanian and Julian Hough

17:10–17:20 *NeuralWOZ: Learning to Collect Task-Oriented Dialogue via Model-Based Simulation*
Sungdong Kim, Minsuk Chang and Sang-Woo Lee

17:20–17:27 *Unsupervised Enrichment of Persona-grounded Dialog with Background Stories*
Bodhisattwa Prasad Majumder, Taylor Berg-Kirkpatrick, Julian McAuley and Harsh Jhamtani

Session 11B: Linguistic Theories, Cognitive Modeling and Psycholinguistics 1

16:30–16:40 *CDRNN: Discovering Complex Dynamics in Human Language Processing*
Cory Shain

16:40–16:50 *Structural Guidance for Transformer Language Models*
Peng Qian, Tahira Naseem, Roger Levy and Ramón Fernandez Astudillo

16:50–17:00 *Surprisal Estimators for Human Reading Times Need Character Models*
Byung-Doh Oh, Christian Clark and William Schuler

17:00–17:10 *CogAlign: Learning to Align Textual Neural Representations to Cognitive Language Processing Signals*
Yuqi Ren and Deyi Xiong

17:10–17:20 *Formal Basis of a Language Universal*
Milos Stanojevic and Mark Steedman

17:20–17:27 *Beyond Laurel/Yanny: An Autoencoder-Enabled Search for Polyperceivable Audio*
Kartik Chandra, Chuma Kabaghe and Gregory Valiant

Session 11C: Machine Learning for NLP 5

16:30–16:40 *Self-Attention Networks Can Process Bounded Hierarchical Languages*
Shunyu Yao, Binghui Peng, Christos Papadimitriou and Karthik Narasimhan

16:40–16:50 *TextSETTR: Few-Shot Text Style Extraction and Tunable Targeted Restyling*
Parker Riley, Noah Constant, Mandy Guo, Girish Kumar, David Uthus and Zarana Parekh

16:50–17:00 *H-Transformer-1D: Fast One-Dimensional Hierarchical Attention for Sequences*
Zhenhai Zhu and Radu Soricut

17:00–17:10 *Making Pre-trained Language Models Better Few-shot Learners*
Tianyu Gao, Adam Fisch and Danqi Chen

17:10–17:20 *A Sweet Rabbit Hole by DARCY: Using Honeypots to Detect Universal Trigger's Adversarial Attacks*
Thai Le, Noseong Park and Dongwon Lee

17:20–17:27 *Don't Let Discourse Confine Your Model: Sequence Perturbations for Improved Event Language Models*
Mahnaz Koupaee, Greg Durrett, Nathanael Chambers and Niranjan Balasubramanian

Session 11D: Information Retrieval and Text Mining 1

16:30–16:40 *Towards Propagation Uncertainty: Edge-enhanced Bayesian Graph Convolutional Networks for Rumor Detection*
Lingwei Wei, Dou Hu, Wei Zhou, Zhaojuan Yue and Songlin Hu

16:40–16:50 *Label-Specific Dual Graph Neural Network for Multi-Label Text Classification*
Qianwen Ma, Chunyuan Yuan, Wei Zhou and Songlin Hu

16:50–17:00 *TAN-NTM: Topic Attention Networks for Neural Topic Modeling*
Madhur Panwar, Shashank Shailabh, Milan Aggarwal and Balaji Krishnamurthy

17:00–17:10 *Cross-language Sentence Selection via Data Augmentation and Rationale Training*
Yanda Chen, Chris Kedzie, Suraj Nair, Petra Galuscakova, Rui Zhang, Douglas Oard and Kathleen McKeown

17:10–17:20 *A Neural Model for Joint Document and Snippet Ranking in Question Answering for Large Document Collections*
Dimitris Pappas and Ion Androutsopoulos

17:20–17:27 *The Curse of Dense Low-Dimensional Information Retrieval for Large Index Sizes*
Nils Reimers and Iryna Gurevych

Session 11E: Discourse and Pragmatics 1

16:30–16:40 *W-RST: Towards a Weighted RST-style Discourse Framework*
Patrick Huber, Wen Xiao and Giuseppe Carenini

16:40–16:50 *ABCD: A Graph Framework to Convert Complex Sentences to a Covering Set of Simple Sentences*
Yanjun Gao, Ting-Hao Huang and Rebecca J. Passonneau

16:50–17:00 *Which Linguist Invented the Lightbulb? Presupposition Verification for Question-Answering*
Najoung Kim, Ellie Pavlick, Burcu Karagol Ayan and Deepak Ramachandran

17:00–17:10 *Adversarial Learning for Discourse Rhetorical Structure Parsing*
Longyin Zhang, Fang Kong and Guodong Zhou

Tuesday, August 3, 2021 (all times UTC+0) (continued)

17:10–17:20 *Exploring Discourse Structures for Argument Impact Classification*
Xin Liu, Jiefu Ou, Yangqiu Song and Xin Jiang

Session 12A: Machine Translation and Multilinguality 7

23:00–23:10 *Point, Disambiguate and Copy: Incorporating Bilingual Dictionaries for Neural Machine Translation*
Tong Zhang, Long Zhang, Wei Ye, Bo Li, Jinan Sun, Xiaoyu Zhu, Wen Zhao and Shikun Zhang

23:10–23:20 *VECO: Variable and Flexible Cross-lingual Pre-training for Language Understanding and Generation*
Fuli Luo, Wei Wang, Jiahao Liu, Yijia Liu, Bin Bi, Songfang Huang, Fei Huang and Luo Si

23:20–23:30 *A unified approach to sentence segmentation of punctuated text in many languages*
Rachel Wicks and Matt Post

23:30–23:40 *Towards User-Driven Neural Machine Translation*
Huan Lin, Liang Yao, Baosong Yang, Dayiheng Liu, Haibo Zhang, Weihua Luo, Degen Huang and Jinsong Su

23:40–23:50 *End-to-End Lexically Constrained Machine Translation for Morphologically Rich Languages*
Josef Jon, João Paulo Aires, Dusan Varis and Ondřej Bojar

23:50–23:57 *Cross-lingual Text Classification with Heterogeneous Graph Neural Network*
Ziyun Wang, Xuan Liu, Peiji Yang, Shixing Liu and zhisheng wang

Session 12B: Resources and Evaluation 4

23:00–23:10 *Handling Extreme Class Imbalance in Technical Logbook Datasets*
Farhad Akhbardeh, Cecilia Ovesdotter Alm, Marcos Zampieri and Travis Desell

23:10–23:20 *ILDC for CJPE: Indian Legal Documents Corpus for Court Judgment Prediction and Explanation*
Vijit Malik, Rishabh Sanjay, Shubham Kumar Nigam, Kripabandhu Ghosh, Shouvik Kumar Guha, Arnab Bhattacharya and Ashutosh Modi

23:20–23:30 *Supporting Cognitive and Emotional Empathic Writing of Students*
Thiemo Wambsganss, Christina Niklaus, Matthias Söllner, Siegfried Handschuh and Jan Marco Leimeister

23:30–23:40 *Context-aware Adversarial Training for Name Regularity Bias in Named Entity Recognition*
Abbas Ghaddar, Philippe Langlais, Ahmad Rashid and Mehdi Rezagholizadeh

23:40–23:50 *SummEval: Re-evaluating Summarization Evaluation*
Alex Fabbri, Wojciech Kryscinski, Bryan McCann, Caiming Xiong and Richard Socher

23:50–24:00 *Towards Question-Answering as an Automatic Metric for Evaluating the Content Quality of a Summary*
Daniel Deutsch, Tania Bedrax-Weiss and Dan Roth

Session 12C: Question Answering 3

23:00–23:10 *Dual Reader-Parser on Hybrid Textual and Tabular Evidence for Open Domain Question Answering*
Alexander Hanbo Li, Patrick Ng, Peng Xu, Henghui Zhu, Zhiguo Wang and Bing Xiang

23:10–23:20 *Generation-Augmented Retrieval for Open-Domain Question Answering*
Yuning Mao, Pengcheng He, Xiaodong Liu, Yelong Shen, Jianfeng Gao, Jiawei Han and Weizhu Chen

23:20–23:30 *Check It Again:Progressive Visual Question Answering via Visual Entailment*
Qingyi Si, Zheng Lin, Ming yu Zheng, Peng Fu and Weiping Wang

23:30–23:40 *A Mutual Information Maximization Approach for the Spurious Solution Problem in Weakly Supervised Question Answering*
Zhihong Shao, Lifeng Shang, Qun Liu and Minlie Huang

23:40–23:50 *Relevance-guided Supervision for OpenQA with ColBERT*
Omar Khattab, Christopher Potts and Matei Zaharia

23:50–23:57 *Towards more equitable question answering systems: How much more data do you need?*
Arnab Debnath, Navid Rajabi, Fardina Fathmiul Alam and Antonios Anastasopoulos

Session 12D: Theme 1

23:00–23:10 *Breaking Down Walls of Text: How Can NLP Benefit Consumer Privacy?*
Abhilasha Ravichander, Alan W Black, Thomas Norton, Shomir Wilson and Norman Sadeh

23:10–23:20 *Supporting Land Reuse of Former Open Pit Mining Sites using Text Classification and Active Learning*
Christopher Schröder, Kim Bürgl, Yves Annanias, Andreas Niekler, Lydia Müller, Daniel Wiegreffe, Christian Bender, Christoph Mengs, Gerik Scheuermann and Gerhard Heyer

23:20–23:30 *Reliability Testing for Natural Language Processing Systems*
Samson Tan, Shafiq Joty, Kathy Baxter, Araz Taeihagh, Gregory A. Bennett and Min-Yen Kan

23:30–23:40 *Learning Language and Multimodal Privacy-Preserving Markers of Mood from Mobile Data*
Paul Pu Liang, Terrance Liu, Anna Cai, Michal Muszynski, Ryo Ishii, Nick Allen, Randy Auerbach, David Brent, Ruslan Salakhutdinov and Louis-Philippe Morency

23:40–23:50 *Anonymisation Models for Text Data: State of the art, Challenges and Future Directions*
Pierre Lison, Ildikó Pilán, David Sanchez, Montserrat Batet and Lilja Øvrelid

Wednesday, August 4, 2021 (all times UTC+0)

Poster 2A: Semantics: Sentence-level Semantics, Textual Inference and Other areas

0:00–2:00 *End-to-End AMR Corefencence Resolution*
Qiankun Fu, Linfeng Song, Wenyu Du and Yue Zhang

Poster 2B: Linguistic Theories, Cognitive Modeling and Psycholinguistics

0:00–2:00 *How is BERT surprised? Layerwise detection of linguistic anomalies*
Bai Li, Zining Zhu, Guillaume Thomas, Yang Xu and Frank Rudzicz

0:00–2:00 *Psycholinguistic Tripartite Graph Network for Personality Detection*
Tao Yang, Feifan Yang, Haolan Ouyang and Xiaojun Quan

Poster 2C: Semantics: Lexical Semantics

0:00–2:00 *Verb Metaphor Detection via Contextual Relation Learning*
Wei Song, Shuhui Zhou, Ruiji Fu, Ting Liu and Lizhen Liu

Poster 2D: Speech and Multimodality

0:00–2:00 *Improving Speech Translation by Understanding and Learning from the Auxiliary Text Translation Task*
Yun Tang, Juan Pino, Xian Li, Changhan Wang and Dmitriy Genzel

Poster 2E: Ethics in NLP

0:00–2:00 *Probing Toxic Content in Large Pre-Trained Language Models*
Nedjma Ousidhoum, Xinran Zhao, Tianqing Fang, Yangqiu Song and Dit-Yan Yeung

0:00–2:00 *Societal Biases in Language Generation: Progress and Challenges*
Emily Sheng, Kai-Wei Chang, Prem Natarajan and Nanyun Peng

Poster 2F: Interpretability and Analysis of Models for NLP

0:00–2:00 *Reservoir Transformers*
Sheng Shen, Alexei Baevski, Ari Morcos, Kurt Keutzer, Michael Auli and Douwe Kiela

Poster 2G: Machine Learning for NLP

0:00–2:00 *Subsequence Based Deep Active Learning for Named Entity Recognition*
Puria Radmard, Yassir Fathullah and Aldo Lipani

0:00–2:00 *Convolutions and Self-Attention: Re-interpreting Relative Positions in Pre-trained Language Models*
Tyler Chang, Yifan Xu, Weijian Xu and Zhuowen Tu

0:00–2:00 *BinaryBERT: Pushing the Limit of BERT Quantization*
Haoli Bai, Wei Zhang, Lu Hou, Lifeng Shang, Jin JIN, Xin Jiang, Qun Liu, Michael Lyu and Irwin King

0:00–2:00 *Embedding Time Differences in Context-sensitive Neural Networks for Learning Time to Event*
Nazanin Dehghani, Hassan Hajipoor and Hadi Amiri

0:00–2:00 *Are Pretrained Convolutions Better than Pretrained Transformers?*
Yi Tay, Mostafa Dehghani, Jai Prakash Gupta, Vamsi Aribandi, Dara Bahri, Zhen Qin and Donald Metzler

0:00–2:00 *PairRE: Knowledge Graph Embeddings via Paired Relation Vectors*
Linlin Chao, Jianshan He, Taifeng Wang and Wei Chu

0:00–2:00 *Improving Compositional Generalization in Classification Tasks via Structure Annotations*
Juyong Kim, Pradeep Ravikumar, Joshua Ainslie and Santiago Ontanon

0:00–2:00 *Learning to Generate Task-Specific Adapters from Task Description*
Qinyuan Ye and Xiang Ren

0:00–2:00 *Hierarchy-aware Label Semantics Matching Network for Hierarchical Text Classification*
Haibin Chen, Qianli Ma, Zhenxi Lin and Jiangyue Yan

0:00–2:00 *HiddenCut: Simple Data Augmentation for Natural Language Understanding with Better Generalizability*
Jiaao Chen, Dinghan Shen, Weizhu Chen and Diyi Yang

0:00–2:00 *Efficient Content-Based Sparse Attention with Routing Transformers*
Aurko Roy, Mohammad Saffar, Ashish Vaswani and David Grangier

Poster 2H: Dialog and Interactive Systems

0:00–2:00 *Neural Stylistic Response Generation with Disentangled Latent Variables*
Qingfu Zhu, Wei-Nan Zhang, Ting Liu and William Yang Wang

0:00–2:00 *Intent Classification and Slot Filling for Privacy Policies*
Wasi Ahmad, Jianfeng Chi, Tu Le, Thomas Norton, Yuan Tian and Kai-Wei Chang

0:00–2:00 *RADDLE: An Evaluation Benchmark and Analysis Platform for Robust Task-oriented Dialog Systems*
Baolin Peng, Chunyuan Li, Zhu Zhang, Chenguang Zhu, Jinchao Li and Jianfeng Gao

0:00–2:00 *QA-Driven Zero-shot Slot Filling with Weak Supervision Pretraining*
Xinya Du, Luheng He, Qi Li, Dian Yu, Panupong Pasupat and Yuan Zhang

0:00–2:00 *Domain-Adaptive Pretraining Methods for Dialogue Understanding*
Han Wu, Kun Xu, Linfeng Song, Lifeng Jin, Haisong Zhang and Linqi Song

0:00–2:00 *Semantic Representation for Dialogue Modeling*
Xuefeng Bai, Yulong Chen, Linfeng Song and Yue Zhang

0:00–2:00 *A Pre-training Strategy for Zero-Resource Response Selection in Knowledge-Grounded Conversations*
Chongyang Tao, Changyu Chen, Jiazhan Feng, Ji-Rong Wen and Rui Yan

0:00–2:00 *SOLOIST: Building Task Bots at Scale with Transfer Learning and Machine Teaching*
Baolin Peng, Chunyuan Li, Jinchao Li, Shahin Shayandeh, Lars Liden and Jianfeng Gao

Poster 2I: Information Retrieval and Text Mining

0:00–2:00 *Dependency-driven Relation Extraction with Attentive Graph Convolutional Networks*
Yuanhe Tian, Guimin Chen, Yan Song and Xiang Wan

0:00–2:00 *Evaluating Entity Disambiguation and the Role of Popularity in Retrieval-Based NLP*
Anthony Chen, Pallavi Gudipati, Shayne Longpre, Xiao Ling and Sameer Singh

Poster 2J: Resources and Evaluation

0:00–2:00 *Targeting the Benchmark: On Methodology in Current Natural Language Processing Research*
David Schlangen

0:00–2:00 *Evaluation Examples are not Equally Informative: How should that change NLP Leaderboards?*
Pedro Rodriguez, Joe Barrow, Alexander Miserlis Hoyle, John P. Lalor, Robin Jia and Jordan Boyd-Graber

Poster 2K: Computational Social Science and Cultural Analytics

0:00–2:00 *Claim Matching Beyond English to Scale Global Fact-Checking*
Ashkan Kazemi, Kiran Garimella, Devin Gaffney and Scott Hale

0:00–2:00 *X-Fact: A New Benchmark Dataset for Multilingual Fact Checking*
Ashim Gupta and Vivek Srikumar

Poster 2L: Machine Translation and Multilinguality

0:00–2:00 *SemFace: Pre-training Encoder and Decoder with a Semantic Interface for Neural Machine Translation*
Shuo Ren, Long Zhou, Shujie Liu, Furu Wei, Ming Zhou and Shuai Ma

0:00–2:00 *Energy-Based Reranking: Improving Neural Machine Translation Using Energy-Based Models*
Sumanta Bhattacharyya, Amirmohammad Rooshenas, Subhajit Naskar, Simeng Sun, Mohit Iyyer and Andrew McCallum

0:00–2:00 *nmT5 - Is parallel data still relevant for pre-training massively multilingual language models?*
Mihir Kale, Aditya Siddhant, Rami Al-Rfou, Linting Xue, Noah Constant and Melvin Johnson

0:00–2:00 *Syntax-augmented Multilingual BERT for Cross-lingual Transfer*
Wasi Ahmad, Haoran Li, Kai-Wei Chang and Yashar Mehdad

0:00–2:00 *How to Adapt Your Pretrained Multilingual Model to 1600 Languages*
Abteen Ebrahimi and Katharina Kann

0:00–2:00 *Synthesizing Parallel Data of User-Generated Texts with Zero-Shot Neural Machine Translation*
Benjamin Marie and Atsushi Fujita

Poster 2M: Syntax: Tagging, Chunking, and Parsing

0:00–2:00 *Weakly Supervised Named Entity Tagging with Learnable Logical Rules*
Jiacheng Li, Haibo Ding, Jingbo Shang, Julian McAuley and Zhe Feng

Poster 2N: NLP Applications

0:00–2:00 *Question Generation for Adaptive Education*
Megha Srivastava and Noah Goodman

Poster 2O: Language Generation

0:00–2:00 *Prefix-Tuning: Optimizing Continuous Prompts for Generation*
Xiang Lisa Li and Percy Liang

0:00–2:00 *One2Set: Generating Diverse Keyphrases as a Set*
Jiacheng Ye, Tao Gui, Yichao Luo, Yige Xu and Qi Zhang

0:00–2:00 *A Simple Recipe for Multilingual Grammatical Error Correction*
Sascha Rothe, Jonathan Mallinson, Eric Malmi, Sebastian Krause and Aliaksei Severyn

0:00–2:00 *Continuous Language Generative Flow*
Zineng Tang, Shiyue Zhang, Hyounghun Kim and Mohit Bansal

0:00–2:00 *RYANSQL: Recursively Applying Sketch-based Slot Fillings for Complex Text-to-SQL in Cross-Domain Databases*
DongHyun Choi, Myeong Cheol Shin, EungGyun Kim and Dong Ryeol Shin

Poster 2P: Summarization

0:00–2:00 *TWAG: A Topic-Guided Wikipedia Abstract Generator*
Fangwei Zhu, Shangqing Tu, Jiaxin Shi, Juanzi Li, Lei Hou and Tong Cui

Poster 2Q: Question Answering

0:00–2:00 *Towards Visual Question Answering on Pathology Images*
Xuehai He, Zhuo Cai, Wenlan Wei, Yichen Zhang, Luntian Mou, Eric Xing and Pengtao Xie

0:00–2:00 *ForecastQA: A Question Answering Challenge for Event Forecasting with Temporal Text Data*
Woojeong Jin, Rahul Khanna, Suji Kim, Dong-Ho Lee, Fred Morstatter, Aram Galstyan and Xiang Ren

0:00–2:00 *Recursive Tree-Structured Self-Attention for Answer Sentence Selection*
Khalil Mrini, Emilia Farcas and Ndapa Nakashole

Poster 2R: Language Grounding to Vision, Robotics and Beyond

0:00–2:00 *Efficient Text-based Reinforcement Learning by Jointly Leveraging State and Commonsense Graph Representations*
Keerthiram Murugesan, Mattia Atzeni, Pavan Kapanipathi, Kartik Talamadupula, Mrinmaya Sachan and Murray Campbell

0:00–2:00 *mTVR: Multilingual Moment Retrieval in Videos*
Jie Lei, Tamara Berg and Mohit Bansal

Poster 2S: Information Extraction

0:00–2:00 *How Knowledge Graph and Attention Help? A Qualitative Analysis into Bag-level Relation Extraction*
Zikun Hu, Yixin Cao, Lifu Huang and Tat-Seng Chua

0:00–2:00 *Trigger is Not Sufficient: Exploiting Frame-aware Knowledge for Implicit Event Argument Extraction*
Kaiwen Wei, Xian Sun, Zequn Zhang, Jingyuan Zhang, Guo Zhi and li jin

0:00–2:00 *Element Intervention for Open Relation Extraction*
Fangchao Liu, Lingyong Yan, Hongyu Lin, Xianpei Han and Le Sun

0:00–2:00 *Explicitly Capturing Relations between Entity Mentions via Graph Neural Networks for Domain-specific Named Entity Recognition*
Pei Chen, Haibo Ding, Jun Araki and Ruihong Huang

0:00–2:00 *AdaTag: Multi-Attribute Value Extraction from Product Profiles with Adaptive Decoding*
Jun Yan, Nasser Zalmout, Yan Liang, Christan Grant, Xiang Ren and Xin Luna Dong

0:00–2:00 *CoRI: Collective Relation Integration with Data Augmentation for Open Information Extraction*
Zhengbao Jiang, Jialong Han, BUNYAMIN SISMAN and Xin Luna Dong

0:00–2:00 *Benchmarking Scalable Methods for Streaming Cross Document Entity Coreference*
Robert L Logan IV, Andrew McCallum, Sameer Singh and Dan Bikel

0:00–2:00 *Search from History and Reason for Future: Two-stage Reasoning on Temporal Knowledge Graphs*
Zixuan Li, Xiaolong Jin, Saiping Guan, Wei Li, Jiafeng Guo, Yuanzhuo Wang and Xueqi Cheng

Poster 2T: Sentiment Analysis, Stylistic Analysis, and Argument Mining

0:00–2:00 *Employing Argumentation Knowledge Graphs for Neural Argument Generation*
Khalid Al Khatib, Lukas Trautner, Henning Wachsmuth, Yufang Hou and Benno Stein

0:00–2:00 *Learning Span-Level Interactions for Aspect Sentiment Triplet Extraction*
Lu Xu, Yew Ken Chia and Lidong Bing

Session 13A: Machine Translation and Multilinguality 8

08:00–08:10 *On Compositional Generalization of Neural Machine Translation*
Yafu Li, Yongjing Yin, Yulong Chen and Yue Zhang

08:10–08:20 *Mask-Align: Self-Supervised Neural Word Alignment*
Chi Chen, Maosong Sun and Yang Liu

08:20–08:30 *GWLAN: General Word-Level AutocompletioN for Computer-Aided Translation*
Huayang Li, Lemao Liu, Guoping Huang and Shuming Shi

08:30–08:37 *Improving Lexically Constrained Neural Machine Translation with Source-Conditioned Masked Span Prediction*
Gyubok Lee, Seongjun Yang and Edward Choi

Session 13B: Information Extraction 6

08:00–08:10 *De-biasing Distantly Supervised Named Entity Recognition via Causal Intervention*
Wenkai Zhang, Hongyu Lin, Xianpei Han and Le Sun

08:10–08:20 *A Span-Based Model for Joint Overlapped and Discontinuous Named Entity Recognition*
Fei Li, ZhiChao Lin, Meishan Zhang and Donghong Ji

08:20–08:30 *MLBiNet: A Cross-Sentence Collective Event Detection Network*
Dongfang Lou, Zhilin Liao, Shumin Deng, Ningyu Zhang and Huajun Chen

08:30–08:40 *Exploiting Document Structures and Cluster Consistencies for Event Coreference Resolution*
Hieu Minh Tran, Duy Phung and Thien Huu Nguyen

08:40–08:50 *StereoRel: Relational Triple Extraction from a Stereoscopic Perspective*
Xuetao Tian, Liping Jing, Lu He and Feng Liu

08:50–09:00 *Knowledge-Enriched Event Causality Identification via Latent Structure Induction Networks*
Pengfei Cao, Xinyu Zuo, Yubo Chen, Kang Liu, Jun Zhao, Yuguang Chen and Weihua Peng

Session 13C: Machine Learning for NLP 6

08:00–08:10 *Turn the Combination Lock: Learnable Textual Backdoor Attacks via Word Substitution*
Fanchao Qi, Yuan Yao, Sophia Xu, Zhiyuan Liu and Maosong Sun

08:10–08:20 *Parameter-Efficient Transfer Learning with Diff Pruning*
Demi Guo, Alexander Rush and Yoon Kim

08:20–08:30 *R2D2: Recursive Transformer based on Differentiable Tree for Interpretable Hierarchical Language Modeling*
Xiang Hu, Haitao Mi, Zujie Wen, Yafang Wang, Yi Su, Jing Zheng and Gerard de Melo

08:30–08:40 *Risk Minimization for Zero-shot Sequence Labeling*
Zechuan Hu, Yong Jiang, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

08:40–08:50 *WARP: Word-level Adversarial ReProgramming*
Karen Hambardzumyan, Hrant Khachatrian and Jonathan May

08:50–09:00 *Lexicon Learning for Few Shot Sequence Modeling*
Ekin Akyurek and Jacob Andreas

Session 13D: NLP Applications 3

08:00–08:10 *Personalized Transformer for Explainable Recommendation*
Lei Li, Yongfeng Zhang and Li Chen

08:10–08:20 *Generating SOAP Notes from Doctor-Patient Conversations Using Modular Summarization Techniques*
Kundan Krishna, Sopan Khosla, Jeffrey Bigham and Zachary C. Lipton

08:20–08:30 *Tail-to-Tail Non-Autoregressive Sequence Prediction for Chinese Grammatical Error Correction*
Piji Li and Shuming Shi

08:30–08:40 *Early Detection of Sexual Predators in Chats*
Matthias Vogt, Ulf Leser and Alan Akbik

08:40–08:50 *Writing by Memorizing: Hierarchical Retrieval-based Medical Report Generation*
Xingyi Yang, Muchao Ye, Quanzeng You and Fenglong Ma

08:50–08:57 *Quotation Recommendation and Interpretation Based on Transformation from Queries to Quotations*
Lingzhi Wang, Xingshan Zeng and Kam-Fai Wong

Session 13E: Information Retrieval and Text Mining 2

08:00–08:10 *Concept-Based Label Embedding via Dynamic Routing for Hierarchical Text Classification*
Xuepeng Wang, Li Zhao, Bing Liu, Tao Chen, Feng Zhang and Di Wang

08:10–08:20 *VisualSparta: An Embarrassingly Simple Approach to Large-scale Text-to-Image Search with Weighted Bag-of-words*
Xiaopeng Lu, Tiancheng Zhao and Kyusong Lee

08:20–08:30 *Few-Shot Text Ranking with Meta Adapted Synthetic Weak Supervision*
Si Sun, Yingzhuo Qian, Zhenghao Liu, Chenyan Xiong, Kaitao Zhang, Jie Bao, Zhiyuan Liu and Paul Bennett

08:30–08:40 *Semi-Supervised Text Classification with Balanced Deep Representation Distributions*
Changchun Li, Ximing Li and Jihong Ouyang

08:40–08:50 *Improving Document Representations by Generating Pseudo Query Embeddings for Dense Retrieval*
Hongyin Tang, Xingwu Sun, Beihong Jin, Jingang Wang, Fuzheng Zhang and Wei Wu

08:50–08:57 *Pre-training is a Hot Topic: Contextualized Document Embeddings Improve Topic Coherence*
Federico Bianchi, Silvia Terragni and Dirk Hovy

Poster 3A: Semantics: Sentence-level Semantics, Textual Inference and Other areas

9:00–11:00 *ConSERT: A Contrastive Framework for Self-Supervised Sentence Representation Transfer*
Yuanmeng Yan, Rumei Li, Sirui Wang, Fuzheng Zhang, Wei Wu and Weiran Xu

9:00–11:00 *Exploring Dynamic Selection of Branch Expansion Orders for Code Generation*
Hui Jiang, Chulun Zhou, Fandong Meng, Biao Zhang, Jie Zhou, Degen Huang, Qingqiang Wu and Jinsong Su

9:00–11:00 *COINS: Dynamically Generating COntextualized Inference Rules for Narrative Story Completion*
Debjit Paul and Anette Frank

9:00–11:00 *Reasoning over Entity-Action-Location Graph for Procedural Text Understanding*
Hao Huang, Xiubo Geng, Jian Pei, Guodong Long and Daxin Jiang

Wednesday, August 4, 2021 (all times UTC+0) (continued)

9:00–11:00 *From Paraphrasing to Semantic Parsing: Unsupervised Semantic Parsing via Synchronous Semantic Decoding*
Shan Wu, Bo Chen, Chunlei Xin, Xianpei Han, Le Sun, Weipeng Zhang, Jiansong Chen, Fan Yang and Xunliang Cai

9:00–11:00 *Pre-training Universal Language Representation*
Yian Li and Hai Zhao

9:00–11:00 *Structural Pre-training for Dialogue Comprehension*
Zhuosheng Zhang and Hai Zhao

9:00–11:00 *AutoTinyBERT: Automatic Hyper-parameter Optimization for Efficient Pre-trained Language Models*
Yichun Yin, Cheng Chen, Lifeng Shang, Xin Jiang, Xiao Chen and Qun Liu

9:00–11:00 *Data Augmentation with Adversarial Training for Cross-Lingual NLI*
Xin Dong, Yaxin Zhu, Zuohui Fu, Dongkuan Xu and Gerard de Melo

9:00–11:00 *Input Representations for Parsing Discourse Representation Structures: Comparing English with Chinese*
Chunliu Wang, Rik van Noord, Arianna Bisazza and Johan Bos

9:00–11:00 *Code Generation from Natural Language with Less Prior Knowledge and More Monolingual Data*
Sajad Norouzi, Keyi Tang and Yanshuai Cao

9:00–11:00 *Bootstrapped Unsupervised Sentence Representation Learning*
Yan Zhang, Ruidan He, ZUOZHU LIU, Lidong Bing and Haizhou Li

9:00–11:00 *Learning Event Graph Knowledge for Abductive Reasoning*
Li Du, Xiao Ding, Ting Liu and Bing Qin

9:00–11:00 *Issues with Entailment-based Zero-shot Text Classification*
Tingting Ma, Jin-Ge Yao, Chin-Yew Lin and Tiejun Zhao

9:00–11:00 *Neural-Symbolic Commonsense Reasoner with Relation Predictors*
Farhad Moghimifar, Lizhen Qu, Terry Yue Zhuo, Gholamreza Haffari and Mahsa Baktashmotlagh

Poster 3B: Linguistic Theories, Cognitive Modeling and Psycholinguistics

9:00–11:00 *A Cognitive Regularizer for Language Modeling*
Jason Wei, Clara Meister and Ryan Cotterell

9:00–11:00 *What Motivates You? Benchmarking Automatic Detection of Basic Needs from Short Posts*
Sanja Stajner, Seren Yenikent, Bilal Ghanem and Marc Franco-Salvador

9:00–11:00 *Lower Perplexity is Not Always Human-Like*
Tatsuki Kuribayashi, Yohei Oseki, Takumi Ito, Ryo Yoshida, Masayuki Asahara and Kentaro Inui

Poster 3C: Semantics: Lexical Semantics

9:00–11:00 *Word Sense Disambiguation: Towards Interactive Context Exploitation from Both Word and Sense Perspectives*
Ming Wang and Yinglin Wang

9:00–11:00 *A Knowledge-Guided Framework for Frame Identification*
Xuefeng Su, Ru Li, Xiaoli Li, Jeff Z. Pan, Hu Zhang, Qinghua Chai and Xiaoqi Han

9:00–11:00 *Obtaining Better Static Word Embeddings Using Contextual Embedding Models*
Prakhar Gupta and Martin Jaggi

9:00–11:00 *Meta-Learning with Variational Semantic Memory for Word Sense Disambiguation*
Yingjun Du, Nithin Holla, Xiantong Zhen, Cees Snoek and Ekaterina Shutova

9:00–11:00 *LexFit: Lexical Fine-Tuning of Pretrained Language Models*
Ivan Vulić, Edoardo Maria Ponti, Anna Korhonen and Goran Glavaš

9:00–11:00 *Semantic Frame Induction using Masked Word Embeddings and Two-Step Clustering*
Kosuke Yamada, Ryohei Sasano and Koichi Takeda

9:00–11:00 *Multi-SimLex: A Large-Scale Evaluation of Multilingual and Cross-Lingual Lexical Semantic Similarity*
Ivan Vulic, Simon Baker, Edoardo Maria Ponti, Ulla Petti, Ira Leviant, Kelly Wing, Olga Majewska, Eden Bar, Matt Malone, Thierry Poibeau, Roi Reichart and Anna Korhonen

Poster 3D: Speech and Multimodality

9:00–11:00 *Text-Free Image-to-Speech Synthesis Using Learned Segmental Units*
Wei-Ning Hsu, David Harwath, Tyler Miller, Christopher Song and James Glass

9:00–11:00 *CTFN: Hierarchical Learning for Multimodal Sentiment Analysis Using Coupled-Translation Fusion Network*
Jiajia Tang, Kang Li, Xuanyu Jin, Andrzej Cichocki, Qibin Zhao and Wanzeng Kong

9:00–11:00 *Lightweight Adapter Tuning for Multilingual Speech Translation*
Hang Le, Juan Pino, Changhan Wang, Jiatao Gu, Didier Schwab and Laurent Besacier

Poster 3E: Interpretability and Analysis of Models for NLP

9:00–11:00 *Parameter Selection: Why We Should Pay More Attention to It*
Jie-Jyun Liu, Tsung-Han Yang, Si-An Chen and Chih-Jen Lin

9:00–11:00 *Positional Artefacts Propagate Through Masked Language Model Embeddings*
Ziyang Luo, Artur Kulmizev and Xiaoxi Mao

9:00–11:00 *Language Model Evaluation Beyond Perplexity*
Clara Meister and Ryan Cotterell

9:00–11:00 *Learning to Explain: Generating Stable Explanations Fast*
Xuelin Situ, Ingrid Zukerman, Cecile Paris, Sameen Maruf and Gholamreza Haffari

9:00–11:00 *StereoSet: Measuring stereotypical bias in pretrained language models*
Moin Nadeem, Anna Bethke and Siva Reddy

9:00–11:00 *Alignment Rationale for Natural Language Inference*
Zhongtao Jiang, Yuanzhe Zhang, Zhao Yang, Jun Zhao and Kang Liu

9:00–11:00 *Enabling Lightweight Fine-tuning for Pre-trained Language Model Compression based on Matrix Product Operators*
Peiyu Liu, Ze-Feng Gao, Wayne Xin Zhao, Zhi-Yuan Xie, Zhong-Yi Lu and Ji-Rong Wen

9:00–11:00 *On Sample Based Explanation Methods for NLP: Faithfulness, Efficiency and Semantic Evaluation*
Wei Zhang, Ziming Huang, Yada Zhu, Guangnan Ye, Xiaodong Cui and Fan Zhang

9:00–11:00 *CausaLM: Causal Model Explanation Through Counterfactual Language Models*
Amir Feder, Nadav Oved, Uri Shalit and Roi Reichart

9:00–11:00 *Amnesic Probing: Behavioral Explanation With Amnesic Counterfactuals*
Yanai Elazar, Shauli Ravfogel, Alon Jacovi and Yoav Goldberg

Poster 3F: Information Retrieval and Text Mining

9:00–11:00 *Syntax-Enhanced Pre-trained Model*
Zenan Xu, Daya Guo, Duyu Tang, Qinliang Su, Linjun Shou, Ming Gong, Wanjun Zhong, Xiaojun Quan, Daxin Jiang and Nan Duan

9:00–11:00 *Matching Distributions between Model and Data: Cross-domain Knowledge Distillation for Unsupervised Domain Adaptation*
Bo Zhang, Xiaoming Zhang, Yun Liu, Lei Cheng and Zhoujun Li

9:00–11:00 *Counterfactual Inference for Text Classification Debiasing*
Chen Qian, Fuli Feng, Lijie Wen, Chunping Ma and Pengjun Xie

9:00–11:00 *HieRec: Hierarchical User Interest Modeling for Personalized News Recommendation*
Tao Qi, Fangzhao Wu, Chuhan Wu, Peiru Yang, Yang Yu, Xing Xie and Yongfeng Huang

9:00–11:00 *Distinct Label Representations for Few-Shot Text Classification*
Sora Ohashi, Junya Takayama, Tomoyuki Kajiwara and Yuki Arase

9:00–11:00 *PP-Rec: News Recommendation with Personalized User Interest and Time-aware News Popularity*
Tao Qi, Fangzhao Wu, Chuhan Wu and Yongfeng Huang

9:00–11:00 *Article Reranking by Memory-Enhanced Key Sentence Matching for Detecting Previously Fact-Checked Claims*
Qiang Sheng, Juan Cao, Xueyao Zhang, Xirong Li and Lei Zhong

9:00–11:00 *Learning to Solve NLP Tasks in an Incremental Number of Languages*
Giuseppe Castellucci, Simone Filice, Danilo Croce and Roberto Basili

Poster 3G: Machine Learning for NLP

9:00–11:00 *Defense against Synonym Substitution-based Adversarial Attacks via Dirichlet Neighborhood Ensemble*
Yi Zhou, Xiaoqing Zheng, Cho-Jui Hsieh, Kai-Wei Chang and Xuanjing Huang

9:00–11:00 *Shortformer: Better Language Modeling using Shorter Inputs*
Ofir Press, Noah A. Smith and Mike Lewis

9:00–11:00 *BanditMTL: Bandit-based Multi-task Learning for Text Classification*
Yuren Mao, Zekai Wang, Weiwei Liu, Xuemin Lin and Wenbin Hu

9:00–11:00 *Unified Interpretation of Softmax Cross-Entropy and Negative Sampling: With Case Study for Knowledge Graph Embedding*
Hidetaka Kamigaito and Katsuhiko Hayashi

9:00–11:00 *Hi-Transformer: Hierarchical Interactive Transformer for Efficient and Effective Long Document Modeling*
Chuhan Wu, Fangzhao Wu, Tao Qi and Yongfeng Huang

9:00–11:00 *De-Confounded Variational Encoder-Decoder for Logical Table-to-Text Generation*
Wenqing Chen, Jidong Tian, Yitian Li, Hao He and Yaohui Jin

9:00–11:00 *Rethinking Stealthiness of Backdoor Attack against NLP Models*
Wenkai Yang, Yankai Lin, Peng Li, Jie Zhou and Xu Sun

9:00–11:00 *Crowdsourcing Learning as Domain Adaptation: A Case Study on Named Entity Recognition*
Xin Zhang, Guangwei Xu, Yueheng Sun, Meishan Zhang and Pengjun Xie

9:00–11:00 *Robust Transfer Learning with Pretrained Language Models through Adapters*
Wenjuan Han, Bo Pang and Ying Nian Wu

9:00–11:00 *Embracing Ambiguity: Shifting the Training Target of NLI Models*
Johannes Mario Meissner, Napat Thumwanit, Saku Sugawara and Akiko Aizawa

9:00–11:00 *Exploring Distantly-Labeled Rationales in Neural Network Models*
Quzhe Huang, Shengqi Zhu, Yansong Feng and Dongyan Zhao

9:00–11:00 *Learning to Perturb Word Embeddings for Out-of-distribution QA*
Seanie Lee, Minki Kang, Juho Lee and Sung Ju Hwang

Poster 3H: Dialog and Interactive Systems

9:00–11:00 *Maria: A Visual Experience Powered Conversational Agent*
Zujie Liang, Huang Hu, Can Xu, Chongyang Tao, Xiubo Geng, yining Chen, Fan Liang and Daxin Jiang

9:00–11:00 *A Human-machine Collaborative Framework for Evaluating Malevolence in Dialogues*
Yangjun Zhang, Pengjie Ren and Maarten de Rijke

9:00–11:00 *Generating Relevant and Coherent Dialogue Responses using Self-Separated Conditional Variational AutoEncoders*
Bin Sun, Shaoxiong Feng, Yiwei Li, Jiamou Liu and Kan Li

9:00–11:00 *Modeling Discriminative Representations for Out-of-Domain Detection with Supervised Contrastive Learning*
Zhiyuan Zeng, Keqing He, Yuanmeng Yan, Zijun Liu, Yanan Wu, Hong Xu, Huixing Jiang and Weiran Xu

9:00–11:00 *Learning to Ask Conversational Questions by Optimizing Levenshtein Distance*
Zhongkun Liu, Pengjie Ren, Zhumin CHEN, Zhaochun Ren, Maarten de Rijke and Ming Zhou

9:00–11:00 *DVD: A Diagnostic Dataset for Multi-step Reasoning in Video Grounded Dialogue*
Hung Le, Chinnadhurai Sankar, Seungwhan Moon, Ahmad Beirami, Alborz Geramifard and Satwik Kottur

9:00–11:00 *Preview, Attend and Review: Schema-Aware Curriculum Learning for Multi-Domain Dialogue State Tracking*
Yinpei Dai, Hangyu Li, Yongbin Li, Jian Sun, Fei Huang, Luo Si and Xiaodan Zhu

9:00–11:00 *On the Generation of Medical Dialogs for COVID-19*
Meng Zhou, Zechen Li, Bowen Tan, Guangtao Zeng, Wenmian Yang, Xuehai He, Zeqian Ju, Subrato Chakravorty, Shu Chen, Xingyi Yang, Yichen Zhang, Qingyang Wu, Zhou Yu, Kun Xu, Eric Xing and Pengtao Xie

9:00–11:00 *Constructing Multi-Modal Dialogue Dataset by Replacing Text with Semantically Relevant Images*
Nyoungwoo Lee, Suwon Shin, Jaegul Choo, Ho-Jin Choi and Sung-Hyon Myaeng

9:00–11:00 *MMGCN: Multimodal Fusion via Deep Graph Convolution Network for Emotion Recognition in Conversation*
Jingwen Hu, Yuchen Liu, Jinming Zhao and Qin Jin

9:00–11:00 *DynaEval: Unifying Turn and Dialogue Level Evaluation*
Chen Zhang, Yiming Chen, Luis Fernando D'Haro, Yan Zhang, Thomas Friedrichs, Grandee Lee and Haizhou Li

9:00–11:00 *Unsupervised Learning of KB Queries in Task-Oriented Dialogs*
Dinesh Raghu, Nikhil Gupta and Mausam

Poster 3I: Ethics in NLP

9:00–11:00 *Exposing the limits of Zero-shot Cross-lingual Hate Speech Detection*
Debora Nozza

Poster 3J: Resources and Evaluation

9:00–11:00 *CoSQA: 20,000+ Web Queries for Code Search and Question Answering*
Junjie Huang, Duyu Tang, Linjun Shou, Ming Gong, Ke Xu, Daxin Jiang, Ming Zhou and Nan Duan

9:00–11:00 *QED: A Framework and Dataset for Explanations in Question Answering*
Matthew Lamm, Jennimaria Palomaki, Chris Alberti, Daniel Andor, Eunsol Choi, Livio Baldini Soares and Michael Collins

Poster 3K: Machine Translation and Multilinguality

9:00–11:00 *Rewriter-Evaluator Architecture for Neural Machine Translation*
Yangming Li and Kaisheng Yao

9:00–11:00 *BERTTune: Fine-Tuning Neural Machine Translation with BERTScore*
Inigo Jauregi Unanue, Jacob Parnell and Massimo Piccardi

9:00–11:00 *Modeling Bilingual Conversational Characteristics for Neural Chat Translation*
Yunlong Liang, Fandong Meng, Yufeng Chen, Jinan Xu and Jie Zhou

9:00–11:00 *Importance-based Neuron Allocation for Multilingual Neural Machine Translation*
Wanying Xie, Yang Feng, Shuhao Gu and Dong Yu

9:00–11:00 *Transfer Learning for Sequence Generation: from Single-source to Multi-source*
Xuancheng Huang, jingfang xu, Maosong Sun and Yang Liu

9:00–11:00 *A Closer Look at Few-Shot Crosslingual Transfer: The Choice of Shots Matters*
Mengjie Zhao, Yi Zhu, Ehsan Shareghi, Ivan Vulić, Roi Reichart, Anna Korhonen and Hinrich Schütze

Poster 3L: Discourse and Pragmatics

9:00–11:00 *Coreference Reasoning in Machine Reading Comprehension*
Mingzhu Wu, Nafise Sadat Moosavi, Dan Roth and Iryna Gurevych

9:00–11:00 *Entity Enhancement for Implicit Discourse Relation Classification in the Biomedical Domain*
Wei Shi and Vera Demberg

9:00–11:00 *Adapting Unsupervised Syntactic Parsing Methodology for Discourse Dependency Parsing*
Liwen Zhang, Ge Wang, Wenjuan Han and Kewei Tu

9:00–11:00 *Unsupervised Pronoun Resolution via Masked Noun-Phrase Prediction*
Ming Shen, Pratyay Banerjee and Chitta Baral

Poster 3M: Syntax: Tagging, Chunking, and Parsing

9:00–11:00 *A Conditional Splitting Framework for Efficient Constituency Parsing*
Thanh-Tung Nguyen, Xuan-Phi Nguyen, Shafiq Joty and Xiaoli Li

9:00–11:00 *A Unified Generative Framework for Various NER Subtasks*
Hang Yan, Tao Gui, Junqi Dai, Qipeng Guo, Zheng Zhang and Xipeng Qiu

9:00–11:00 *An In-depth Study on Internal Structure of Chinese Words*
Chen Gong, Saihao Huang, Houquan Zhou, Zhenghua Li, Min Zhang, Zhefeng Wang, baoxing Huai and Nicholas Jing Yuan

9:00–11:00 *MulDA: A Multilingual Data Augmentation Framework for Low-Resource Cross-Lingual NER*
Linlin Liu, BOSHENG DING, Lidong Bing, Shafiq Joty, Luo Si and Chunyan Miao

9:00–11:00 *Lexicon Enhanced Chinese Sequence Labeling Using BERT Adapter*
Wei Liu, Xiyan Fu, Yue Zhang and Wenming Xiao

Poster 3N: NLP Applications

9:00–11:00 *Math Word Problem Solving with Explicit Numerical Values*
Qinzhuo Wu, Qi Zhang, Zhongyu Wei and Xuanjing Huang

9:00–11:00 *Neural-Symbolic Solver for Math Word Problems with Auxiliary Tasks*
Jinghui Qin, Xiaodan Liang, Yining Hong, Jianheng Tang and Liang Lin

9:00–11:00 *SMedBERT: A Knowledge-Enhanced Pre-trained Language Model with Structured Semantics for Medical Text Mining*
Taolin Zhang, Zerui Cai, Chengyu Wang, Minghui Qiu, Bite Yang and XIAOFENG HE

9:00–11:00 *What is Your Article Based On? Inferring Fine-grained Provenance*
Yi Zhang, Zachary Ives and Dan Roth

9:00–11:00 *Cross-modal Memory Networks for Radiology Report Generation*
Zhihong Chen, Yaling Shen, Yan Song and Xiang Wan

9:00–11:00 *Controversy and Conformity: from Generalized to Personalized Aggressiveness Detection*
Kamil Kanclerz, Alicja Figas, Marcin Gruza, Tomasz Kajdanowicz, Jan Kocon, Daria Puchalska and Przemyslaw Kazienko

9:00–11:00 *Multi-perspective Coherent Reasoning for Helpfulness Prediction of Multimodal Reviews*
Junhao Liu, Zhen Hai, Min Yang and Lidong Bing

9:00–11:00 *Instantaneous Grammatical Error Correction with Shallow Aggressive Decoding*
Xin Sun, Tao Ge, Furu Wei and Houfeng Wang

9:00–11:00 *Automatic ICD Coding via Interactive Shared Representation Networks with Self-distillation Mechanism*
Tong Zhou, Pengfei Cao, Yubo Chen, Kang Liu, Jun Zhao, Kun Niu, Weifeng Chong and Shengping Liu

9:00–11:00 *PHMOSpell: Phonological and Morphological Knowledge Guided Chinese Spelling Check*
Li Huang, Junjie Li, Weiwei Jiang, Zhiyu Zhang, Minchuan Chen, Shaojun Wang and Jing Xiao

Poster 3O: Language Generation

9:00–11:00 *Guiding the Growth: Difficulty-Controllable Question Generation through Step-by-Step Rewriting*
Yi Cheng, Siyao Li, Bang Liu, Ruihui Zhao, Sujian Li, Chenghua Lin and Yefeng Zheng

9:00–11:00 *Improving Encoder by Auxiliary Supervision Tasks for Table-to-Text Generation*
Liang Li, Can Ma, Yinliang Yue and Dayong Hu

9:00–11:00 *POS-Constrained Parallel Decoding for Non-autoregressive Generation*
Kexin Yang, Wenqiang Lei, Dayiheng Liu, Weizhen Qi and Jiancheng Lv

9:00–11:00 *Bridging Subword Gaps in Pretrain-Finetune Paradigm for Natural Language Generation*
Xin Liu, Baosong Yang, Dayiheng Liu, Haibo Zhang, Weihua Luo, Min Zhang, Haiying Zhang and Jinsong Su

9:00–11:00 *TGEA: An Error-Annotated Dataset and Benchmark Tasks for TextGeneration from Pretrained Language Models*
Jie He, Bo Peng, Yi Liao, Qun Liu and Deyi Xiong

9:00–11:00 *Addressing Semantic Drift in Generative Question Answering with Auxiliary Extraction*
Chenliang Li, Bin Bi, Ming Yan, Wei Wang and Songfang Huang

Poster 3P: Summarization

9:00–11:00 *Long-Span Summarization via Local Attention and Content Selection*
Potsawee Manakul and Mark Gales

9:00–11:00 *RepSum: Unsupervised Dialogue Summarization based on Replacement Strategy*
Xiyan Fu, Yating Zhang, Tianyi Wang, Xiaozhong Liu, Changlong Sun and Zhenglu Yang

9:00–11:00 *BASS: Boosting Abstractive Summarization with Unified Semantic Graph*
Wenhao Wu, Wei Li, Xinyan Xiao, Jiachen Liu, Ziqiang Cao, Sujian Li, Hua Wu and Haifeng Wang

9:00–11:00 *Capturing Relations between Scientific Papers: An Abstractive Model for Related Work Section Generation*
Xiuying Chen, Hind Alamro, Mingzhe Li, Shen Gao, Xiangliang Zhang, Dongyan Zhao and Rui Yan

9:00–11:00 *Focus Attention: Promoting Faithfulness and Diversity in Summarization*
Rahul Aralikatte, Shashi Narayan, Joshua Maynez, Sascha Rothe and Ryan McDonald

9:00–11:00 *Generating Query Focused Summaries from Query-Free Resources*
Yumo Xu and Mirella Lapata

9:00–11:00 *Demoting the Lead Bias in News Summarization via Alternating Adversarial Learning*
Linzi Xing, Wen Xiao and Giuseppe Carenini

Poster 3Q: Question Answering

9:00–11:00 *DuReader_robust: A Chinese Dataset Towards Evaluating Robustness and Generalization of Machine Reading Comprehension in Real-World Applications*
Hongxuan Tang, Hongyu Li, Jing Liu, Yu Hong, Hua Wu and Haifeng Wang

9:00–11:00 *Sequence to General Tree: Knowledge-Guided Geometry Word Problem Solving*
Shih-hung Tsai, Chao-Chun Liang, Hsin-Min Wang and Keh-Yih Su

9:00–11:00 *Robustifying Multi-hop QA through Pseudo-Evidentiality Training*
Kyungjae Lee, Seung-won Hwang, Sang-eun Han and Dohyeon Lee

9:00–11:00 *Multi-Scale Progressive Attention Network for Video Question Answering*
Zhicheng Guo, Jiaxuan Zhao, Licheng Jiao, Xu Liu and Lingling Li

9:00–11:00 *Efficient Passage Retrieval with Hashing for Open-domain Question Answering*
Ikuya Yamada, Akari Asai and Hannaneh Hajishirzi

9:00–11:00 *xMoCo: Cross Momentum Contrastive Learning for Open-Domain Question Answering*
Nan Yang, Furu Wei, Binxing Jiao, Daxing Jiang and Linjun Yang

9:00–11:00 *Learn to Resolve Conversational Dependency: A Consistency Training Framework for Conversational Question Answering*
Gangwoo Kim, Hyunjae Kim, Jungsoo Park and Jaewoo Kang

Poster 3R: Language Grounding to Vision, Robotics and Beyond

9:00–11:00 *PhotoChat: A Human-Human Dialogue Dataset With Photo Sharing Behavior For Joint Image-Text Modeling*
Xiaoxue Zang, Lijuan Liu, Maria Wang, Yang Song, Hao Zhang and Jindong Chen

9:00–11:00 *Good for Misconceived Reasons: An Empirical Revisiting on the Need for Visual Context in Multimodal Machine Translation*
Zhiyong Wu, Lingpeng Kong, Wei Bi, Xiang Li and Ben Kao

9:00–11:00 *Attend What You Need: Motion-Appearance Synergistic Networks for Video Question Answering*
Ahjeong Seo, Gi-Cheon Kang, Joonhan Park and Byoung-Tak Zhang

9:00–11:00 *Decoupling the Role of Data, Attention, and Losses in Multimodal Transformers*
Lisa Anne Hendricks, John Mellor, Rosalia Schneider, Jean-Baptiste Alayrac and Aida Nematzadeh

Poster 3S: Information Extraction

9:00–11:00 *BERTifying the Hidden Markov Model for Multi-Source Weakly Supervised Named Entity Recognition*
Yinghao Li, Pranav Shetty, Lucas Liu, Chao Zhang and Le Song

9:00–11:00 *CIL: Contrastive Instance Learning Framework for Distantly Supervised Relation Extraction*
Tao Chen, Haizhou Shi, Siliang Tang, Zhigang Chen, Fei Wu and Yueting Zhuang

9:00–11:00 *SENT: Sentence-level Distant Relation Extraction via Negative Training*
Ruotian Ma, Tao Gui, Linyang Li, Qi Zhang, Xuanjing Huang and Yaqian Zhou

9:00–11:00 *An End-to-End Progressive Multi-Task Learning Framework for Medical Named Entity Recognition and Normalization*
Baohang Zhou, Xiangrui Cai, Ying Zhang and Xiaojie Yuan

9:00–11:00 *PRGC: Potential Relation and Global Correspondence Based Joint Relational Triple Extraction*
Hengyi Zheng, rui wen, Xi Chen, Yifan Yang, Yunyan Zhang, Ziheng Zhang, Ningyu Zhang, Bin Qin, Xu Ming and Yefeng Zheng

9:00–11:00 *Learning from Miscellaneous Other-Class Words for Few-shot Named Entity Recognition*
Meihan Tong, Shuai Wang, Bin Xu, Yixin Cao, Minghui Liu, Lei Hou and Juanzi Li

Wednesday, August 4, 2021 (all times UTC+0) (continued)

9:00–11:00 *Joint Biomedical Entity and Relation Extraction with Knowledge-Enhanced Collective Inference*
Tuan Lai, Heng Ji, ChengXiang Zhai and Quan Hung Tran

9:00–11:00 *Entity Concept-enhanced Few-shot Relation Extraction*
Shan Yang, Yongfei Zhang, Guanglin Niu, Qinghua Zhao and Shiliang Pu

9:00–11:00 *Fine-grained Information Extraction from Biomedical Literature based on Knowledge-enriched Abstract Meaning Representation*
Zixuan Zhang, Nikolaus Parulian, Heng Ji, Ahmed Elsayed, Skatje Myers and Martha Palmer

9:00–11:00 *Unleash GPT-2 Power for Event Detection*
Amir Pouran Ben Veyseh, Viet Lai, Franck Dernoncourt and Thien Huu Nguyen

9:00–11:00 *Improving Model Generalization: A Chinese Named Entity Recognition Case Study*
Guanqing Liang and Cane Wing-Ki Leung

9:00–11:00 *CLEVE: Contrastive Pre-training for Event Extraction*
Ziqi Wang, Xiaozhi Wang, Xu Han, Yankai Lin, Lei Hou, Zhiyuan Liu, Peng Li, Juanzi Li and Jie Zhou

9:00–11:00 *Three Sentences Are All You Need: Local Path Enhanced Document Relation Extraction*
Quzhe Huang, Shengqi Zhu, Yansong Feng, Yuan Ye, Yuxuan Lai and Dongyan Zhao

9:00–11:00 *Document-level Event Extraction via Parallel Prediction Networks*
Hang Yang, Dianbo Sui, Yubo Chen, Kang Liu, Jun Zhao and Taifeng Wang

9:00–11:00 *StructuralLM: Structural Pre-training for Form Understanding*
Chenliang Li, Bin Bi, Ming Yan, Wei Wang, Songfang Huang, Fei Huang and Luo Si

Poster 3T: Sentiment Analysis, Stylistic Analysis, and Argument Mining

9:00–11:00 *Dual Graph Convolutional Networks for Aspect-based Sentiment Analysis*
Ruifan Li, Hao Chen, Fangxiang Feng, Zhanyu Ma, Xiaojie WANG and Eduard Hovy

9:00–11:00 *Multi-Label Few-Shot Learning for Aspect Category Detection*
Mengting Hu, Shiwan Zhao, Honglei Guo, Chao Xue, Hang Gao, Tiegang Gao, renhong cheng and Zhong Su

9:00–11:00 *Argument Pair Extraction via Attention-guided Multi-Layer Multi-Cross Encoding*
Liying Cheng, Tianyu Wu, Lidong Bing and Luo Si

9:00–11:00 *A Neural Transition-based Model for Argumentation Mining*
Jianzhu Bao, Chuang Fan, Jipeng Wu, Yixue Dang, Jiachen Du and Ruifeng Xu

11:00–12:00 ***Lifetime Award***

Session 14A: Language Generation 2

14:00–14:10 *Keep It Simple: Unsupervised Simplification of Multi-Paragraph Text*
Philippe Laban, Tobias Schnabel, Paul Bennett and Marti A. Hearst

14:10–14:20 *Long Text Generation by Modeling Sentence-Level and Discourse-Level Coherence*
Jian Guan, Xiaoxi Mao, changjie fan, Zitao Liu, Wenbiao Ding and Minlie Huang

14:20–14:30 *OpenMEVA: A Benchmark for Evaluating Open-ended Story Generation Metrics*
Jian Guan, Zhexin Zhang, Zhuoer Feng, Zitao Liu, Wenbiao Ding, Xiaoxi Mao, changjie fan and Minlie Huang

14:30–14:40 *DYPLOC: Dynamic Planning of Content Using Mixed Language Models for Text Generation*
Xinyu Hua, Ashwin Sreevatsa and Lu Wang

14:40–14:50 *Controllable Open-ended Question Generation with A New Question Type Ontology*
Shuyang Cao and Lu Wang

14:50–15:00 *BERTGen: Multi-task Generation through BERT*
Faidon Mitzalis, Ozan Caglayan, Pranava Madhyastha and Lucia Specia

Session 14B: Machine Translation and Multilinguality 9

14:00–14:10 *Selective Knowledge Distillation for Neural Machine Translation*
Fusheng Wang, Jianhao Yan, Fandong Meng and Jie Zhou

14:10–14:20 *Measuring and Increasing Context Usage in Context-Aware Machine Translation*
Patrick Fernandes, Kayo Yin, Graham Neubig and André F. T. Martins

14:20–14:30 *Beyond Offline Mapping: Learning Cross-lingual Word Embeddings through Context Anchoring*
Aitor Ormazabal, Mikel Artetxe, Aitor Soroa, Gorka Labaka and Eneko Agirre

14:30–14:40 *CCMatrix: Mining Billions of High-Quality Parallel Sentences on the Web*
Holger Schwenk, Guillaume Wenzek, Sergey Edunov, Edouard Grave, Armand Joulin and Angela Fan

14:40–14:50 *EDITOR: an Edit-Based Transformer with Repositioning for Neural Machine Translation with Soft Lexical Constraints*
Weijia Xu and Marine Carpuat

14:50–15:00 *Gender Bias in Machine Translation*
Beatrice Savoldi, Marco Gaido, Luisa Bentivogli, Matteo Negri and Marco Turchi

Session 14C: Machine Learning for NLP 7

14:00–14:10 *Length-Adaptive Transformer: Train Once with Length Drop, Use Anytime with Search*
Gyuwan Kim and Kyunghyun Cho

14:10–14:20 *GhostBERT: Generate More Features with Cheap Operations for BERT*
Zhiqi Huang, Lu Hou, Lifeng Shang, Xin Jiang, Xiao Chen and Qun Liu

14:20–14:30 *Super Tickets in Pre-Trained Language Models: From Model Compression to Improving Generalization*
Chen Liang, Simiao Zuo, Minshuo Chen, Haoming Jiang, Xiaodong Liu, Pengcheng He, Tuo Zhao and Weizhu Chen

14:30–14:40 *A Novel Estimator of Mutual Information for Learning to Disentangle Textual Representations*
Pierre Colombo, Pablo Piantanida and Chloé Clavel

14:40–14:50 *Determinantal Beam Search*

Catchphrase: Automatic Detection of Cultural References

Nir Sweed

dshahaf@cs.huji.ac.il

Abstract

A *snowclone* is a customizable phrasal template that can be realized in multiple, instantly recognized variants. For example, "* is the new *" (Orange is the new black, 40 is the new 30). Snowclones are extensively used in social media. In this paper, we study snowclones originating from pop-culture quotes; our goal is to automatically detect cultural references in text. We introduce a new, publicly available data set of pop-culture quotes and their corresponding snowclone usages and train models on them. We publish code for CATCHPHRASE, an internet browser plugin to automatically detect and mark references in real-time, and examine its performance via a user study. Aside from assisting people to better comprehend cultural references, we hope that detecting snowclones can complement work on paraphrasing and help to tackle long-standing questions in social science about the dynamics of information propagation.

1 Introduction

First coined by Richard Dawkins (Dawkins, 1976), a meme is a unit of cultural transmission: any idea or behavior that can be transferred by imitation. Internet memes have become an integral part of modern digital culture (Shifman, 2014). Pullum (Pullum, 2004) coined the term *snowclones* to describe a specific type of meme – phrasal templates that are easily reusable in many different contexts. Pullum described a snowclone as "a multi-use, customizable, instantly recognizable, time-worn, quoted or misquoted phrase or sentence that can be used in an entirely open array of different jokey variants". For example, the quote "One does not simply walk into Mordor" from the "Lord of the Rings" films became a well-known pattern – *"One does not simply *"* – used extensively online (see Figure 1).

In this paper, our goal is to develop algorithms to **detect snowclones** in text. We envision an "Englishman in New York" – a foreigner, perhaps, or someone who does not easily understand contemporary cultural references and could use the help of an automated system to communicate better. In particular, we focus on pop-culture references over the internet.

From a linguistic point of view, snowclones complement the paraphrasing task (Barzilay and McKeown, 2001; Fernando and Stevenson, 2008; Dolan et al., 2004). Paraphrase detection identifies alternative ways to convey the same meaning, while snowclones keep (some of) the original sentence structure but completely change the meaning.

Detection and tracking of digital memes have been the focus of multiple computational studies. The closest to our work are MEMETRACKER and NIFTY (Leskovec et al., 2009; Suen et al., 2013), that tracked quotations attributed to individuals. These works focused on short, distinctive phrases that travel *relatively intact* through on-line text. Other related tasks are multi-word expression/idiom identification (Haagsma et al., 2020; Zarrieß and Kuhn, 2009; Muzny and Zettlemoyer, 2013) and cliché detection (Cook and Hirst, 2013; van Cranenburgh, 2018). Again, idioms and multi-word expressions are chiefly fixed expressions ("cat got your tongue?", "jumped the shark") that rarely change their meaning across mutations. Therefore,

Figure 1: Snowclone example, based on "One does not simply walk into Mordor" from "Lord of the Rings".

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 1–7
August 1–6, 2021. ©2021 Association for Computational Linguistics

these settings are much more restrictive than ours.

Our contributions are the following: we propose a novel task of snowclone detection, identifying cultural references. We first formulate it as a tagging task, treating snowclones as regular expressions; we conduct a user study to show humans have an intuitive notion of the "correct" pattern(s), and develop a sequence-to-sequence tagger to reveal such patterns. We then extend the formulation to softer notions of similarity. We experiment with feature-based and neural approaches, achieving high accuracies. To further show the utility of our methods, we develop CATCHPHRASE, a browser extension to detect pop-culture references, conduct a user study and show it indeed helps users identify cultural references. We publish data and code[1]. We believe tracking snowclones will find interesting applications in social science, exploring the diffusion and evolution of highly dynamic content online.

2 Snowclones as Regular Expressions

The common view of snowclones treats them as regular expressions (The-Snowclones-Database, 2007). Thus, in this section, we formulate the snowclone detection problem as a tagging task. Intuitively, we want to predict for each word in the original sentence whether it is replaced by a wildcard. We use the resulting pattern to match new sentences to the original sentence. For example, given a sentence $s = \langle One, does, not, simply, walk, into, Mordor \rangle$ we would like to find a mapping: $T(s) = \langle One, does, not, simply, *, *, * \rangle$. (Adjacent wildcards can be merged)

2.1 Can People do This?

Before we set out to find an algorithm to uncover the underlying snowclone form of an input sentence, we try to evaluate the feasibility of this task. It is not clear that such patterns exist, or are agreed upon by human annotators. To that end, we conduct a user study to test if people have an intuitive notion of snowclone patterns.

We recruited 22 volunteers through social media. The participants were 80% males. 85% of them were 25-35 years old, the rest being 40-55. All participants were Israeli and identified as non-native English speakers. Participants were given a short explanation of snowclones and instructed to find the snowclone form of a set of (the same) 20 sentences, chosen from the memorable movie quote database (Danescu-Niculescu-Mizil et al., 2012). We chose sentences at random, filtering out quotes that became known internet memes. Participants marked words that should become wildcards, generating up to 3 patterns per sentence, as they saw fit. We asked participants to report whether they were familiar with any sentence, and discarded the entire questionnaire of two who did.

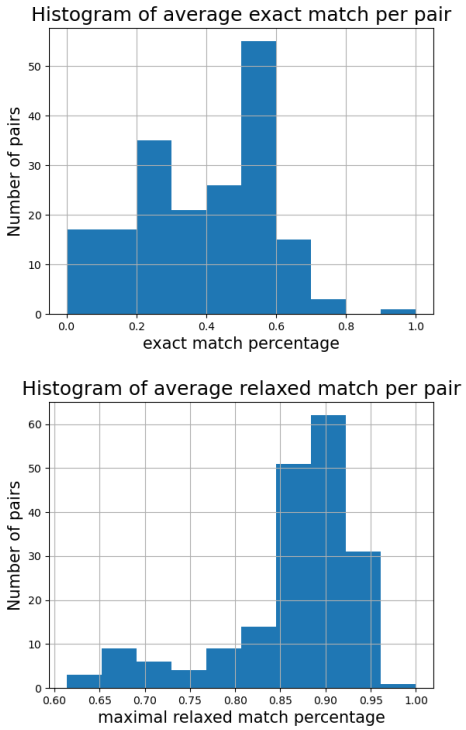

Figure 2: Histogram of the exact-match similarity measure (top) and relaxed-match measure (bottom), averaged over all sentences, for all pairs of participants.

Evaluation and Results. To compute similarity between pairs of people, we propose two measures. In **exact-match**, the score is the percentage of sentences (out of 20) on which the two people had at least one exact-match pattern. In **relaxed-match**, we compute for each sentence the closest match between the patterns of both people (in terms of simple % agreement). The score is the percentage of agreement over all 20 closest matches.

Figure 2 shows histograms over all pairs of participants. For exact-match, most pairs of participants agree on roughly half the patterns. A careful examination of the results indicates that participants are divided into those that prefer a single, general pattern (annotating "The pavement was his enemy" as "The * was his *"), and those preferring

[1] https://github.com/sweedy12/CATCHPHRASE

Snowclone Form Tagging - Results		
Model	Accuracy	Recall
Naive	0.74	0
Bi-LSTM-CRF	**0.92**	0.82
BERT	0.9	**0.88**

Table 1: Accuracy and recall for each of the proposed models for the snowclone form tagging task.

several narrower patterns (marking both "The * was his enemy" and "The pavement was his *"). Another contributing factor is that many mismatched pairs of patterns differ only in stopwords. The relaxed-match measure is less sensitive to this issue and indeed demonstrates high agreement. We hypothesize that this indicates the feasibility of training machine learning models for this task.

3 Snowclone Pattern Tagger

We create and publish our own data set for this task, and use it to train two different ML models for it.

Data. To train ML models to solve the task of snowclone tagging, we needed examples for sentences and their underlying snowclone form. To this end, we use the snowclone patterns along with the original quotes from The Snowclone Database (The-Snowclones-Database, 2007). As this is not enough data to train on, we use the patterns to lookup more instances online, collecting 7700 $\langle$*snowclone pattern, instance*$\rangle$ pairs. When splitting to train-dev-test sets (60%/20%/20%), we make sure all variants of the same pattern are put in the same set. We release our dataset[1].

Bi-LSTM-CRF. We adapt the model of (Huang et al., 2015), tested on part of speech tagging, chunking and named entity recognition tasks. Its CRF layer performs a structured prediction over the sentence tags, using sentence-level information rather than predicting a label for each word separately, rendering it useful for our task. For optimization, we use negative log-likelihood.

BERT S2S. We use BERT (Devlin et al., 2019), as it has shown to produce good results when fine-tuned to specific sequence-to-sequence tasks. We fine-tune BERT for a token classification task using the snowclone form dataset. Since this model outputs a probability measure for each token, we use binary cross-entropy as the objective function.

See Appendix A for implementation details and hyper-parameter tuning.

Evaluation and results. Since most words in an input sentence are not replaceable, wildcards are infrequent. Thus, we prioritize models with higher recall than precision. Table 1 shows recall and accuracy of the models. The naive majority baseline (no words are wildcards) yields 74% accuracy (and, naturally, 0% recall). The Bi-LSTM-CRF model reaches an accuracy of 92%, and 82% recall. BERT achieves an accuracy of 90%, and recall 88%.

4 Going Beyond Regular Expressions

When we tried to apply our models to find snowclones in online community text (looking for regex matches), we realized that the regex formulation might be too simplistic, as some cultural references do not follow the snowclone pattern exactly, and some sentences that do follow it are not really references. Take Apocalypse Now's famous "I love the smell of napalm in the morning". A natural corresponding pattern is "I love the smell of * in the morning", and indeed, "I love the smell of bureaucracy in the morning" is most likely a reference to the movie. However, the case of "I love the smell of *pancakes* in the morning" is a lot less clear. On the other hand, "30 is the old 40" does not perfectly match the "* is the new *" pattern, but still might be considered a reference. In this section we reformulate the problem, using the output of the sequence-to-sequence tagger as one input to a machine learning model.

We reformulate the problem as a binary classification task over pairs of sentences. Given a seed sentence s representing an original pop-culture quote, and a candidate sentence c, decide whether c is a reference to s. We note this is not an easy task, as it is hard to put our finger on why "One does not simply forget to social distance" is likely a reference to "One does not simply walk into Mordor", but "One cannot just walk right into jail" is not.

5 Snowclone Reference Detector

Data. We searched the web and found 20 famous movie quotes that turned into snowclone internet memes. We removed three quotes appearing in the data of Section 3, not to contaminate our evaluation. Next, we defined overly general regular expressions for each seed (attempting to catch both snowclones and not) and crawled Reddit conversations to find matches. We choose Reddit due to its popularity and comprehensive use of memes. We collected 3850 pairs of seed and sentence and had

Snowclone Detection - Results			
Model	Accuracy	Precision	Recall
Naive	0.64	1	0
SVM	**0.85±0.08**	**0.84±0.13**	**0.78±0.12**
RoBERTa	0.81±0.94	0.7± 0.15	0.74±0.18

Table 2: Snowclone detection task. We performed 20 splits for the SVM model and 5 for RoBERTa, and report standard deviation.

an expert manually annotate them (after calibration). The dataset is imbalanced, with 64% of pairs tagged as non-reference. When splitting to train-dev-test (60%/20%/20%), we ensure all examples from the same seed are put in the same set. We take a supervised approach and train two models.

Feature-based SVM model. We calculate three sets of features, focusing on sentence *structure*. (1) Similarity between s and c: edit distance, longest common sequence, and longest substring between s, c. (2) We use the snowclone tagger of Section 3 to predict $\hat{s}$, the snowclone form of s and use the same features of group (1) between $\hat{s}, c$. (3) To characterize the shared and replaced words we calculate the idf statistic for words shared between s, c and words in s but not in c (idf over movie quotes (Danescu-Niculescu-Mizil and Lee, 2011)). We tried decision trees, random forests, and SVM, and chose SVM due to its performance.

RoBERTa-based model. We chose RoBERTa as our second model, as it showed impressive results on a related 2-sentence classification task. We use a model pre-trained on SNLI (Nie et al., 2020), which achieved state-of-the-art result on a natural language inference task. We replace its classification head with a binary classification head, and fine-tune the model on the dataset of Section 4. Unlike SVM, we expect this model to capture semantic similarity (e.g., between "old" and "new").

See Appendix B for implementation details and hyper-parameter tuning.

Evaluation and results. The accuracy, precision and recall measures for all models are presented in Table 2. The naive majority baseline achieves 64% accuracy on the full data set (as the data is not balanced). For our feature-based SVM model, we randomly select 20 different splits, reaching an average of 85% accuracy, 84% precision and 78% recall, with a corresponding std of 8.7%, 13.8% and 12%. The RoBERTa-based model achieved average results of 81% accuracy, 70% precision and 74% recall, with std 9.4%, 15.7% and 18.7%. Thus, we chose the SVM model. This perhaps indicates the importance of structure in the snowclone problem; alternatively, perhaps the amount of data was not sufficient to fine-tune RoBERTa.

Observations. As a (qualitative) reality check, we choose 10 seeds unseen during training. We crawl all Reddit posts from March 2016 (month and year chosen at random). We choose Reddit as a diverse and popular online community, where internet memes are used regularly. We use the SVM model to collect new candidate references for the seeds. We analyze the candidate references and observe that (not surprisingly) their quality is heavily influenced by the snowclone tagger feature. When the regex is too general (e.g., "I am your *" for "I am your father"), the number of false positives is high. Importantly, over all seeds our method is capable of detecting true references that do not exactly match the predicted snowclone-form.

6 Evaluation: Web Extension

Our main motivation in this study was to help the proverbial "Englishman in New York" identify cultural references. In this section, we ask whether *our algorithms can help users detect pop-culture references online*. We create CATCHPHRASE, a web browser extension able to detect and mark pop-culture references in web pages (see Figure 3). The extension inspects the web page source and identifies candidate sentences. We use locality-sensitive hashing (Gionis et al., 1999) with similarity threshold = 0.2 for filtering, allowing us to reduce computation time and maintain a small number of false negatives. Next, the extension runs the reference-detector on each (seed, candidate sentence) pair and highlights the predicted references.

Experimental design. We choose a set of 20 pop-culture quotes (seeds) unseen by our reference-detector during training time, and whose snowclone form is the basis to many variations. All sentences chosen are ones that became popular internet memes. For each seed quote, we manually crawled Reddit and found threads containing references to it. After filtering out threads that were over 10 messages long, we were left with 106 threads.

We recruited 10 volunteers through social media, all Israeli, non-native English speakers, who self-identified as having low familiarity with pop-culture. 80% of the volunteers were 20-35 years old, and the remaining 20% were 40-60 years old.

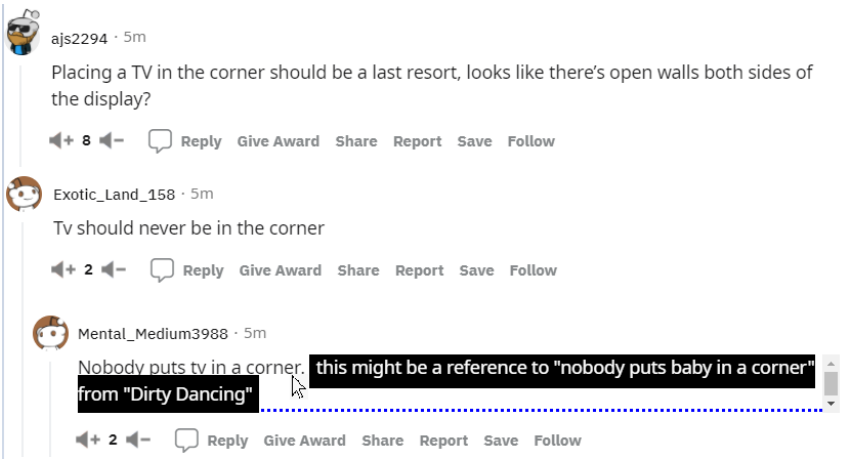

Figure 3: Screenshot of our web extension, suggesting "Nobody puts TV in a corner" is a reference to Dirty Dancing's "Nobody puts baby in a corner". The suggested reference is underlined in blue. Hovering over the underlined sentence prompts a message containing original quote information.

70% of the participants were females. We randomly selected 16 seeds for each participant and randomly split them into two groups, one per condition (with and without our extension). The threads were shown in random order. The participants were asked to go over each thread and point out any pop-culture references they detect, specifying their origin if they knew it.

Evaluation and results. Under the no-extension condition, participants correctly identified a pop-culture reference 38.7% of the time. The reference origin was correctly identified in 61.2% of these. This is interesting, as it shows people can identify that a sentence *looks* like a cultural reference, even when they do not recognize the source.

When using the extension, participants correctly identified a reference 68.7% of the times, recognizing the origin in 98.1% of these. In 26.3% of the threads, the algorithm did not recognize the reference. 5% of the times, we believe the algorithm was right but people thought it was not (e.g., "I solemnly swear I'm up for good tea" as a reference to "I solemnly swear I'm up to no good"). The reason source recognition is not perfect is one user finding a sentence the algorithm missed (but not attributing it). To check our hypothesis that web-extension users recognize more pop-culture references, we run t-test with $\alpha = 0.95$ and reject the null hypothesis with $pval = 0.00005$.

7 Conclusions and Future Work

In this work we proposed the novel task of detecting snowclones in text. Motivated by the high agreement achieved by humans on a snowclone annotation task, we first developed algorithms for finding snowclones which are regular expressions, then extended the formulation to a softer notion of similarity. We introduce a new data set of pop-culture quotes and their corresponding snowclone variants and train models on them. We publish code for CATCHPHRASE, an internet browser plugin to automatically detect and mark references in real-time. Our results demonstrate our algorithms can indeed help users detect pop-culture references.

In the future, our work might be used in conversational AI context, supporting agents' ability to understand and even generate pop-culture references. Another direction worth pursuing is applying our methods to domains outside pop-culture (or at the very least, to pop-culture of different cultures).

We believe snowclones, complementing the notion of paraphrases, are worth exploring and can give us new insights into how ideas spread and evolve. Our approach opens an opportunity to better answer long-standing questions in social science about the dynamics of information.

Below we provide implementation details for the sake of reproducibility.

A Snowclone Pattern Tagger: Hyper-parameter tuning

For the BI-LSTM-CRF model, we perform a small grid search to determine the values for the learning rate, weight decay, and the number of layers and hidden dimension of the the BI-LSTM. As the search space, we used $learning - rate \in \{0.01, 0.001, 0.0001\}$, *weight-decay* $\in \{0, 0.01, 0.001\}$, *num-layers* $\in \{1, 2, 3\}$ and *hidden-dim* $\in \{32, 64, 128\}$. Finally, we choose *learning-rate* $= 0.01$,*weight-decay* $= 0$, *num-layers* $= 2$,*hidden-dim* $= 32$. For the BERT model, we use a smaller grid search over the learning rate ($\in \{0.001, 0.0001\}$) and the weight decay ($\{0, 0.01, 0.001\}$) hyper-parameters, and train it for a single epoch using *learning-rate* $= 0.0001$,*weight-decay* $= 0.01$.

B Snowclone Reference Detector: Hyper-parameter tuning

For the RoBERTa model, we perform the same hyper-parameter search as described in Section A, and use the same values. For the SVM model, we search over kernels (RBF, linear and polynomial), degree (when applicable, over $[2, 3, 4]$) and C-values ($\{0.1 \cdot i\}_{i=1}^{10}$). Our search dictates using a polynomial kernel of degree 3, with $C = 0.5$.

On Training Instance Selection for Few-Shot Neural Text Generation

Ernie Chang[*], **Xiaoyu Shen**[*], **Hui-Syuan Yeh, Vera Demberg,**
Dept. of Language Science and Technology, Saarland University
{cychang,xshen}@coli.uni-saarland.de

Abstract

Large-scale pretrained language models have led to dramatic improvements in text generation. Impressive performance can be achieved by finetuning only on a small number of instances (few-shot setting). Nonetheless, almost all previous work simply applies random sampling to select the few-shot training instances. Little to no attention has been paid to the selection strategies and how they would affect model performance. In this work, we present a study on training instance selection in few-shot neural text generation. The selection decision is made based only on the unlabeled data so as to identify the most worthwhile data points that should be annotated under some budget of labeling cost. Based on the intuition that the few-shot training instances should be diverse and representative of the entire data distribution, we propose a simple selection strategy with K-means clustering. We show that even with the naive clustering-based approach, the generation models consistently outperform random sampling on three text generation tasks: data-to-text generation, document summarization and question generation. The code and training data are made available at https://gitlab.com/erniecyc/few-selector. We hope that this work will call for more attention on this largely unexplored area.

1 Introduction

Few-shot text generation is an important research topic since obtaining large-scale training data for each individual downstream task is prohibitively expensive. Recently, pretraining large neural networks with a language modeling objective has led to significant improvement across different few-shot text generation tasks (Radford et al., 2019; Lewis et al., 2020) and many techniques are proposed based on them (Chen et al., 2020; Schick and Schütze, 2020a; Zhang et al., 2020; Kale, 2020; Chang et al., 2020, 2021b; Li and Liang, 2021; Chang et al., 2021a). However, all the previous works simulate the few-shot scenario by randomly sampling a subset from the full training data. Little to no attention has been paid to the selection strategies.

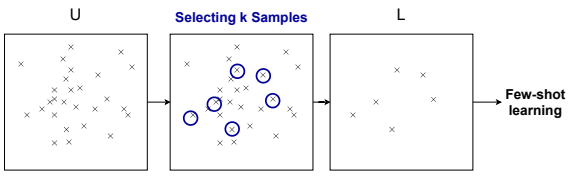

Figure 1: **Training scenario**: **U** represents unlabeled data and **L** indicates labeled instances. The annotation budget only allows selecting K data for annotating the reference text.

In this work, we present a preliminary study at searching for an optimal strategy to select the few-shot training instances. Studying the selection strategy is motivated by two rationales. First, random sampling leads to a large variance of model performance (Zhang et al., 2020; Schick and Schütze, 2020a,b). Yet current works sample their own training data which makes it difficult to compare across different models. One can then not be sure whether an improved performance can be really ascribed to the model or the randomness of sampling. Using a stable selection strategy to find the most informative few-shot instances can provide a fair platform and better benchmark different few-shot generative models. Second, in practical applications, e.g. document summarization, the training data is usually obtained by manually annotating the summaries for some selected documents. In Figure 1, we illustrate the typical training scenario for text generation where the annotation budget only allows annotating a limited amount of data. Studying the optimal selection strategy can help make the most use of our annotation budget. Specifically, we focus on

the label-free setting where *the selection can only condition on the unannotated data*. Although leveraging the reference text may benefit the selection strategy, it conflicts with the realistic setting where we need to first select the data then get its annotated reference text.

The selection task resembles the theme of active learning (Balcan et al., 2007), where the model keeps identifying the most informative instances to get labeled. Existing active learning approaches can be roughly divided to uncertainty-based sampling and representative sampling (Settles, 2009). Uncertainty-based sampling select samples that maximally reduce the uncertainty of the model (Tur et al., 2005). This, however, requires a well-trained model with decent confidence score estimations in order to perform well. Therefore, in this paper, we opt for the representative-sampling where the selected training instances are expected to be dissimilar to each other and representative enough to cover all important patterns in the whole data distribution (Agarwal et al., 2005; Wei et al., 2015). This naturally matches the objectives of k-means clustering which minimizes the within-cluster variances while maximizing the between-cluster variances to encourage the diversity and representativeness of each cluster (Krishna and Murty, 1999; Kanungo et al., 2002). As has been shown in image classification tasks, data points closer to the cluster centroids are usually most important, while other faraway points can even be safely removed without hurting model performance (Kaushal et al., 2018; Birodkar et al., 2019). Inspired by this, we propose a simple selection strategy which first clusters the whole unlabeled dataset with the K-means algorithm, and then from each cluster, selects the data point that is closest to the cluster centroid.

We conduct experiments on three popular text generation tasks: data-to-text, document summarization and question generation. The proposed selection strategy consistently outperforms random sampling and exhibits much smaller variance.

Contribution. We present a preliminary study on training instance selection for few-shot text generation and propose a selection strategy based on K-means clustering. The proposed method shows consistent superior performance over random sampling, which can be used to make most use of the annotation budget in practical applications. Meanwhile, the selected training instances can serve as a better benchmark for few-shot text generation since they are not biased towards specific generative methods and do not have the large variance issue as found in random sampling. We further perform a set of ablation studies to analyze what contributes to a good selection. Our findings can also benefit research in active learning (Konyushkova et al., 2017) since identifying the most informative training instances is a critical step before collecting more annotations through active learning.

2 Problem Formulation

Following the training scenario shown in Figure 1, we denote the unlabeled data as $U_1, U_2, \ldots, U_n$ where n is the data size. Depending on the downstream task, "data" can mean unlabeled structured data, documents and paragraphs respectively in the context of data-to-text, document summarization and question generation. We will select K instances from the whole unlabeled dataset, annotate them with reference text, and then train a neural generative model based on the annotated data. K is defined based on the annotation budget. In this work, since we focus on the few-shot scenario, K is set to be small (≤ 100). The goal is to *find the most representative K instances that can lead to the optimal performance when trained on them*.

3 Selection by K-means Clustering

The general idea of our proposed method is to first split the whole unlabeled data into K clusters, then select one data point from each cluster. Specifically, we first map each data point into a vector, then cluster the vectors with the K-means algorithm. The objective is sum of the squared errors (SSE), which is also called cluster inertia:

$$SSE = \sum_{i=1}^{n} \sum_{j=1}^{K} w_{i,j} ||x^i - \mu^j||_2^2 \qquad (1)$$

where μ^j is the centroid of the jth cluster. x^i is the embedding vector of U_i. $w_{i,j} = 1$ if x^i belongs to the cluster j and 0 otherwise. We optimize the objective function with the EM algorithm (Dempster et al., 1977) which iteratively assigns each data point into its closest cluster centroid. The initial centroid points are chosen based on the K-means++ algorithm (Arthur and Vassilvitskii, 2007). The first cluster center is chosen uniformly at random from the data points, after which each subsequent cluster center is chosen from the remaining data points with probability proportional to its squared distance from the point's closest existing cluster

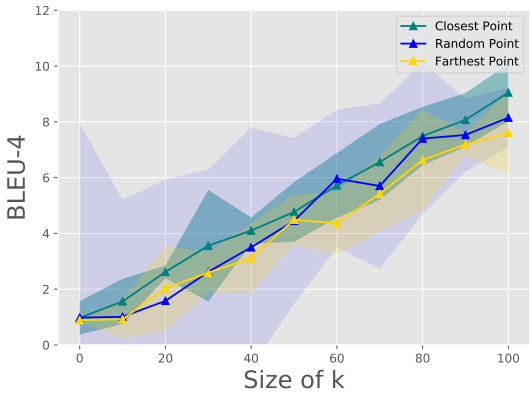

Figure 2: Ablation studies on the SQUAD corpus. Performance in BLEU-4 with increasing K between different variants of K-means where selection is based on the **closest point**, **Random point**, or **Farthest point** from the centroid.

center. By this means, we maximize the chance of spreading out the K initial cluster centers. We use 10 random seeds for selecting initial centers and the clustering with the minimum SSE is chosen.

After splitting them into K clusters, we pick from each cluster the data point that is closest to the center. We use the Euclidean distance to select, the same as the metric used for K-means clustering. The intuition is that the test performance usually depends on the nearest neighbor in the training set (Khandelwal et al., 2020; Rajani et al., 2020). Ideally data points closest to the cluster centers are most representative samples, selecting them will maximize the chance that a similar sample will be found in the training dataset.

4 Experiments

We perform our experiments on the following three representative datasets which cover three different text generation tasks:

1. Data-to-text: We use the dataset for the E2E challenge (Novikova et al., 2017) which contain 50,602 data-text pairs with 8 unique slots in the restaurant domain.

2. Document Summarization: We use the CNN/Dailymail dataset (non-anonymized version) (Hermann et al., 2015) which contains 312,084 document-summary pairs.

3. Question generation: We use the SQuAD dataset (Rajpurkar et al., 2016) with over 100k questions. Following Du et al. (2017), we focus on the answer-independent scenario to directly generate questions from passages.

For all experiments, we finetune the open-sourced Bart model (Lewis et al., 2020) as our generative model. Bart is pretrained with a denoising autoencoder objective on large amount of text data and has been the state-of-the-arts for many text generation tasks. To extract vectors used for clustering, we finetune the Bart model with its original self-supervised objective on the unlabeled data, then apply mean pooling over the last hidden states of the encoder.

In the later sections, we will first compare the model performance based on our proposed selection strategy and random sampling, then analyze the variance of them. Finally, we perform an ablation study to see the effects of in-cluster selection and embedding choices.

Comparison of Selection Strategies. In Table 1, we compare the model performance based on different selection strategies. Apart from random sampling and our proposed method, we also compare with a lower bound where all instances are randomly sampled from one cluster (within-cluster random). Adding this for comparison aims to illustrate that it is important to select diverse samples across different clusters. The performance scores are averaged over 10 different trials for each selection strategy. As can be seen, K-means based selections consistently outperforms the others. Within-cluster random sampling performs the worst, proving the importance of having diverse samples in the training instance. However, it is worth noting that although random sampling underperforms K-means selection on average, *its upper bound is much higher, suggesting the proposed K-means selection is by no means optimal*. There is still much room for improvement.

Variance of Model Performance. Table 1 also shows the variance of model performance with different selection strategies. The variance is computed based on 10 different runs. For within-cluster random sampling, the variance comes from both the choice of the cluster and the in-cluster sampling. For K-means selection, the variance comes from the choice of initial center points. We can see random sampling and within-cluster random sampling have a very large variance of up to 7.12 for $K = 100$. This further suggests that comparing few-shot models based on random sampling can be be prone to variability and prevent drawing reliable conclusions. K-means-based selection, on

the contrary, is rather robust with random seeds. Therefore, for future work on few-shot text generation, we suggest that models be tested on instances selected from our proposed strategy for a fair comparison.

Effects of In-cluster Selection. In Figure 2, we show the effects of the in-cluster selection method. In our proposed method, within each cluster, we select one data point that is closest to the cluster center. To see whether it is important to select the closest data point, we compare with two selection variants that within each cluster, we select (1) one data point randomly sampled from the cluster, and (2) one data point that is farthest to the cluster center. We can observe that the choice of selection does have a big impact on the model performance. Choosing data points farthest to the cluster centers leads to the worst performance. This is consistent with previous findings (Kaushal et al., 2018; Birodkar et al., 2019) that data points farthest from cluster centers are usually outliers and less representative. Selecting them might mislead the model to capture non-generic patterns and thereby generalize poorly. In contrast, choosing data points closest to cluster centers performs slightly better than random selection. However, random selection has a much larger variance compared with closest/farthest point selection (shown as shadow).

Effects of Embedding Methods. As the K-means clustering is performed on top of the embedding vectors of unlabeled data, the choice of embedding methods could affect the performance on selected points. In Table 2, we show the effects of the different embedding methods. Apart from the finetuned Bart, we compare with embeddings extracted from (1) Bart without being finetuned on the task-specific data, (2) Glove (Pennington et al., 2014) and (3) FastText (Bojanowski et al., 2017), both finetuned on the task-specific data. For each embedding method, we compare using mean pooling and sum pooling to extract the final vector representation. The results show that finetuned Bart generally outperforms the other embedding choices. We attribute this to the similarity in the embedding space between selection with BART embeddings and and the BART generation model. Moreover, *FastText* offers a strong baseline as it does relatively well on two scenarios in E2E and SQUAD respectively. Further, we observe that *mean* pooling is generally better than the *sum* of word vectors, which is also observed in Chen et al. (2018).

Human Evaluation. To obtain further insights with respect to the generation outputs, five annotators were instructed to evaluate 100 samples for each of the three tasks to judge (1) whether the text is *fluent* (score 0-5 with 5 being fully fluent), and (2) whether it contains relevant information about its input source (*adequacy*). These scores are averaged and presented in Table 3. For **Random** selection, we sampled 10 outputs from each of the 10 trials to make it 100 samples, and the same goes for **IC-random**. We observe that the K-means algorithm select better subsets of the training samples that allow for better generalizability to unseen input sources. In particular, the outputs are generally more *adequate*. However, we see that the *fluency* of outputs remain relatively similar.

5 Conclusion

In this work, we target at the unexplored problem of training instance selection for few-shot text generation. We show that random sampling can lead to large variance and suboptimal performance. To address this problem, we propose a selection strategy based on K-mean clustering and demonstrate

	E2E	CNNDM	SQUAD
Random	4.08/4.15	**4.55**/3.27	**4.62**/3.84
IC-Random	4.32/3.54	3.62/3.01	4.23/2.74
K-means	**4.12/4.24**	4.32/**3.66**	4.51/**3.98**

Table 3: Human evaluation on 100 samples of the finetuned BART generation performance comparison on **E2E**, **CNNDM**, and **SQUAD**. Scores are presented as (*fluency* / *adequacy*).

that it consistently outperforms random sampling, and has much lower variance. We further perform a set of ablation studies to analyze the effects of data size, embedding and selection methods, showing that this is still much room for improvement. Future work can consider other clustering methods.

Coreference Resolution without Span Representations

Yuval Kirstain* **Ori Ram*** **Omer Levy**

Blavatnik School of Computer Science, Tel Aviv University
{yuval.kirstain,ori.ram,levyomer}@cs.tau.ac.il

Abstract

The introduction of pretrained language models has reduced many complex task-specific NLP models to simple lightweight layers. An exception to this trend is coreference resolution, where a sophisticated task-specific model is appended to a pretrained transformer encoder. While highly effective, the model has a very large memory footprint – primarily due to dynamically-constructed span and span-pair representations – which hinders the processing of complete documents and the ability to train on multiple instances in a single batch. We introduce a lightweight end-to-end coreference model that removes the dependency on span representations, handcrafted features, and heuristics. Our model performs competitively with the current standard model, while being simpler and more efficient.

1 Introduction

Until recently, the standard methodology in NLP was to design task-specific models, such as BiDAF for question answering (Seo et al., 2017) and ESIM for natural language inference (Chen et al., 2017). With the introduction of pretraining, many of these models were replaced with simple output layers, effectively fine-tuning the transformer layers below to perform the traditional model's function (Radford et al., 2018). A notable exception to this trend is *coreference resolution*, where a multi-layer task-specific model (Lee et al., 2017, 2018) is appended to a pretrained model (Joshi et al., 2019, 2020). This model uses intricate span and span-pair representations, a representation refinement mechanism, handcrafted features, pruning heuristics, and more. While the model is highly effective, it comes at a great cost in memory consumption, limiting the amount of examples that can be loaded on a large GPU to a single document, which often needs to be truncated or processed in sliding windows. Can this coreference model be simplified?

We present *start-to-end* (s2e) coreference resolution: a simple coreference model that does *not* construct span representations. Instead, our model propagates information to the span boundaries (i.e., its start and end tokens) and computes mention and antecedent scores through a series of bilinear functions over their contextualized representations. Our model has a significantly lighter memory footprint, allowing us to process multiple documents in a single batch, with no truncation or sliding windows. We do not use any handcrafted features, priors, or pruning heuristics.

Experiments show that our minimalist approach performs on par with the standard model, despite removing a significant amount of complexity, parameters, and heuristics. Without any hyperparameter tuning, our model achieves 80.3 F1 on the English OntoNotes dataset (Pradhan et al., 2012), with the best comparable baseline reaching 80.2 F1 (Joshi et al., 2020), while consuming less than a third of the memory. These results suggest that transformers can learn even difficult structured prediction tasks such as coreference resolution without investing in complex task-specific architectures.[1]

2 Background: Coreference Resolution

Coreference resolution is the task of clustering multiple mentions of the same entity within a given text. It is typically modeled by identifying entity mentions (contiguous spans of text), and predicting an *antecedent* mention a for each span q (query) that refers to a previously-mentioned entity, or a null-span ε otherwise.

Lee et al. (2017, 2018) introduce *coarse-to-fine* (c2f), an end-to-end model for coreference resolu-

*Equal contribution.

tion that predicts, for each span q, an antecedent probability distribution over the candidate spans c:

$$P\left(a = c|q\right) = \frac{\exp(f(c,q))}{\sum_{c'} \exp(f(c',q))}$$

Here, $f(c,q)$ is a function that scores how likely c is to be an antecedent of q. This function is comprised of mention scores $f_m(c), f_m(q)$ (i.e. is the given span a mention?) and a separate antecedent score $f_a(c,q)$:

$$f(c,q) = \begin{cases} f_m(c) + f_m(q) + f_a(c,q) & c \neq \varepsilon \\ 0 & c = \varepsilon \end{cases}$$

Our model (Section 3) follows the scoring function above, but differs in how the different elements $f_m(\cdot)$ and $f_a(\cdot)$ are computed. We now describe how f_m and f_a are implemented in the c2f model.

Scoring Mentions In the c2f model, the mention score $f_m(q)$ is derived from a vector representation $\mathbf{v}_q$ of the span q (analogously, $f_m(c)$ is computed from $\mathbf{v}_c$). Let $\mathbf{x}_i$ be the contextualized representation of the i-th token produced by the underlying encoder. Every span representation is a concatenation of four elements: the representations of the span's start and end tokens $\mathbf{x}_{q_s}, \mathbf{x}_{q_e}$, a weighted average of the span's tokens $\hat{\mathbf{x}}_q$ computed via self-attentive pooling, and a feature vector $\phi(q)$ that represents the span's length:

$$\mathbf{v}_q = [\mathbf{x}_{q_s}; \mathbf{x}_{q_e}; \hat{\mathbf{x}}_q; \phi(q)]$$

The mention score $f_m(q)$ is then computed from the span representation $\mathbf{v}_q$:

$$f_m(q) = \mathbf{v}_m \cdot \text{ReLU}(\mathbf{W}_m \mathbf{v}_q)$$

where $\mathbf{W}_m$ and $\mathbf{v}_m$ are learned parameters. Then, span representations are enhanced with more global information through a refinement process that interpolates each span representation with a weighted average of its candidate antecedents. More recently, Xu and Choi (2020) demonstrated that this span refinement technique, as well as other modifications to it (e.g. entity equalization (Kantor and Globerson, 2019)) do not improve performance.

Scoring Antecedents The antecedent score $f_a(c,q)$ is derived from a vector representation of the span *pair* $\mathbf{v}_{(c,q)}$. This, in turn, is a function of the individual span representations $\mathbf{v}_c$ and $\mathbf{v}_q$, as well as a vector of handcrafted features $\phi(c,q)$ such as the distance between the spans c and q, the document's genre, and whether c and q were said/written by the same speaker:

$$\mathbf{v}_{(c,q)} = [\mathbf{v}_c; \mathbf{v}_q; \mathbf{v}_c \circ \mathbf{v}_q; \phi(c,q)]$$

The antecedent score $f_a(c,q)$ is parameterized with $\mathbf{W}_a$ and $\mathbf{v}_a$ as follows:

$$f_a(c,q) = \mathbf{v}_a \cdot \text{ReLU}(\mathbf{W}_a \mathbf{v}_{(c,q)})$$

Pruning Holding the vector representation of every possible span in memory has a space complexity of $O(n^2 d)$ (where n is the number of input tokens, and d is the model's hidden dimension). This problem becomes even more acute when considering the space of span *pairs* ($O(n^4 d)$). Since this is not feasible, candidate mentions and antecedents are pruned through a variety of model-based and heuristic methods.

Specifically, mention spans are limited to a certain maximum length ℓ. The remaining mentions are then ranked according to their scores $f_m(\cdot)$, and only the top λn are retained, while avoiding overlapping spans. Antecedents (span pairs) are further pruned using a lightweight antecedent scoring function (which is added to the overall antecedent score), retaining only a constant number of antecedent candidates c for each target mention q.

Training For each remaining span q, the training objective optimizes the marginal log-likelihood of all of its unpruned gold antecedents c, as there may be multiple mentions referring to the same entity:

$$\log \sum_{c} P(a = c|q)$$

Processing Long Documents Due to the c2f model's high memory consumption and the limited sequence length of most pretrained transformers, documents are often split into segments of a few hundred tokens each (Joshi et al., 2019). Recent work on efficient transformers (Beltagy et al., 2020) has been able to shift towards processing complete documents, albeit with a smaller model (base) and only one training example per batch.

3 Model

We present *start-to-end* (s2e) coreference resolution, a simpler and more efficient model with respect to c2f (Section 2). Our model utilizes the endpoints of a span (rather than all span tokens) to compute the mention and antecedent scores $f_m(\cdot)$

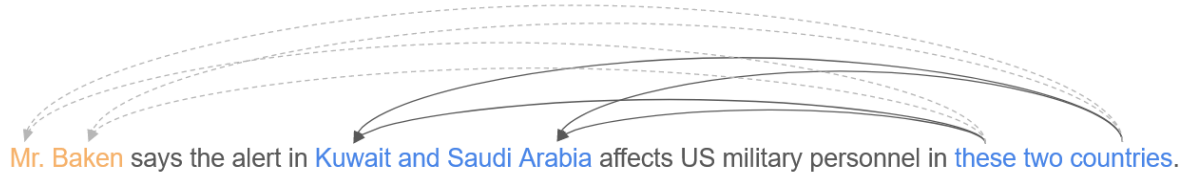

Figure 1: The antecedent score $f_a(c, q)$ of a query mention $q = (q_s, q_e)$ and a candidate antecedent $c = (c_s, c_e)$ is defined via bilinear functions over the representations of their endpoints c_s, c_e, q_s, q_e. Solid lines reflect factors participating in positive examples (coreferring mentions), and dashed lines correspond to negative examples.

and $f_a(\cdot, \cdot)$ *without* constructing span or span-pair representations; instead, we rely on a combination of lightweight bilinear functions between pairs of endpoint token representations. Furthermore, our model does not use any handcrafted features, does not prune antecedents, and prunes mention candidates solely based on their mention score $f_m(q)$.

Our computation begins by extracting a *start* and *end* token representation from the contextualized representation $\mathbf{x}$ of each token in the sequence:

$$\mathbf{m}^s = \text{GeLU}(\mathbf{W}_m^s \mathbf{x}) \qquad \mathbf{m}^e = \text{GeLU}(\mathbf{W}_m^e \mathbf{x})$$

We then compute each mention score as a biaffine product over the start and end tokens' representations, similar to Dozat and Manning (2017):

$$f_m(q) = \mathbf{v}_s \cdot \mathbf{m}_{q_s}^s + \mathbf{v}_e \cdot \mathbf{m}_{q_e}^e + \mathbf{m}_{q_s}^s \cdot \mathbf{B}_m \cdot \mathbf{m}_{q_e}^e$$

The first two factors measure how likely the span's start/end token q_s/q_e is a beginning/ending of an entity mention. The third measures whether those tokens are the boundary points of the *same* entity mention. The vectors $\mathbf{v}_s, \mathbf{v}_e$ and the matrix $\mathbf{B}_m$ are the trainable parameters of our mention scoring function f_m. We efficiently compute mention scores for all possible spans while masking spans that exceed a certain length ℓ.[2] We then retain only the top-scoring λn mention candidates to avoid $O(n^4)$ complexity when computing antecedents.

Similarly, we extract *start* and *end* token representations for the antecedent scoring function f_a:

$$\mathbf{a}^s = \text{GeLU}(\mathbf{W}_a^s \mathbf{x}) \qquad \mathbf{a}^e = \text{GeLU}(\mathbf{W}_a^e \mathbf{x})$$

Then, we sum over four bilinear functions:

$$\begin{aligned} f_a(c, q) = \mathbf{a}_{c_s}^s \cdot \mathbf{B}_a^{ss} \cdot \mathbf{a}_{q_s}^s + \mathbf{a}_{c_s}^s \cdot \mathbf{B}_a^{se} \cdot \mathbf{a}_{q_e}^e \\ + \mathbf{a}_{c_e}^e \cdot \mathbf{B}_a^{es} \cdot \mathbf{a}_{q_s}^s + \mathbf{a}_{c_e}^e \cdot \mathbf{B}_a^{ee} \cdot \mathbf{a}_{q_e}^e \end{aligned}$$

Each component measures the compatibility of the spans c and q by an interaction between different boundary tokens of each span. The first component compares the *start* representations of c and q, while the fourth component compares the *end* representations. The second and third facilitate a cross-comparison of the *start* token of span c with the *end* token of span q, and vice versa. Figure 1 (bottom) illustrates these interactions.

This calculation is equivalent to computing a bilinear transformation between the concatenation of each span's boundary tokens' representations:

$$f_a(c, q) = [\mathbf{a}_{c_s}^s; \mathbf{a}_{c_e}^e] \cdot \mathbf{B}_a \cdot [\mathbf{a}_{q_s}^s; \mathbf{a}_{q_e}^e]$$

However, computing the factors *directly* bypasses the need to create n^2 explicit span representations. Thus, we avoid a theoretical space complexity of $O(n^2 d)$, while keeping it equivalent to that of a transformer layer, namely $O(n^2 + nd)$.

4 Experiments

Dataset We train and evaluate on two datasets: the document-level English OntoNotes 5.0 dataset (Pradhan et al., 2012), and the GAP coreference dataset (Webster et al., 2018). The OntoNotes dataset contains speaker metadata, which the baselines use through a hand-crafted feature that indicates whether two spans were uttered by the same speaker. Instead, we insert the speaker's name to the text every time the speaker changes, making the metadata available to any model.

Pretrained Model We use Longformer-Large (Beltagy et al., 2020) as our underlying pretrained model, since it is able to process long documents without resorting to sliding windows or truncation.

Baseline We consider Joshi et al.'s (2019) expansion to the c2f model as our baseline. Specifically, we use the implementation of Xu and Choi (2020) with minor adaptations for supporting Longformer. We do not use higher-order inference, as Xu and Choi (2020) demonstrate that it does not result in significant improvements. We train the baseline

[2] While pruning by length is not necessary for efficiency, we found it to be a good inductive bias.

c2f + Longformer-Large	15.7
s2e + Longformer-Large	**4.3**

Table 3: Peak GPU memory usage during inference on OntoNotes, when processing one document at a time.

model over three pretrained models: Longformer-Base, Longformer-Large, and SpanBERT-Large (Beltagy et al., 2020; Joshi et al., 2020).

Hyperparameters All models use the same hyperparameters as the baseline. The only hyperparameters we change are the maximum sequence length and batch size, which we enlarge to fit as many tokens as possible into a 32GB GPU.[3] For our model, we use dynamic batching with 5,000 max tokens, which allows us to fit an average of 5-6 documents in every training batch. The baseline, however, has a much higher memory footprint, and is barely able to fit a single example with Longformer-Base (max 4,096 tokens). When combining the baseline with SpanBERT-Large or Longformer-Large, the baseline must resort to sliding windows to process the full document (512 and 2,048 tokens, respectively).

Performance Table 1 and Table 2 show that, despite our model's simplicity, it performs as well as the best performing baseline. Our model with Longformer-Large achieves 80.3 F1 on OntoNotes, while the best performing baseline achieves 80.2 F1. When the baseline model is combined with either version of Longformer, it is not able to reach the same performance level as our model. We see similar trends for GAP. Our findings indicate that there is little to lose from simplifying the coreference resolution architecture, while there are potential gains to be had from optimizing with larger batches.

Efficiency We also compare our model's memory usage using the OntoNotes development set. Table 3 shows that our implementation is at least three times more memory efficient than the baseline. This improvement results from a combination of three factors: (1) the fact that our model is lighter on memory and does not need to construct span or span-pair representations, (2) our simplified framework, which does not use sliding windows, and (3) our implementation, which was written "from scratch", and might thus be more (or less) efficient than the original.

5 Related Work

Recent work on memory-efficient coreference resolution sacrifices speed and parallelism for guarantees on memory consumption. Xia et al. (2020) and Toshniwal et al. (2020) present variants of the c2f model (Lee et al., 2017, 2018) that use an iterative process to maintain a fixed number of span representations at all times. Specifically, spans are processed sequentially, either joining existing clusters or forming new ones, and an eviction mechanism ensures the use of a constant number of clusters. While these approach constrains the space complexity, their sequential nature slows down the computation, and slightly deteriorates the performance. Our approach is able to alleviate the large

[3] We made one exception, and tried to tune the Longformer-Large baseline's hyperparameters. Despite our efforts, it still performs worse than Longformer-Base.

memory footprint of c2f while maintaining fast parallel processing and high performance.

CorefQA (Wu et al., 2020) propose an alternative solution by casting the task of coreference resolution as one of extractive question answering. It first detects potential mentions, and then creates dedicated queries for each one, creating a pseudo-question-answering instance for each candidate mention. This method significantly improves performance, but at the cost of processing hundreds of individual context-question-answer instances for a single document, substantially increasing execution time. Our work provides a simple alternative, which can scale well in terms of both speed and memory.

6 Conclusion

We introduce a new model for coreference resolution, suggesting a lightweight alternative to the sophisticated model that has dominated the task over the past few years. Our model is competitive with the baseline, while being simpler and more efficient. This finding once again demonstrates the spectacular ability of deep pretrained transformers to model complex natural language phenomena.

Enhancing Entity Boundary Detection for Better Chinese Named Entity Recognition

Chun Chen, Fang Kong*
School of Computer Science and Technology
Soochow University
20195227037@stu.suda.edu.cn, kongfang@suda.edu.cn

Abstract

In comparison with English, due to the lack of explicit word boundary and tenses information, Chinese Named Entity Recognition (NER) is much more challenging. In this paper, we propose a boundary enhanced approach for better Chinese NER. In particular, our approach enhances the boundary information from two perspectives. On one hand, we enhance the representation of the internal dependency of phrases by an additional Graph Attention Network(GAT) layer. On the other hand, taking the entity head-tail prediction (i.e., boundaries) as an auxiliary task, we propose an unified framework to learn the boundary information and recognize the NE jointly. Experiments on both the OntoNotes and the Weibo corpora show the effectiveness of our approach.

1 Introduction

Given a sentence, the NER task aims to identify the noun phrases having special meanings that predefined. Due to its importance on many downstream tasks, such as relation extraction(Ji et al., 2017), coreference resolution(Clark and Manning, 2016) and knowledge graphs(Zhang et al., 2019), NER has attracted much attention for long time.

In comparison with English, due to the lack of explicit word boundary and tenses information, Chinese NER is much more challenging. In fact, the performance of the current SOTAs in Chinese is far inferior to that in English, the gap is about 10% in F1-measure. In this paper, we propose a boundary enhancing approach for better Chinese NER.

Firstly, using Star-Transformer(Guo et al., 2019), we construct a lightweight baseline system. Benefit from the unique star topological structure, Star-Transformer is more dominant in representing long distance sequence, and thus, our baseline achieves comparable performance to the SOTAs. Considering the deficiency in the representation of local sequence information, we then try to enhance the local boundary information. In particular, our approach enhances the boundary information from two perspectives. On one hand, we add an additional GAT(Veličković et al., 2017) layer to capture the internal dependency of phrases. In this way, boundaries can be distinguished implicitly, while the semantic information within the phrase is enhanced. On the other hand, we add an auxiliary task to predict the head and tail of entities. In this way, using the framework of multi-tasking learning, we can learn the boundary information explicitly and help the NER task. Experiments show the effectiveness of our approach. It should be noted that, our approach obtains the new state-of-the-art results on both the OntoNotes and the Weibo corpora. That means our approach can perform well for both written and non-written texts.

2 Related Work

As is well known, most researches cast the NER task as a traditional sequence labelling problem, and many models extending the Bi-LSTM+CRF architecture are proposed (Huang et al., 2015; Chiu and Nichols, 2016; Dong et al., 2016; Lample et al., 2016; Ma and Hovy, 2016). Although the attention-based model, i.e., Transformer(Vaswani et al., 2017), has gradually surpassed the traditional RNN model(Zaremba et al., 2014) in various fields, Yan et al. (2019) has verified that the fully connected Transformer mechanism does not work well on NER. Until recently, some researches show that Star-Transformer can work well on NER owing to its lightweight topological structure(Guo et al., 2019; Chen et al., 2020). Moreover, lexical and dependent information has been widely used in this task (Zhang and Yang, 2018; Ma et al., 2020; Li et al., 2020; Gui et al., 2019; Sui et al., 2019; Tang et al., 2020) to better capture local semantic information.

In this paper, using Star-transformer as our base-

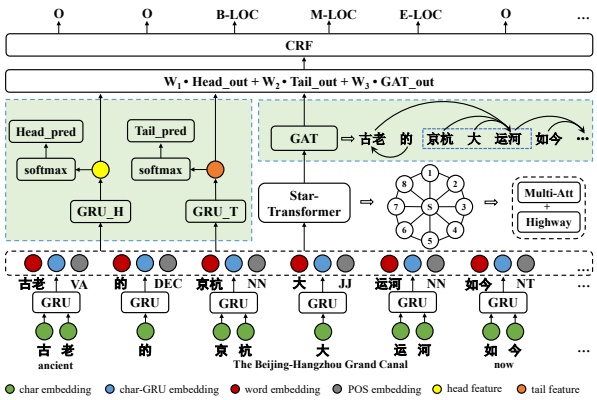

Figure 1: The general architecture for the boundary enhanced model.

line, we mainly focus on enhancing the boundary information to improve Chinese NER.

3 Model

We also treat NER as a sequence labeling task, decoding with a classical CRF(Lafferty et al., 2001). Figure 1 shows the complete model. We can find that the encoder of our model consists of three parts, i.e., GRU-based head and tail representation layer, Star-transformer based contextual embedding layer, and GAT-based dependency embedding layer.

3.1 Token embedding layer

Considering the lack of explit word boundary, we combine word-level represention with character, avoiding the error propagation caused by word segmentation.

For a given sentence, we represent each word and character by looking up the pre-trained word embeddings[1](Li et al., 2018). The sequence of character embeddings contained in a word will be fed to a bi-direction GRU layer. The hidden state of bi-direction GRU can be expressed as folowing:

$$\overrightarrow{h}_i^t = \overrightarrow{GRU}(x_i^t, \overrightarrow{h}_{i-1}^t) \quad (1)$$

$$\overleftarrow{h}_i^t = \overleftarrow{GRU}(x_i^t, \overleftarrow{h}_{i+1}^t) \quad (2)$$

$$h_i^t = [\overrightarrow{h}_i^t; \overleftarrow{h}_i^t] \quad (3)$$

where x_i^t is the token representation, $\overrightarrow{h}_i^t$ and $\overleftarrow{h}_i^t$ denote the t-th forward and backward hidden state of GRU layer.

The final token representation is obtained as equation(4) $\sim$ (6):

$$x_i^w = e(word_i) \quad (4)$$

$$x_i^c = GRU(e(char_i)) \quad (5)$$

$$x_i = [x_i^w; x_i^c; pos_i] \quad (6)$$

where [;] denotes concatenation, and pos_i is the Part-of-Speech tagging of $word_i$.

3.2 Star-transformer based contextual embedding layer

Star-Transformer abandons redundant connections and has an approximate ability to model the long-range dependencies. For NER task, entities are sparse, so it is unnecessary to pay attention on all nodes in the sentence all the time. We utilize this structured model to encode the words in a sentence, which shows comparable performance with the traditional RNN models, but with the capability of capturing long-range dependencies.

3.2.1 Multi-Head Attention

Transformer employs h attention heads to implement self-attention on an input sequence separately. The result of each attention head will be integrated together, called Multi-Head Attention.

Given a sequence of vectors X, we use a query vector Q to soft select the relevant information with attention:

$$Att(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}}) \cdot V \quad (7)$$

$$K = XW^K, V = XW^V \quad (8)$$

where W^K and W^V are learnable parameters. Then Multi-Head Attention can be defined as equation(9) $\sim$ (10):

$$MulAtt = (z_1 \oplus z_2 \oplus \cdots \oplus z_h) \cdot W^o \quad (9)$$

$$z_i = Att(QW_i^Q, KW_i^K, VW_i^V) \quad (10)$$

where $\oplus$ denotes concatenation, and W^o, W_i^Q, W_i^K, W_i^V are learnable parameters.

3.2.2 Star-Transformer Encoder

The topological structure of Star-Transformer is made up of one relay node and n satellite nodes. The state of i-th satellite node represents the feature of the i-th token in a text sequence. The relay node acts as a virtual hub to gather and scatter information from and to all the satellite nodes(Guo et al., 2019).

[1]https://github.com/Embedding/Chinese-Word-Vectors

Star-Transformer proposes a time-step cyclic updating method, in which each satellite node is initialized by the input vector, and the relay node is initialized as the average value of all tokens. The status of each satellite node is updated according to its adjacent nodes, including the previous node in the previous round h_{i-1}^{t-1}, the current node in the previous round h_i^{t-1}, the next node in the previous round h_{i+1}^{t-1}, the current node e^i and the relay node in the previous round s^{t-1}. The update process is shown in the equation(11) $\sim$ (12):

$$C_i^t = [h_{i-1}^{t-1}; h_i^{t-1}; h_{i+1}^{t-1}; e^i; s^{t-1}] \quad (11)$$

$$h_i^t = MulAtt(h_i^{t-1}, C_i^t, C_i^t) \quad (12)$$

where C_i^t denotes contextual information of i-th.

The update of relay node is determined by the information of all the satellite nodes and the status of the previous round :

$$s^t = MulAtt(s^{t-1}, [s^{t-1}; H^t], [s^{t-1}; H^t]) \quad (13)$$

3.2.3 Highway Networks

Highway Networks(Srivastava et al., 2015) can alleviate the blocked gradient backflow when the network deepens. Such gating mechanisms can be of vital significance to Transformer(Chai et al., 2020). We use Highway Networks to mitigate the depth and complexity of Star-Transformer.

After calculating the Multi-Head Attention, a new branch dominated by Highway Networks joins in, indicating the self-updating and dynamic adjustment of satellite node.

$$g = \sigma(w_1 h_i + b_1) \quad (14)$$

$$f(h_i) = w_2 h_i + b_2 \quad (15)$$

$$HW(h_i) = (1-g) \cdot h_i + g \cdot f(h_i) \quad (16)$$

where w_1, w_2, b_1, b_2 are learnable parameters, and σ is the activation function.

Finally, the updated satellite node is denoted as:

$$h_i = HW(h_i) + MulAtt(h_i, C_i, C_i) \quad (17)$$

Highway Networks not only enhances the inherent characteristics of the satellite nodes, but also avoids gradient blocking.

3.3 GAT-based dependency embedding layer

In this work, we propose the use of dependencies between words to construct graph neural networks. The dependency is directional, and the current word is only related to the word with shared edge. This kind of directed linkage further obtains the internal structural information of the entity, enriching the sequential representation.

Graph Attention Networks(GAT)(Veličković et al., 2017), leveraging masked self-attention layers to assign different importance to neighbouring nodes, works well with our work.

The attention coefficient e_{ij} and α_{ij} represents the importance of node j to node i:

$$e_{ij} = att(W\overrightarrow{h}_i, W\overrightarrow{h}_j) \quad (18)$$

$$\alpha_{ij} = softmax_j(e_{ij}) \quad (19)$$

$$= \frac{exp(e_{ij})}{\sum_{k \epsilon N_i} exp(e_{ik})} \quad (20)$$

$$= \frac{exp(LeakyReLU(\overrightarrow{a}^T[Wh_i \oplus Wh_j]))}{\Sigma_{k \epsilon N_i} exp(LeakyReLU(\overrightarrow{a}^T[Wh_i \oplus Wh_k]))} \quad (21)$$

A GAT operation with K independent attention heads can be expressed as:

$$\overrightarrow{h}'_i = \sigma(\frac{1}{K}\sum_{k=1}^{K}\sum_{j \epsilon N_i} \alpha_{ij}^k W^k \overrightarrow{h}_j) \quad (22)$$

where $\oplus$ denotes concatenation, W and $\overrightarrow{a}$ are learnable parameters, N_i is the neighborhood of node i, σ is the activation function.

In addition to the strong focus on the associated nodes of GAT layer, it can well make up for the deficiency of Star-Transformer in capturing the internal dependency of the phrases.

3.4 GRU-based head and tail representation layer

While GAT is effective in capturing internal dependency within an entity, the boundary of the entity need to be strengthened. We then regard the entity boundary detection as binary classification task, which trains with NER at the same time, giving NER clear entity boundary information.

During training phase, two separate GRU layers are used to make head and tail prediction of the entities, whose hidden features are added with the output of GAT layer:

$$H_h = GRU_{head}(x_i) \quad (23)$$

$$H_t = GRU_{tail}(x_i) \quad (24)$$

$$H = W_1 \cdot H_h + W_2 \cdot H_t + W_3 \cdot H_{GAT} \quad (25)$$

W_1, W_2, W_3 are learnable parameters, and H is the final input for CRF.

Table 1: Performance on OntoNotes V4.0, OntoNotes V5.0 and Weibo. Named Entity is the same to the entity of OntoNotes, while Nominal Mention is the reference words which have the property of nouns.

3.5 Model Learning

Entities boundaries are not only the task we deal with, but the perfect natural assistance by NER, which transform from outside to inside of the mention and vice versa.

The multi-task loss function is composed of the categorical cross-entroy loss for boundary detection and entity categorical label prediction:

$$L_{multi} = L_{head} + L_{tail} + L_{label} \quad (26)$$

4 Experiments

4.1 Datasets

The label in our work is marked by BIESO, and we use Precision(P), Recall(R) and $F1$ score($F1$) as evaluation metrics.

OntoNotes V4.0[2](Pradhan, 2011) is a Chinese dataset and consists of texts from news domain. We use the same split as Zhang and Yang (2018).

OntoNotes V5.0[3](Pradhan et al., 2013) is also a Chinese dataset from news domain, but with larger scale and more entity types. We use the same split as Jie and Lu (2019).

Weibo NER[4](Peng and Dredze, 2015) contains annotated NER messages drawn from the social meida Sina Weibo. We use the same split as Peng and Dredze (2015).

Additionally, the tool used to parse syntactic dependency in this paper is DDParser[5].

4.2 Results and Analysis

We conduct experiments on the OntoNotes and Weibo corpora and compare the results with the existing models, as shown in table 1[6].

	OntoNotes V4.0			OntoNotes V5.0		
error types	TE	UE	BE	TE	UE	BE
Star	2236	1912	151	1921	1896	139
Star + GAT	1787	1916	140	1877	1596	169
Star + MultiTask	1772	**1563**	114	1814	1590	127
Star + GAT + MultiTask	**1701**	1564	**108**	**1762**	**1505**	**121**

Table 2: Entity recognition errors of our models, including Type Error(TE), Unidentification Error(UE) and Boundary Error(BE).

We begin by establishing a Star-Transformer baseline, which is more effective on the smaller social media Weibo corpus than OntoNotes. Star-Transformer could be superior to all existing models in Weibo, at least 6.29%(F1) and 8.85%(F1) for Named Entity(NE) and Nominal Entity(NM).

Considering the structural peculiarity of OntoNotes, where entities have similar composition, we utilize GAT to simulate the feature inside the entity. The precision on the OntoNotes are both improved by 3.93% and 1.62%. Futhermore, boundary prediction used as multi-task has been trained with label classification, supplying local sequence information for NER. Tabel 2 shows the number of different entity recognition errors of our models, including Type Error(TE), Unidentification Error(UE) and Boundary Error(BE).The addition of entity head-tail prediction reduces the number of boundary errors on OntoNotes V4.0 by 37. There is no doubt that the boundary enhanced model are quite profitable to the recognition of both entity boundary and entity type.

For Weibo, NE and NM illustrate different performance. The more standard NE has a similar performance to OntoNotes, while NM shows less

[6]Our code is available at: https://github.com/cchen-reese/Boundary-Enhanced-NER.

impact from GAT, due to its short length and non-structue.

Combining the respective advantages of the three layers above, an unified and lightweight model can be applied to Chinese NER, getting the new state-of-the-art results on both the OntoNotes and Weibo corpora.

5 Conclusion

In this paper, we mainly focus on the impact of boundary information on Chinese NER. We firstly propose a Star-transformer based NER system. Then both explicit head and tail boundary information and Dependency GAT-based implicit boundary information are combined to improve Chinese NER. Experiments on both the OntoNotes and the Weibo corpora show the effectiveness of our approach.

Difficulty-Aware Machine Translation Evaluation

Runzhe Zhan* **Xuebo Liu*** **Derek F. Wong†** **Lidia S. Chao**

Abstract

The high-quality translation results produced by machine translation (MT) systems still pose a huge challenge for automatic evaluation. Current MT evaluation pays the same attention to each sentence component, while the questions of real-world examinations (e.g., university examinations) have different difficulties and weightings. In this paper, we propose a novel *difficulty-aware MT evaluation* metric, expanding the evaluation dimension by taking translation difficulty into consideration. A translation that fails to be predicted by most MT systems will be treated as a difficult one and assigned a large weight in the final score function, and conversely. Experimental results on the WMT19 English↔German Metrics shared tasks show that our proposed method outperforms commonly-used MT metrics in terms of human correlation. In particular, our proposed method performs well even when all the MT systems are very competitive, which is when most existing metrics fail to distinguish between them. The source code is freely available at https://github.com/NLP2CT/Difficulty-Aware-MT-Evaluation.

1 Introduction

The human labor needed to evaluate machine translation (MT) evaluation is expensive. To alleviate this, various automatic evaluation metrics are continuously being introduced to correlate with human judgements. Unfortunately, cutting-edge MT systems are too close in performance and generation style for such metrics to rank systems. Even for a metric whose correlation is reliable in most cases, empirical research has shown that it poorly correlates with human ratings when evaluating competitive systems (Ma et al., 2019; Mathur et al., 2020), limiting the development of MT systems.

Current MT evaluation still faces the challenge of how to better evaluate the overlap between the reference and the model hypothesis taking into consideration *adequacy* and *fluency*, where all the evaluation units are treated the same, i.e., all the matching scores have an equal weighting. However, in real-world examinations, the questions vary in their difficulty. Those questions which are easily answered by most subjects tend to have low weightings, while those which are hard to answer have high weightings. A subject who is able to solve the more difficult questions can receive a high final score and gain a better ranking. MT evaluation is also a kind of examination. For bridging the gap between human examination and MT evaluation, it is advisable to incorporate a *difficulty* dimension into the MT evaluation metric.

In this paper, we take translation difficulty into account in MT evaluation and test the effectiveness on a representative MT metric BERTScore (Zhang et al., 2020) to verify the feasibility. More specifically, the difficulty is first determined across the systems with the help of pairwise similarity, and then exploited as the weight in the final score function for distinguishing the contribution of different sub-units. Experimental results on the WMT19 English↔German evaluation task show that difficulty-aware BERTScore has a better correlation than do the existing metrics. Moreover, it agrees very well with the human rankings when evaluating competitive systems.

2 Related Work

The existing MT evaluation metrics can be categorized into the following types according to their underlying matching sub-units: n-gram based (Papineni et al., 2002; Doddington, 2002; Lin and Och, 2004; Han et al., 2012; Popović, 2015),

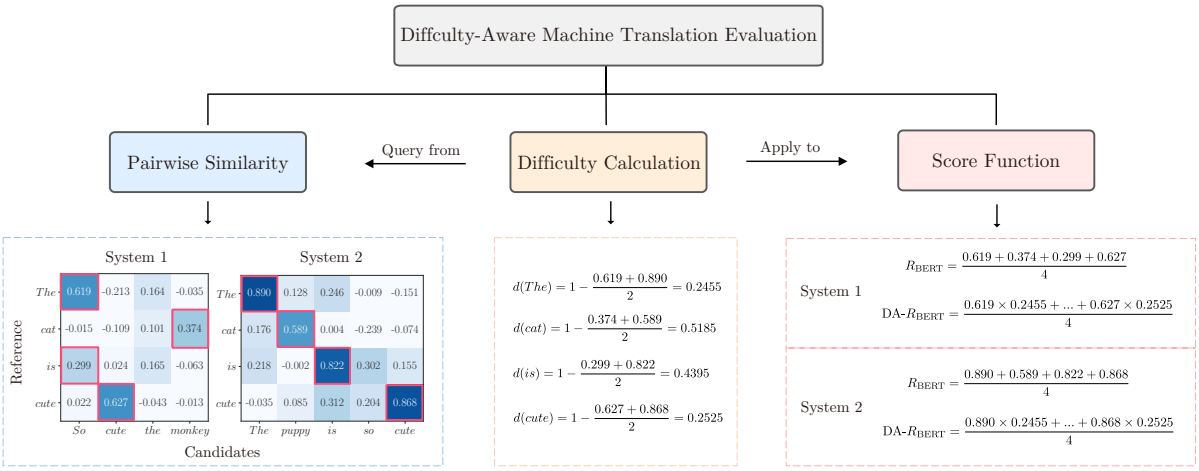

Figure 1: Illustration of combining difficulty weight with BERTScore. R_{BERT} denotes the vanilla recall-based BERTScore while DA-R_{BERT} denotes the score augmented with translation difficulty.

edit-distance based (Snover et al., 2006; Leusch et al., 2006), alignment-based (Banerjee and Lavie, 2005), embedding-based (Zhang et al., 2020; Chow et al., 2019; Lo, 2019) and end-to-end based (Sellam et al., 2020). BLEU (Papineni et al., 2002) is widely used as a vital criterion in the comparison of MT system performance but its reliability has been doubted on entering neural machine translation age (Shterionov et al., 2018; Mathur et al., 2020). Due to the fact that BLEU and its variants only assess surface linguistic features, some metrics leveraging contextual embedding and end-to-end training bring semantic information into the evaluation, which further improves the correlation with human judgement. Among them, BERTScore (Zhang et al., 2020) has achieved a remarkable performance across MT evaluation benchmarks balancing speed and correlation. In this paper, we choose BERTScore as our testbed.

3 Our Proposed Method

3.1 Motivation

In real-world examinations, the questions are empirically divided into various levels of difficulty. Since the difficulty varies from question to question, the corresponding role a question plays in the evaluation does also. Simple question, which can be answered by most of the subjects, usually receive of a low weighting. But a difficult question, which has more discriminative power, can only be answered by a small number of good subjects, and thus receives a higher weighting.

Motivated by this evaluation mechanism, we measure difficulty of a translation by viewing the MT systems and sub-units of the sentence as the subjects and questions, respectively. From this perspective, the impact of the sentence-level sub-units on the evaluation results supported a differentiation. Those sub-units that may be incorrectly translated by most systems (e.g., polysemy) should have a higher weight in the assessment, while easier-to-translate sub-units (e.g., the definite article) should receive less weight.

3.2 Difficulty-Aware BERTScore

In this part, we aim to answer two questions: 1) how to automatically collect the translation difficulty from BERTScore; and 2) how to integrate the difficulty into the score function. Figure 1 presents an overall illustration.

Pairwise Similarity Traditional n-gram overlap cannot extract semantic similarity, word embedding provides a means of quantifying the degree of overlap, which allows obtaining more accurate difficulty information. Since BERT is a strong language model, it can be utilized as a contextual embedding $\mathbf{O}_{\text{BERT}}$ (i.e., the output of BERT) for obtaining the representations of the reference $\mathbf{t}$ and the hypothesis $\mathbf{h}$. Given a specific hypothesis token h and reference token t, the similarity score $\text{sim}(t, h)$ is computed as follows:

$$\text{sim}(t, h) = \frac{\mathbf{O}_{\text{BERT}}(t)^{\top} \mathbf{O}_{\text{BERT}}(h)}{\|\mathbf{O}_{\text{BERT}}(t)\| \cdot \|\mathbf{O}_{\text{BERT}}(h)\|} \quad (1)$$

Subsequently, a similarity matrix is constructed by pairwise calculating the token similarity. Then the token-level matching score is obtained by greedily

Table 1: Absolute correlations with system-level human judgments on WMT19 metrics shared task. For each metric, higher values are better. Difficulty-aware BERTScore consistently outperforms vanilla BERTScore across different evaluation metrics and translation directions, especially when the evaluated systems are very competitive (i.e., evaluating on the top 30% systems).

searching for the maximal similarity in the matrix, which will be further taken into account in sentence-level score aggregation.

Difficulty Calculation The calculation of difficulty can be tailored for different metrics based on the overlap matching score. In this case, BERTScore evaluates the token-level overlap status by the pairwise semantic similarity, thus the token-level similarity is viewed as the bedrock of difficulty calculation. For instance, if one token (like "cat") in the reference may only find identical or synonymous substitutions in a few MT system outputs, then the corresponding translation difficulty weight ought to be larger than for other reference tokens, which further indicates that it is more valuable for evaluating the translation capability. Combined with BERTScore mechanism, it is implemented by averaging the token similarities across systems. Given K systems and their corresponding generated hypotheses $\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_K$, the difficulty of a specific token t in the reference $\mathbf{t}$ is formulated as

$$d(t) = 1 - \frac{\sum_{k=1}^{K} \max_{h \in \mathbf{h}_k} \mathrm{sim}(t, h)}{K} \quad (2)$$

An example is shown in Figure 1: the entity "cat" is improperly translated to "monkey" and "puppy", resulting in a lower pairwise similarity of the token "cat", which indicates higher translation difficulty. Therefore, by incorporating the translation difficulty into the evaluation process, the token "cat" is more contributive while the other words like "cute" are less important in the overall score.

Score Function Due to the fact that the translation generated by a current NMT model is fluent enough but not adequate yet, F-score which takes into account the *Precision* and *Recall*, is more appropriate to aggregate the matching scores, instead of only considering precision. We thus follow vanilla BERTScore in using F-score as the final score. The proposed method directly assigns difficulty weights to the counterpart of the similarity score **without any hyperparameter**:

$$\text{DA-}R_{\text{BERT}} = \frac{1}{|\mathbf{t}|} \sum_{t \in \mathbf{t}} d(t) \max_{h \in \mathbf{h}} \mathrm{sim}(t, h) \quad (3)$$

$$\text{DA-}P_{\text{BERT}} = \frac{1}{|\mathbf{h}|} \sum_{h \in \mathbf{h}} d(h) \max_{t \in \mathbf{t}} \mathrm{sim}(t, h) \quad (4)$$

$$\text{DA-}F_{\text{BERT}} = 2 \cdot \frac{\text{DA-}R_{\text{BERT}} \cdot \text{DA-}P_{\text{BERT}}}{\text{DA-}R_{\text{BERT}} + \text{DA-}P_{\text{BERT}}} \quad (5)$$

For any $h \notin \mathbf{t}$, we simply let $d(h) = 1$, i.e., retaining the original calculation. The motivation is that the human assessor keeps their initial matching judgement if the test taker produces a unique but reasonable alternative answer. We regard DA-F_{BERT} as the DA-BERTScore in the following part.

There are many variants of our proposed method: 1) designing more elaborate difficulty function (Liu et al., 2020; Zhan et al., 2021); 2) applying a smoothing function to the difficulty distribution; and 3) using other kinds of F-score, e.g., $F_{0.5}$-score. The aim of this paper is not to explore this whole space but simply to show that a straightforward implementation works well for MT evaluation.

4 Experiments

Data The WMT19 English↔German (En↔De) evaluation tasks are challenging due to the large discrepancy between human and automated assessments in terms of reporting the best system (Bojar et al., 2018; Barrault et al., 2019; Freitag et al., 2020). To sufficiently validate the effectiveness of

Table 2: Agreement of system ranking with human judgement on the top 30% systems (k=6) of WMT19 En→De Metrics task. ⇑/⇓ denotes that the rank given by the evaluation metric is higher/lower than human judgement, and ✓ denotes that the given rank is equal to human ranking. DA-BERTScore successfully ranks the best system that the other metrics failed. Besides, it also shows the lowest rank difference.

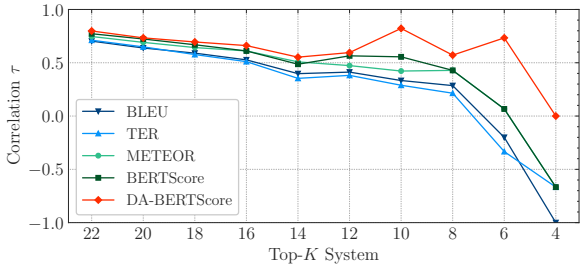

Figure 2: Effect of top-K systems in the En→De evaluation. DA-BERTScore is highly correlated with human judgment for different values of K, especially when all the systems are competitive (i.e., $K \leq 10$).

our approach, we choose these tasks as our evaluation subjects. There are 22 systems for En→De and 16 for De→En. Each system has its corresponding human assessment results. The experiments were centered on the correlation with system-level human ratings.

Comparing Metrics In order to compare with the metrics that have different underlying evaluation mechanism, four representative metrics: BLEU (Papineni et al., 2002), TER (Snover et al., 2006), METEOR (Banerjee and Lavie, 2005; Denkowski and Lavie, 2014), BERTScore (Zhang et al., 2020), which are correspondingly driven by n-gram, edit distance, word alignment and embedding similarity, are involved in the comparison experiments without losing popularity. For ensuring reproducibility, the original[1][2] and widely used implementation[3] was used in the experiments.

Main Results Following the correlation criterion adopted by the WMT official organization, Pearson's correlation r is used for validating the system-level correlation with human ratings. In addition, two rank-correlations Spearman's ρ and original Kendall's τ are also used to examine the agreement with human ranking, as has been done in recent research (Freitag et al., 2020). Table 1 lists the results. DA-BERTScore achieves competitive correlation results and further improves the correlation of BERTScore. In addition to the results on all systems, we also present the results on the top 30% systems where the calculated difficulty is more reliable and our approach should be more effective. The result confirms our intuition that DA-BERTScore can significantly improve the correlations under the competitive scenario, e.g., improving the $|r|$ score from 0.204 to 0.974 on En→De and 0.271 to 0.693 on De→En.

Effect of Top-K Systems Figure 2 compares the Kendall's correlation variation of the top-K systems. Echoing previous research, the vast majority of metrics fail to correlate with human ranking and even perform negative correlation when K is lower than 6, meaning that the current metrics are ineffective when facing competitive systems. With the help of difficulty weights, the degradation in the correlation is alleviated, e.g., improving τ score from 0.07 to 0.73 for BERTScore ($K = 6$). These results indicate the effectiveness of our approach, establishing the necessity for adding difficulty.

Case Study of Ranking Table 2 presents a case study on the En→De task. Existing metrics consistently select MSRA's system as the best system, which shows a large divergence from human judgement. DA-BERTScore ranks it the same as human (4th) because most of its translations have low difficulty, thus lower weights are applied in the scores. Encouragingly, DA-BERTScore ranks Facebook's system as the best one, which implies that it overco-

Table 3: Examples from the En→De evaluation. BERTS. denotes BERTScore. Words indicate the difficult translations given by our approach on the top 30% systems. DA-BERTScores are more in line with human judgements.

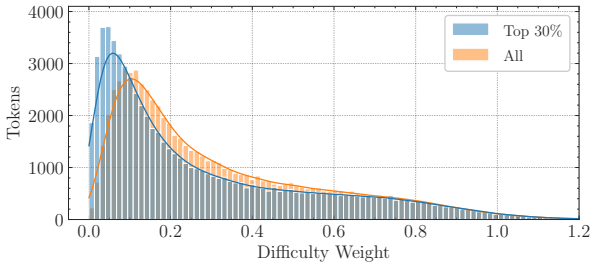

Figure 3: Distribution of token-level difficulty weights extracted from the En→De evaluation.

mes more challenging translation difficulties. This testifies to the importance and effectiveness of considering translation difficulty in MT evaluation.

Case Study of Token-Level Difficulty Table 3 presents two cases, illustrating that our proposed difficulty-aware method successfully identifies the omission errors ignored by BERTScore. In the first case, the Facebook's system correctly translates the token "right", and in the second case, uses the substitute "Soldaten am Boden" which is lexically similar to the ground-truth token "Bodensoldaten". Although the MSRA's system suffers word omissions in the two cases, its hypotheses receive the higher ranking given by BERTScore, which is inconsistent with human judgements. The reason might be that the semantic of the hypothesis is highly close to the reference, thus the slight lexical difference is hard to be found when calculating the similarity score. By distinguishing the difficulty of the reference tokens, DA-BERTScore successfully makes the evaluation focus on the difficult parts, and eventually correct the score of the Facebook's system, thus giving the right rankings.

Distribution of Difficulty Weights The difficulty weights can reflect the translation ability of a group of MT systems. If the systems in a group are of higher translation ability, the calculated difficulty weights will be smaller. Starting from this intuition, we visualize the distribution of difficulty weights as shown in Figure 3. Clearly, we can see that the difficulty weights are centrally distributed at lower values, indicating that most of the tokens can be correctly translated by all the MT systems. For the difficulty weights calculated on the top 30% systems, the whole distribution skews to zero since these competitive systems have better translation ability and thus most of the translations are easy for them. This confirms that the difficulty weight produced by our approach is reasonable.

5 Conclusion and Future Work

This paper introduces the conception of difficulty into machine translation evaluation, and verifies our assumption with a representative metric BERTScore. Experimental results on the WMT19 English↔German metric tasks show that our approach achieves a remarkable correlation with human assessment, especially for evaluating competitive systems, revealing the importance of incorporating difficulty into machine translation evaluation. Further analyses show that our proposed difficulty-aware BERTScore can strengthen the evaluation of word omission problems and generate reasonable distributions of difficulty weights.

Future works include: 1) optimizing the difficulty calculation; 2) applying to other MT metrics; and 3) testing on other generation tasks, e.g., speech recognition and text summarization.

Uncertainty and Surprisal Jointly Deliver the Punchline: Exploiting Incongruity-Based Features for Humor Recognition

Yubo Xie, Junze Li, and Pearl Pu

Abstract

Humor recognition has been widely studied as a text classification problem using data-driven approaches. However, most existing work does not examine the actual joke mechanism to understand humor. We break down any joke into two distinct components: the set-up and the punchline, and further explore the special relationship between them. Inspired by the incongruity theory of humor, we model the set-up as the part developing semantic uncertainty, and the punchline disrupting audience expectations. With increasingly powerful language models, we were able to feed the set-up along with the punchline into the GPT-2 language model, and calculate the uncertainty and surprisal values of the jokes. By conducting experiments on the SemEval 2021 Task 7 dataset, we found that these two features have better capabilities of telling jokes from non-jokes, compared with existing baselines.

1 Introduction

One of the important aspects of computational humor is to develop computer programs capable of recognizing humor in text. Early work on humor recognition (Mihalcea and Strapparava, 2005) proposed heuristic-based humor-specific stylistic features, for example alliteration, antonymy, and adult slang. More recent work (Yang et al., 2015; Chen and Soo, 2018; Weller and Seppi, 2019) regarded the problem as a text classification task, and adopted statistical machine learning methods and neural networks to train models on humor datasets. However, only few of the deep learning methods have tried to establish a connection between humor recognition and humor theories. Thus, one research direction in humor recognition is to bridge the disciplines of linguistics and artificial intelligence.

In this paper, we restrict the subject of investigation to jokes, one of the most common humor types in text form. As shown in Figure 1, these jokes usually consist of a *set-up* and a *punchline*. The set-up creates a situation that introduces the hearer into the story framework, and the punchline concludes the joke in a succinct way, intended to make the hearer laugh. Perhaps the most suitable humor theory for explaining such humor phenomenon is the *incongruity theory*, which states that the cause of laughter is the perception of something incongruous (the punchline) that violates the hearer's expectation (the set-up).

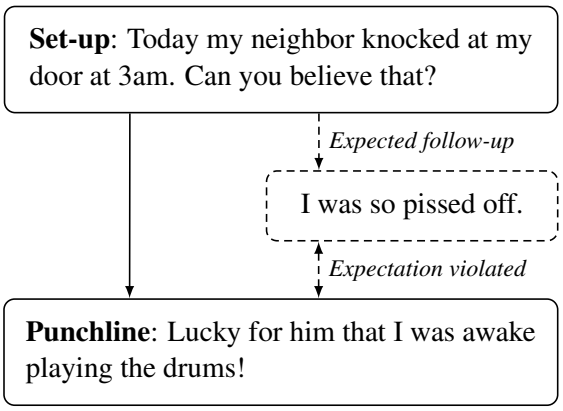

Figure 1: A joke example consisting of a set-up and a punchline. A violation can be observed between the punchline and the expectation.

Based on the incongruity theory, we propose two features for humor recognition, by calculating the degree of incongruity between the set-up and the punchline. Recently popular pre-trained language models enable us to study such relationship based on large-scale corpora. Specifically, we fed the set-up along with the punchline into the GPT-2 language model (Radford et al., 2019), and obtained the surprisal and uncertainty values of the joke, indicating how surprising it is for the model to generate the punchline, and the uncertainty while generating it. We conducted experiments on a manually labeled humor dataset, and the results showed that

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 33–39
August 1–6, 2021. ©2021 Association for Computational Linguistics

these two features could better distinguish jokes from non-jokes, compared with existing baselines. Our work made an attempt to bridge humor theories and humor recognition by applying large-scale pre-trained language models, and we hope it could inspire future research in computational humor.

2 Related Work

Humor Data Mihalcea and Strapparava (2005) created a one-liner dataset with humorous examples extracted from webpages with humor theme and non-humorous examples from Reuters titles, British National Corpus (BNC) sentences, and English Proverbs. Yang et al. (2015) scraped puns from the Pun of the Day website[1] and negative examples from various news websites. There is also work on the curation of non-English humor datasets (Zhang et al., 2019; Blinov et al., 2019). Hasan et al. (2019) developed UR-FUNNY, a multimodal humor dataset that involves text, audio and video information extracted from TED talks.

Humor Recognition Most of the existing work on humor recognition in text focuses on one-liners, one type of jokes that delivers the laughter in a single line. The methodologies typically fall into two categories: feature engineering and deep learning. Mihalcea and Strapparava (2005) designed three human-centric features (alliteration, antonymy and synonym) for recognizing humor in the curated one-liner dataset. Mihalcea et al. (2010) approached the problem by calculating the semantic relatedness between the set-up and the punchline (they evaluated 150 one-liners by manually splitting them into "set-up" and "punchline"). Shahaf et al. (2015) investigated funny captions for cartoons and proposed several features including perplexity to distinguish between funny and less funny captions. Morales and Zhai (2017) proposed a probabilistic model and leveraged background text sources (such as Wikipedia) to identify humorous Yelp reviews. Liu et al. (2018) proposed to model sentiment association between elementary discourse units and designed features based on discourse relations. Cattle and Ma (2018) explored the usage of word associations as a semantic relatedness feature in a binary humor classification task. With neural networks being popular in recent years, some deep learning structures have been developed for the recognition of humor in text. Chen and Lee (2017) and Chen and Soo (2018) adopted convolutional neural networks, while Weller and Seppi (2019) used a Transformer architecture to do the classification task. Fan et al. (2020) incorporated extra phonetic and semantic (ambiguity) information into the deep learning framework. In addition to these methodological papers, there are also some tasks dedicated to computational humor in recent years. SemEval 2020 Task 7 (Hossain et al., 2020) aims at assessing humor in edited news headlines. SemEval 2021 Task 7 (Meaney et al., 2021) involves predicting the humor rating of the given text, and if the rating is controversial or not. In this task, Xie et al. (2021) adopted the DeBERTa architecture (He et al., 2020) with disentangled attention mechanism to predict the humor labels.

Although the work of Mihalcea et al. (2010) is the closest to ours, we are the first to bridge the incongruity theory of humor and large-scale pre-trained language models. Other work (Bertero and Fung, 2016) has attempted to predict punchlines in conversations extracted from TV series, but their subject of investigation should be inherently different from ours—punchlines in conversations largely depend on the preceding utterances, while jokes are much more succinct and self-contained.

3 Humor Theories

The attempts to explain humor date back to the age of ancient Greece, where philosophers like Plato and Aristotle regarded the enjoyment of comedy as a form of scorn, and held critical opinions towards laughter. These philosophical comments on humor were summarized as the *superiority theory*, which states that laughter expresses a feeling of superiority over other people's misfortunes or shortcomings. Starting from the 18th century, two other humor theories began to challenge the dominance of the superiority theory: the *relief theory* and the *incongruity theory*. The relief theory argues that laughter serves to facilitate the relief of pressure for the nervous system (Morreall, 2020). This explains why laughter is caused when people recognize taboo subjects—one typical example is the wide usage of sexual terms in jokes. The incongruity theory, supported by Kant (1790), Schopenhauer (1883), and many later philosophers and psychologists, states that laughter comes from the perception of something incongruous that violates the expectations. This view of humor fits well the types of jokes commonly found in stand-up comedies,

[1] http://www.punoftheday.com/

where the set-up establishes an expectation, and then the punchline violates it. As an expansion of the incongruity theory, Raskin (1979) proposed the Semantic Script-based Theory of Humor (SSTH) by applying the semantic script theory. It posits that, in order to produce verbal humor, two requirements should be fulfilled: (1) The text is compatible with two different scripts; (2) The two scripts with which the text is compatible are opposite.

4 Methodology

The incongruity theory attributes humor to the violation of expectation. This means the punchline delivers the incongruity that turns over the expectation established by the set-up, making it possible to interpret the set-up in a completely different way. With neural networks blooming in recent years, pretrained language models make it possible to study such relationship between the set-up and the punchline based on large-scale corpora. Given the set-up, language models are capable of writing expected continuations, enabling us to measure the degree of incongruity, by comparing the actual punchline with what the language model is likely to generate.

In this paper, we leverage the GPT-2 language model (Radford et al., 2019), a Transformer-based architecture trained on the WebText dataset. We chose GPT-2 because: (1) GPT-2 is already pretrained on massive data and publicly available online, which spares us the training process; (2) it is domain independent, thus suitable for modeling various styles of English text. Our goal is to model the set-up and the punchline as a whole piece of text using GPT-2, and analyze the probability of generating the punchline given the set-up. In the following text, we denote the set-up as x, and the punchline as y. Basically, we are interested in two quantities regarding the probability distribution $p(y|x)$: uncertainty and surprisal, which are elaborated in the next two sections.

4.1 Uncertainty

The first question we are interested in is: given the set-up, how uncertain it is for the language model to continue? This question is related to SSTH, which states that, for a piece of text to be humorous, it should be compatible with two different scripts. To put it under the framework of set-up and punchline, this means the set-up could have multiple ways of interpretation, according to the following punchline. Thus, one would expect a higher uncertainty

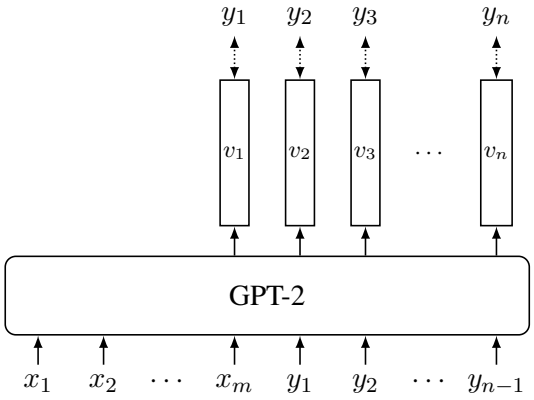

Figure 2: The set-up x and the punchline y are concatenated and fed into GPT-2 for predicting the next token. v_i's are probability distributions on the vocabulary.

value when the language model tries to continue the set-up and generate the punchline.

We propose to calculate the averaged entropy of the probability distributions at all token positions of the punchline, to represent the degree of uncertainty. As shown in Figure 2, the set-up x and the punchline y are concatenated and then fed into GPT-2 to predict the next token. While predicting the tokens of y, GPT-2 produces a probability distribution v_i over the vocabulary. The averaged entropy is then defined as

$$U(x,y) = -\frac{1}{|y|}\sum_{i=1}^{n}\sum_{w\in V} v_i^w \log v_i^w, \qquad (1)$$

where V is the vocabulary.

4.2 Surprisal

The second question we would like to address is: how surprising it is when the language model actually generates the punchline? As the incongruity theory states, laughter is caused when something incongruous is observed and it violates the previously established expectation. Therefore, we expect the probability of the language model generating the actual punchline to be relatively low, which indicates the surprisal value should be high. Formally, the surprisal is defined as

$$\begin{aligned} S(x,y) &= -\frac{1}{|y|}\log p(y|x) \\ &= -\frac{1}{|y|}\sum_{i=1}^{n}\log v_i^{y_i}. \end{aligned} \qquad (2)$$

5 Experiments

We evaluated and compared the proposed features with several baselines by conducting experiments

in two settings: predicting using individual features, and combining the features with a content-based text classifier.

5.1 Baselines

Similar to our approach of analyzing the relationship between the set-up and the punchline, Mihalcea et al. (2010) proposed to calculate the semantic relatedness between the set-up and the punchline. The intuition is that the punchline (which delivers the surprise) will have a minimum relatedness to the set-up. For our experiments, we chose two relatedness metrics that perform the best in their paper as our baselines, plus another similarity metric based on shortest paths in WordNet (Miller, 1995):

- **Leacock & Chodorow similarity** (Leacock and Chodorow, 1998), defined as

$$\text{Sim}_{lch} = -\log \frac{length}{2 * D}, \quad (3)$$

  where *length* is the length of the shortest path between two concepts using node-counting, and D is the maximum depth of WordNet.

- **Wu & Palmer similarity** (Wu and Palmer, 1994) calculates similarity by considering the depths of the two synsets in WordNet, along with the depth of their *LCS* (Least Common Subsumer), which is defined as

$$\text{Sim}_{wup} = \frac{2 * \text{depth}(LCS)}{\text{depth}(C_1) + \text{depth}(C_2)}, \quad (4)$$

  where C_1 and C_2 denote synset 1 and synset 2 respectively.

- **Path similarity** (Rada et al., 1989) is also based on the length of the shortest path between two concepts in WordNet, which is defined as

$$\text{Sim}_{path} = \frac{1}{1 + length}. \quad (5)$$

In addition to the metrics mentioned above, we also consider the following two baselines related to the phonetic and semantic styles of the input text:

- **Alliteration**. The alliteration value is computed as the total number of alliteration chains and rhyme chains found in the input text (Mihalcea and Strapparava, 2005).

- **Ambiguity**. Semantic ambiguity is found to be a crucial part of humor (Miller and Gurevych, 2015). We follow the work of Liu et al. (2018) to compute the ambiguity value:

$$\log \prod_{w \in s} \text{num\_of\_senses}(w), \quad (6)$$

  where w is a word in the input text s.

5.2 Dataset

We took the dataset from SemEval 2021 Task 7.[2] The released training set contains 8,000 manually labeled examples in total, with 4,932 being positive, and 3,068 negative. To adapt the dataset for our purpose, we only considered positive examples with exactly two sentences, and negative examples with at least two sentences. For positive examples (jokes), the first sentence was treated as the set-up and the second the punchline. For negative examples (non-jokes), consecutive two sentences were treated as the set-up and the punchline, respectively.[3] After splitting, we cleaned the data with the following rules: (1) We restricted the length of set-ups and punchlines to be under 20 (by counting the number of tokens); (2) We only kept punchlines whose percentage of alphabetical letters is greater than or equal to 75%; (3) We discarded punchlines that do not begin with an alphabetical letter. As a result, we obtained 3,341 examples in total, consisting of 1,815 jokes and 1,526 non-jokes. To further balance the data, we randomly selected 1,526 jokes, and thus the final dataset contains 3,052 labeled examples in total. For the following experiments, we used 10-fold cross validation, and the averaged scores are reported.

5.3 Predicting Using Individual Features

To test the effectiveness of our features in distinguishing jokes from non-jokes, we built an SVM classifier (parameters can be found in Appendix A) for each individual feature (uncertainty and surprisal, plus the baselines). The resulted scores are reported in Table 1. Compared with the baselines, both of our features (uncertainty and surprisal) achieved higher scores for all the four metrics. In addition, we also tested the performance of uncertainty combined with surprisal (last row

[2] https://semeval.github.io/SemEval2021/

[3] We refer to them as set-up and punchline for the sake of convenience, but since they are not jokes, the two sentences are not real set-up and punchline.

of the table), and the resulting classifier shows a further increase in the performance. This suggests that, by jointly considering uncertainty and surprisal of the set-up and the punchline, we are better at recognizing jokes.

5.4 Boosting a Content-Based Classifier

Now that we have shown the advantage of our features when used individually in prediction, we would like to validate their effectiveness when combined with the commonly used word embeddings. Thus, we evaluated our features as well as the baselines under the framework of a content-based classifier. The idea is to see if the features could further boost the performance of existing text classifiers. To create a starting point, we encoded each set-up and punchline into vector representations by aggregating the GloVe (Pennington et al., 2014) embeddings of the tokens (sum up and then normalize by the length). We used the GloVe embeddings

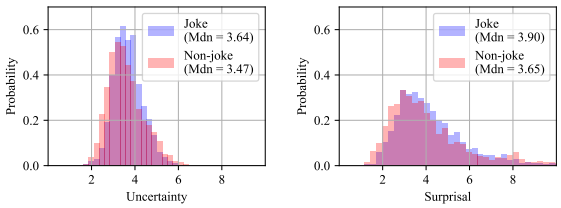

Figure 3: Histograms of uncertainty (left) and surprisal (right), plotted separately for jokes and non-jokes. Mdn stands for Median.

with dimension 50, and then concatenated the set-up vector and the punchline vector, to represent the whole piece of text as a vector of dimension 100. For each of the features (uncertainty and surprisal, plus the baselines), we appended it to the GloVe vector, and built an SVM classifier to do the prediction. Scores are reported in Table 2. As we can see, compared with the baselines, our features produce larger increases in the performance of the content-based classifier, and similar to what we have observed in Table 1, jointly considering uncertainty and surprisal gives further increase in the performance.

6 Visualizing Uncertainty and Surprisal

To get a straightforward vision of the uncertainty and surprisal values for jokes versus non-jokes, we plot their histograms in Figure 3 (for all 3,052 labeled examples). It can be observed that, for both uncertainty and surprisal, jokes tend to have higher values than non-jokes, which is consistent with our expectations in Section 4.

7 Conclusion

This paper makes an attempt in establishing a connection between the humor theories and the nowadays popular pre-trained language models. We proposed two features according to the incongruity theory of humor: uncertainty and surprisal. We conducted experiments on a humor dataset, and the results suggest that our approach has an advantage in humor recognition over the baselines. The proposed features can also provide insight for the task of two-line joke generation—when designing the text generation algorithm, one could exert extra constraints so that the set-up is chosen to be compatible with multiple possible interpretations, and the punchline should be surprising in a way that violates the most obvious interpretation. We hope our work could inspire future research in the community of computational humor.

A Model Parameters

For the SVM classifier, we set the regularization parameter $C = 1.0$, and used the RBF kernel with the kernel coefficient $\gamma = 1/n_{\text{features}}$. All models were trained and evaluated on a machine with Intel Core i7-6700K CPU, Nvidia GeForce GTX 1080 GPU, and 16GB RAM. The running time of each method is listed in Table 3 and Table 4.

Counterfactuals to Control Latent Disentangled Text Representations for Style Transfer

Abstract

Disentanglement of latent representations into content and style spaces has been a commonly employed method for unsupervised text style transfer. These techniques aim to learn the disentangled representations and tweak them to modify the style of a sentence. In this paper, we propose a counterfactual-based method to modify the latent representation, by posing a 'what-if' scenario. This simple and disciplined approach also enables a fine-grained control on the transfer strength. We conduct experiments with the proposed methodology on multiple attribute transfer tasks like Sentiment, Formality and Excitement to support our hypothesis.

1 Introduction

Counterfactual Reasoning (Bottou et al., 2013) is leveraged in structured data analysis and econometrics towards generation of alternatives and estimation of alternate scenarios. Counterfactuals describe a causal situation of the form 'If X would have (not) occurred, Y would have (not) occurred' (Molnar, 2019). In interpretable machine learning, counterfactuals have been used to explain predictions of individual instances across various types of datasets and tasks (Neal et al., 2018; Martens and Provost, 2014; Wachter et al., 2017). Laugel et al.(2018) and Neal et al.(2018) use counterfactuals towards generating training data. Counterfactual reasoning also provides us with a unique ability to generate explanations and make causal analysis on the latent space. However, this technique has never been explored in natural language generation tasks. Here, we plug-in the concept of counterfactuals to the text-style transfer task, to enable the manipulation of latent spaces towards controlled transfer of style.

Existing works in text style transfer focus on transferring a specific target attribute. Unsupervised methods based on adversarial attacks (Fu et al., 2018; she), back translation (Prabhumoye et al., 2018), learning disentangled representations(John et al., 2019) have been popular in this domain. Other techniques include deletion of style-specific words and conditionally generate sentences in the target style (Li et al., 2018; Sudhakar et al., 2019). However, all of them fail to provide a control over the target style strength i.e. a clever manipulation of the latent space is non-trivial.

Recent works on controlled text generation include (Wang et al., 2019), which brings in a transformer-based model that modifies the gradient functions leading to controlled generation in the output space. Jin et al.(2019) is an unsupervised approach integrated during end-to-end model training. The drawback in all these efforts is the lack of a prefixed logic towards controlling the latent space. Our proposed method of counterfactuals fills in this gap and provides a logical method to control the latent spaces for enabling a smooth style transfer.

Our approach is based on the premise of disentangled representation spaces inspired from John et al.(2019). Separating out the style and content representations introduce an opportunity to fine-tune, resulting in the ability to control the output sentences specific to style. We **introduce a counterfactual reasoning module for controlling latent disentangled spaces for style transfer**. Figure 1 shows an illustrative example for the variants generated through our approach. To the best of our knowledge, this is the first work leveraging such a concept towards controlled text generation. Through extensive quantitative and qualitative experiments, across attributes and datasets, we conclude that the proposed approach is effective in providing control over the style strength and also shows that the best transfer performance is on par

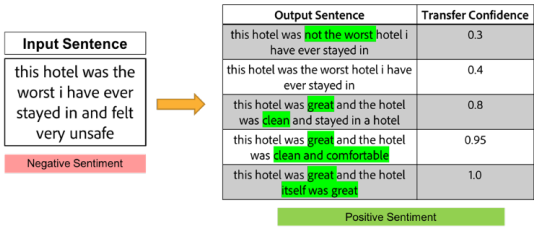

Figure 1: Example Counterfactuals showing the gradual 'control' introduced in the text style transfer.

with the existing baseline style-transfer techniques.

2 Approach

Figure 2 illustrates our proposed approach, that incorporates counterfactual reasoning to latent disentangled representations for manipulating style in text. It consists of (1) A Variational Autoencoder (VAE) model to learn the disentangled style and content representations for different stylistic attributes, (2) A Counterfactual Reasoning Module to control the latent representations for generating style variants.

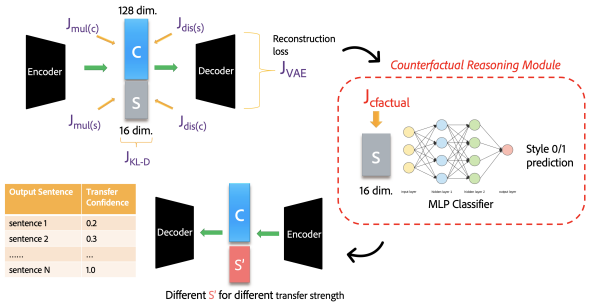

Figure 2: Proposed approach with Counterfactual Reasoning Module for Style Transfer

2.1 Learning Disentangled Representations

We adopt the model described in (John et al., 2019) for learning the disentangled content and style representations. Here, a VAE with an encoder-decoder is used to encode a sentence x into a latent distribution $H = q_E(h|x)$, guided by the loss function:

$$J_{VAE}(\theta_E, \theta_D) = J_{REC} + \lambda_{kl}\mathbb{KL}[q_E(h|x) \parallel p(h)]$$

where, θ_E and θ_D are the encoder and decoder parameters respectively. The first term encourages reconstruction, while the second term regularizes the latent space to a prior distribution $p(h)$ $(\mathcal{N}(0,1))$. We experiment with some variations of this architecture, which are detailed in section 3.

Additionally, Multi-Task $(J_{mul(s)}, J_{mul(c)})$ and Adversarial losses $(J_{adv(s)}, J_{adv(c)})$ are imposed on the latent space h to disentangle the embeddings into representing content c and style s, i.e., $h = [s; c]$, where $[;]$ denotes concatenation. These four losses ensure that the style and content information are present in, and *only* in their respective style(s) and content(c) embeddings.

Once we have the disentangled representations, our basic idea is to feed the generative model with the *same* content and a *different* style embedding to produce sentences of altering style. In (John et al., 2019), the average style embeddings of the target style is fed to the decoder. Intuitively, changing these style embeddings will produce different variants of target style sentences, but a disciplined approach to generate smooth style variants of the sentence is missing. We propose the counterfactual reasoning for this purpose.

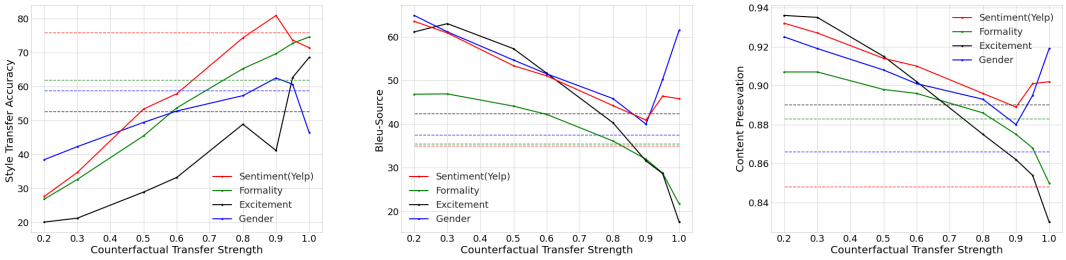
2.2 Counterfactual Reasoning Module

Counterfactuals (CF) are used for gradually changing the style representation along the target-style axis. A counterfactual explanation of an outcome Y takes the form 'if X had not occurred, Y would not have occurred'. We leverage this notion here. A Multi-layer Perceptron (MLP) classifier is trained on the disentangled style latent representations learnt by the VAE, such that every instance of style embedding s, predicts a target style (T) of a sentence. Now, the aim is to find s' such that it is close to s in the latent space but leads to a different prediction T', i.e. the target class. The CF generation loss is given by,

$$J_{cfactual} = L(s'|s) = \lambda(f_t(s') - p_t)^2 + L_1(s', s),$$

where t is the desired target style class for s', p_t is the probability with which we want to predict this target class (perfect transfer would mean $p_t = 1$), f_t is the model prediction on class t and L_1 is the distance between s' and s. The first term in the loss guides towards finding an s' that changes the model prediction to the target class and use of the L_1 distance ensures that minimum number of features are changed in order to change the prediction. λ is the weighting term. The resulting set of CFs are obtained by optimizing (Wachter et al., 2017) the following equation: $arg\min_{s'} \max_{\lambda} L(s'|s)$, subject to $|f_t(s' - p_t)| \leq \epsilon$ (tolerance parameter).

The CF generator is generalizable across different stylistic attributes. To generate multiple variants for a target style, CFs are generated varying



(a) Accuracy (b) Bleu-S (c) Cosine Similarity (CP)

Figure 3: Performance of the counterfactual model on multiple datasets. Style transfer accuracy (ACC) increases and the content preservation (BLEU-S, CP) decreases with increasing transfer strength.

the probability of target specific generation (or confidence), p_t. This results in different sentence variants with a similar target style but varied degrees for transfer strength. Finally, the disentangled representations enable finer control over the style dimensions with no risk of content loss during the counterfactual reasoning stage (as the content representations are retained).

3 Experiments

3.1 Proposed models

The VAE model adapted from (John et al., 2019), with RNN encoder-decoder blocks is R-VAE. We experiment with a variation by replacing RNNs with the transformer blocks (T-VAE). T-VAE-CF uses counterfactuals for generating variants, while models with -AVG use average style embedding of the target style to enable transfer. For T-VAE, we experimented with different loss combinations.-1,-2,-3,-4 refers to the inclusion of $J_{mul(s)}$, $J_{mul(s)} + J_{adv(s)}$, $J_{mul(s)} + J_{adv(s)} + J_{mul(c}$, $J_{mul(s)} + J_{adv(s)} + J_{mul(c)} + J_{adv(c)}$, respectively along with J_{VAE} in the overall loss function.

3.2 Baselines

We compare our best transfer models (with $p_t \approx 1$) against standard unsupervised style-transfer approaches. CrossAligned (CA)(Fu et al., 2018) aligns the hidden representations of original and style transferred sentences. T-D and T-DRG (Sudhakar et al., 2019) models delete attribute related words and conditionally generate words with the target style through transformer architecture.

3.3 Implementation

The counterfactual module has a linear classifier with a sigmoid activation, taking input dim. of 16 (s) and a output dim. 2 (style label). It is trained with Adam optimizer and 0.001 learning rate is used to minimize CCE loss. The transfer strength in CF-module, p_t, is varied from 0 to 1. Experiments with the following values $(0.2, 0.3, 0.5, 0.5, 0.8, 0.9, 0.95, 1.0)$ are reported.*

3.4 Datasets

We experiment with varied style attributes using 5 datasets. YELP is used for sentiment. Human gold standard references of these datasets from (Sudhakar et al., 2019) are used for evaluation. GYAFC dataset (Rao and Tetreault, 2018) is used for Formality and a new dataset GYAFC-excite with custom annotations for excitement is created†. POLITICAL (Voigt et al., 2018) and GENDER (Reddy and Knight, 2016)(similar to (Prabhumoye et al., 2018)) are used for the respective styles. The train-dev-test split as defined by original authors are used for all experiments.

3.5 Evaluation criteria

Style transfer accuracy (ACC) is measured by a dataset-specific Fasttext style classifier (Joulin et al., 2017). The classifiers report a % accuracy of 93.6, 87.6, 82.5, 78.3, 93.5 on the Yelp, GYAFC, GYAFC-Excite, Gender and Political datasets. *Content preservation* is measured through BLEU(Papineni et al., 2002) scores calculated against the source sentences(BLEU-S) and human references (BLEU-H), if available. We compute the cosine similarity (CP) to measure the vector-space similarity‡. *Language fluency* (PPL) is reported by

*Other implementation details, hyper-parameters, compute setup, and training times are provided in the appendix

†We cannot share the GYAFC-excitement dataset due to its license

‡Sentence embeddings for CP are calculated by concatenating the min, max, and mean of its word embeddings, ex-

4 Results and Analysis

Transfer Control. Figure 3 shows the performance of CF variants across metrics for different styles. The CF generated variants from T-VAE-CF (solid lines) are compared against the reference values which take avg. embeddings (T-VAE-AVG) for target style (dotted lines). To recollect, the higher the CF transfer confidence (strength), the closer is the generated variant to the target attribute. Thus, the ideal performance is to have the highest accuracies for the highest CF confidence values (see figure 3(a)). Note that CF strength = 1 alludes to perfect transfer. This is difficult to achieve as CF in the representation space may not be generated for such a strict target. Hence, the variants generated with near perfect transfer target (CF strength = 0.8,0.9,0.95) show the best performance across metrics. The low transfer accuracies for models with low CF confidence establishes the ability of the model to stay near the source when the target strength is low. All models implemented with transfer control report improved performance w.r.t BLEU scores establishing the utility of the alternatives generator.

Table 2, 3 compares baselines with the proposed models. Note that the evaluation metrics for text style-transfer cannot be compared in isolation. There is always a trade-off between content preservation and transfer accuracy. Amongst the baselines, we observe that T-D and T-DRG report high content preservation with some loss in accuracy, but these models only cater to generating a single output sentence and there is no provision to generate the variants. Note that in most style dimensions, T-VAE based models show highest performance in transfer accuracy with good content preservation (CP), but, lower BLEU-S score. The lower BLEU-S scores indicates the ability of our model to generate variants that are not mere repetition of the input samples. R-VAE models show impressive perplexity values. For the

cluding stopwords(Fu et al., 2018)

political dataset, R-VAE baseline shows very high transfer accuracy but takes a tremendous hit in content preservation (BLEU), which is improved with the use of counterfactuals. Examples in Table 1 illustrate the gradual changes introduced by T-VAE-CF across different styles.

Human Evaluation: We conducted a crowdsourcing based experiment (through Amazon Mechanical Turk) to understand both - (A) How baselines compare to the generated text and (B) The interpretation of control as seen by human annotators. For the first experiment, the annotators were presented with sentences generated by our model, baselines and ground truth to evaluate and rank. Specifically, they were asked to score each of the output sentences on a Likert scale of range 1-5 across three aspects - transfer strength, content preservation and fluency. The key takeaways highlight that the sentences generated by our model are at par in terms of grammar and fluency and are better in terms of transfer control. As against text generated by baselines, the text generated by our proposed models is preferred by humans 70% of times (inter-annotator agreement 0.42).

For the second experiment to evaluate the control, we presented the sentence variants generated through different CFs (by varying p_t) and asked the annotators to rank them from best to worst based on their transfer strength. On an average, 60% individuals could grade the gradual control as intended by the model. If we bucket the sentences into low (with $p_t < 0.4$) and high groups (with $p_t > 0.7$), the annotators' preference for bucketing the output into the right confidence goes up to 73% on average (68% for low, and 81% for high), hence, confirming our hypothesis towards using CF for controlled generation.

5 Conclusion

We introduce the use of counterfactual reasoning towards controlling the latent disentangled representations for text style transfer. Experiments not only establish the superiority of the proposed models across standard metrics for a multitude of styles but also illustrate the utility of the gradual control variable in this model. We further validate the use for CF via a human evaluation establishing improved text attribute transfer.

A VAE Models - Further Details

RNN-based (R-VAE). We adopt the model described in John et al.(2019) to disentangle the content and style representations with a recurrent neural network (RNN)-based VAE. The RNN encoder with Bi-GRUs (Cho et al., 2014) learns the hidden representation $q_E(h|x)$ by reading the input $x = (x_1, x_2, ..., x_n)$ sequentially. The RNN decoder, then decodes sequentially over time, predicting the probabilities of each token conditioned on the previous tokens and the latent representation. The reconstruction loss, which is the key loss for the generation objective, is the negative-log-likelihood loss as follows:

$$J_{REC} = \mathbb{E}_{h\sim q_E(h|x)}[-\sum_{t=1}^{n} \log P],$$

$$where \quad P = p(x_t|h, x_1, ..., x_{t-1})$$

The hidden space, h, is separated into 2 spaces while disentangling the style (s) and content (c) representations. Disentanglement is achieved using well-defined auxilliary losses.

Transformer-based (T-VAE). Transformers (Vaswani et al., 2017) have gained popularity for text generation due to their robust architectures. We introduce a transformer-based VAE inspired from Wang et al.(2019). The transformer encoder has a multi-headed self-attention block followed by a feed forward network (FFN). The decoder is similar to the encoder with an additional encoder-decoder attention block. Given an input sentence $x = (x_1, x_2, ..., x_n)$, the transformer encoder, E_{trans} learns a hidden word representation $(z_1, z_2, ..., z_n)$. They are pooled to get a sentence representation z, which is further encoded into a probabilistic latent space $q_E(h|x)$. A sample from this latent representation is given as an input to the encoder-decoder attention block in the decoder. The decoder reconstructs the input sentence x with condition on h. We adopt the label smoothing regularization (Li et al., 2020) while training, for performance improvement. The reconstruction loss (J_{REC}) is :

$$\mathbb{E}_{h\sim q_E(h|x)}[-\sum^{|x|}((1-\epsilon)\sum_{i=1}^{v}\bar{p_i}log(p_i)+ \frac{\epsilon}{v}\sum_{i=1}^{v}log(p_i))]$$

where, v is the vocabulary size, ϵ is the label smoothing parameter, p_i and $\bar{p_i}$ are the predicted and the ground truth probabilities over the vocabulary at every time step for word-wise decoding.

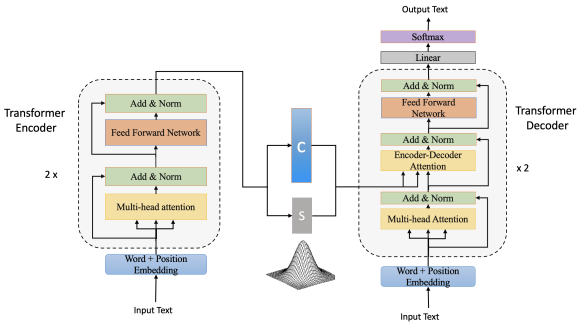

Figure 4: Transformer-based: T-VAE

KL Annealing. We also use an Adam optimiser and KL cost annealing technique (Bowman et al., 2016) to train our model. KL cost annealing refers to slow increase in the weight of the KL term (λ_{kl}) in the loss function from 0 to 1. This aids the training process as the model is warm-started to minimize the reconstruction loss in the initial iterations, followed by a gradual inclusion of KL loss term in the subsequent iterations.

A.1 Loss Functions

Auxiliary loss functions are used to achieve the text rewriting objectives. Note that the reconstruction loss is the primary loss generation but this does not take into consideration the style or the controlled generation.

We use Multi-task and Adversarial losses on the latent space h to disentangle the embeddings into representing content c and style s (i.e., $h = [s; c]$, where $[;]$ denotes concatenation) separately.

Style-oriented losses. Multitask Loss ensures that the style space s is discriminative for the style. We train a style classifier on s jointly with the autoencoder loss.

$$J_{mul(s)}(\theta_E; \theta_{mul(s)}) = -\sum_{l\in labels} t_s(l)\, log(y_s(l))$$

Table 4: Datasets

where $\theta_{mul(s)}$ are the parameters for style multitask classifier, y_s is the style probability distribution predicted by the classifier and t_s is the ground truth style distribution.

Adversarial loss for style is introduced to ensure that the content space c is not-discriminative of the style. An adversarial classifier is trained, that deliberately discriminates the true style label using the content vector c, with the following loss.

$$J_{dis(s)}(\theta_{dis(s)}) = -\sum_{l \in labels} t_s(l) log(y_s^{'}(l))$$

where $\theta_{dis(s)}$ are the parameters for style adversary, $y_s^{'}$ is the style probability distribution predicted by the classifier on the content space.The encoder is then trained to learn a content vector space c, from which its adversary cannot predict style information. The objective is to maximize the cross entropy $H(p) = -\sum_{i \in labels} p_i log(p_i)$ with:

$$J_{adv(s)}(\theta_E) = H(y_s^{'}|c; \theta_{dis(s)})$$

Content-oriented losses. Multi-task loss aims to ensure that all content information is in the content space c. We define the content information using a bag-of-words (BoW) concept. Here, *part-of-speech* tags , i.e. *nouns* are used. (Liu et al., 2020; DBL) argue nouns in the text are considered as attribute-independent content. This definition allows a generic content loss for all style dimensions as against the previous work where content is defined as bag-of-words in a sentence, excluding stopwords and specific style (sentiment) related lexicon. The content multitask loss is analogical to style multitask loss as follows:

$$J_{mul(c)}(\theta_E; \theta_{mul(c)}) = -\sum_{w \in content} t_c(w)\, log(y_c(w))$$

Adversarial loss for content ensures that the style space does not contain content information. A classifier (content adversary), is trained on the style space to predict the content (BoW) features. Then similar to style, encoder is trained to learn s, from which this adversary cannot predict content information.

$$J_{dis(c)}(\theta_{dis(c)}) = -\sum_{w \in content} t_c(w) log({y_c}'(w))$$

$$J_{adv(c)}(\theta_E) = H({y_c}'|s; \theta_{dis(c)}),$$

Training with these losses along with reconstruction loss ensures that the latent space is disentangled, resulting in the final loss given by,

$$J_{total} = J_{VAE} + \lambda_{mul(s)} J_{mul(s)} - \lambda_{adv(s)} J_{adv(s)} + \lambda_{mul(c)} J_{mul(c)} - \lambda_{adv(c)} J_{adv(c)}$$

B Dataset details

The brief descriptions for datsets are as follows:
YELP: Reviews from Yelp. Each review is labeled with a sentiment class - positive or negative. The task is to change the label while rewriting.
GYAFC: Corpus created from a subset of Yahoo Answers. Each sample is tagged either formal or informal. The task is to switch the label.
GYAFC-Excitment: The task here is to convert the sentences from 'exciting' to 'non-exciting'. We create a subset of the GYAFC data where annotators (using Amazon Mechanical Turk), were asked to tag the sentence to be either showing excitement or not. Excitement follows the definition as given by (Aaker, 1997). We follow annotation scheme provided by Rao(2017).
POLITICAL: Comments from Facebook posts from United States Senate and House members. Each comment is labelled is with either Republican or Democrat tag. Task is to interchange between the two.
GENDER: Reviews from Yelp for food businesses. Each review is labeled with either male or female based on the author of the review. Task is to switch between the two.

Table 4 refers to the number of sentences in train-dev-test split available for each dataset. The URL

link to the data files are also provided for each of them.

C Implementation details

The dimensions of c and s are set to 128 and 16 respectively. The posterior probability distributions (μ, σ) learnt for the respective content and style also have the same dimensions. The learnt hidden state representation is converted to 128 (c) and 16 (s) with a linear layer.

For R-VAE, hidden state dimension is set to 256. For the T-VAE, the embedding size, latent layer and the self-attention layers all are set to 256. The inner dimension of FFN in the transformer is set to 1024. Each of the encoder and decoder is stacked with two layers of transformer blocks. We used the Adam optimizer for the VAE and the RMSProp optimizer for the discriminators, following stability tricks in adversarial training (Arjovsky and Bottou, 2017). Each optimizer has an initial learning rate of 10^{-3}. Models are trained for 50 epochs. Figure 4 illustrates the architecture of T-VAE.

Word embeddings initiated with word2vec (Mikolov et al., 2013) are trained on respective training sets. Both, the autoencoder and the discriminators are trained once per mini batch with $\lambda_{mul(s)}$, $\lambda_{mul(c)}$, $\lambda_{adv(s)}$, and $\lambda_{adv(c)} = 1$. The label smoothing parameter in the transformer loss ϵ is set to 0.1. The KL-Divergence penalty is weighted by $\lambda_{kl}(s)$ and $\lambda_{kl}(c)$ on style and content, respectively. During training, we also used the sigmoid KL annealing schedule

The hyper-parameter weights in the loss function $\lambda_{mul(s)}$, $\lambda_{mul(c)}$, $\lambda_{adv(s)}$, and $\lambda_{adv(c)}$ are chosen to be 1, as the values were Observed to be converging over iterations.

We implement our model based on Pytorch 0.4. We trained our models on a machine with 4 NVIDIA Tesla V100-SXM2-16GB GPUs. On a single GPU, our transformer model with all the losses (T-VAE-4) took approximately 0.4 s to train for one step with a batch of size 128. It takes around 10 hours to train our model on 1 GPU. Table 5 depicts the runtime details for all the model variations.

For our counterfactual generator model, we use the counterfactual model from Alibi library in Python[§]. On an average it takes 3 seconds to generate a counterfactual for a given input representation and transfer strength (p_t).

Attention Flows are Shapley Value Explanations

Kawin Ethayarajh
Stanford University
kawin@stanford.edu

Dan Jurafsky
Stanford University
jurafsky@stanford.edu

Abstract

Shapley Values, a solution to the credit assignment problem in cooperative game theory, are a popular type of explanation in machine learning, having been used to explain the importance of features, embeddings, and even neurons. In NLP, however, leave-one-out and attention-based explanations still predominate. Can we draw a connection between these different methods? We formally prove that — save for the degenerate case — attention weights and leave-one-out values cannot be Shapley Values. *Attention flow* is a post-processed variant of attention weights obtained by running the max-flow algorithm on the attention graph. Perhaps surprisingly, we prove that attention flows are indeed Shapley Values, at least at the layerwise level. Given the many desirable theoretical qualities of Shapley Values — which has driven their adoption among the ML community — we argue that NLP practitioners should, when possible, adopt attention flow explanations alongside more traditional ones.

1 Introduction

The approaches to model interpretability taken by the ML and NLP communities overlap in some areas and diverge in others. Notably, in machine learning, model prediction has sometimes been framed as a cooperative effort between the potential subjects of an explanation (e.g., input tokens) (Lundberg and Lee, 2017). But how should we allocate the credit for a prediction, given that some subjects contribute more than others (e.g., the sentiment words in sentiment classification)? The Shapley Value is a solution to this problem that uniquely satisfies several criteria for equitable allocation (Shapley, 1953). However, while Shapley Value explanations have been widely adopted by the ML community — to analyze the importance of features, neurons, and even training data (Ghorbani and Zou, 2019, 2020) — they have had far less traction in NLP, where leave-one-out and attention-based explanations still predominate.

What is the connection between these different paradigms? When, if ever, are attention weights and leave-one-out values effectively Shapley Values? The adoption of Shapley Values — which have their origins in game theory (Shapley, 1953) — by the ML community can be ascribed to their many desirable theoretical qualities. For example, consider a token whose masking out does not impact the model prediction in any way, regardless of how many other tokens in the sentence are also masked out. In game theory, such a token would be called a *null player*, whose Shapley Value is guaranteed to be zero (Myerson, 1977; Young, 1985). If we could provably identify the conditions under which attention weights and leave-one-out values are Shapley Values, we could extend such theoretical guarantees to them as well.

In this work, we first prove that — save for the degenerate case — attention weights and leave-one-out values cannot be Shapley Values. More formally, there is no set of *players* (i.e., possible subjects of an explanation, such as tokens) and *payoff* (i.e., function defining prediction quality) such that the values induced by attention or leave-one-out also satisfy the definition of a Shapley Value. We then turn to *attention flow*, a post-processed variant of attention weights obtained by running the max-flow algorithm on the attention graph (Abnar and Zuidema, 2020). We prove that when the players all come from the same layer (e.g., tokens in the input layer), there exists a payoff function such that attention flows are Shapley Values.

This means that under certain conditions, we can extend the theoretical guarantees associated with the Shapley Value to attention flow as well. As we show, these guarantees are axioms of faithful interpretation, and having them can increase

confidence in interpretations of black-box NLP models. For this reason, we argue that whenever possible, NLP practitioners should use attention flow-based explanations alongside more traditional ones, such as gradients (Feng et al., 2018; Smilkov et al., 2017). We conclude by discussing some of the limitations in calculating Shapley Values for any arbitrary player set and payoff function in NLP.

2 Model Interpretation as a Game

The Shapley Value (Shapley, 1953) was proposed as a solution to a classic problem in game theory: When a group of players work together to achieve a payoff, how can we fairly allocate the payoff to each player, given that some contribute more than others? The players here are the potential subjects of the explanation (e.g., input tokens); the payoff is some quality of the model prediction (e.g., correctness). We contextualize the game theoretic terms with respect to model interpretability below.

Definition 2.1. A *player* is a possible subject of the explanation (e.g., character, token, embedding, neuron). $N = \{1, ..., n\}$ is the set of all players.

Definition 2.2. A *coalition* is a subset of players $S \subseteq N$ that work together. There are 2^n possible coalitions. The other players $N \setminus S$ are left out by being replaced with a non-subject that cannot affect the outcome (e.g., a zeroed-out embedding or a dropped-out neuron).

Definition 2.3. The *payoff* reflects some quality of the model prediction — e.g., correctness, confidence, entropy — made using a given coalition. It is defined by a *payoff function* $v : 2^N \rightarrow \mathbb{R}$, where $v(\emptyset) = 0$. The *value* $\phi_i(v)$ of a player i is the share of the payoff allocated to it. In other words, it is the importance accorded to subject i of an explanation.

Definition 2.4. A *game* is defined by (N, v), a player set N and payoff function v. It is a *transferable utility* game (TU-game), where the payoff can be distributed among the players as desired. In the game of model interpretation, the subjects of the explanation are framed as players working cooperatively to make the best possible prediction.

2.1 Equitable Allocation

How can we allocate the payoff equitably, in a way that reflects the actual contribution made by each player? In other words, how can we faithfully interpret a prediction? The game theory literature proposes that any equitable payoff allocation satisfies these three conditions (Myerson, 1977; Young, 1985; Ghorbani and Zou, 2019):

Condition 1. (*Null Player*): A player that induces no change in the payoff from joining any coalition has zero value. Formally, $\forall\ S \subseteq N \setminus \{i\}, v(S \cup \{i\}) = v(S) \implies \phi_i = 0$.

Condition 2. (*Symmetry*): Two players who induce the same change in payoff upon joining every coalition (that excludes them) have the same value. Formally, $\forall\ S \subseteq N \setminus \{i, j\}, v(S \cup \{i\}) = v(S \cup \{j\}) \implies \phi_i = \phi_j$.

Condition 3. (*Additivity*): The value of a player across two different games with payoff v, w should be the sum of its value in each game. Formally, $\forall\ i \in N, \phi_i(v + w) = \phi_i(v) + \phi_i(w)$.

2.2 The Shapley Value

The Shapley Value is a well-known solution to the problem of payoff allocation in a cooperative setting, as it uniquely satisfies the three criteria for equitable allocation in 2.1 (Shapley, 1953; Myerson, 1977; Young, 1985). It sets the value of a player to be its expected incremental contribution to a coalition, over all possible coalitions.

Definition 2.5. Where R is one of $n!$ possible permutations of the player set N, let $P_{R[:i]}$ be the subset of players that precede player i in the permutation. Then, for a given payoff function v, the Shapley Value of player i is

$$\phi_i(v) = \frac{1}{n!} \sum_R [v(P_{R[:i]} \cup \{i\}) - v(P_{R[:i]})] \quad (1)$$

There are other equivalent ways of expressing the Shapley Value, including as a sum over the 2^n possible coalitions.

In addition to satisfying our three criteria of equitable allocation (2.1), a Shapley Value distribution always exists and is unique for a TU-game (N, v). Unlike with attention weights, which have been criticized for allowing counterfactual explanations (Jain and Wallace, 2019; Serrano and Smith, 2019), there can thus be no counterfactual Shapley Value distribution for a given input and payoff function v. The distribution is also said to be *efficient*, since it allocates all of the payoff: $v(N) = \sum_{i \in N} \phi_i(v)$ (Myerson, 1977; Young, 1985). The Shapley Value can, in theory, be computed for any player set and payoff function. However, in practice, there are typically too many players to calculate this combinatorial expression exactly. Generally, estimates

are taken by uniformly sampling m random permutations $\mathcal{R}$ (Ghorbani and Zou, 2019):

$$\hat{\phi}_i(v) = \frac{1}{m} \sum_{R \in \mathcal{R}} [v(P_{R[:i]} \cup \{i\}) - v(P_{R[:i]})] \quad (2)$$

In the rest of this paper, we ask: Is there *some* TU-game (N, v) for which attention weights / attention flows / leave-one-out values are Shapley Values? If so, for which games?

3 Attention Weights

Many have argued that attention weights are not a faithful explanation, on the basis of *consistency* (i.e., poor correlation with other importance measures) and *non-exclusivity* (i.e., multiple explanations leading to the same outcome) (Jain and Wallace, 2019). Others have countered that they have some utility (Wiegreffe and Pinter, 2019). Without making assumptions about their inherent utility, we prove in this section that they cannot be Shapley Value explanations, outside of the degenerate case.

Proposition 1. If some player is attended to more than another, there is no TU-game (N, v) for which attention weights are Shapley Values.

Proof. Assume that attention weights are Shapley Values for some TU-game. Shapley Values are necessarily efficient (i.e., $v(N) = \sum_i \phi_i(v)$) (Myerson, 1977; Young, 1985), so for attention weights to be efficient, the only applicable payoff function would be the sum of attention weights. Since each player only has one Shapley Value for a given v, if it is attended to multiple times, its value must be the *total* attention paid to it: where $a_{j,i}$ denotes the attention j pays to i, $\phi_i(v) = \sum_{j \in N} a_{j,i}$. Note that the payoff for a coalition S is within some constant of its cardinality, since for a player j, the weights $a_{j,\cdot}$ of the players that it attends to sum to 1 (Bahdanau et al., 2015). We consider two cases.

Case 1 For a player j that attends to some other player, its contribution to the payoff of every $S \in N \setminus \{j\}$ is $\sum a_{j,\cdot} = 1$, implying $\phi_j(v) = 1$ by the Shapley Value definition (1). If some player (that pays attention) is more or less attended to than another — which is the point of using attention — this results in a contradiction. Thus ϕ_j cannot be the total attention paid to j.

Case 2 For a player i that doesn't attend to any other player, its contribution to the payoff of every $S \in N \setminus \{i\}$ is 0, since the attention paid to i is redistributed among other players when it is absent. This implies $\phi_i(v) = 0$ by (1). However, all input embeddings fall under this case, and we know at least one will be attended to; its attention weights will be non-zero, making this a contradiction. Thus ϕ_i cannot be the total attention paid to i. □

4 Attention Flows

What if we restricted the players to those from the same layer of a model? The remaining players still affect the prediction but can't have any of the payoff allocated to them. In this case, attention weights still cannot be Shapley Values. However, attention weights can be post-processed. Abnar and Zuidema (2020) proposed treating the self-attention graph as a flow network — where the attention weights are capacities — and then applying a max-flow algorithm (Ford and Fulkerson, 1956) to this network to calculate the maximum flow on each edge. We prove (by construction) that these *attention flows* are Shapley Values when the players are restricted to those from the same layer and the payoff is the total flow, as visualized in Figure 1.

Proposition 2. Consider a TU-game (N, v), where $N = \{1, ..., n\}$ players are all from the same layer. Let f denote the flow obtained by running a max-flow algorithm on the graph defined by the self-attention matrix, where the capacities are the attention weights. Let $v(S) = |f(S)|$, the *value of the flow* when only permitting flow through players in the coalition $S \subseteq N$. Then for each player i, its total outflow $|f_o(i)|$ is its Shapley Value.

Proof. Blocking the flow through a player $i \in S$ decreases $v(S)$ by that player's outflow $|f_o(i)|$, since the attention flow is only calculated once — with the entire graph — and not for each possible subgraph. Since the players are all disjoint and have no connections, blocking the flow through one player does not affect the outflow of any of the other players. This would not be the case, for example, if the players were in different layers, in which case changes in flow upstream would cause changes in flow downstream. Then for any coalition $S \subseteq N$ and player $i \notin S$, $v(S \cup \{i\}) = v(S) + |f_o(i)|$. We can rewrite the total outflow for player i as

$$\begin{aligned} |f_o(i)| &= v(S \cup \{i\}) - v(S), \forall\, S \subseteq N \\ &= \frac{n!}{n!} v(S \cup \{i\}) - v(S), \forall\, S \subseteq N \\ &= \frac{1}{n!} \sum_R \left[v(P_{R[:i]} \cup \{i\}) - v(P_{R[:i]}) \right] \end{aligned}$$

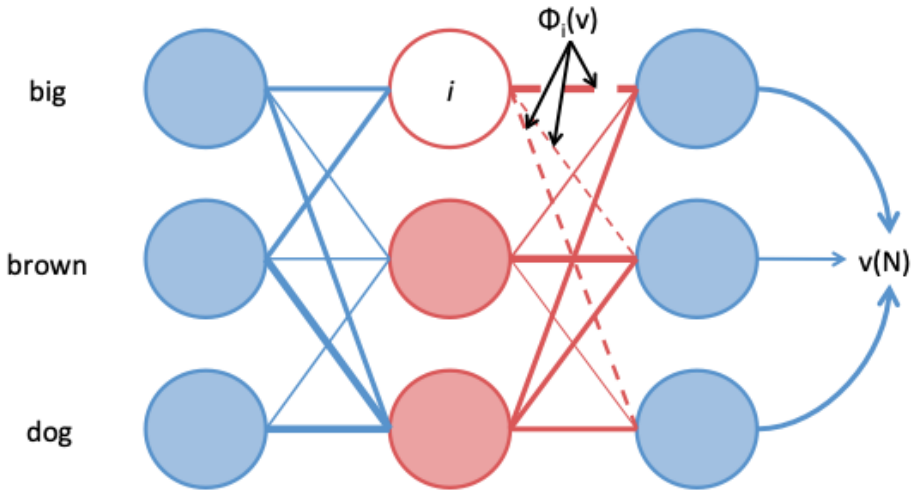

Figure 1: The attention flow network for three tokens across three layers, with player nodes (red) and non-player nodes (blue). The payoff $v(N)$ is the total flow through the network. $\phi_i(v)$ is the total outgoing flow of player i. Note that if we remove player i, then the total flow will decrease by $\phi_i(v)$, but the outgoing flow of the other two players (red) will stay the same. In other words, the contribution of player i to the total flow $v(N)$ is always $\phi_i(v)$; therefore, $\phi_i(v)$ is its Shapley Value. This construction is possible because the players are all in the same layer and therefore parallel; if one depended on another, then its outgoing flow could not be its Shapley Value.

which is just the Shapley Value definition (1). Note that the players cannot be from different layers — at least for the definition of v as the total flow value — because the Shapley Value distribution would not be efficient (i.e., $v(N) \neq \sum_{i \in N} \phi_i(v)$) and efficiency necessarily holds for Shapley Values. This in turn implies that the theoretical properties that hold for Shapley Values extend to attention flows under these conditions. □

Attention Rollout Abnar and Zuidema (2020) also proposed another post-processed variant of attention called *attention rollout*, in which the attention weight matrices from each layer are multiplied with those before it to get aggregated attention values. Attention roll-out values cannot be Shapley Values, however; this can be shown with a trivial extension of the proof to Proposition 1.

5 Leave-One-Out

Erasure describes a class of interpretability methods that aim to understand the importance of a representation, token, or neuron by erasing it and recording the resulting effect on model prediction (Li et al., 2016; Arras et al., 2017; Feng et al., 2018; Serrano and Smith, 2019). Although the Shapley Value technically falls under this class, most erasure-based methods only remove one entity — the one whose importance they want to estimate — and this only takes two forward passes, compared to $O(2^n)$ passes for the Shapley Value. Since only one entity is erased, this simpler group of erasure-based methods is called *leave-one-out* (Jain and Wallace, 2019; Abnar and Zuidema, 2020). We show in this section that leave-one-out values are not Shapley Values, except in the degenerate case.

Proposition 3. If $\exists\ i \in N$ such that player i is not a null player even when excluding the coalition $N \setminus \{i\}$, then there is no TU-game (N, v) for which leave-one-out values are Shapley Values.

Proof. Let the leave-one-out value of player i be denoted by $\text{LOO}_i(v)$. Let R' denote any permutation of N where $P_{R'[:i]} \neq N \setminus \{i\}$. By definition,

$$\begin{aligned}\phi_i(v) &= \frac{1}{n!} \sum_R \left[v(P_{R[:i]} \cup \{i\}) - v(P_{R[:i]}) \right] \\ &= \frac{1}{n!} \sum_{R'} \left[v(P_{R'[:i]} \cup \{i\}) - v(P_{R'[:i]}) \right] \\ &\quad + \frac{1}{n} \underbrace{\left(v(N) - v(N \setminus \{i\}) \right)}_{\text{LOO}_i(v)}\end{aligned}$$

By our assumption, the first term is non-zero, so there is no equivalence with $\text{LOO}_i(v)$. In practice, this assumption is almost always satisfied. □

Note that leave-one-out tells us very little about player importance for discrete payoff functions.

For example, if the payoff were the correctness (i.e., 1 if correct and 0 otherwise), then the importance of a player would be binary: it would either be critically important to prediction or totally irrelevant. This provides an incomplete picture — while there is enough redundancy in BERT-based models to tolerate some missing embeddings, this does not mean those embeddings are of no importance (Kovaleva et al., 2019; Ethayarajh, 2019; Michel et al., 2019). For example, if two representations played a critical and identical role in a prediction — but only one was necessary — then leave-one-out would assign each a value of zero, despite both being important. In contrast, the Shapley Value of both players would be non-zero and identical.

6 Applications

Because Shapley Values have many useful applications, attentions flows — and any other score that meets the criteria for a Shapley Value — have many useful applications as well:

- For one, using the various properties of the Shapley Value, we can provide more specific interpretations of model behavior than is currently the case, backed by theoretical guarantees. For example, if a token has zero attention flow in layer k but non-zero flow in layer $k-1$, then we can conclude that all the information it contains about the label (e.g., sentiment) was extracted by the model prior to the kth layer; this derives from the "null player" property of the Shapley Value. The same could not be said if the token only had a leave-one-out value of zero, since leave-one-out values are not Shapley Values.

- Interpretability in NLP often takes a single token or embedding to be the unit of analysis (i.e., a "player" in game theoretic terms). However, what if we wanted to understand the role of entire groups of tokens rather than individual ones? For most interpretability methods, there is no canonical way to aggregate scores across multiple units — we cannot necessarily add the raw attention scores of two tokens, since the usefulness of one may depend on the other. If we used a method that provided Shapley Values, we could easily redefine a "player" to be a group of tokens, such that all tokens in the same player group would simultaneously be included or excluded from a coalition.

- Recent work has used the Data Shapley — an extension of the Shapley Value — to estimate the contribution of each example in the training data to a model's decision boundary (Ghorbani and Zou, 2019). If we're fine-tuning BERT for sentiment classification, for example, we might want to know which sentence is more helpful: "This movie was great!" or "This was better than I expected." We can answer such questions by using the Data Shapley. To our knowledge, this has been done in computer vision but not in NLP.

7 Limitations and Future Work

Because Shapley Values — and by extension, attention flows — have many theoretical guarantees that are axioms of faithful interpretation, we encourage NLP practitioners to provide attention flow-based explanations alongside more traditional ones. This is not without limitations, however. As proven in Proposition 2, this equivalence only holds for a specific payoff function — the total flow through a layer — which is reflective of model confidence but not of the prediction correctness.

But why do we need attention flows at all if, in theory, Shapley Values can be calculated for any arbitrary player set and payoff function? While this is true in theory, because of the combinatorial calculation (1), it is computationally intractable in most cases. While it is possible to take a Monte Carlo estimate (2), in practice the bounds can be quite loose (Maleki et al., 2013). Finding TU-games for which the Shapley Value can be calculated exactly in polynomial time — as with attention flow -– is an important line of future work. These explanations may come with trade-offs: for example, SHAP is a kind of Shapley Value that assumes contributions are linear (i.e., a coalition can't be greater than the sum of its parts), which makes it much faster to calculate but restricts the set of possible payoff functions (Lundberg and Lee, 2017). Still, such methods will be critical to providing explanations that are both fast and faithful.

Video Paragraph Captioning as a Text Summarization Task

Hui Liu, Xiaojun Wan

{xinkeliuhui, wanxiaojun}@pku.edu.cn

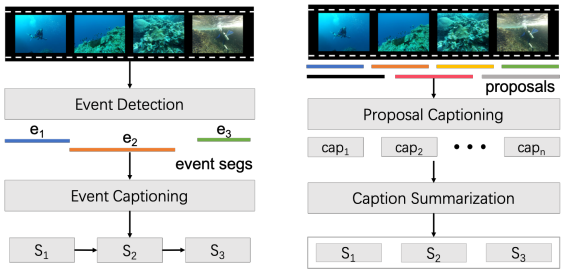
Abstract

Video paragraph captioning aims to generate a set of coherent sentences to describe a video that contains several events. Most previous methods simplify this task by using ground-truth event segments. In this work, we propose a novel framework by taking this task as a text summarization task. We first generate lots of sentence-level captions focusing on different video clips and then summarize these captions to obtain the final paragraph caption. Our method does not depend on ground-truth event segments. Experiments on two popular datasets ActivityNet Captions and YouCookII demonstrate the advantages of our new framework. On the ActivityNet dataset, our method even outperforms some previous methods using ground-truth event segment labels.

1 Introduction

Video captioning, the task of describing the content of a video in natural language, is a popular task both in computer vision and natural language processing. In the beginning, researchers try to generate sentence-level captions for short video clips (Venugopalan et al., 2015). Krishna et al. (2017) propose the task of dense video captioning. The system needs to detect event segments first and then generate captions. Park et al. (2019) propose the task of video paragraph captioning: they use ground-truth event segments and focus on generating coherent paragraphs. Lei et al. (2020) follow the task setting and propose a recurrent transformer model that can generate more coherent and less repetitive paragraphs. Considering the ground-truth event segments are often unavailable in practice, our goal is to generate paragraph captions without ground-truth segments.

The conventional framework of video paragraph captioning is shown in Figure 1a. Given an untrimmed video, an Event Detection module outputs a set of non-redundant event segments. The Event Captioning module generates captions for these segments. The works of (Park et al., 2019; Zhou et al., 2019; Lei et al., 2020) use ground-truth event segments and focus on the Event Captioning module. Zhou et al. (2019) use extra human-annotated bounding boxes as supervision. (Sah et al., 2017; Zhou et al., 2018; Mun et al., 2019) use predicted event segments and generate captions based on them. Sah et al. (2017) also summarizes these captions to generate a paragraph. The above methods heavily depend on accurate event segments. According to previous works (Zhou et al., 2018; Mun et al., 2019), the performance of the Event Detection module is not so good, making it a performance bottleneck. To tackle this problem, we propose a novel framework VPCSum as shown in Figure 1b. For a given video, we first extract dense event segment candidates (we call proposals), and a Proposal Captioning module is used to generate proposal captions. Then we treat video paragraph captioning as a text summarization task to obtain the final summary (paragraph caption).



(a) Conventional Framework (b) Our Framework

Figure 1: Comparison between conventional framework and ours.

In this work, we only consider extractive summarization, where the paragraph caption is composed by selecting from proposal captions. We conduct experiments on two popular datasets ActivityNet

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 55–60

Captions and YouCookII. The results demonstrate the advantages of our framework. On the ActivityNet Captions dataset, our method even outperforms some previous methods using ground-truth event segment labels.

2 Our VPCSum Method

As illustrated in Figure 1b, our framework has three modules. **Proposal Extraction**: it extracts dense proposals for a video; **Proposal Captioning**: it generates captions for extracted proposals; **Caption Summarization**: it summarizes the generated proposal captions to obtain the video paragraph caption. We will introduce each module next.

2.1 Proposal Extraction

For proposal extraction, we use the BMN model (Lin et al., 2019), a popular model for temporal action proposal generation. It can extract complete and accurate proposals. We extract the top 100 proposals for each video.

2.2 Proposal Captioning

For proposal captioning, we choose the TSRM-RNN model (Wang et al., 2020) for ActivityNet Captions and VTransformer model (Lei et al., 2020) for YouCookII according to proposal captioning performance. We believe that if we choose a better sentence-level captioning model, the performance can be further improved.

2.3 Caption Summarization

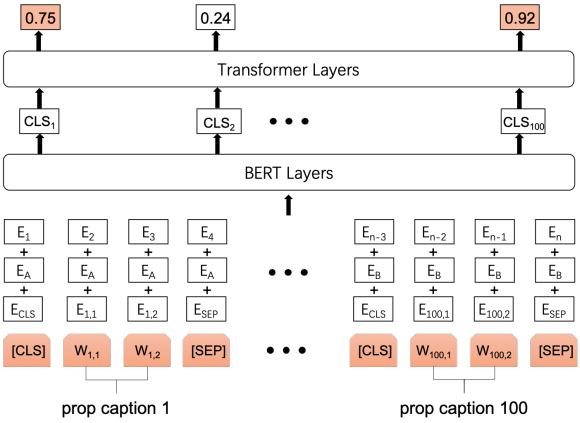

Figure 2: Architecture of the caption summarization model.

The caption summarization module summarizes proposal captions to generate the final video paragraph caption. In this work, we focus on extractive summarization. The architecture of our summarization model is illustrated in Figure 2. We first sort the proposal captions according to the proposal start time and add special [CLS] and [SEP] tokens to the beginning and end of each caption. We use the summation of token embeddings, segment embeddings, and position embeddings to represent each word. The input representations are fed into a pre-trained BERT model (Devlin et al., 2018), after which we obtain the contextual token representations. We use the contextual vectors of [CLS]s to represent each caption and feed them into stacked transformer layers (Vaswani et al., 2017). We use a sigmoid layer to compute the score of each caption:

$$x_i = \sigma(W h_i^L + b) \quad (1)$$

where W and b are trainable parameters, h_i^L is the vector for caption i from the top transformer layer.

For extractive summarization, we need to annotate each sentence according to the gold summary as our training target. Many researchers use a greedy algorithm (Nallapati et al., 2016), sentences are selected one by one to maximize the ROUGE score against the gold summary. The selected sentences are labeled 1 while others are labeled 0 (hard-label). In our task, we find a more effective soft-label annotation method. We label caption c_i with the max ROUGE score against gold captions and use binary cross-entropy as our loss function:

$$y_i = \max_{g_j \in gold} ROUGE(c_i, g_j) \quad (2)$$

$$\mathcal{L} = -\sum_i (y_i \log x_i + (1 - y_i) \log(1 - x_i)) \quad (3)$$

where g_j is the j-th gold caption.

2.4 Leverage Visual Information

The above caption summarization module assigns each proposal caption a predicted score, indicating how likely it appears in the final paragraph caption. The predicted score only depends on text information. To leverage visual information, we need a "visual summarization" module, which gives a visually weighting score to each proposal. The ESGN model (Mun et al., 2019) seems a good choice for us. It uses a pointer network to select events from proposals and assigns a visually weighting score for each proposal. We use this model to compute the visually weighting score.

Now we can extract the final paragraph caption. The final score of each proposal caption is a

weighted sum of the textually weighting score s_{txt} and the visually weighting score s_{vis}:

$$score(i) = s_{txt,i} + \lambda s_{vis,i} \quad (4)$$

where λ is a hyper-parameter tuned on validation set. We select captions according to $score(i)$ and use Trigram Blocking to reduce redundancy, as in Liu and Lapata (2019).

3 Experiments

3.1 Datasets

We conduct experiments on ActivityNet Captions (Krishna et al., 2017) and YouCookII (Zhou et al., 2017). ActivityNet Captions contains 10,009 videos in train set, 4,917 videos in val set. Each video has 3.65 event segments on average. Following (Lei et al., 2020), the original val set is split into ae-val with 2,460 videos for validation and ae-test with 2,457 videos for test. YouCookII contains 1,333 videos in train set, 457 videos in val set. Each video has 7.70 event segments on average.

3.2 Evaluation Metrics

Following (Lei et al., 2020; Park et al., 2019), we evaluate the captioning performance at paragraph level. We report standard caption metrics, including BLEU@4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), CIDEr (Vedantam et al., 2015). We also evaluate repetition using R@4 (Xiong et al., 2018). We use the scripts provided by (Lei et al., 2020) for evaluation[1].

3.3 Implementation Details

For video preprocessing, we use appearance and optical flow features provided by Zhou et al. (2018). For BMN model and captioning models, we use the same hyperparameters suggested by the authors. For ESGN model, we use a transformer encoder instead of an RNN encoder, with hidden size set to 512, number of heads set to 8, number of layers set to 3. For our caption summarization model, we use the base BERT model, 2 stacked transformer layers with hidden size set to 768, number of heads set to 8. We set max input length to 1,700, batch size to 10, λ to 1 for ActivityNet Captions and max input length to 1,000, batch size to 1, λ to 1 for YouCookII. Warmup steps are set to step num of 1 epoch. We use Adam optimizer with an initial learning rate of $6e-4$.

3.4 Baselines and Results

We compare our **VPCSum** model with the following baselines. **Soft-NMS**: it uses Soft-NMS (Bodla et al., 2017) to select event segments from BMN proposals, and uses the proposal captioning model to generate captions; **ESGN**: similar to Soft-NMS, but it uses ESGN model (Mun et al., 2019) to select event segments from BMN proposals; **V-Trans**: a Vanilla Transformer model, proposed by (Zhou et al., 2018); **Trans-XL**: a Transformer-XL model, proposed by (Lei et al., 2020); **MART**: a recurrent transformer model (Lei et al., 2020); **COOT**: it uses pretrained features to train MART model (Ging et al., 2020). Originally, the last four models deal with ground-truth event segments. For fair comparison, we also test them with predicted event segments generated by ESGN model [2].

Models	B@4	M	C	R@4↓
Soft-NMS	10.33	14.93	22.58	10.17
ESGN	10.38	15.74	21.85	6.51
V-Trans	9.89	15.11	20.95	7.04
Trans-XL	10.36	14.89	20.73	7.45
MART	10.13	14.94	20.16	6.09
COOT	9.85	14.67	21.83	7.15
VPCSum	**10.89**	**15.84**	**24.33**	**1.54**
V-trans*	9.31	15.54	21.33	7.45
Trans-XL*	10.25	14.91	21.71	8.79
MART*	9.78	15.57	22.16	**5.44**
COOT*	**10.85**	**15.99**	**28.19**	6.64

Table 1: Comparison with baselines on ActivityNet Captions ae-test split. * means the model uses ground-truth event segments. We report BLEU@4 (B@4), METEOR (M), CIDEr (C), Repetition (R@4).

Tables 1 and 2 show the results on ActivityNet Captions and YouCookII. We can observe that on the ActivityNet Captions, our model **VPCSum** within the new framework can generate better paragraph captions with higher Bleu@4, METEOR, and CIDEr and lower repetition score R@4, even outperforming V-trans*, Trans-XL*, MART* models using ground-truth event segments on every metric. On the YouCookII dataset, our model outperforms the models in the same setting but is inferior to the models using ground-truth segments. This may be because YouCookII has more segments

[2] We use the codes and pretrained models provided by the authors and only replace ground-truth event segments with ESGN predicted event segments.

Models	B@4	M	C	R@4↓
Soft-NMS	5.58	13.67	18.18	4.94
ESGN	5.36	13.37	17.01	2.82
V-Trans	5.35	13.37	16.88	2.85
Trans-XL	4.78	12.67	14.24	3.20
MART	5.61	13.44	16.56	4.63
COOT	5.96	14.21	19.67	5.99
VPCSum	**6.14**	**15.11**	**23.92**	**0.65**
V-trans*	7.62	15.65	32.26	7.83
Trans-XL*	6.56	14.76	26.35	6.30
MART*	8.00	15.90	35.74	**4.39**
COOT*	**9.44**	**18.17**	**46.06**	6.30

Table 2: Comparison with baselines on YouCookII val split.

(7.70 vs 3.65) than ActivityNet Captions.

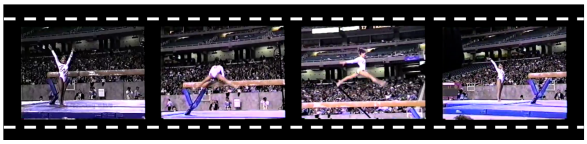
3.5 Ablation Study

Table 3 shows the ablation study on ActivityNet Captions. Compared to our full model (Full), the traditional extractive summarization annotation method (Hard-label) is not suitable for our task. If we set λ in Eq.(4) to 0 (w/o vis), the model loses useful visual information and performs not well. If we remove Trigram Blocking (w/o tri-blk), the performance also degrades and repetition becomes a problem (R@4 increases to 7.91). To verify the role of pretrained BERT model, we retrain our VPCSum without BERT pretrained weights (w/o pretrain). We can see that BERT pretrained weights are not the major factor to the final performance. We also replace our summarization model with unsupervised methods LexRank (Erkan and Radev, 2004) and LSA(Steinberger and Jezek, 2004). The results show that simple unsupervised summarization methods cannot handle our data well and supervised training is necessary.

Models	B@4	M	C	R@4↓
Full	10.89	15.84	24.33	1.54
Hard-label	10.29	14.99	21.71	1.19
w/o vis	10.68	15.78	23.34	1.36
w/o tri-blk	10.46	15.61	21.40	7.91
w/o pretrain	10.84	15.81	24.00	1.55
LexRank	7.78	13.65	14.19	26.51
LSA	7.24	14.48	12.43	28.14

Table 3: Model ablation study on ActivityNet Captions ae-test split.

3.6 Qualitative Results



Ground Truth: A girl jumps onto a balance beam. She does a gymnastics routine on the balance beam. She does a flip off the balance beam and lands on a mat.
MART: A gymnast is seen standing ready with her arms up and leads into her performing a gymnastics routine. She continues performing several flips and tricks and tricks and ends with her jumping down and walking away. She continues her routine and ends with her jumping down and jumping down and walking away.
MART*: A gymnast is seen standing before a beam and begins performing a gymnastics routine. The girl then performs a routine on the beam and ends with her jumping down and jumping down and jumping. The girl jumps off the beam and lands on the mat and jumps off the beam.
VPCSum: A gymnast is seen standing ready with her arms up and begins to do a routine. She does a gymnastics routine on the beam. She dismounts and lands on the mat.

Figure 3: An example from ActivityNet Captions.

We show an example in Figure 3 with paragraph captions generated by MART, MART* and our VPCSum model. Compared to other models, our model can generate more clear and correct sentences with less redundancy. The generated paragraph of our model can better describe the process of the whole event.

3.7 Human Evaluation

	Ours	MART	Ours	MART*
rel.	56.0%†	44.0%†	52.7%	47.3%
div.	56.7%†	43.3%†	56.7%†	43.3%†

Table 4: Human evaluation results. Statistically significant differences ($p < 0.05$) are marked with †.

We also conduct a human evaluation on randomly sampled 50 videos from the ActivityNet Captions val set. The annotators are asked to choose the better caption from two models in two aspects: **relevance** (how related is the caption to the video content) and **diversity** (how diverse is the generated text). We compare our VPCSum model with MART and MART* respectively. We have 17 college students as our annotators. Each video is judged by 3 annotators. We show the results of the pairwise experiments in Table 4. Our VPCSum model performs better in relevance and diversity,

and more people choose the caption of our model as the better one.

4 Conclusion

In this work, we view the task of video paragraph captioning as a text summarization task and propose a novel framework VPCSum. It allows us to use text summarization techniques to handle this challenging task. Experimental results on two popular datasets show the advantages of our model. In the future, we will explore using abstractive summarization methods to generate better video paragraph captions.

Are VQA Systems RAD?
Measuring Robustness to Augmented Data with Focused Interventions

Abstract

Deep learning algorithms have shown promising results in visual question answering (VQA) tasks, but a more careful look reveals that they often do not understand the rich signal they are being fed with. To understand and better measure the generalization capabilities of VQA systems, we look at their robustness to counterfactually augmented data. Our proposed augmentations are designed to make a focused intervention on a specific property of the question such that the answer changes. Using these augmentations, we propose a new robustness measure, Robustness to Augmented Data (RAD), which measures the consistency of model predictions between original and augmented examples. Through extensive experimentation, we show that RAD, unlike classical accuracy measures, can quantify when state-of-the-art systems are not robust to counterfactuals. We find substantial failure cases which reveal that current VQA systems are still brittle. Finally, we connect between robustness and generalization, demonstrating the predictive power of RAD for performance on unseen augmentations.[1]

1 Introduction

In the task of Visual Question Answering (VQA), given an image and a natural language question about the image, a system is required to answer the question accurately (Antol et al., 2015). While the accuracy of these systems appears to be constantly improving (Fukui et al., 2016; Yang et al., 2016; Lu et al., 2016), they are sensitive to small perturbations in their input and seem overfitted to their training data (Kafle et al., 2019).

To address the problem of overfitting, the VQA-CP dataset was proposed (Agrawal et al., 2018). It is a reshuffling of the original VQA dataset, such that the distribution of answers per question type (e.g., "what color", "how many") differs between the train and test sets. Using VQA-CP, Kafle et al. (2019) demonstrated the poor out-of-distribution generalization of many VQA systems. While many models were subsequently designed to deal with the VQA-CP dataset (Cadene et al., 2019; Clark et al., 2019; Chen et al., 2020; Gat et al., 2020), aiming to solve the out-of-distribution generalization problem in VQA, they were later demonstrated to overfit the unique properties of this dataset (Teney et al., 2020). Moreover, no measures for robustness to distribution shifts have been proposed.

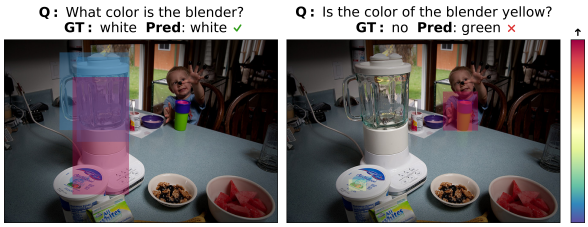

Figure 1: Predictions and attention maps of a state-of-the-art VQA-CP model over a VQA example (left) and its augmentation (right). A robust model should use the information it utilizes in the original example to correctly answer the augmented one.

In this work we propose a consistency-based measure that can indicate on the robustness of VQA models to distribution shifts. Our robustness measure is based on counterfactual data augmentations (CADs), which were shown useful for both training (Kaushik et al., 2019) and evaluation (Garg et al., 2019; Agarwal et al., 2020). CADs are aimed at manipulating a specific property while preserving all other information, allowing us to evaluate the robustness of the model to changes to this property.

For example, consider transforming a "what color" question to a "yes/no" question, as depicted in Figure 1. The counterfactual reasoning for such a transformation is: "what would be the question if it had a yes/no answer?". While VQA models

[1] Our code and data are available at: https://danrosenberg.github.io/rad-measure/

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 61–70
August 1–6, 2021. ©2021 Association for Computational Linguistics

have seen many of both question types, their combination (yes/no questions about color) has been scarcely seen. If a model errs on such a combination, this suggests that to answer the original question correctly, the model uses a spurious signal such as the correlation between the appearance of the word "color" in the question and a particular color in the answer (e.g. here, color ⇒ white). Further, this example shows that some models cannot even identify that they are being asked a "yes/no" question, distracted by the word "color" in the augmented question and answering "green".

Our robustness measure is named RAD: Robustness to (counterfactually) Augmented Data (Section 2.1). RAD receives (image, question, answer) triplets, each augmented with a triplet where the question and answer were manipulated. It measures the consistency of model predictions when changing a triplet to its augmentation, i.e., the robustness of the model to (counterfactual) augmentations. We show that using RAD with focused interventions may uncover substantial weaknesses to specific phenomenon (Section 3.2), namely, users are encouraged to precisely define their interventions such that they create *counterfactual* augmentations. As a result, pairing RAD values with accuracy gives a better description of model behavior.

In general, to effectively choose a model in complex tasks, complementary measures are required (D'Amour et al., 2020). Thus, it is important to have interpretable measures that are widely applicable. Note that in this work we manipulate only textual inputs - questions and answers, but RAD can be applied to any dataset for which augmentations are available. In particular, exploring visual augmentations would be beneficial for the analysis of VQA systems. Further, representation-level counterfactual augmentations are also valid, which is useful when generating meaningful counterfactual text is difficult (Feder et al., 2020).

Our augmentations (CADs) are generated semi-automatically (Section 2.2), allowing us to directly intervene on a property of choice through simple templates. As in the above example, our augmentations are based on compositions of two frequent properties in the data (e.g., "what color" and "yes/no" questions), while their combination is scarce. Intuitively, we would expect a model with good generalization capacities to properly handle such augmentations. While this approach can promise coverage of only a subset of the examples in the VQA and VQA-CP datasets, it allows us to control the sources of the model's prediction errors.

We conduct extensive experiments and report three key findings. First, for three datasets, VQA, VQA-CP, and VisDial (Das et al., 2017), models with seemingly similar accuracy are very different in terms of robustness, when considering RAD with our CADs (Section 3). Second, we show that RAD with alternative augmentation methods, which prioritize coverage over focused intervention, cannot reveal the robustness differences. Finally, we show that measuring robustness using RAD with our CADs predicts the accuracy of VQA models on unseen augmentations, establishing the connection between robustness to our controlled augmentations and generalization (Section 4).

2 Robustness to Counterfactuals

In this section, we first present RAD (Section 2.1), which measures model consistency on question-answer pairs and their augmented modifications. Then, we describe our template-based CAD generation approach (Section 2.2), designed to provide control over the augmentation process.

2.1 Model Robustness

We denote a VQA dataset with $\mathcal{U} = \{(x_v, x_q, y) \in \mathcal{V} \times \mathcal{Q} \times \mathcal{Y}\}$, where x_v is an image, x_q is a question and y is an answer. We consider a subset $\mathcal{D} \subseteq \mathcal{U}$ for which we can generate augmentations. For an example $(x_v, x_q, y) \in \mathcal{D}$, we denote an augmented example as $(x_v, x'_q, y') \in \mathcal{D}'$. In this paper we generate a single augmentation for each example in $\mathcal{D}$, resulting in a one-to-one correspondence between $\mathcal{D}$ and the dataset of modified examples $\mathcal{D}'$. We further define $J(\mathcal{D}; f)$ as the set of example indices for which a model f correctly predicts y given x_v and x_q.

RAD assesses the proportion of correctly answered modified questions, among correctly answered original questions, and is defined as,

$$\mathrm{RAD}(\mathcal{D}, \mathcal{D}'; f) = \frac{|J(\mathcal{D}; f) \cap J(\mathcal{D}'; f)|}{|J(\mathcal{D}; f)|}. \quad (1)$$

Note that RAD is in $[0, 1]$ and the higher the RAD of f is, the more robust f is.

As original examples and their augmentations may differ in terms of their difficulty to the model, it is important to maintain symmetry between $\mathcal{D}$ and $\mathcal{D}'$. We hence also consider the backward view

of RAD, defined as $\mathrm{RAD}(\mathcal{D}', \mathcal{D}; f)$. For example, "yes/no" VQA questions are easier to answer compared to "what color" questions, as the former have two possible answers while the latter have as many as eight. Indeed, state-of-the-art VQA models are much more accurate on yes/no questions compared to other question types (Yu et al., 2019). Hence, if "what color" questions are augmented with "yes/no" counterfactuals, we would not expect $\mathrm{RAD}(\mathcal{D}', \mathcal{D}; f) = 1$ as generalizing from "yes/no" questions ($\mathcal{D}'$) to "what color" questions ($\mathcal{D}$) requires additional reasoning capabilities.

RAD is not dependant on the accuracy of the model on the test set. A model may perform poorly overall but be very consistent on questions that it has answered correctly. Conversely, a model that demonstrates seemingly high performance may be achieving this by exploiting many dataset biases and be very inconsistent on similar questions.

2.2 Counterfactual Augmentations

In the VQA dataset there are three answer types: "yes/no", "number" (e.g., '2', '0') and "other" (e.g., 'red', 'tennis'), and 65 question types (e.g., "what color", "how many", "what sport"). In our augmentations, we generate "yes/no" questions from "number" and "other" questions.

For example, consider the question-answer pair "What color is the vehicle? Red", this question-answer pair can be easily transformed into "Is the color of the vehicle red? Yes". In general, "what color" questions can be represented by the template: "What color is the <*Subj*>? <*Color*>". To generate a new question, we first identify the subject (<*Subj*>) for every "what color" question, and then integrate it into the template "Is the color of the <*Subj*> <*Color*>? Yes". As the model was exposed to both "what color" and "yes/no" questions, we expect it to correctly answer the augmented question given that it correctly answers the original. Yet, this augmentation requires some generalization capacity because the VQA dataset contains very few yes/no questions about color.

Our templates are presented in Table 1 (see Table 6 in the appendix for some realizations). The augmentations are counterfactual since we intervene on the question type, a prior that many VQA systems exploit (Goyal et al., 2017), keeping everything else equal. The generation process is semi-automatic, as we had to first manually specify templates that would yield augmented questions that we can expect the model to answer correctly given that it succeeds on the original question.

	Original	Augmented
Y/N ← C	What color is the <*S*>? <*C1*>	Is the color of the <*S*> <*C2*>? Yes/No
Y/N ← HM	How many <*S*>? <*N1*>	Are there <*N2*> <*S*>? Yes/No
Y/N ← WK	What kind of <*S*> is this? <*O1*>	Is this <*S*> <*O2*>? Yes/No

Table 1: Our proposed template-based augmentations.

To achieve this goal, we apply two criteria: **(a)** The template should generate a grammatical English question; and **(b)** The generated question type should be included in the dataset, but not in questions that address the same semantic property as the original question. Indeed, yes/no questions are frequent in the VQA datasets, but few of them address color (first template), number of objects (second template), and object types (third template). When both criteria are fulfilled, it is reasonable to expect the model to generalize from its training set to the new question type.

Criterion (a) led us to focus on yes/no questions since other transformations required manual verification for output grammaticality. While we could have employed augmentation templates from additional question types into yes/no questions, we believe that our three templates are sufficient for evaluating model robustness. Overall, our templates cover 11% of the VQA examples (Section 3.1).

3 Robustness with RAD and CADs

In the following, we perform experiments to test the robustness of VQA models to augmentations. We describe the experimental setup, and evaluate VQAv2, VQA-CPv2, VisDial models, each on our augmentations and on other alternatives.[2]

3.1 Experimental Setup

Baseline Augmentations We compare our augmentations to three alternatives: VQA-Rephrasings (Reph, Shah et al., 2019), ConVQA (Ray et al., 2019), and back-translation (BT, Sennrich et al., 2016). VQA-Rephrasings is a manual generation method, where annotators augment each validation question with three re-phrasings. ConVQA is divided into the L-ConVQA and CS-ConVQA subsets. In both subsets, original validation examples are augmented to create new question-answer pairs. L-ConVQA is automatically generated based

[2]The URLs of the software and datasets, and the implementation details are all provided in Appendices C and D.

Dataset	Model\$\mathcal{D}'$	RAD$(\mathcal{D}, \mathcal{D}')$ (%)							Acc.

Table 2: RAD over our proposed augmentations (Y/N ← C, Y/N ← HM, Y/N ← WK) and alternatives (BT, Reph, ConVQA). The rows correspond to state-of-the-art models on VQA-CP (top), VQA (middle) and Visual Dialog (bottom). Reph and ConVQA were not created for VisDial, and it does not have "what kind" questions. The last column corresponds to validation accuracy.

Dataset	Model\$\mathcal{D}'$	Accuracy$(\mathcal{D})$ (%)						
		Y/N ← C	Y/N ← HM	Y/N ← WK	BT	Reph	L-ConVQA	CS-ConVQA
VQA-CP	RUBi	65.85	17.35	44.14	45.80	46.51	72.14	66.67
	LMH	68.87	44.24	50.58	52.35	53.78	65.07	61.76
	CSS	72.87	63.16	51.83	56.37	58.81	49.84	56.12
VQA	BUTD	79.44	54.43	63.49	60.37	62.23	75.05	62.42
	BAN	80.72	62.37	66.48	63.02	64.81	74.94	65.01
	Pythia	81.62	57.49	64.42	61.69	63.88	74.55	63.79
	VisualBERT	80.85	58.89	64.46	62.71	64.96	76.50	66.01
VisDial	FGA	55.62	40.00	-	61.53	-	-	-
	VisDialBERT	68.99	50.77	-	63.47	-	-	-

Table 3: Original accuracy over our proposed augmentations (Y/N ← C, Y/N ← HM, Y/N ← WK) and alternatives (BT, Reph, ConVQA). The rows correspond to state-of-the-art models on VQA-CP (top), VQA (middle) and Visual Dialog (bottom). Reph and ConVQA were not created for VisDial, and it does not have "what kind" questions.

on scene graphs attached to each image, and CS-ConVQA is manually generated by annotators. Finally, back-translation, translating to another language and back, is a high-coverage although low-quality approach to text augmentation. It was used during training and shown to improve NLP models (Sennrich et al., 2016), but was not considered in VQA. We use English-German translations.

Models The VQA-CP models we consider are RUBi (Cadene et al., 2019), LMH (Clark et al., 2019) and CSS (Chen et al., 2020). The VQA models we consider are BUTD (Anderson et al., 2018), BAN (Kim et al., 2018), Pythia (Jiang et al., 2018) and VisualBERT (Li et al., 2019). For VisDial we use FGA (Schwartz et al., 2019) and VisDialBERT (Murahari et al., 2020). We trained all the models using their official implementations.

3.2 Results

Table 2 presents our main results. RAD values for all of our augmentations are substantially lower than those of the alternatives, supporting the value of our focused intervention approach for measuring robustness. The high RAD values for BT and Reph might indicate that VQA models are indeed robust to linguistic variation, as long as the answer does not change. Interestingly, our augmentations also reveal that VQA-CP models are less robust than VQA models. This suggests that despite the attempt to design more robust models, VQA-CP models still overfit their training data.

In VQA-CP, RUBi has the lowest accuracy performance in terms of its validation accuracy, even though it is more robust to augmentations compared with LMH and CSS. For VQA models, in contrast, BUTD has the lowest RAD scores on our augmentations and the lowest accuracy. VisualBERT, the only model that utilizes contextual word embeddings, demonstrates the highest robustness among the VQA models.

Finally, while both VisDial models have similar accuracy, they have significantly different RAD scores on our augmentations. Specifically, VisDialBERT performs better than FGA on Y/N ← C

augmentations. This is another indication of the value of our approach as it can help distinguish between two seemingly very similar models.

Complementary to the RAD values in Table 2 we also provide accuracies on original questions in Table 3. Note that across all the original questions, except ConVQA questions, RUBi has the lowest accuracy while CSS has the highest accuracy. This trend is reversed when looking at RAD scores - CSS has the lowest score while RUBi has the highest score. This emphasizes the importance of RAD as a complementary metric, since considering only accuracy in this case would be misleading. Namely, RAD provides additional critical information for model selection.

4 Measuring Generalization with RAD

To establish the connection between RAD and generalization, we design experiments to demonstrate RAD's added value in predicting model accuracy on unseen modified examples. Concretely, we generate 45 BUTD (VQA) and LMH (VQA-CP) instances, differing by the distribution of question types observed during training (for each model instance we drop between 10% and 99% of each of the question types "what color", "how many" and "what kind" from its training data; see Appendix E for exact implementation details). For each of the above models we calculate RAD values and accuracies in the following manner.

We split the validation set into two parts: $\mathcal{D}$ (features) and $\mathcal{T}$ (target). Consider a pool of four original question sets that are taken from their corresponding modifications: Y/N ← C, Y/N ← HM, Y/N ← WK, Reph. Then we have four possible configurations in which $\mathcal{D}$ is three sets from the pool and $\mathcal{T}$ is the remaining set. For each model and for each configuration, we compute model accuracy on $\mathcal{D}$ ($\mathrm{Accuracy}(\mathcal{D})$) and on the modifications of questions in $\mathcal{T}$ (the predicted variable $y(\mathcal{T}) = \mathrm{Accuracy}(\mathcal{T}')$) which are modified with the target augmentation of the experiment. We also compute the RAD values of the model on the modified questions in $\mathcal{D}$ which are generated using the other three augmentations ($\mathrm{RAD}(\mathcal{D}, \mathcal{D}')$, and $\mathrm{RAD}(\mathcal{D}', \mathcal{D})$). Then, we train a linear regression model using $\mathrm{Accuracy}(\mathcal{D})$, $\mathrm{RAD}(\mathcal{D}, \mathcal{D}')$, and $\mathrm{RAD}(\mathcal{D}', \mathcal{D})$, trying to predict $y(\mathcal{T})$. We perform this experiment four times, each using a different configuration (different augmentation type as our target), and average across the configurations.

Features\Model	R^2
	LMH
$\mathrm{Accuracy}(\mathcal{D})$, $\mathrm{RAD}(\mathcal{D}, \mathcal{D}')$, $\mathrm{RAD}(\mathcal{D}', \mathcal{D})$	0.917 ± 0.117
$\mathrm{Accuracy}(\mathcal{D})$	0.829 ± 0.237
$\mathrm{RAD}(\mathcal{D}, \mathcal{D}')$	0.899 ± 0.133
$\mathrm{RAD}(\mathcal{D}', \mathcal{D})$	0.849 ± 0.213

Table 4: Linear regression experiments, predicting accuracy performance on unseen augmentation types.

Results Table 4 presents the average R^2 values and standard deviations over the four experiments. RAD improves the R^2 when used alongside the validation accuracy. Interestingly, a model's accuracy on one set of augmentations does not always generalize to other, unseen augmentations. Only when adding RAD to the regression model are we able to identify a robust model. Notably, for LMH the usefulness of RAD is significant, as it improves the R^2 by 11%. It also predicts performance better than validation accuracy when used without it in the regression. The standard deviations further confirm that the above claims hold over all configurations. These observations hold when running the same experiment with respect to the BUTD model, however, the improvements are smaller since the regression task is much easier with respect to this model (R^2 of 0.995 with all features).

5 Conclusion

We proposed RAD, a new measure that penalizes models for inconsistent predictions over data augmentations. We used it to show that state-of-the-art VQA models fail on CADs that we would expect them to properly address. Moreover, we have demonstrated the value of our CADs by showing that alternative augmentation methods cannot identify robustness differences as effectively. Finally, we have shown that RAD is predictive of generalization to unseen augmentation types.

We believe that the RAD measure brings substantial value to model evaluation and consequently to model selection. It encourages the good practice of testing on augmented data, which was shown to uncover considerable model weaknesses in NLP (Ribeiro et al., 2020). Further, given visual augmentations, which we plan to explore in future work, or linguistic augmentations, RAD is applicable to any classification task, providing researchers with meaningful indications of robustness.

A Dataset Statistics

Please see Table 5 for the number of examples in each dataset that we use (VQA, VQA-CP and VisDial). We also report the number of augmentations we produce for each of our three augmentation types (Y/N ← C, Y/N ← HM and Y/N ← WK), alongside previous augmentation approaches used in our experiments (BT, Reph, L-ConVQA and CS-ConVQA).

B Our Augmentations

We describe the manual steps required to meet the desired standard for each augmentation type. For Y/N ← C, we filter out questions that start with "What color is the". For Y/N ← HM, we use questions that starts with "How many". For Y/N ← WK, we consider questions that match the pattern "What kind of <*S*> is this? <*O1*>". Table 6 presents several realizations of the templates we define (see Section 2.2 for a discussion of these templates).

In Y/N ← HM, we ensure that when the answer is '1', we use "Is there ..." instead of "Are there ...". We also ensure that the subsequent word to "How many" is a noun. We verify it is a noun using the part-of-speech tagger available through the spaCy library (Honnibal et al., 2020).

We allow the generation of both 'yes' and 'no' answers. Creating a modified question that is answered with a 'yes' requires a simple permutation of words in the original question-answer pair, e.g., for Y/N ← C, take "<*C1*>" = "<*C2*>" (see Table 1). Similarly, to generate a question that should be answered with a 'no', we repeat the above process and change "<*C2*>". In this case, we randomly pick an answer and replace it with the original answer with probability weighted with respect to the frequency in the data, among the pool of possible answers for the given augmentation type. When generating a new question, we first randomly decide whether to generate a 'yes' or 'no' question (with a probability of 0.5 for each). Then, for example, if we choose to generate a 'no', and "<*C1*>" = "red", we have a 63% chance of having "<*C2*>" = "blue".

C URLs of Data and Code

Data We consider three VQA datasets:

- The VQAv2 dataset (Goyal et al., 2017): https://visualqa.org/.
- The VQA-CPv2 dataset (Agrawal et al., 2018): https://www.cc.gatech.edu/grads/a/aagrawal307/vqa-cp/.
- The VisDial dataset (Das et al., 2017): https://visualdialog.org/

We also consider three previous augmentation methods:

- VQA-Rephrasings (Shah et al., 2019): https://facebookresearch.github.io/VQA-Rephrasings/.
- ConVQA (Ray et al., 2019): https://arijitray1993.github.io/ConVQA/.
- Back-translations (Sennrich et al., 2016). We have generated these utilizing the transformers library (Wolf et al., 2020), https://github.com/huggingface/transformers. Specifically, we used two pre-trained translation models, English to German, and German to English: https://huggingface.co/Helsinki-NLP/opus-mt-en-de, https://huggingface.co/Helsinki-NLP/opus-mt-de-en.

Models We consider nine models, where each model's code was taken from the official implementation. All implementations are via PyTorch (Paszke et al., 2019).

The three VQA-CPv2 models:

- RUBi (Cadene et al., 2019): https://github.com/cdancette/rubi.bootstrap.pytorch.
- LMH (Clark et al., 2019): https://github.com/chrisc36/bottom-up-attention-vqa.
- CSS (Chen et al., 2020): https://github.com/yanxinzju/CSS-VQA.

The four VQAv2 models:

- BUTD (Anderson et al., 2018): https://github.com/hengyuan-hu/bottom-up-attention-vqa.
- BAN (Kim et al., 2018): https://github.com/jnhwkim/ban-vqa.
- Pythia (Jiang et al., 2018): Using the implementation in the MMF library (Singh et al., 2020), https://github.com/facebookresearch/mmf.
- VisualBERT (Li et al., 2019): Using the implementation in the MMF library.

And the two VisDial models:

Dataset	Augmentation Count							Validation Count
	Y/N ← C	Y/N ← HM	Y/N ← WK	BT	Reph	L-ConVQA	CS-ConVQA	
VQA-CP	12,910	13,437	1,346	149,329	39,936	127,924	423	219,928
VQA	12,835	10,233	1,654	138,043	121,512	127,924	1,365	214,354
VisDial	516	130	-	1,136	-	-	-	20,640

Table 5: Number of examples in each of the datasets we use.

Yes/No ← Colors	Yes/No ← How Many	Yes/No ← What Kind
What color is the cat? White Is the color of the cat white? Yes	How many athletes are on the field? 5 Are there five athletes on the field? Yes	What kind of food is this? Breakfast Is this food breakfast? Yes
What color is the court? Green Is the color of the court green? Yes	How many dogs are in the picture? 3 Are there two dogs in the picture? No	What kind of event is this? Skiing Is this a skiing event? Yes
What color is the vase? Blue Is the color of the vase red? No	How many giraffes are walking around? 2 Are there four giraffes walking around? No	What kind of animal is this? Cow Is this animal an elephant? No
What color is the man's hat? Red Is the color of the man's hat red? Yes	How many cakes are on the table? 0 Is there one cake on the table? No	What kind of building is this? Church Is this building a church? Yes
What color is the sky? Blue Is the color of the sky blue? Yes	How many dogs? 1 Are there zero dogs? No	What kind of floor is this? Wood Is this a wood floor? Yes

Table 6: Some realizations of our templates (defined in Table 1). The black text (top) is the original question-answer pair and the blue text (bottom) is the corresponding augmented question-answer pair.

- FGA (Schwartz et al., 2019): `https://github.com/idansc/fga`.
- VisDialBERT (Murahari et al., 2020): `https://github.com/vmurahari3/visdial-bert`.

D Model Settings

We have trained the VQAv2 and the VQA-CPv2 models that we use, as pre-trained weights were not available for our requirements. For our evaluations, we require a model that is trained solely on the VQAv2 train set, such that we match the VQA-CPv2 settings, where there are only two sets, train and validation. In contrast, pre-trained models that are built for VQAv2 are trained on the VQAv2 training set and on the VQAv2 validation set together, as the dataset contains a third development set that is commonly used for validation.

We have trained six VQA models using the default hyper-parameters from their official implementations (URLs in Appendix C): RUBi, LMH, CSS, BUTD, BAN and Pythia. We trained the above models on a single Nvidia GeForce RTX 2080 Ti GPU, when the training time for each of the models was less than 12 hours. In addition, inference in this setting took less than an hour for all models.

The VisualBERT model is more computationally intensive, and we had to reduce the default batch size from 480 to 54 to fit it on our resources. Using three Nvidia GeForce RTX 2080 Ti GPUs for VisualBERT, training took 36 hours and inference took 4 hours.

For the VisDial models, FGA, and VisDialBERT, we have downloaded the pre-trained weights and used them solely for inference. On a single Nvidia GeForce RTX 2080 Ti GPU, inference took 15 minutes for FGA, and 8 hours for VisDialBERT.

All the models we consider have less than 200M parameters.

When accuracies are reported on VQAv2 and on VQA-CP (Tables 2 and 3) we use the VQA-accuracy metric (Antol et al., 2015). For VisDial we use the standard accuracy metric (denoted originally as R@1).

E Regression Experiments

We generate 45 BUTD (VQA) instances and 45 LMH (VQA-CP) instances. To generate different model instances, we create 45 new training sets by removing examples from the original train set. For each of the three question types, "what color", "how many" and "what kind", we remove the following 15 percentage values of examples from the original train set: [10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, 92%, 95%, 96%, 97%, 98%, 99%], resulting in 45 new training sets. Then, each model instance is created by training on one of the 45 training sets.

We split the validation set into two parts: $\mathcal{D}$ and $\mathcal{T}$. $\mathcal{D}$ is used to calculate the features in our linear

regression model. We denote with $\mathcal{D}'_1$ the questions in $\mathcal{D}$ that can be modified using the Y/N $\leftarrow$ C augmentation, after these questions were modified. Similarly, we define $\mathcal{D}'_2$, $\mathcal{D}'_3$, and $\mathcal{D}'_4$ for Y/N $\leftarrow$ HM, Y/N $\leftarrow$ WK, and Reph, respectively.

We average the R^2 of four linear regression experiments, when in each experiment we set a different i ($i \in \{1, 2, 3, 4\}$) for which $\mathcal{T} = \mathcal{D}'_i$ and use the remaining three templates to calculate our features. We denote the regression features with $x_1 = \mathrm{Accuracy}(\mathcal{D})$, $x_2 = \mathrm{RAD}(\mathcal{D}, \mathcal{D}')$, and $x_3 = \mathrm{RAD}(\mathcal{D}', \mathcal{D})$, where $\mathrm{RAD}(\mathcal{D}, \mathcal{D}')$ and $\mathrm{RAD}(\mathcal{D}', \mathcal{D})$ are computed with respect to the three other templates ($j \in \{1, 2, 3, 4\}, j \neq i$). The predicted label is $y(\mathcal{T}) = \mathrm{Accuracy}(\mathcal{T})$.

Thus the equation for our regression is:

$$y(\mathcal{T}) = b_1 x_1 + b_2 x_2 + b_3 x_3 + \epsilon \ .$$

We also perform three regression experiment for each feature alone:

$$y(\mathcal{T}) = b x_k + \epsilon, \quad k = 1, 2, 3 \ ,$$

and compare the results of these experiments in Table 4.

How Helpful is Inverse Reinforcement Learning for Table-to-Text Generation?

Abstract

Existing approaches for the Table-to-Text task suffer from issues such as missing information, hallucination and repetition. Many approaches to this problem use Reinforcement Learning (RL), which maximizes a single manually defined reward, such as BLEU. In this work, we instead pose the Table-to-Text task as Inverse Reinforcement Learning (IRL) problem. We explore using multiple interpretable unsupervised reward components that are combined linearly to form a composite reward function. The composite reward function and the description generator are learned jointly. We find that IRL outperforms strong RL baselines marginally. We further study the generalization of learned IRL rewards in scenarios involving domain adaptation. Our experiments reveal significant challenges in using IRL for this task.

1 Introduction

Table-to-Text generation focuses on explaining tabular data in natural language. This is increasingly relevant due to the vast amounts of tabular data created in domains including e-commerce, healthcare and industry (for example, infoboxes in Wikipedia, tabular product descriptions in online shopping sites, etc.). Table-to-Text can make data easily accessible to non-experts and can automate certain pipelines like auto-generation of product descriptions. Traditional methods approached the general problem of converting structured data to text using slot-filling techniques (Kukich, 1983; Reiter and Dale, 2000; McKeown, 1992; Cawsey et al., 1997; Konstas and Lapata, 2013; Flanigan et al., 2016). While recent advances in data-to-text generation using neural networks (Sutskever et al., 2011; Mei et al., 2015; Gardent et al., 2017; Wiseman et al., 2017; Song et al., 2018; Zhao et al., 2020) have led to improved fluency, current systems still suffer from issues such as lack of coverage (where the generated text misses information present in the source), repetition (where the generated text repeats information) and hallucination (where the generated text asserts information not present in the source)(Lee et al., 2019). A significant reason for these issues is that models often lack explicit inductive biases to avoid these problems. Most extant approaches utilize Reinforcement Learning-based (RL) training, using a single reward (such as BLEU or task-specific rewards) that optimizes for a specific aspect. For example, Liu et al. (2019) and Nishino et al. (2020) use domain-specific rewards to improve the accuracy of medical report generation.

However, defining a single reward that addresses all of the above-described issues is difficult. To use multiple reward components with RL, one has to manually find an optimal set of weights of each component either through a trial-and-error approach or expensive grid search which gets infeasible as the number of such reward components increases. Inverse Reinforcement Learning (Abbeel and Ng, 2004; Ratliff et al., 2006; Ziebart et al., 2008) can be a natural approach for this task since it can learn an underlying composite reward function from labeled examples incorporating multiple rewards. Motivated by existing applications of IRL in other domains and tasks (Finn et al., 2016; Fu et al., 2017; Shi et al., 2018), we explore its utility for Table-to-Text generation. We diverge from previous work on IRL in designing a set of intuitive and interpretable reward components that are linearly combined to get the reward function. Figure 1 illustrates the overall idea of this work. We learn a "Description Generator" (also referred as policy later) to generate descriptions given a table. The IRL framework includes "Reward Approximator" that leverages the "expert" or the ground-truth de-

scriptions corresponding to tables to jointly learn the underlying composite reward function combining multiple reward components such as "Recall", "Fluency", etc. This composite reward function quantifies the quality of the generated descriptions. We see IRL performs at par with RL baselines. For investigating when IRL helps and when it does not, we conduct experiments to evaluate generalization capabilities of IRL in limited data setting and identify challenges involved in IRL training. Our contributions are:

- We formulate a set of interpretable reward components and learn the composite linear reward function in a data-driven manner for Table-to-Text generation[1].
- We study the utility of IRL for Table-to-Text generation.

2 Method

The training data for this task consists of pairs of tables and corresponding natural language descriptions, as shown in Figure 1. A table T is a sequence of tuples of slot types (e.g. "Name") and slot values (e.g. "Asgar") and let D denote the expert description. We formulate the "Table-to-Text" task as generating D from source table T. In the rest of this section, we first explain how to formulate Table-to-Text under the IRL framework, followed by the formulation of the reward components and a brief description of the text generation network that is at the core of our method.

2.1 Table-to-Text as IRL

We pose Table-to-Text under the IRL framework where we aim to jointly learn a policy for generating description from the table and the underlying composite reward function. At the core of our approach, we have a neural description generator that we adapt from Wang et al. (2018). The description generator is first trained using maximum likelihood estimation (MLE) followed by fine-tuning it using Maximum Entropy Inverse Reinforcement Learning (MaxEnt IRL) (Ziebart et al., 2008). Under the MaxEnt IRL framework, we iteratively perform two steps: (1) approximate the underlying composite reward function by leveraging the expert descriptions and the current policy for description generation; (2) Using the updated reward function, we update the current policy for description generation using RL. In this work, we model the composite reward $R_\phi(D)$ as a linear combination of multiple reward components.

$$R_\phi(D) = \sum_{t=1}^{\tau} \phi^\intercal C^t \tag{1}$$

where ϕ is a weight vector, C^t is the vector of reward component values at step t in a generated description and τ denotes total steps.

Following the MaxEnt IRL paradigm, we assume the expert descriptions come from a log-linear distribution ($p_\phi(D)$) on reward values. The objective of the reward approximator ($J_r(\phi)$) is to maximize the likelihood of the expert descriptions. The partition function for this distribution ($p_\phi(D)$) is approximated by using importance sampling from the learned description generation policy. For sake of brevity, we skip the mathematical derivation here. Please refer to Appendix A.1 for detailed derivation. We draw N expert descriptions and M descriptions from the learned policy. The gradient of the objective ($J_r(\phi)$) w.r.t. reward function parameters ϕ is then the difference between the expected expert reward and expected reward obtained by the policy (Ziebart et al., 2008):

$$\nabla_\phi J_r(\phi) = \frac{1}{N}\sum_{i=1}^{N} \nabla_\phi R_\phi(D_i) - \frac{1}{\sum_j \beta_j}\sum_{j=1}^{M} \beta_j \nabla_\phi R_\phi(D'_j) \tag{2}$$

where D_i and D'_j are drawn from the training data and the learned policy respectively and β's are importance sampling weights.

[1]Code and dataset splits for the paper are provided in https://github.com/issacqzh/IRL_Table2Text

The linear functional form of the reward simplifies individual weight updates as a simple difference of the expected expert and the expected roll out reward component from policy. Weight update for component c is:

$$\nabla_\phi J_r(\phi)_c = \frac{1}{N}\sum_{i=1}^{N} c_i - \frac{1}{\sum_j \beta_j}\sum_{j=1}^{M} \beta_j c'_j \quad (3)$$

where c_i is total value of reward component over all steps for i^{th} expert description and c'_j is total value of reward component over all steps for j^{th} generated description. To stabilize training when learning the policy for description generation we mix in weighted MLE loss with the policy gradient loss before backpropagation. Please refer to supplementary material (Appendix A.5) for model training details.

2.2 Reward Components

We aim to find a reward function that can combine multiple characteristics present in a good description such as faithfulness to the table and fluency. To encourage faithfulness, we use *recall* and *reconstruction* as reward components, while to characterize grammatical correctness and fluency we use *repetition* and *perplexity*. We also consider *BLEU* score as a reward component. BLEU is a supervised reward component as it requires ground-truth descriptions for its computation. However, all other reward components are unsupervised.

- **Recall:** Fraction of slot values in the table mentioned in the description.
- **Reconstruction:** We use QA models to extract answers from the description against a few "extractor" slot types (for example, "What is the name of the person in the description?" is used as a question for the slot type "Name_ID"). Details about other extractor slot types are provided in Appendix A.3. Reconstruction score is the average of lexical overlap scores between predicted and true slot values, corresponding to the extractor slot types present in the table.
- **Repetition:** Fraction of unique trigrams in the description.
- **Perplexity:** This is the normalized perplexity of the description calculated using GPT-2 model (Radford et al., 2019).
- **BLEU:** This is the BLEU score (Papineni et al., 2002) of the description.

Additional details on implementation of reward components are in Appendix A.3.

3 Experiments and Results

In this section we describe our experiments and their results in detail.

3.1 Data and Metrics

Wang et al. (2018) proposed a dataset of tables and their corresponding descriptions related to people and animals from Wikipedia. However, the original released dataset is noisy (many descriptions have low precision/recall, most examples have very few distinct slot types, etc.). For our experiments, we filtered this dataset to get a smaller high-quality dataset of 4623 examples using the following criteria : (1) Recall (defined in §2.2) of 1.0 (2) High precision (fraction of entities in the description mentioned in the table) greater than 0.7 (3) number of distinct slot types greater than 6. We split the entire dataset as 80%, 10% and 10% for training, validation and testing respectively. Details of the dataset are provided in Appendix A.2. To aid reproducibility we make the data splits used by us publicly available[2].

For evaluation, we report BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) along with their harmonic mean (called F1 hereon). Additionally, we report the mean reward value for Recall and Perplexity as proxies for faithfulness and fluency of generated descriptions respectively.

3.2 Automatic Evaluation

Table 1 shows the performance of models trained using maximum likelihood estimation (MLE), RL

[2]Data splits are provided in https://github.com/issacqzh/IRL_Table2Text

and IRL. For RL and IRL we report results with various sets of reward components. When using multiple reward components with RL we consider the total reward as the uniformly weighted sum of each component. We note that while IRL variants achieve higher performance than RL methods for all metrics, the gain in performance is marginal.

In Table 1 we choose the best model for each setting based on the performance on the validation split. For the best IRL (All) model, we find the learned weights for repetition, recall, BLEU, reconstruction and perplexity are 0.02, 0.12, 0.65, 0.05 and 0.15 respectively. However, we noticed that the weights of the IRL reward components failed to converge in our training runs. This is a consequence of the fact that reward components such as BLEU achieve their maximum value for the ground-truth description, and the value quickly drops as descriptions diverge from the ground truth description. Thus the gap between the expert value and the value achieved by the model for BLEU is always large, hindering the convergence of weights in IRL (Eqn 3). This results in a peaked distribution of weights where the model tends to favor the BLEU reward component excessively. We attempt scaling down the expert BLEU reward values by using multiplier. We dynamically update the multiplier using an adaptive binary search method (refer to Appendix A.4 for details) to induce convergence in weights. We observe that the multiplier acts as a "regularizer" in learning a more balanced weight for the reward components considered. For example, when we train IRL with BLEU, recall and perplexity without using multiplier, the learned weights of the components are 0.72, 0.15 and 0.13 respectively. On using multipliers for IRL training, the learned weights for BLEU, recall and perplexity are 0.45, 0.31 and 0.24 respectively. The model variants using multipliers get the best F1 score as seen in the second last row of Table 1.

We also find that having more reward components does not help IRL improve significantly. We note that IRL using all reward components gets the best BLEU but suffers a marginal drop in ROUGE.

3.3 Domain adaptation

To evaluate if rewards learned using IRL generalize better to unseen data distributions, we evaluate it for scenarios involving domain adaptation. For this, we divide the dataset into disjoint subsets of categories involving people in sports, academia, art, etc. (category details in Appendix A.2). Each category has different table schemas. We train RL and IRL models on one category and test them on a different category. Since training on a single category limits the amount of labelled data, we consider training with unsupervised rewards that do not rely on the ground truth. Table 2 shows the F1 results when using IRL and RL with recall, perplexity and reconstruction. For each training category, we show results of the test category with the highest absolute value of relative change in F1. We notice mixed results. For instance, when training on the "Sports" domain, IRL's performance is much worse than RL. This may be because slot types with high frequency in the "Sports" category are significantly different from all other categories. Thus, IRL may be susceptible to learning a reward function that overfits the domain and actually generalizes worse than a fixed reward function. However, in several cases IRL leads to big improvements in performance (e.g. when training on Politics, Law, and Military) indicating the promise of this method in limited data settings.

TRAIN CAT.	TEST CAT.	RL	IRL
Politics	Sports	18.59	**21.04**
Law	Academia	28.54	**31.17**
Military	Politics	30.07	**32.01**
Art	Academia	**32.78**	31.37
Academia	Sports	**21.25**	20.67
Sports	Academia	**24.43**	22.25

Table 2: F1 scores on using IRL and RL for domain adaptation. IRL leads to higher F1 scores in a few settings indicating its usefulness for domain adaptation. However, IRL performs worse than RL when trained on domains which have significantly different slot types with high frequency (e.g. "Sports").

4 Discussion

We highlight some challenges with IRL training that potentially hinder IRL to get significantly better than RL baselines. Further, we discuss qualitative differences between RL and IRL models.

4.1 Challenges in IRL training

Importance of reward components: During training, for most reward components, their values for expert and generated descriptions are close. However, the values of BLEU for generated descriptions are quite smaller than the BLEU value for expert descriptions. This shadows the contribution of other reward components irrespective of

the weights assigned to them. Since BLEU optimizes for n-gram overlap with the expert text, it is undesirable to drop this component as it leads to text degeneration. As described in Section 3.2, we use adaptive multipliers to alleviate its dominance. However, its effect is limited and the method does not correspond to optimizing a fixed objective.

Unstable training: To stabilize training, we mix the weighted MLE loss (cross-entropy loss) and the policy gradient objective. However, these losses can differ largely in scale. Having a larger weight to MLE loss diminishes the contribution of reward components, while larger weight to policy gradient leads to degeneration.

These observations indicate the need for future research on training paradigms and better-designed reward components to address these challenges.

4.2 Qualitative analysis

Using only BLEU as a reward leads to generated descriptions that fit a general template resembling descriptions from the most common category ("Sports"). Including other reward components helps the model avoid this behavior. We still observe hallucination from both IRL and RL fine-tuned models. However, hallucinated information generated from IRL fine-tuned models often matches the overall theme (for example, it generates incorrect football league names but gets the name of the club mentioned in the table correct). Appendix A.7 shows an example of description generated by IRL (All) model.

5 Conclusion

We present an approach using IRL for Table-to-Text generation using a set of interpretable reward components. While the approach outperforms RL, improvements are marginal, and we identify several challenges. In particular, using metrics like BLEU as reward components is problematic, since they affect weight convergence for IRL. Based on our study, the application of IRL for Table-to-Text generation would broadly benefit from designing better-calibrated reward components and improvements in training paradigms. We hope our exploration encourages the community to engage in interesting directions of future work.

A Appendices

A.1 Derivation of gradient for MaxEnt IRL

We show the detailed mathematical steps to approximate the gradient calculation under the MaxEnt IRL framework for Table-to-Text generation.

We assume that expert descriptions are drawn from a distribution $p_\phi(D)$.

$$p_\phi(D) = \frac{1}{Z} exp(R_\phi(D)) \text{ and } Z = \int_D exp(R_\phi(D)) \quad (4)$$

where the reward function, $R_\phi(D)$ has parameters ϕ, and Z is the partition function. The total reward

of a description is sum of rewards at each step. Let $q_\theta(D)$ be the policy for description generation. We maximise the log-likelihood of the samples in the training set (Equation 5).

$$J_r(\phi) = \frac{1}{N}\sum_{n=1}^{N} log(p_\phi(D_n)) = \frac{1}{N}\sum_{n=1}^{N} R_\phi(D_n) - logZ \tag{5}$$

The gradient w.r.t. reward parameters is given by

$$\begin{aligned}\nabla_\phi J_r(\phi) &= \frac{1}{N}\sum_{n} \nabla_\phi R_\phi(D_n) \\ &\quad - \frac{1}{Z}\int_D exp(R_\phi(D))\nabla_\phi R_\phi(D) dD \\ &= \mathbb{E}_{D\sim p_{data}} \nabla_\phi R_\phi(D) - \mathbb{E}_{D\sim p_{\phi(D)}} \nabla_\phi R_\phi(D)\end{aligned} \tag{6}$$

The partition function requires enumerating all possible descriptions which makes this intractable. This is tackled by approximating the partition function by sampling descriptions from the policy using importance sampling. The importance weight β_i for a generated description D_i is given by

$$\beta_i \propto \frac{exp(R_\phi(D_i))}{q_\theta(D_i)} \tag{7}$$

The gradient is now approximated as:

$$\nabla_\phi J_r(\phi) = \frac{1}{N}\sum_{i=1}^{N} \nabla_\phi R_\phi(D_i) - \frac{1}{\sum_j \beta_j}\sum_{j=1}^{M} \beta_j \nabla_\phi R_\phi(D'_j) \tag{8}$$

where D_i and D'_j are drawn from training data and $q_\theta(D)$ respectively.

A.2 Dataset statistics

We split the entire dataset as 80%, 10% and 10% for training, validation and testing respectively. Table 3 shows the statistics for our dataset.

Table 4 shows the various disjoint category splits of our data.

A.3 Detailed description of some reward components

- **Reconstruction:** We use Question Answering models to extract answers from the description corresponding to few slot types. For example, to extract the name from the description we ask a question "What is the name of the person?". The questions corresponding to each slot type is pre-determined. We extract values for four most common slot types occurring in the dataset – "name", "place of birth", "place of death" and "country". We will refer to these slots as "extraction slot types". The questions for these extractor slot types are "What is the name of the person in the description?", "What is the place of birth of the person in the description?", "What is the place of death of the person in the description?" and "Which country does the person in the description belong to?" respectively. All extraction slot types are not present in every table of the dataset (example, "place of death" is not present for a living sportsperson). Following SQUAD-like (Rajpurkar et al., 2018) formalisation, for each slot-type we train a BERT-based (Devlin et al., 2019) model to get the answer from the description given the question. We calculate overlap score of predicted answer with the correct answer (slot value from table). The final reconstruction score is the arithmetic mean of answer overlap scores corresponding to the extractor slot types present in the table.
- **Perplexity:** This is the negative perplexity of the description. We further normalize it by using

$$\frac{\text{Perplexity} - \text{Perplexity}_{low}}{\text{Perplexity}_{high} - \text{Perplexity}_{low}} \tag{9}$$

where Perplexity_{high} and Perplexity_{low} are the maximum and minimum perplexity of expert texts and texts generated by pretrained MLE model respectively.

A.4 Learning Multiplier for BLEU

Let us assume that after the i^{th} iteration of IRL, we have the multiplier value as m_i. Let b be the average BLEU score obtained by the model. For $(i+1)^{th}$ iteration we update the multiplier value as

$$m_{i+1} = \frac{m_i + b}{2} \tag{10}$$

In case the change in weight is less than 0.00001, we instead increase multiplier value by 0.1. The maximum of multiplier value is 1. We start with initial multiplier value (m_0) as 1.

A.5 Training details

Model parameters We follow the same training scheme and model parameters from Wang et al. (2018). Our model roughly has around 7.8M parameters. We perform MLE for 20 epochs. For RL finetuning we perform 100 epochs. For the IRL

model, we perform two weight updates followed by five RL epochs and this is repeated 20 times. For training we use Adam optimizer (Kingma and Ba, 2014). We choose the hyperparameters and best epoch for each model by obtaining results on the validation set using beam search with beam size of 3.

Hyper-parameter tuning We adapt the model and optimizer hyper-parameters from Wang et al. (2018). For choosing the weights for cross-entropy loss and policy gradient loss we tried combinations in the set 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9 keeping sum of weights as 1. For IRL reward component weight updates we sample 500 descriptions from ground-truth and from the descriptions generated from the policy. We chose the size as 500 based on validation set performance. Based on the performance on the validation set we chose 0.9 as policy gradient loss weight and 0.1 for cross-entropy loss. This also helps to bring both the loss terms in same scale.

Software and hardware specifications All the models are coded using Pytorch 1.4.0[3] (Paszke et al., 2019) and related libraries like numpy (Oliphant, 2006), scipy (Virtanen et al., 2020) etc. We run all experiments on GeForce RTX 2080 GPU of size 12 GB. The system has 256 GB RAM and 40 CPU cores.

Time for training and inference It takes around 16 seconds for one epoch of MLE training while it takes close to 150 seconds for an epoch when using RL fine-tuning with all the reward components. The reward component weight approximation stage of IRL is very fast and takes less than a second generally.

Automatic Fake News Detection: Are Models Learning to Reason?

Abstract

Most fact checking models for automatic fake news detection are based on reasoning: given a claim with associated evidence, the models aim to estimate the claim veracity based on the supporting or refuting content within the evidence. When these models perform well, it is generally assumed to be due to the models having learned to reason over the evidence with regards to the claim. In this paper, we investigate this assumption of reasoning, by exploring the relationship and importance of both claim and evidence. Surprisingly, we find on political fact checking datasets that most often the highest effectiveness is obtained by utilizing only the evidence, as the impact of including the claim is either negligible or harmful to the effectiveness. This highlights an important problem in what constitutes evidence in existing approaches for automatic fake news detection.

1 Introduction

Misinformation is spreading at increasing rates (Vosoughi et al., 2018), particularly online, and is considered a highly pressing issue by the World Economic Forum (Howell et al, 2013). To combat this problem, automatic fact checking, especially for estimating the veracity of potential fake news, have been extensively researched (Hassan et al., 2017; Hansen et al., 2019; Thorne and Vlachos, 2018; Elsayed et al., 2019; Allein et al., 2020; Popat et al., 2018; Augenstein et al., 2019). Given a claim, most fact checking systems are *evidence-based*, meaning they utilize external knowledge to determine the claim veracity. Such external knowledge may consist of previously fact checked claims (Shaar et al., 2020), but it typically consists of using the claim to query the web through a search API to retrieve relevant hits. While including the evidence in the model increases the effectiveness over using only the claim, existing work has not focused on the predictive power of isolated evidence, and hence whether it assists the model in enabling better reasoning.

In this work we investigate if fact checking models learn reasoning, i.e., provided a claim and associated evidence, whether the model determines the claim veracity by reasoning over the evidence. If the model learns reasoning, we would expect the following proposition to hold: *A model using both the claim and evidence should perform better on the task of fact checking compared to a model using only the claim or evidence*. If a model is only given the claim as input, it does not necessarily have the information needed to determine the veracity. Similarly, if the model is only given the evidence, the predictive signal must come from dataset bias or the differences in the evidence obtained from claims with varying veracity, as it otherwise corresponds to being able to provide an answer to an unknown question. In our experimental evaluation on two political fact checking datasets, across multiple types of claim and evidence representations, we find the evidence provides a very strong predictive signal independent of the claim, and that the best performance is most often obtained while entirely ignoring the claim. This highlights that fact checking models may not be learning to reason, but instead exploit an inherent signal in the evidence itself, which can be used to determine factuality independent of using the claim as part of the model input. This highlights an important problem in what constitutes evidence in existing approaches for automatic fake news detection. We make our code publicly available[1].

2 Related Work

Automatic fact checking models include deep learning approaches, based on contextual and non-contextual embeddings, which encode the claim and evidence using RNNs or Transformers (Shaar et al., 2020; Elsayed et al., 2019; Allein et al., 2020; Popat et al., 2018; Augenstein et al., 2019; Hassan et al., 2017), and non-deep learning approaches (Wang, 2017; Pérez-Rosas et al., 2018), which uses hand-crafted features or bag-of-word representations as input to traditional machine learning classifiers such as random forests, SVM, and MLP (Mihalcea and Strapparava, 2009; Pérez-Rosas et al., 2018; Baly et al., 2018; Reddy et al., 2018).

Generally, models may learn to memorize artifact and biases rather than truly learning (Gururangan et al., 2018; Moosavi and Strube, 2017; Agrawal et al., 2016), e.g., from political individuals often leaning towards one side of the truth spectrum. Additionally, language models have been shown to implicitly store world knowledge (Roberts et al., 2020), which in principle could enhance the aforementioned biases. To this end, we design our experimental setup to include representative fact checking models of varying complexity (from simple term-frequency based representations to contextual embeddings), while always evaluating each trained model on multiple different datasets to determine generalizability.

3 Methods

Problem definition. In automatic fact checking of fake news we are provided with a dataset of $D = \{(c_1, e_1, y_1), ..., (c_n, e_n, y_n)\}$, where c_i corresponds to a textual claim, e_i is evidence used to support or refute the claim, and y_i is the associated truth label to be predicted based on the claim and evidence. Following current work on fact checking of fake news (Hassan et al., 2017; Thorne and Vlachos, 2018; Elsayed et al., 2019; Allein et al., 2020; Popat et al., 2018; Augenstein et al., 2019), we consider the evidence to be a list of top-10 search snippets as returned by Google search API when using the claim as the query. Note that while additional metadata may be available–such as speaker, checker, and tags–this work focuses specifically on whether models learn to reason based on the combination of claim and evidence, hence we keep the input representation to consist only of the latter.

Overview. In the following we describe the different models used for the experimental comparison (Section 4), which consists of models based on term frequency (term-frequency weighted bag-of-words (Salton and Buckley, 1988)), word embeddings (GloVe word embeddings (Pennington et al., 2014)), and contextual word embeddings (BERT (Devlin et al., 2019)). These representations are chosen as to include the typical representations most broadly used among past and current NLP models.

Term-frequency based Random Forest. We construct a term-frequency weighted bag-of-words representation per sample based on concatenating the text content of the claim and associated evidence snippets. We train a Random Forest (Breiman, 2001) as the classifier using the Gini impurity measure. In the setting of only using either the claim or evidence snippets as the input, only the relevant part is used for constructing the bag-of-words representation.

GloVe-based LSTM model. We adapt the model by Augenstein et al. (2019), which originally was proposed for multi-domain veracity prediction. Using a pretrained GloVe embedding (Pennington et al., 2014)[2], claim and snippet tokens are embedded into a joint space. We encode the claim and snippets using an attention-weighted bidirectional LSTM (Hochreiter and Schmidhuber, 1997):

$$h_{c_i} = \text{attn}\left(\text{BiLSTM}(c_i)\right) \quad (1)$$

$$h_{e_{i,j}} = \text{attn}\left(\text{BiLSTM}(e_{i,j})\right) \quad (2)$$

where attn$(\cdot)$ is a function that learns an attention score per element, which is normalized using a softmax, and returns a weighted sum. We combine the claim and snippet encodings using using the matching model by Mou et al. (2016) as:

$$s_{i,j} = \left[h_{c_i} \; ; \; h_{e_{i,j}} \; ; \; h_{c_i} - h_{e_{i,j}} \; ; \; h_{c_i} \cdot h_{e_{i,j}}\right] \quad (3)$$

where ";" denotes concatenation. The joint claim-evidence encodings are attention weighted and summed, projected through a fully connected layer into $\mathbb{R}^L$, where L is the number of possible labels:

$$o_i = \text{attn}([s_{i,1} \; ; \; ... \; ; \; s_{i,10}]) \quad (4)$$

$$p_i = \text{softmax}\left(\text{FC}(o_i)\right) \quad (5)$$

Lastly, the model is trained using cross entropy as the loss function. In the setting of using only the claim as the input (i.e., without the evidence), then h_{c_i} is used in Eq. 5 instead of o_i. If only the

evidence is used, then an attention weighted sum of the evidence snippet encodings is used in Eq. 5 instead of o_i.

BERT-based model. In a similar fashion to the LSTM model, we construct a model based on BERT (Devlin et al., 2019)[3], where the `[CLS]` token encoding is used for claim and evidence representations. Specifically, the claim and evidence snippets are encoded as:

$$h_{c_i} = \text{BERT}(c_i),\ h_{e_{i,j}} = \text{BERT}(c_i, e_{i,j}) \quad (6)$$

$$h_{e_i} = \text{attn}([h_{e_{i,1}}\ ;\ ...\ ;\ h_{e_{i,10}}]) \quad (7)$$

where the claim acts as the question when encoding the evidence snippets. Similarly to Eq. 5, the prediction is obtained by concatenating the claim and evidence representations and project it through a fully connected layer into $\mathbb{R}^L$:

$$p_i = \text{softmax}(FC([h_{c_i}\ ;\ h_{e_i}])) \quad (8)$$

where cross entropy is used as the loss function for training the model. In the setting that only the claim is used as input, then only h_{c_i} is used in Eq. 8. If only the evidence is used, then $h_{e_{i,j}}$ is computed without including c_i, and only h_{e_i} is used in Eq. 8.

[3]We use `bert-base-uncased` from https://huggingface.co/bert-base-uncased.

	#Claims	Labels

Table 2: Dataset statistics.

4 Experimental Evaluation

4.1 Datasets

We focus on the domain of political fact checking, where we use claims and associated evidence from PolitiFact and Snopes, which we extract from the MultiFC dataset (Augenstein et al., 2019). Using the claim as a query, the evidence is crawled from Google search API as the search snippets of the top-10 results, and is filtered such that the website origin of a given claim does not appear as evidence. To facilitate better comparison between the datasets, we filter claims with non-veracity related labels[4]. The dataset statistics are shown in Table 2.

4.2 Experimental setup

Both datasets are split into train/val/test sets using label-stratified sampling (70/10/20% splits). We tune all models on the validation split, and use early stopping with a patience of 10 for neural

[4]For PolitiFact we exclude [full flop, half flip, no flip] and for Snopes we exclude [unproven, miscaptioned, legend, outdated, misattributed, scam, correct attribution].

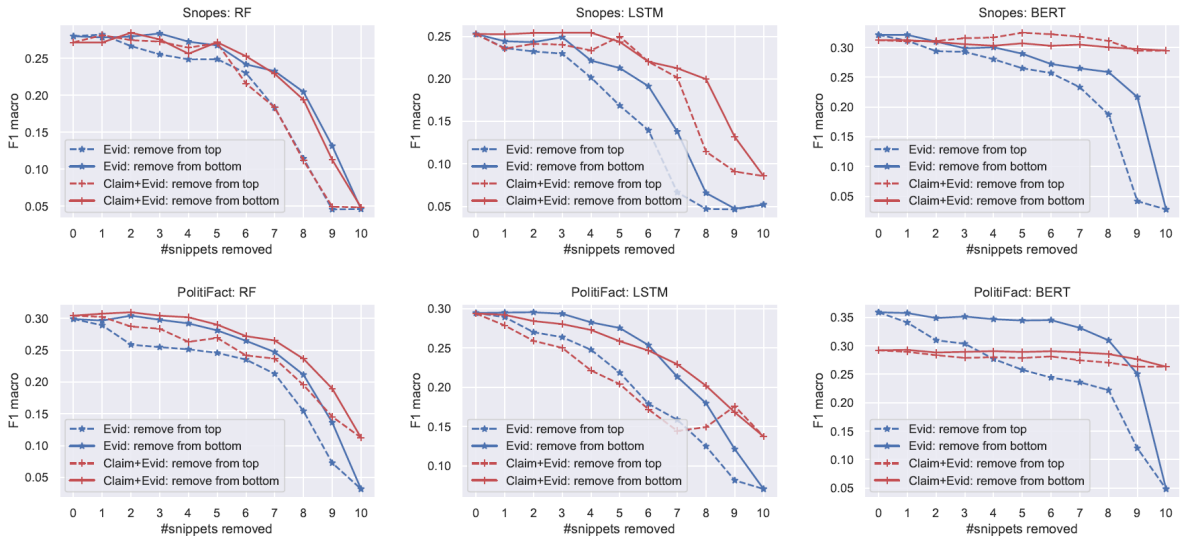

Figure 1: Macro F1 scores when removing evidence from either the top or bottom of the evidence snippet ranking.

models. Following Augenstein et al. (2019), we use micro and macro F1 for evaluation. The models are evaluated on both the within dataset test sets, but also out-of dataset test sets (e.g., a model trained on Snopes is evaluated on both Snopes and PolitiFact). In the out-of dataset evaluation we need the labels to be comparable, hence in that setting we merge "pants on fire!" and "false" for PolitiFact.

5 Tuning details

In the following, the best overall parameter configurations are underlined. The best configuration is chosen based on the average of the micro and macro F1[5]. For RF, we tune the number of trees from [100,500,1000], the minimum number of samples in a leaf from [1,3,5,10], and the minimum number of samples per split from [2,5,10]. For the LSTM model, we tune the learning rate from [1e-4,5e-4,1e-5], batch size [16,32], number of LSTM layers from [1,2], dropout from [0, 0.1], and fix the number of hidden dimensions to 128. For the BERT model, we tune the learning rate from [3e-5, 3e-6, 3e-7] and fix the batch size to 8.

5.1 Results

The results can be seen in Table 1. Overall, we see that the BERT model trained only on Evidence obtains the best results in 4/8 columns, and, notably, in 3/4 cases the BERT model with Evidence obtains the best macro F1 score on within and out-of dataset prediction. Random forest using term-frequency as input obtains the best out-of dataset micro F1 for both datasets (using either only Claim or only Evidence). Across all methods, the combination of Claim+Evidence only marginally obtains the best results a single time (for Snopes micro F1). For further details, in Table 3 we compute the accuracy scores for all the false labels, mixture or half-true label, and true labels.

Surprisingly, a BERT model using only the Evidence is capable of predicting the veracity of the claim used for obtaining the evidence. This shows that a strong signal must exist in the evidence itself, and the evidence found by the search engine appears to be implicitly affected by the veracity of the claim used as the query in some way[6]. The improvements reported in the literature by combining claim and evidence, are therefore not evident of the model learning to reason over the evidence with regards to the claim, but instead exploiting a signal inherent in the evidence itself. This highlights that the current approach for evidence gathering is problematic, as the strong signal makes it possible (and most often beneficial) for the model to entirely ignore the claim. This makes the model entirely reliant on the process behind how the evidence is generated, which is outside the scope of the model, and thereby undesirable, as any change in the search system may change the model performance significantly. It may also be problematic on a more fundamental level, e.g., to predict the

Table 3: Accuracy scores computed on the false labels, mixture or half-true label, and true labels. All labels within a group (e.g., any false label such as false or mostly false) are considered to be the same and as such this reduces the problem to a three class classification problem.

veracity of the following two claims: "the earth is round" and "the earth is flat", the evidence could be the same, but a model entirely dependent on the evidence, and not the claim, would be incapable of predicting both claims correctly.

5.2 Removal of evidence

We observed a strong predictive signal in the evidence alone and now consider the performance impact when gradually removing evidence snippets. The evidence is removed consecutively either from the top down or bottom up (i.e., removing the most relevant snippets first and vice versa), until no evidence is used. Figure 1 shows the macro F1 as a function of removed evidence when using the Evidence or Claim+Evidence models. We observe a distinct difference between the random forest and LSTM model compared to BERT: for random forest and LSTM, the Claim+Evidence models on both datasets drop rapidly in performance when the evidence is removed, while the BERT model only experiences a very small drop. This shows that when the Claim+Evidence is used in the BERT model, the influence of the evidence is minimal, while the evidence is vital for the Claim+Evidence RF and LSTM models. For all models, we observe that when evidence is removed from the top down, the performance drop is larger than when evidence is removed from the bottom up. Thus, the ranking of the evidence as provided by the search engine is related to its usefulness as evidence for fact checking.

6 Conclusion

We investigate if fact checking models for fake news detection are learning to process claim and evidence jointly in a way resembling reasoning. Across models of varying complexity and evaluated on multiple datasets, we find that the best performance can most often be obtained using only the evidence. This highlights that models using both claim and evidence are inherently not learning to reason, and points to a potential problem in how evidence is currently obtained in existing approaches for automatic fake news detection.

Abstract

Despite end-to-end neural systems making significant progress in the last decade for task-oriented as well as chit-chat based dialogue systems, most dialogue systems rely on hybrid approaches which use a combination of rule-based, retrieval and generative approaches for generating a set of ranked responses. Such dialogue systems need to rely on a fallback mechanism to respond to out-of-domain or novel user queries which are not answerable within the scope of the dialogue system. While, dialogue systems today rely on static and unnatural responses like "I don't know the answer to that question" or "I'm not sure about that", we design a neural approach which generates responses which are contextually aware with the user query as well as say no to the user. Such customized responses provide paraphrasing ability and contextualization as well as improve the interaction with the user and reduce dialogue monotonicity. Our simple approach makes use of rules over dependency parses and a text-to-text transformer fine-tuned on synthetic data of question-response pairs generating highly relevant, grammatical as well as diverse questions. We perform automatic and manual evaluations to demonstrate the efficacy of the system.

1 Introduction

In order to cater to the diversity of questions spanning across various domains, dialogue systems generally follow a hybrid architecture wherein an ensemble of individual response subsystems (Kuratov et al.; Harrison et al., 2020) are employed from which an appropriate response is presented to the user (Serban et al., 2017; Finch et al., 2020; Paranjape et al., 2020). However, it is common for dialogue systems to encounter queries which are not within their scope of knowledge. While increasing the number of such subsystems would be a good strategy to increase coverage, it can be a never ending process and a default fallback strategy would always be needed. Besides, domain specific dialogue systems, especially those deployed in professional settings generally prefer restricting themselves to a fixed set of domains, and purposely refrain from responding to out-of-domain and random or toxic user queries.

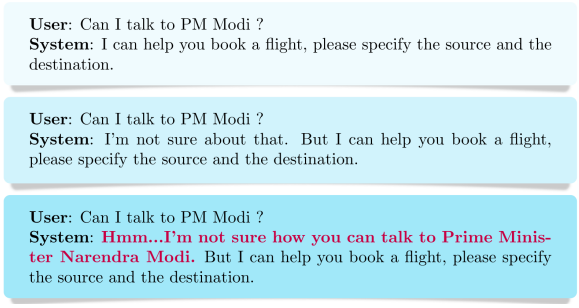

Figure 1: Comparison of responses of three flight booking dialogue systems: The first one does not handle unknown responses. The second one has a default fallback response. The third one has a fall-back response which is contextualized with the user query.

One approach to acknowledge such queries is to have a fallback mechanism with responses like "I don't know the answer to this question" or "I'm not sure how to answer that." However, such responses are static and unengaging and give an impression that the user's query has gone unacknowledged or is not understood by the system as shown in Figure 1 above.

Yu et al. (2016) have shown that static and predefined responses lead to lower levels of user engagement and decrease users' interest in interacting with the system. Yu et al. (2016) shows that a system which reacts to system breakdowns and to low user engagement leads to a better user engagement.

Our fallback approach attempts to address these limitations by generating "don't-know" responses which are engaging and contextually closer with the user query. 1) Since there are no publicly available datasets to generate such contextualised responses, we synthetically generate (query, fallback

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 87–92
August 1–6, 2021. ©2021 Association for Computational Linguistics

response) pairs using a set of highly accurate handcrafted dependency patterns. 2) We then train a sequence-to-sequence model over synthetic and natural paraphrases of these queries. 3) Finally, we measure the grammaticality and relevance of our models using a crowd-sourced setting to assess the generation capability. We have released the code and training dataset used in our experiments publicly. [1]

2 Related Work

Improving the coverage to address out-of-domain queries is not a new problem in designing dialogue systems. The most popular approach has been via presenting the user with chit-chat responses. Other systems such as Blender (Roller et al., 2020) and Meena (Adiwardana et al., 2020) promise to be successful for open-domain settings. Paranjape et al. (2020) finetune a GPT-2 model (Radford et al., 2019) on the EmpatheticDialogues dataset (Rashkin et al., 2019) to generate social talk responses. While this might seem fitting for chit-chat and social talk dialogue systems, domain-specific scenarios often dealing with professional settings would refrain from performing friendly or social talk especially avoiding the possibility of the randomness of generative models. Also, multiple subsystem architectures always have the possibility of cascading errors and profane or toxic queries. Hence systems should always have a foolproof mechanism in the form of static templates to reply from. Liang et al. (2020) uses an interesting approach for error handling by mapping dialogue acts and intents to templates. Besides, like Finch et al. (2020) it is always safer to generate fallback responses on encountering queries which might be toxic, biased or profane. [2]

Another line of work attempts to handle user queries which are ambiguous by asking back clarification questions (Dhole, 2020; Zamani et al., 2020; Yu et al., 2020). While this increases user interaction and coverage to an appreciable extent, it does not eliminate the requirement of a failsafe fallback responder. This paper's contribution is to address this requirement with an enhanced version of a fallback response generator.

[1] github.com/kaustubhdhole/natural-dont-know

[2] Handling programming exceptions and code failures also necessitates a simple fallback approach.

3 Methods

We describe two approaches to generate such contextual don't-know responses.

3.1 The Dependency Based Approach (DBA)

Inspired by previous approaches which use parse structures to generate questions (Heilman and Smith, 2009; Mazidi and Tarau, 2016; Dhole and Manning, 2020), we create a rule-based generator by handcrafting dependency templates to cater to a wide variety of question patterns as shown in Table 1. We perform extensive manual testing to improve the generations from these rules and increase overall coverage. The purpose of these rules is two-fold: i) To create a high-precision fall-back response generator as a baseline and ii) to help create (query, don't-know-response) pairs which could be paired with natural paraphrases to serve as seed training data for other deep learning architectures.

To build this baseline generator, we utilize few dependency templates in the style of SynQG (Dhole and Manning, 2020). We utilize the dependency parser from Andor et al. (2016) to get the Universal Dependencies (Nivre et al., 2016, 2017, 2020) of the user query. We then convert it to a don't-know-response by re-arranging nodes to a matched template. We further change pronouns, incorporate named entity information, and add rules to handle modals and auxiliaries. Finally, we also add rules for flipping pronouns to convert an agent targeted question to a user targeted response by interchanging pronouns and their supporting verbs. E.g. You to I and vice-versa.

We incorporate a bit of paraphrasing by randomizing various prefixes like "I'm not sure whether", "I don't know if", etc. and randomly using named entities. We describe the high-level algorithm below and in Algorithm 1.

$$prefix = pickRandom(prefixPool)$$
$$response = DBR(Question)$$
$$suffix = pickRandom(suffixPool)$$
$$fallbackResponse = Concat(prefix, response, suffix)$$

3.2 Sequence-to-Sequence Approach

Owing to the expected low coverage and scalability of the rule-based approach, we resort to take advantage of pre-trained neural architectures to attempt

Dependency Rules	Sample Question	Natural Don't Know Response
WhatBeRule()	What is the Pandora box ?	I am not really sure what the Pandora box is.
DidVerbRule()	Did Daniel cook today's meal ?	I don't know if Daniel cooked today's meal.
QuestionCanIRule()	Could you tell me the location of the tower ?	hmm..I don't know if I could tell you...
BeRule()	Are you predictive about conversation ?	I'm not sure if I am predictive about...
WhoBeRule()	Who is the Duke of Scotland ?	I can't be sure who the Duke of Scotland is.
WhoBeVerbRule()	Who is playing baseball and cricket both ?	I am not actually sure who is playing...
WhereBeRule()	Where did Bates translate this document ?	I don't know where Bates did translate...
HowBeRule()	How are the people of the Italy ?	I'm not sure how the people of that place are.
WhenBeRule()	When is the deadline of ACL ?	I can't be sure when the deadline of ACL is.
WhereBeVerbRule()	Where is Mr. Potter going ?	I'm not sure where Mr. Potter is going.
WhenBeVerbRule()	When will you submit your thesis ?	I'm not really sure when I will submit my thesis.

Table 1: Few Dependency Rules with the class of questions they cater too and their corresponding responses. In the 8^{th} sentence, the named entity "Italy" is randomly replaced by "that place".

Algorithm 1 Dependency Based Response (DBR)

```
nodes ← dependencyParse(Question)
for each template in templatePool do
    if (template condition matched) then
        Populate template using nodes
        Handle modals & auxilliaries
        Flip pronoun
        Randomly substitute Named Entity
if no template condition matched then
    return pickRandom(defaultResponse pool)
return filled template response
```

to create a sequence-to-sequence fallback responder. To incorporate noise and avoid the model to over-fit on the handcrafted transformations, we do not train the model directly on (query, don't-know-response) pairs generated from the previous section. From all possible questions of the Quora Questions Pairs dataset (QQP) [3], we first filter all the questions which generate a reply from the dependency based rules. Then we pair these dont-know-responses with the paraphrases of the input questions rather than the input questions themselves. [4] Primarily attempting to avoid over-fitting on the dependency patterns, this also helps generate dont-know-responses which are paraphrastic in nature.

After incorporating paraphrases from QQP, we are able to build a dataset of 100k pairs, which we call the "I Dont Know Dataset" (IDKD). After witnessing the success of text-to-text transformers, we use the pre-trained T5 transformer (Raffel et al., 2020a,b) as our sequence-to-sequence model. We divide IDKD into a train and validation split of 80:20. We use the Transformers code from HuggingFace (Wolf et al., 2020) to fine-tune a T5-base model over IDKD for 2 epochs. [5]

Metrics	DBA	Seq-To-Seq
%GC	81.6	87.2
ARS	3.97	3.66

Table 2: Human evaluation between the two approaches. %GC= % of Grammatically correct responses, ARS=Average Relevance Score.

4 Results

Most prior generated systems are evaluated on a range of automatic metrics like BLEU and ROGUE (Papineni et al., 2002) used in the machine translation literature. However, owing to the drawbacks of these metrics, we perform human evaluation of the generated responses using two metrics - namely "relevance" and "grammaticality" as defined in Dhole and Manning (2020). We evaluate the performance of both the approaches in a crowd-sourced setting by requesting English-schooled individuals to rate. [6] Raters were asked to evaluate grammaticality in a binary setting (grammatical/ungrammatical) and relevance on a Likert scale (1 to 5).

Our human evaluations are shown in Table-2. T5 responses tend to be more grammatical than their dependency counterparts by a large margin of 6%. Relevance scores drop slightly from 3.97 to 3.66.

[3] Quora Question Pairs Dataset

[4] Those question pairs which have the label "1" or are similar are used as paraphrases.

[5] Increasing the epochs to 3 and 4 tended to overfit and not generate paraphrases.

[6] Our pool of English-schooled raters consisted of engineering graduates having attained high school and engineering education with English as a medium of instruction.

Metrics	Question	Dependency Based Approach	Seq2Seq Approach
Coverage	–	54.56%	100%
Average Sentence Length	9.41	11.83	11.78
Sentence Length Variance	11.74	11.60	10.66
Average #Novel Words	–	0.91	2.57

Table 3: System evaluation between Dependency Based Approach and Sequence to Sequence Approach.

Question: Are you excited about natural language processing research ?
DBA: I'm not sure if I am excited about natural language processing research.
Seq2Seq: I'm not actually sure what the benefits of natural language processing are.

Question: What is the quickest way to increase Instagram followers?
DBA: I am not sure what the quickest way to increase Instagram followers is.
Seq2Seq: I cannot be sure how a user can increase Instagram followers.

Question: How can I join MIT?
DBA: I am not sure how you can join MIT.
Seq2Seq: I am not sure what the eligibility criteria for MIT are.

Question: How can I drive more traffic to my website?
DBA: I'm not really sure how you can drive more traffic.
Seq2Seq: I am not sure what the best way to get free traffic to your website is.

Question: Where can I find a collection of poetry by William Shakespeare?
DBA: I'm not really sure where you can find a collection of poetry by William Shakespeare.
Seq2Seq: I'm not actually sure where you can get a collection of his poems.

Question: What is the effect of demonetization of 500 and 1000 rupees notes?
DBA: I cannot be sure what the effect of demonetization of 500 and 1000 rupees notes is.
Seq2Seq: I'm not really sure what my views on PM Modi's decision on discontinuing 500 & 1000 rs notes are.

Table 4: Natural don't know responses generated by both the approaches. Highlights in blue depict words, phrases or events not mentioned by the user.

This can be largely attributed to the model's paraphrastic ability of describing words and connected events outside the knowledge of the user's query. Eg. in the second query in Table 4, if the string "MIT" were something other than an institution, the dependency based approach would seem safer than the seq2seq approach.

In addition, T5 responses on an average generate at least double the number of novel words than their dependency counterparts as shown in Table 3. Sentence length mostly remains unaffected across the two models. Undoubtedly, the rule-based model despite being highly relevant is only able to reply to 54.5% of random QQP queries.

The T5 model helped to not only add paraphrastic variations but also scale to user queries outside of the scope of the dependency templates. More importantly, without losing the original ability of saying no, the model was able to generate more natural sounding dont-know-reponses by utilizing it's inherent world-knowledge acquired during pre-training. Table 4 shows some interesting examples. The highlighted phrases in blue show the benefits of the model's pre-training ability.

5 Conclusion and Future work

We describe two simple approaches which enhance user interaction to cater to the necessities of real-life dialogue systems which are generally a tapestry of multiple solitary subsystems. In order to avoid cascading errors from such systems, as well as refrain from answering out-of-domain and toxic queries it is but natural to have a fallback approach to say no. We argue that such a fallback approach could be contextualised to generate engaging responses by having multiple ways of saying no rather than a one common string for all approach. The appeal of our approach is the ease with which

it can rightly fit within any larger dialogue design framework.

Of course, this is not to deny that as we give more paraphrasing power to the fallback system, it would tend to retract from succinctly replying with a no - as is evident from the drop in the relevance scores. Nevertheless, we still believe that both our fallback approaches could serve as effective baselines for future work.

N-Best ASR Transformer: Enhancing SLU Performance using Multiple ASR Hypotheses

Abstract

Spoken Language Understanding (SLU) systems parse speech into semantic structures like dialog acts and slots. This involves the use of an Automatic Speech Recognizer (ASR) to transcribe speech into multiple text alternatives (hypotheses). Transcription errors, common in ASRs, impact downstream SLU performance negatively. Approaches to mitigate such errors involve using richer information from the ASR, either in form of N-best hypotheses or word-lattices. We hypothesize that transformer models learn better with a simpler utterance representation using the concatenation of the N-best ASR alternatives, where each alternative is separated by a special delimiter [SEP]. In our work, we test our hypothesis by using concatenated N-best ASR alternatives as the input to transformer encoder models, namely BERT and XLM-RoBERTa, and achieve performance equivalent to the prior state-of-the-art model on DSTC2 dataset. We also show that our approach significantly outperforms the prior state-of-the-art when subjected to the low data regime. Additionally, this methodology is accessible to users of third-party ASR APIs which do not provide word-lattice information.

1 Introduction

Spoken Language Understanding (SLU) systems are an integral part of Spoken Dialog Systems. They parse spoken utterances into corresponding semantic structures e.g. dialog acts. For this, a spoken utterance is usually first transcribed into text via an Automated Speech Recognition (ASR) module. Often these ASR transcriptions are noisy and erroneous. This can heavily impact the performance of downstream tasks performed by the SLU systems.

To counter the effects of ASR errors, SLU systems can utilise additional feature inputs from ASR. A common approach is to use N-best hypotheses where multiple ranked ASR hypotheses are used, instead of only 1 ASR hypothesis. A few ASR systems also provide additional information like word-lattices and word confusion networks. Word-lattice information represents alternative word-sequences that are likely for a particular utterance, while word confusion networks are an alternative topology for representing a lattice where the lattice has been transformed into a linear graph. Additionally, dialog context can help in resolving ambiguities in parses and reducing impact of ASR noise.

N-best hypotheses: Li et al. (2019) work with 1-best ASR hypothesis and exploits unsupervised ASR error adaption method to map ASR hypotheses and transcripts to a similar feature space. On the other hand, Khan et al. (2015) uses multiple ASR hypotheses to predict multiple semantic frames per ASR choice and determine the true spoken dialog system's output using additional context. **Word-lattices:** Ladhak et al. (2016) propose using recurrent neural networks (RNNs) to process weighted lattices as input to SLU. Švec et al. (2015) presents a method for converting word-based ASR lattices into word-semantic (W-SE) which reduces the sparsity of the training data. Huang and Chen (2019) provides an approach for adapting lattices with pretrained transformers. **Word confusion networks (WCN):** Jagfeld and Vu (2017) proposes a technique to exploit word confusion networks (WCNs) as training or testing units for slot filling. Masumura et al. (2018) models WCN as sequence of bag-of-weighted-arcs and introduce a mechanism that converts the bag-of-weighted-arcs into a continuous representation to build a neural network based spoken utterance classification. Liu et al. (2020) proposes a BERT based SLU model to encode WCNs and the dialog context jointly to

* The first three authors have equal contribution.

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 93–98
August 1–6, 2021. ©2021 Association for Computational Linguistics

reduce ambiguity from ASR errors and improve SLU performance with pre-trained models.

The motivation of this paper is to improve performance on downstream SLU tasks by exploiting *transfer learning* capabilities of the pre-trained transformer models. Richer information representations like word-lattices (Huang and Chen (2019)) and word confusion networks (Liu et al. (2020)) have been used with GPT and BERT respectively. These representations are non-native to Transformer models, that are pre-trained on plain text sequences. We hypothesize that transformer models will learn better with a simpler utterance representation using concatenation of the N-best ASR hypotheses, where each hypothesis is separated by a special delimiter [SEP]. We test the effectiveness of our approach on a dialog state tracking dataset - DSTC2 (Henderson et al., 2014), which is a standard benchmark for SLU.

Contributions: (i) Our proposed approach, trained with a simple input representation, exceeds the competitive baselines in terms of accuracy and shows equivalent performance on the F1-score to the prior state-of-the-art model. (ii) We significantly outperform the prior state-of-the-art model in the low data regime. We attribute this to the effective *transfer learning* from the pre-trained Transformer model. (iii) This approach is accessible to users of third party ASR APIs unlike the methods that use word-lattices and word confusion networks which need deeper access to the ASR system.

2 N-Best ASR Transformer

N-Best ASR Transformer[1] works with a simple input representation achieved by concatenating the N-Best ASR hypotheses together with the dialog context (system utterance). Pre-trained transformer models, specifically BERT and XLMRoBERTa, are used to encode the input representation. For output layer, we use a semantic tuple classifier (STC) to predict *act-slot-value* triplets. The following sub-sections describe our approach in detail.

2.1 Input Representation

For representing the input we concatenate the last system utterance S (dialog context), and the user utterance U. U is represented as concatenation of the N-best[2] ASR hypotheses, separated by a special delimiter, [SEP]. The final representation is shown in equation 1 below:

$$x_i = [\text{CLS}] \oplus \text{TOK}(S_i) \oplus \bigoplus_{j=1}^{N} (\text{TOK}(U_i^j) \oplus [\text{SEP}]) \quad (1)$$

Here, U_i^j refers to the j^{th} ASR hypothesis for the i^{th} sample, $\oplus$ denotes the concatenation operator, TOK(.) is the tokenizer, [CLS] and [SEP] are the special tokens.

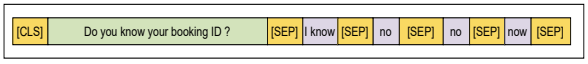

Figure 1: Input representation: The green boxes represents the last system utterances followed by ASR hypotheses of user utterances concatenated together with a [SEP] token.

As represented in figure 2, we also pass segment IDs along with the input to differentiate between segment a (last system utterance) and segment b (user utterance).

2.2 Transformer Encoder

The above mentioned input representation can be easily used with any pre-trained transformer model. For our experiments, we select BERT (Devlin et al., 2019) and XLM-RoBERTa[3] (Conneau et al., 2020) for their recent popularity in NLP research community.

2.3 Output Representation

The final hidden state of the transformer encoder corresponding to the special classification token [CLS] is used as an aggregated input representation for the downstream classification task by a semantic tuple classifier (STC) (Mairesse et al., 2009). STC uses two classifiers to predict the *act-slot-value* for a user utterance. A binary classifier is used to predict the presence of each *act-slot* pair, and a multi-class classifier is used to predict the *value* corresponding to the predicted act-slot pairs. We omit the latter classifier for the act-slot pairs with no value (like *goodbye*, *thankyou*, *request_food* etc.).

[1]The code is available at https://github.com/Vernacular-ai/N-Best-ASR-Transformer

[2]We use ASR transcriptions (N $\leq$ 10) provided by DSTC2 dataset to perform our experiments. Our input structure can support variable N during training and inference.

[3]The model name XLM-RoBERTa and XLM-R will be used interchangeably throughout the paper.

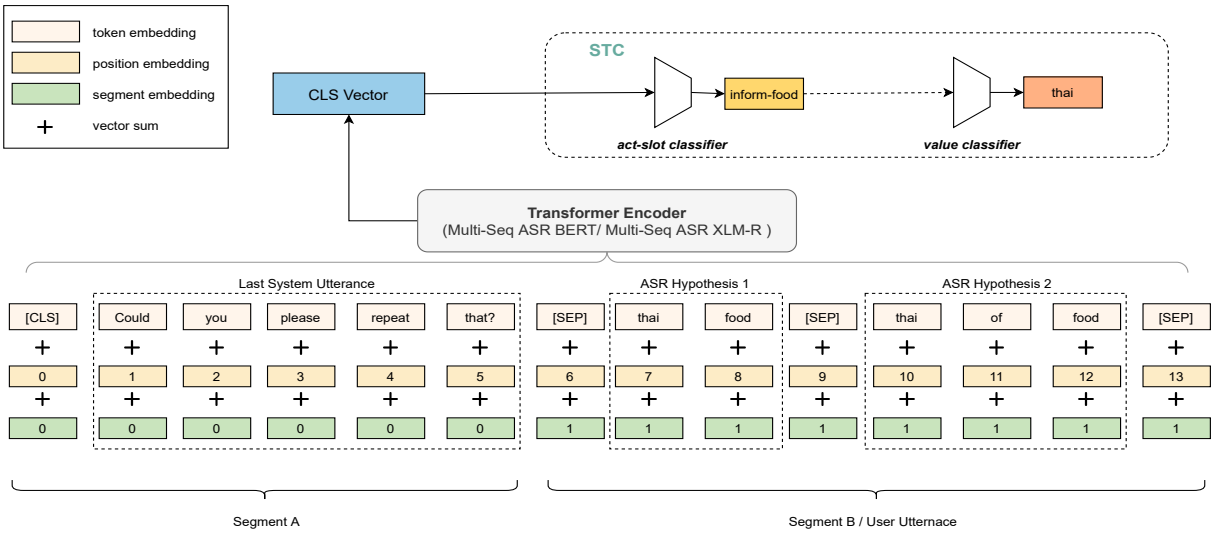

Figure 2: **N-Best ASR Transformer:** The input representation is encoded by a transformer model which forms an input for a Semantic Tuple Classifier (STC). STC uses binary classifiers to predict the presence of act-slot pairs, followed by a multi-class classifier that predicts the value for each act-slot pair.

3 Experimental Setup

3.1 Dataset

We perform our experiments on data released by the Dialog State Tracking Challenge (DSTC2) (Henderson et al., 2014). It includes pairs of utterances and the corresponding set of *act-slot-value* triplets for training (11,677 samples), development (3,934 samples), and testing (9,890 samples). The task in the dataset is to parse the user utterances like "*I want a moderately priced restaurant.*" into a corresponding semantic representation in the form of "*inform(pricerange=moderate)*" triplet. For each utterance, both the manual transcription and a maximum of 10-best ASR hypotheses are provided. The utterances are annotated with multiple *act-slot-value* triplets. For transcribing the utterances DSTC2 uses two ASRs - one with an artificially degraded statistical acoustic model, and one which is fully optimized for the domain. Training and development sets include transcriptions from both the ASRs. To utilise this dataset we first transform it into the input format as discussed in section 2.1.

3.2 Baselines

We compare our approach with the following baselines:

- **SLU2** (Williams, 2014): Two binary classifiers (decision trees) are used with word n-grams from the ASR N-best list and the word confusion network. One predicts the presence of that slot-value pair in the utterance and the other estimate for each user dialog act.

- **CNN+LSTMw4** (Rojas-Barahona et al., 2016): A convolution neural network (CNN) is trained with the N-best ASR hypotheses to output the utterance representation. A long-short term memory network (LSTM) with a context window size of 4 outputs a context representation. The models are jointly trained to predict for the act-slot pair. Another model with the same architecture is trained to predict for the value corresponding to the predicted act-slot pair.

- **CNN** (Zhao and Feng, 2018): Proposes CNN based models for dialog act and slot-type prediction using 1-best ASR hypothesis.

- **Hierarchical Decoding** (Zhao et al., 2019): A neural-network based binary classifier is used to predict the act and slot type. A hybrid of sequence-to-sequence model with attention and pointer network is used to predict the value corresponding to the detected act-slot pair.1-Best ASR hypothesis was used for both training and evaluation tasks.

- **WCN-BERT + STC** (Liu et al., 2020): Input utterance is encoded using the Word Confusion Network (WCN) using BERT by having the same position ids for all words in the bin of a lattice and modifying self-attention to work with word probabilities. A semantic tuple classifier uses a binary classifier to predict the act-slot value, followed by a multi-class classifier that predicts the value corresponding

to the act-slot tuple.

3.3 Experimental Settings

We perform hyper-parameter tuning on the validation set to get optimal values for dropout rate δ, learning rate lr, and the batch size b. Based on the best F1-score, the final selected parameters were δ = 0.3, lr = 3e-5 and b = 16. We set the warm-up rate wr = 0.1, and L2 weight decay $L2$ = 0.01. We make use of Huggingface's *Transformers* library (Wolf et al., 2020) to fine-tune the *bert-base-uncased* and *xlm-roberta-base*, which is optimized over Huggingface's BertAdam optimizer. We trained the model on Nvidia T4 single GPU on AWS EC2 g4dn.2xlarge instance for 50 epochs. We apply early stopping and save the best-performing model based on its performance on the validation set.

4 Results

In this section, we compare the performance of our approach with the baselines on the DSTC2 dataset. To compare the *transfer learning* effectiveness of pre-trained transformers with *N-Best ASR BERT* (our approach) and the previous state-of-the-art model *WCN-BERT STC*, we perform comparative analysis in the low data regime. Additionally, we perform an ablation study on *N-Best ASR BERT* to see the impact of modeling dialog context (last system utterance) with the user utterances.

4.1 Performance Evaluation

Model	F1-score	Accuracy
SLU2	82.1	-
CNN+LSTM_w4	83.6	-
CNN	85.3	-
Hierarchical Decoding	86.9	-
WCN-BERT + STC	**87.9**	81.1
N-Best ASR XLM-R (Ours)	87.4	**81.9**
N-Best ASR BERT (Ours)	87.8	81.8

Table 1: F1-scores (%) and utterance-level accuracy (%) of baseline models and our proposed model on the test set.

Since the task is a multi-label classification of *act-slot-value* triplets, we report utterance level accuracy and F1-score. A prediction is correct if the set of labels predicted for a sample exactly matches the corresponding set of labels in the ground truth. As shown in Table 1, we compare our models, *N-Best ASR BERT* and *N-Best ASR XLM-R*, with baselines mentioned in section . Both of our proposed models, trained with concatenated N-Best ASR hypotheses, outperform the competitive baselines in terms of accuracy and show comparable performance on F1-score with *WCN-BERT STC*.

4.2 Performance in Low Data Regime

Train Data (%age)	WCN-BERT STC	*N-Best ASR BERT*
5	78.5	**83.9**
10	80.3	**85.5**
20	84.4	**86.7**
50	85.9	**87.7**

Table 2: F1-scores (%) for our proposed model *N-Best ASR BERT* (ours) and *WCN-BERT STC* (previous state-of-the-art.

To study the performance of model in the low data regime, we randomly select p percentage of samples from the training set in a stratified fashion, where $p \in \{5, 10, 20, 50\}$. We pick our model *N-Best ASR BERT* and *WCN-BERT STC* for this study because both use BERT as the encoder model. For both models, we perform experiments using the same training, development, and testing splits. From Table 2, we find that *N-Best ASR BERT* outperforms *WCN-BERT STC* model significantly for low data regime, especially when trained on 5% and 10% of the training data. It shows that our approach effectively *transfer learns* from pre-trained transformer's knowledge. We believe this is due to the structural similarity between our input representation and the input BERT was pre-trained on.

4.3 Significance of Dialog Context

Model	Variation	F1-score	Accuracy
N-Best ASR BERT	without system utterance	86.5	80.2
	with system utterance	**87.8**	**81.8**

Table 3: F1-scores (%) and utterance-level accuracy (%) of our model *N-Best ASR BERT* on the test set when trained with and without system utterances.

Through this ablation study, we try to understand the impact of dialog context on model's performance. For this, we train *N-Best ASR BERT* in the following two settings:

- When input representation consists of only the user utterance.
- When input representation consists of both the last system utterance (dialog context) and the user utterance as shown in figure 3.

As presented in Table 3, we observe that modeling the last system utterance helps in achieving better F1 and utterance-level accuracy by the difference of 1.3% and 1.6% respectively.

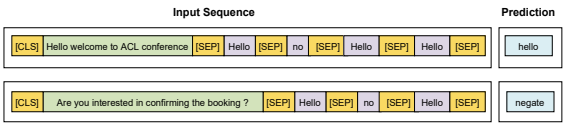

Figure 3: Significance of Dialog Context: The green box depicts the dialog context that helps disambiguate the very similar ASR hypotheses shown in purple boxes.

It proves that dialog context helps in improving the performance of downstream SLU tasks. Figure 3 represents one such example where having dialog context in form of the last system utterance helps disambiguate between the two similar user utterances.

5 Conclusion

In this work, building on a simple input representation, we propose *N-Best ASR Transformer*, which outperforms all the competitive baselines on utterance-level accuracy for the DSTC2 dataset. However, the highlight of our work is in achieving significantly higher performance in an extremely low data regime. This approach is accessible to users of third-party ASR APIs, unlike the methods that use word-lattices and word confusion networks. As future extensions to this work, we plan to :

- Enable our proposed model to generalize to out-of-vocabulary (OOV) slot values.
- Evaluate our approach in a multi-lingual setting.
- Evaluate on different values N in N-best ASR.
- Compare the performance of our approach on ASRs with different Word Error Rates (WERs).

Acknowledgement

We are highly grateful to our organization Vernacular.ai and our Machine Learning Team for (i) exposing us to practical problems related to multilingual voice-bots, (ii) giving us access to resources to solve this problem, (iii) helping us deploy this work in production for real-world users, and (iv) for their excellent feedback on this work.

Gender Bias Amplification During Speed-Quality Optimization in Neural Machine Translation

denisedeediaz@gmail.com

Abstract

Is bias amplified when neural machine translation (NMT) models are optimized for speed and evaluated on generic test sets using BLEU? We investigate architectures and techniques commonly used to speed up decoding in Transformer-based models, such as greedy search, quantization, average attention networks (AANs) and shallow decoder models and show their effect on gendered noun translation. We construct a new gender bias test set, SimpleGEN, based on gendered noun phrases in which there is a single, unambiguous, correct answer. While we find minimal overall BLEU degradation as we apply speed optimizations, we observe that gendered noun translation performance degrades at a much faster rate.

1 Introduction

Optimizing machine translation models for production, where it has the most impact on society at large, will invariably include speed-accuracy trade-offs, where accuracy is typically approximated by BLEU scores (Papineni et al., 2002) on generic test sets. However, BLEU is notably not sensitive to specific biases such as gender. Even when speed optimizations are evaluated in shared tasks, they typically use BLEU (Papineni et al., 2002; Heafield et al., 2020) to approximate quality, thereby missing gender bias. Furthermore, these biases probably evade detection in shared tasks that focus on quality without a speed incentive (Guillou et al., 2016) because participants would not typically optimize their systems for speed. Hence, it is not clear if Neural Machine Translation (NMT) speed-accuracy optimizations amplify biases. This work attempts to shed light on the *algorithmic choices* made during speed-accuracy optimizations and their impact on gender biases in an NMT system, complementing existing work on data bias.

source	That physician is a funny lady!
reference	¡Esa médica/doctora es una mujer graciosa!
system A	¡Ese médico es una dama graciosa!
system B	¡Ese médico es una dama divertida!
system C	¡Ese médico es una mujer divertida!
system D	¡Ese médico es una dama divertida!

Table 1: Translation of a simple source sentence by 4 different commercial English to Spanish MT systems. All of these systems fail to consider the token "lady" when translating the occupation-noun, rendering it in with the masculine gender "doctor/médico".

We explore optimizations choices such as (i) search (changing the beam size in beam search); (ii) architecture configurations (changing the number of encoder and decoder layers); (iii) model based speedups (using Averaged attention networks (Zhang et al., 2018)); and (iv) 8-bit quantization of a trained model..

Prominent prior work on gender bias evaluation forces the system to "guess" the gender (Stanovsky et al., 2019a) of certain occupation nouns in the source sentence. Consider, the English source sentence "That physician is funny.", containing no information regarding the physician's gender. When translating this sentence into Spanish (where the occupation nouns are explicitly specified for gender), an NMT model is forced to guess the gender of the physician and choose between masculine forms, doctor/médico or feminine forms doctora/médica. While investigating bias in these settings is valuable, in this paper, we hope to highlight that the problem is much worse — despite an explicit gender reference in the sentence, NMT systems still generate the wrong gender in translation (see Table 1), resulting in egregious errors where not only is the gender specification incorrect but the generated sentence also fails in morphological gender

Templates			That `f/m-occ-sg` is a funny `f/m-n-sg`! My `f/m-rel` is a `f/m-occ-sg`.
Keywords			`f-occ-sg` = {nurse, nanny...} `m-occ-sg` = {physician, mechanic...} `f-rel` = {sister, mother..} `m-rel` = {brother, father...} `f-n-sg` = {woman, gal, lady...} `m-n-sg` = {man, guy...}
Generated	pro.	MoMc	That engineer is a funny guy! My father is a mechanic.
		FoFc	That nanny is a funny lady! My mother is a nurse.
	anti.	MoFc	That mechanic is my funny woman! My sister is a physician.
		FoMc	That nurse is funny man! My brother is a nanny.

Table 2: Example Templates, Keywords and a sample of the resulting generated source sentences.

agreement. To focus on these egregious errors, we construct a new data set, SimpleGEN. In SimpleGEN, all source sentences include an occupation noun (such as "mechanic", "nurse" etc.) *and* an unambiguous "signal" specifying the gender of the person being referred to by the occupation noun. For example, we modify the previous example to "That physician is a funny *lady*". We call our dataset "Simple" because it contains all the information needed by a model to produce correctly gendered occupation nouns. Furthermore, our sentences are short (up to 12 tokens) and do not contain complicated syntactic structures. Ideally, SimpleGEN should obviate the need for an NMT model to incorrectly guess the gender of occupation nouns, but using this dataset we show that gender translation accuracy, particularly in female context sentences (see Section 2), is negatively impacted by various speed optimizations at a *greater rate* than a drop in BLEU scores. A small drop in BLEU can hide a large increase in biased behavior in an NMT system. Further illustrating how insensitive BLEU is as a metric to such biases.

2 SimpleGEN: A gender bias test set

Similar to Stanovsky et al. (2019b), our goal is to provide English input to an NMT model and evaluate if it correctly genders occupation-nouns. We focus on English to Spanish (En-Es) and English to German (En-De) translation directions as occupation-nouns are explicitly specified for gender in these target languages while English is underspecified for such a morphological phenomenon which forces the model to attend to contextual clues. Furthermore, these language directions are considered "high-resource" and often cited as exemplars for advancement in NMT.

A key differentiating characterization of our test set is that there is no ambiguity about the gender of the occupation-noun. We achieve this by using carefully constructed templates such that there is enough contextual evidence to *unambiguously specify* the gender of the occupation-noun. Our templates specify a "scaffolding" for sentences with *keywords* acting as placeholders for *values* (see Table 2). For the occupation keywords such as `f-occ-sg` and `m-occ-sg`, we select the occupations for our test set using the U.S Department of Labor statistics of high-demand occupations.[1] A full list of templates, keywords and values is in table A6. Using our templates, we generate English source sentences which fall into two categories: (i) *pro-stereotypical* (pro) sentences contain either stereotypical male occupations situated in male contexts (MOMC) or female occupations in female contexts (FOFC), and (ii) *anti-stereotypical* (anti) sentences in which the context gender and occupation gender are mismatched, i.e. male occupations in female context (MOFC) and female occupations in male contexts (FOMC). Note that we use the terms "male context" or "female context" to categorize sentences in which there is an unambiguous signal that the occupation noun refers to a male or female person, respectively. We generated 1332 pro-stereotypical and anti-stereotypical sentences, 814 in the MOMC and MOFC subgroups and 518 in the FOMC and FOFC subgroups (we collect more male stereotypical occupations compared to female, which causes this disparity).

To evaluate the translations of NMT models on SimpleGEN, we also create an occupation-noun bilingual dictionary, that considers the number and gender as well as synonyms for the occupations. For example for the En-Es direction, the English occupation term 'physician", has corresponding entries for its feminine forms in Spanish as "doctora" and "médica" and for its masculine forms "doctor" and "médico" (See table A8 for our full dictionary). By design, non-occupation keywords such as `f-rel` and `f-n-sg` specify the expected gender of the occupation-noun on the target side, enabling dictionary based correctness verification.

3 Speeding up NMT

There are several "knobs" that can be tweaked to speed up inference for NMT models. Setting the beam-size (bs) to 1 during beam search is likely the

	¡Esa médica es una mujer feliz!	Correct
	¡Ese médico es una mujer graciosa!	Incorrect
	¡Ese medicación es una mujer graciosa!	NA

Table 3: Our evaluation protocol with an example source sentence and four example translations.

simplest approach to obtain quick speedups. Low-bit quantization (INT8) is another recent approach which improves decoding speed and reduces the memory footprint of models (Zafrir et al., 2019; Quinn and Ballesteros, 2018).

For model and architecture based speedups, we focus our attention on Transformer based NMT models which are now the work-horses in NLP and MT (Vaswani et al., 2017). While transformers are faster to train compared to their predecessors, Recurrent Neural Network (RNN) encoder-decoders (Bahdanau et al., 2014; Luong et al., 2015), transformers suffer from slower decoding speed. Subsequently, there has been interest in improving the decoding speed of transformers.

Shallow Decoders (SD): Shallow decoder models simply reduce the decoder depth and increase the encoder depth in response to the observation that decoding latency is proportional to the number of decoder layers (Kim et al., 2019; Miceli Barone et al., 2017; Wang et al., 2019; Kasai et al., 2020). Alternatively, one can employ SD models without increasing the encoder layers resulting in smaller (and faster) models.

Average Attention Networks (AAN): Average Attention Networks reduce the quadratic complexity of the decoder attention mechanism to linear time by replacing the decoder-side self-attention with an average-attention operation using a fixed weight for all time-steps (Zhang et al., 2018). This results in a $\approx$ 3-4x decoding speedup over the standard transformer.

4 Experimental Setup

Our objective is not to compare the various optimization methods against each other, but rather surface the impact of these algorithmic choices on gender biases. We treat all the optimization choices described in section 3 as data points available to conduct our analysis. To this end, we train models with all combinations of optimizations described in section 3 using the Fairseq toolkit (Ott et al., 2019). Our baseline is a standard large transformer with a $(6, 6)$ encoder-decoder layer configuration. For our SD models we use the following encoder-decoder layer configurations $\{(8, 4), (10, 2), (11, 1)\}$. We also train smaller shallow decoder (SSD) models without increasing the encoder depth $\{(6, 4), (6, 2), (6, 1)\}$. For each of these 7 configurations, we train AAN versions. Next, we save quantized and non-quantized versions for the 14 models, and decode with beam sizes of 1 and 5. We repeat our analysis for English to Spanish and English to German directions, using WMT13 En-Es and WMT14 En-De data sets, respectively. For the En-Es we limited the training data to $4M$ sentence pairs (picked at random without replacement) to ensure that the training for the two language directions have comparable data sizes. We apply Byte-Pair Encoding (BPE) with $32k$ merge operations to the data (Sennrich et al., 2016).

We measure decoding times and BLEU scores for the model's translations using the WMT test sets. Next, we evaluate each model's performance on SimpleGEN, specifically calculating the percent of correctly gendered nouns, incorrectly gendered nouns as well as inconclusive results. Table 3 shows an example of our evaluation protocol for an example source sentences and four possible translations. We deem the first two as correct even though the second translation incorrectly translates "funny" as "feliz" since we focus on the translation of "physician" only. The third translation is deemed incorrect because the masculine form "médico" is used and the last translation is deemed inconclusive since it is in the plural form. We average these metrics over 3 trials, each initialized with different random seeds. We obtained 56 data points for each language direction.

5 Analysis

Table 4a shows the performance of 6 selected models including a baseline transformer model with 6 encoder and decoder layers. The first two columns (time and BLEU) were computed using the WMT test sets. The remaining columns report metrics using SimpleGEN. The algorithmic choices resulting in the highest speed-up, result in a 1.5% and 4% relative drop in BLEU for En-Es and En-De, respectively (compared to the baseline model). The pro-stereotypical (pro) column shows the percentage correct gendered translation for sentences where the occupation gender matches the context gender. As expected the accuracies are relatively high (80.9 to 77.7) for all the models. The

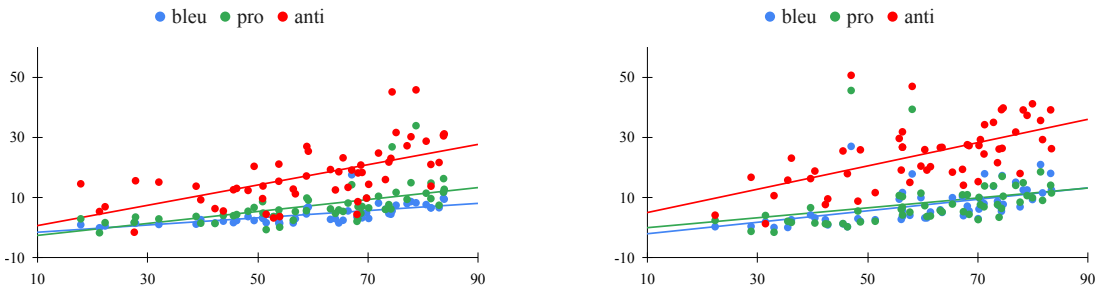
(b) "Stacked" speed-up optimizations.

Table 4: Results showing the effect of speed-up optimizations applied individually (in Table 4a) and stacked in Table 4b). We selected 6 models in both sections to highlight their effect on decoding time, BLEU and the % correctness on gender-bias metrics. The last row for each section (and each direction), shows the relative % drops in all the metrics between the fastest optimization method and the baseline. For example, for En-Es the relative % drop of decoding time for Table 4a is calculated as $100 * (3662.8 - 1993.5)/3662.8$.

last row in each section shows the *maximum relative drop* in each metric. We find that for the pro-stereotypical column the maximum relative drop is 1.5 and 6.5 for Spanish and German, respectively, which is similar to the relative change in BLEU scores. However, we find that the models are able to perform better on MOMC compared to FOFC suggesting biases even within the pro-stereotypical setting. In the anti-stereotypical (anti) column, we observe below-chance accuracies of only 44.2% and 39.7% for the two language directions, even from our best model. Columns FOFC and MOFC, show the difference in performance for sentences in the female context (FC) category in the presence of a stereotypical female occupation versus a stereotypical male occupation. We see a large imbalance in performance in these two columns summarized in ΔFC. Similarly, ΔMC summarizes the drop in performance when the model is confronted with stereotypical female occupations in a male context when compared to a male occupation in a male context. This suggests that the transformer's handling of grammatical agreement especially in cases where an occupation and contextual gender mismatch could be improved. The speedups disproportionately affect female context (FC) sentences across all categories.

In terms of model choices, we find that AANs deliver moderate speed-ups and minimal BLEU reduction compared to the baseline. However, AANs suffer the most degradation in terms of gender-bias. Δ, ΔFC and ΔMC are the highest for the ANN model in both language directions. On the other hand, greedy decoding with the baseline model has the smallest degradation in terms of gender-bias.

While Table 4a reveals the effect of select individual model choices, NMT practitioners, typically "stack" the optimization techniques together for large-scale deployment of NMT systems. Table 4b shows that stacking can provide $\approx 80 - 81\%$ relative drop in decoding time. However, we again see a disturbing trend where large speedups and small BLEU drops are accompanied with large drops in gender test performance. Again, FC sentences disproportionately suffer large drops in accuracy, particularly in MOFC in the En-De direction, where



(a) English-Spanish (b) English-German

Figure 1: Plots showing *relative percentage drop* of BLEU and gender-test metrics on the y-axis and *relative percentage drop* in decoding time in the x-axis FOr the two language directions analyzed. A breakdown of pro and anti into their constituent groups MOMC, FOFC, MOFc and FOMC is shown in Appendix A.3.

we see a 53.2% relative drop between the baseline and the fastest optimization stack.

While tables 4a and 4b show select models, we illustrate and further confirm our findings using all the data points (56 models trained) using scatter plots shown in fig. 1. We see that relative % drop in BLEU aligns closely with the relative % drop in gendered translation in the pro-stereotypical setting. In the case of German, the two trendlines are virtually overlapping. However, we see a steep drop for the anti-stereotypical settings, suggesting that BLEU scores computed using a typical test set only captures the stereotypical cases and even small reduction in BLEU could result in more instances of biased translations, especially in female context sentences.

6 Related Work

Previous research investigating gender bias in NMT has focused on data bias, ranging from assessment to mitigation. For example, Stanovsky et al. (2019b) adapted an evaluation data set for co-reference resolution to measure gender biases in machine translation. The sentences in this test set were created with ambiguous syntax, thus forcing the NMT model to "guess" the gender of the occupations. In contrast, there is always an unambiguous signal specifying the occupation-noun's gender in SimpleGEN. Similar work in speech-translation also studies contextual hints, but their work uses real-world sentences with complicated syntactic structures and sometimes the contextual hints are across sentence boundaries resulting in gender-ambiguous sentences (Bentivogli et al., 2020).

Zmigrod et al. (2019) create a counterfactual data-augmentation scheme by converting between masculine and feminine inflected sentences. Thus, with the additional modified sentences, the augmented data set equally represents both genders. Vanmassenhove et al. (2018), Stafanovičs et al. (2020) and Saunders et al. (2020) propose a data-annotation scheme in which the NMT model is trained to obey gender-specific tags provided with the source sentence. While Escudé Font and Costa-jussà (2019) employ pre-trained word-embeddings which have undergone a "debiasing" process (Bolukbasi et al., 2016; Zhao et al., 2018). Saunders and Byrne (2020) and Costa-jussà and de Jorge (2020) propose domain-adaptation on a carefully curated data set that "corrects" the model's misgendering problems. Costa-jussà et al. (2020) consider variations involving the amount of parameter-sharing between different language directions in multilingual NMT models.

7 Conclusion

With the current mainstreaming of machine translation, and its impact on people's everyday lives, bias mitigation in NMT should extend beyond data modifications and counter bias amplification due to algorithmic choices as well. We focus on algorithmic choices typically considered in speed-accuracy trade offs during productionization of NMT models. Our work illustrates that such trade offs, given current algorithmic choice practices, result in significant impact on gender translation, namely amplifying biases. In the process of this investigation, we construct a new gender translation evaluation set, SimpleGEN, and use it to show that modern NMT architectures struggle to overcome gender biases even when translating source sentences that are syntactically unambiguous and clearly marked for gender.

A Appendices

A.1 Impact Statement

This work identifies a weakness of NMT models where they appear to ignore contextual evidence regarding the gender of an occupation noun and apply an incorrect gender marker. It is difficult to measure the adverse effects of biases in NMT, but errors like the ones we highlight reduce trust in the NMT system.

Intended use: We hope that this type of error is further studied by NMT researchers leading to a solution. Furthermore, we expect the speed-optimization aspect of our work provides NMT engineers with an extra point of consideration, as we show gender-bias (errors in our dataset) increases rapidly compared to metrics like BLEU on standard datasets. In this work, we limit ourselves to viewing gender in the linguistic sense. SimpleGEN is not meant to be a replacement for traditional MT evaluation.

Risks: We recognize that socially, gendered language evolves (e.g. in English, "actress" is rarely used anymore). To the best of our knowledge, we selected occupations that are typically gendered (in Spanish and German) at present. Furthermore, we only regard the gender binary as a linguistic construct. It would be incorrect to use this work in the context of gender identity or gender expression etc.

Dataset: The dataset is "synthetic" in that it has been constructed using templates. We did not use crowd-sourcing or private data.

A.2 Full Template and Terms

Keywords	Values
f-n	female, women
m-n	male, men
f-n-pl	women, ladies, females, gals
m-n-pl	men, guys, males, fellows
f-n-sg	gal, woman, lady
m-n-sg	man, guy, fellow
f-obj-prn	her
m-obj-prn	him
f-pos-prn	her
m-pos-prn	his
f-obj-pos-prn	her
m-obj-pos-prn	his
f-sbj-prn	she
m-sbj-prn	he
f-rel	wife, mother, sister, girlfriend
m-rel	husband, father, brother, boyfriend

Table A5: Keywords and the values they can take.

Occupation Keywords	Values
f-occ-sg	clerk, designer, hairdresser, housekeeper, nanny, nurse, secretary
m-occ-sg	director, engineer, truck driver, farmer, laborer, mechanic, physician, president, plumber, carpenter, groundskeeper
f-occ-pl	clerks, designers, hairdressers, housekeepers, nannies, nurses, secretaries
m-occ-pl	directors, engineers, truck drivers, farmers, laborers, mechanics, physicians, presidents, plumbers, carpenters, groundskeepers
f-occ-sg-C	clerk, designer, hairdresser, housekeeper, nanny, nurse, secretary
m-occ-sg-C	director, truck driver, farmer, laborer, mechanic, physician, president, plumber, carpenter, groundskeeper
f-occ-pl-C	clerks, designers, hairdressers, housekeepers, nannies, nurses, secretaries
m-occ-pl-C	directors, truck drivers, farmers, laborers, mechanics, physicians, presidents, plumbers, carpenters, groundskeepers
f-occ-sg-V	
m-occ-sg-V	engineer,
f-occ-pl-V	
m-occ-pl-V	engineers,

Table A6: Occupation keywords and the values they can take. The prefix "m-" and "f-" indicate that according to the U.S Department of Labor these occupations have a higher percentage of male and female works, respectively.

Table A7 shows the template we use to generate our source sentences in SimpleGEN. We can generate sentences in one of the four sub-categories (MOMC, MOFC, FOFC, FOMC) by setting occupation keywords with the prefix m- or f- from our terminology set Table A6). For example, to generate MOFC sentences, we set occupation-keywords with prefix m- and non-occupation keywords with prefix f-.

A.3 Breakdown of scatter plots

Figures A2a and A2b further divides pro-stereotypical into male-occupations in male contexts (MoMc) and female-occupations in female context (FoFc), and anti-stereotypical into male-occupations in female contexts (MoFc) and female-occupations in male contexts (FoMc).

A.4 Evaluation Dictionary

Table A8 shows the dictionary we use for evaluation.

My {f/m}-rel is a {f/m}-occ-sg-C .
My {f/m}-rel is an {f/m}-occ-sg-V .
His {f/m}-rel is a {f/m}-occ-sg-C .
His {f/m}-rel is an {f/m}-occ-sg-V .
Alex's {f/m}-rel became a {f/m}-occ-sg-C .
Alex's {f/m}-rel became an {f/m}-occ-sg-V .
My {f/m}-rel enjoys {f/m}-pos-prn work a {f/m}-occ-sg-C .
My {f/m}-rel enjoys {f/m}-pos-prn work an {f/m}-occ-sg-V .
Those {f/m}-n-pl are {f/m}-occ-pl .
These {f/m}-n-pl work hard {f/m}-occ-pl .
I talked to {f/m}-obj-prn , {f/m}-sbj-prn is a {f/m}-occ-sg-C .
I talked to {f/m}-obj-prn , {f/m}-sbj-prn is an {f/m}-occ-sg-V .
{f/m}-sbj-prn works a {f/m}-occ-sg-C .
{f/m}-sbj-prn works an {f/m}-occ-sg-V .
I worked with {f/m}-obj-prn , {f/m}-sbj-prn is a very qualified {f/m}-occ-sg .
{f/m}-n {f/m}-occ-pl are rare .
{f/m}-n {f/m}-occ-pl are not predisposed for self-promotion .
{f/m}-n {f/m}-occ-pl performed well .
{f/m}-n {f/m}-occ-pl earn less than their counterparts .
{f/m}-sbj-prn enjoys {f/m}-pos-prn work a {f/m}-occ-sg-C .
{f/m}-sbj-prn enjoys {f/m}-pos-prn work an {f/m}-occ-sg-V .
Though {f/m}-sbj-prn argued with {f/m}-pos-prn colleagues, the {f/m}-occ-sg was always respectful .
People laughed at the {f/m}-occ-sg behind {f/m}-obj-pos-prn back .
The {f/m}-occ-sg screamed when {f/m}-sbj-prn saw the mouse .
That {f/m}-occ-sg chooses {f/m}-obj-prn words very carefully .
That {f/m}-occ-sg is a funny {f/m}-n-sg !
Those {f/m}-occ-pl are talented {f/m}-n-pl !
Their {f/m}-occ-sg is a smart {f/m}-n-sg !
The {f/m}-occ-sg is a very dynamic {f/m}-n-sg !
The {f/m}-occ-sg is a {f/m}-n-sg with a lot of experience.
This {f/m}-occ-sg happens to be my {f/m}-rel .
The {f/m}-occ-sg works hard and {f/m}-sbj-prn excels !
The {f/m}-occ-sg drove fast and {f/m}-sbj-prn was on time .
As a {f/m}-occ-sg-C , {f/m}-sbj-prn is very competent .
As an {f/m}-occ-sg-V , {f/m}-sbj-prn is very competent .
When the {f/m}-occ-sg arrived, everyone applauded {f/m}-obj-prn .
The {f/m}-occ-pl with the highest success rate per the polls, were {f/m}-n .
That {f/m}-occ-sg is also my {f/m}-rel .
The {f/m}-occ-sg moved here from Ethiopia where {f/m}-sbj-prn is from .
The {f/m}-occ-sg arrives early for {f/m}-pos-prn shift .
That {f/m}-occ-sg is hella strict, watch out for {f/m}-obj-prn .
That {f/m}-occ-sg retired early, good for {f/m}-obj-prn .

Abstract

State-of-the-art machine translation (MT) systems are typically trained to generate "standard" target language; however, many languages have multiple varieties (regional varieties, dialects, sociolects, non-native varieties) that are different from the standard language. Such varieties are often low-resource, and hence do not benefit from contemporary NLP solutions, MT included. We propose a general framework to rapidly adapt MT systems to generate language varieties that are close to, but different from, the standard target language, using no parallel (source–variety) data. This also includes adaptation of MT systems to low-resource typologically-related target languages.[1] We experiment with adapting an English–Russian MT system to generate Ukrainian and Belarusian, an English–Norwegian Bokmål system to generate Nynorsk, and an English–Arabic system to generate four Arabic dialects, obtaining significant improvements over competitive baselines.

1 Introduction

Despite tremendous progress in machine translation (Bahdanau et al., 2015; Vaswani et al., 2017) and language generation in general, current state-of-the-art systems often work under the assumption that a language is homogeneously spoken and understood by its speakers: they generate a "standard" form of the target language, typically based on the availability of parallel data. But language use varies with regions, socio-economic backgrounds, ethnicity, and fluency, and many widely spoken languages consist of dozens of varieties or dialects, with differing lexical, morphological, and syntactic patterns for which no translation data are typically available. As a result, models trained to translate from a source language (SRC) to a standard language variety (STD) lead to a sub-par experience for speakers of other varieties.

Motivated by these issues, we focus on the task of adapting a trained SRC→STD translation model to generate text in a different target variety (TGT), having access only to limited monolingual corpora in TGT and no SRC–TGT parallel data. TGT may be a dialect of, a language variety of, or a typologically-related language to STD.

We present an effective transfer-learning framework for translation into low resource language varieties. Our method reuses SRC→STD MT models and finetunes them on synthesized (pseudo-parallel) SRC–TGT texts. This allows for rapid adaptation of MT models to new varieties without having to train everything from scratch. Using word-embedding adaptation techniques, we show that MT models which predict continuous word vectors (Kumar and Tsvetkov, 2019) rather than softmax probabilities lead to superior performance since they allow additional knowledge to be injected into the models through transfer between word embeddings of high-resource (STD) and low-resource (TGT) monolingual corpora.

We evaluate our framework on three translation tasks: English to Ukrainian and Belarusian, assuming parallel data are only available for English→Russian; English to Nynorsk, with only English to Norwegian Bokmål parallel data; and English to four Arabic dialects, with only English→Modern Standard Arabic (MSA) parallel data. Our approach outperforms competitive baselines based on unsupervised MT, and methods based on finetuning softmax-based models.

2 A Transfer-learning Architecture

We first formalize the task setup. We are given a parallel SRC→STD corpus, which allows us to

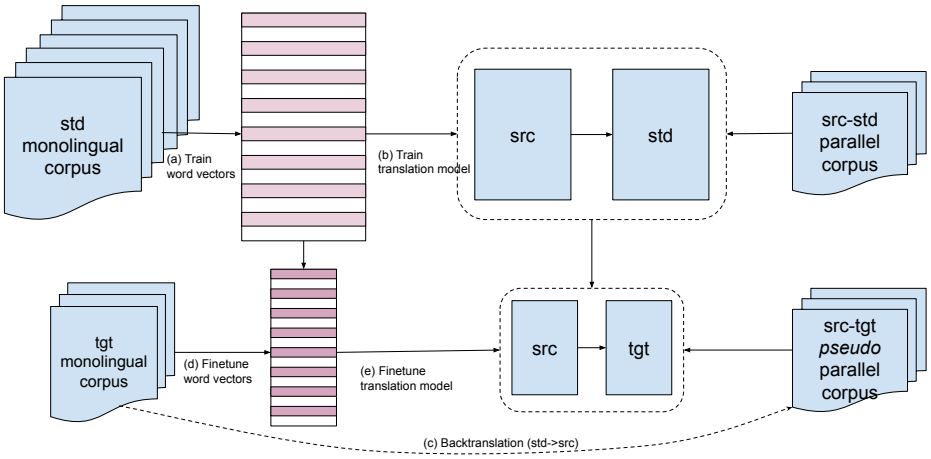

Figure 1: An overview of our approach. (a) Using the available STD monolingual corpora, we first train word vectors using `fasttext`; (b) we then train a SRC→STD translation model using the parallel corpora to predict the pretrained word vectors; (c) next, we train STD→SRC model and use it to translate TGT monolingual corpora to SRC; (d) now, we finetune STD subword embeddings to learn TGT word embeddings; and finally (e) we finetune a SRC→STD model to generate TGT pretrained embeddings using the back-translated SRC→TGT data.

train a translation model $f(\cdot;\theta)$ that takes an input sentence x in SRC and generates its translation in the standard veriety STD, $\hat{y}_{\text{STD}} = f(x;\theta)$. Here, θ are the learnable parameters of the model. We are also given monolingual corpora in both the standard STD and target variety TGT. Our goal now is to modify f to generate translations $\hat{y}_{\text{TGT}}$ in the target variety TGT. At training time, we assume no SRC–TGT or STD–TGT parallel data are available.

Our solution (Figure 1) is based on a transformer-based encoder-decoder architecture (Vaswani et al., 2017) which we modify to predict word vectors. Following Kumar and Tsvetkov (2019), instead of treating each token in the vocabulary as a discrete unit, we represent it using a unit-normalized d-dimensional pre-trained vector. These vectors are learned from a STD monolingual corpus using `fasttext` (Bojanowski et al., 2017). A word's representation is computed as the average of the vectors of its character n-grams, allowing surface-level linguistic information to be shared among words. At each step in the decoder, we feed this pretrained vector at the input and instead of predicting a probability distribution over the vocabulary using a softmax layer, we predict a d-dimensional continuous-valued vector. We train this model by minimizing the von Mises-Fisher (vMF) loss—a probabilistic variant of cosine distance—between the predicted vector and the pre-trained vector. The pre-trained vectors (at both input and output of the decoder) are not trained with the model. To decode from this model, at each step, the output word is generated by finding the closest neighbor (in terms of cosine similarity) of the predicted output vector in the pre-trained embedding table.

We train f in this fashion using SRC–STD parallel data. As shown below, training a softmax-based SRC→STD model to later finetune with TGT suffers from vocabulary mismatch between STD and TGT and thus is detrimental to downstream performance. By replacing the decoder input and output with pre-trained vectors, we separate the vocabulary from the MT model, making adaptation easier.

Now, to finetune this model to generate TGT, we need TGT embeddings. Since the TGT monolingual corpus is small, training `fasttext` vectors on this corpus from scratch will lead (as we show) to low-quality embeddings. Leveraging the relatedness of STD and TGT and their vocabulary overlap, we use STD embeddings to transfer knowledge to TGT embeddings: for each character n-gram in the TGT corpus, we initialize its embedding with the corresponding STD embedding, if available. We then continue training `fasttext` on the TGT monolingual corpus (Chaudhary et al., 2018). Last, we use a supervised embedding alignment method (Lample et al., 2018a) to project the learned TGT embeddings in the same space as STD. STD and TGT are expected to have a large lexical overlap, so we use identical tokens in both varieties as supervision for this alignment. The obtained embeddings, due to transfer learning from STD, inject additional knowledge in the model.

Finally, to obtain a SRC→TGT model, we finetune f on psuedo-parallel SRC–TGT data. Using a STD→SRC MT model (a back-translation model

trained using large STD–SRC parallel data with standard settings) we (back)-translate TGT data to SRC. Naturally, these synthetic parallel data will be noisy despite the similarity between STD and TGT, but we show that they improve the overall performance. We discuss the implications of this noise in §4.

3 Experimental Setup

Datasets We experiment with two setups. In the first (synthetic) setup, we use English (EN) as SRC, Russian (RU) as STD, and Ukrainian (UK) and Belarusian (BE) as TGTs. We sample 10M EN-RU sentences from the WMT'19 shared task (Ma et al., 2019), and 80M RU sentences from the CoNLL'17 shared task to train embeddings. To simulate low-resource scenarios, we sample 10K, 100K and 1M UK sentences from the CoNLL'17 shared task and BE sentences from the OSCAR corpus (Ortiz Suárez et al., 2020). We use TED dev/test sets for both languages pairs (Cettolo et al., 2012).

The second (real world) setup has two language sets: the first one defines English as SRC, with Modern Standard Arabic (MSA) as STD and four Arabic varieties spoken in Doha, Beirut, Rabat and Tunis as TGTs. We sample 10M EN-MSA sentences from the UNPC corpus (Ziemski et al., 2016), and 80M MSA sentences from the CoNLL'17 shared task. For Arabic varieties, we use the MADAR corpus (Bouamor et al., 2018) which consists of 12K 6-way parallel sentences between English, MSA and the 4 considered varieties. We ignore the English sentences, sample dev/test sets of 1K sentences each, and consider 10K monolingual sentences for each TGT variety. The second set also has English as SRC with Norwegian Bokmål (NO) as STD and its written variety Nynorsk (NN) as TGT. We use 630K EN-NO sentences from WikiMatrix (Schwenk et al., 2021), and 26M NO sentences from ParaCrawl (Esplà et al., 2019) combined with the WikiMatrix NO sentences to train embeddings. We use 310K NN sentences from WikiMatrix, and TED dev/test sets for both varieties (Reimers and Gurevych, 2020).

Preprocessing We preprocess raw text using Byte Pair Encoding (BPE, Sennrich et al., 2016) with 24K merge operations on each SRC–STD corpus trained separately on SRC and STD. We use the same BPE model to tokenize the monolingual STD data and learn `fasttext` embeddings (we consider character n-grams of length 3 to 6).[2] Splitting the TGT words with the same STD BPE model will result in heavy segmentation, especially when TGT contains characters not present in STD.[3] To counter this, we train a joint BPE model with 24K operations on the concatenation of STD and TGT corpora to tokenize TGT corpus following Chronopoulou et al. (2020). This technique increases the number of shared tokens between STD and TGT, thus enabling better cross-variety transfer while learning embeddings *and* while finetuning. We follow Chaudhary et al. (2018) to train embeddings on the generated TGT vocabulary where we initialize the character n-gram representations for TGT words with STD's `fasttext` model wherever available and finetune them on the TGT corpus.

Implementation and Evaluation We modify the standard OpenNMT-py seq2seq models of PyTorch (Klein et al., 2017) to train our model with vMF loss (Kumar and Tsvetkov, 2019). Additional hyperparameter details are outlined in Appendix B. We evaluate our methods using BLEU score (Papineni et al., 2002) based on the SacreBLEU implementation (Post, 2018).[4] For the Arabic varieties, we also report a macro-average. In addition, to measure the expected impact on actual systems' users, we follow Faisal et al. (2021) in computing a population-weighted macro-average ($\textbf{avg}_{\textbf{pop}}$) based on language community populations provided by Ethnologue (Eberhard et al., 2019).

3.1 Experiments

Our proposed framework, **LANGVARMT**, consists of three main components: (1) A supervised SRC→STD model is trained to predict continuous STD word embeddings rather than discrete softmax probabilities. (2) Output STD embeddings are replaced with TGT embeddings. The TGT embeddings are trained by finetuning STD embeddings on monolingual TGT data and aligning the two embedding spaces. (3) The resulting model is finetuned with pseudo-parallel SRC→TGT data.

We compare LANGVARMT with the following competitive baselines. **SUP(SRC→STD)**: train a standard (softmax-based) supervised SRC→STD model, and consider the output of this model as

[2] We slightly modify `fasttext` to not consider BPE token markers "@@" in the character n-grams.

[3] For example, both RU and UK alphabets consist of 33 letters; RU has the letters Ёё, ъ, ы and Ээ, which are not used in UK. Instead, UK has Ґґ, Єє, Ii and Її.

[4] While we recognize the limitations of BLEU (Mathur et al., 2020), more sophisticated embedding-based metrics for MT evaluation (Zhang et al., 2020; Sellam et al., 2020) are unfortunately not available for low-resource language varieties.

Size of TGT corpus	UK 10K	UK 100K	UK 1M	BE 10K	BE 100K	BE 1M	NN 300K	Arabic Varieties (10K) Doha	Beirut	Rabat	Tunis
SUP(SRC→STD)	1.7	1.7	1.7	1.5	1.5	1.5	11.3	3.7	1.8	2.0	1.3
UNSUP(SRC→TGT)	0.3	0.6	0.9	0.4	0.6	1.4	2.7	0.2	0.1	0.1	0.1
PIVOT	1.5	8.6	14.9	1.15	3.9	8.0	11.9	1.8	2.1	1.7	1.1
SOFTMAX	1.9	12.7	15.4	1.5	4.5	7.9	14.4	14.5	7.4	4.9	3.9
LANGVARMT	**6.1**	**13.5**	**15.3**	**2.3**	**8.8**	**9.8**	**16.6**	**20.1**	**8.1**	**7.4**	**4.6**

Table 1: BLEU scores on translation from English to Ukrainian, Belarusian, Nynorsk, and Arabic dialects with varying amounts of monolingual target data (TGT sentences) available for finetuning. Our approach (LANGVARMT) outperforms all baselines.

TGT under the assumption that STD and TGT may be very similar. **UNSUP(SRC→TGT)**: train an unsupervised MT model (Lample et al., 2018a) in which the encoder and decoder are initialized with cross-lingual masked language models (MLM, Conneau and Lample, 2019). These MLMs are pre-trained on SRC monolingual data, and then finetuned on TGT monolingual data with an expanded vocabulary as described above. This baseline is taken from Chronopoulou et al. (2020), where it showed state-of-the-art performance for low-monolingual-resource scenarios. **Pivot**: train a UNSUP(STD→TGT) model as described above using STD and TGT monolingual corpora. During inference, translate the SRC sentence to STD with the SUP(SRC→STD) model and then to TGT with the UNSUP(STD→TGT) model. We also perform several ablation experiments, showing that every component of LANGVARMT is necessary for good downstream performance. Specifically, we report results with LANGVARMT but using a standard softmax layer (**SOFTMAX**) to predict tokens instead of continuous vectors.[5]

4 Results and Analysis

Table 1 compares the performance of LANGVARMT with the baselines for Ukrainian, Belarusian, Nynorsk, and the four Arabic varieties. For reference, note that the EN→RU, EN→MSA, and EN→NO models are relatively strong, yielding BLEU scores of 24.3, 21.2, and 24.9, respectively.

Synthetic Setup Considering STD and TGT as the same language is sub-optimal, as is evident from the poor performance of the non-adapted SUP(SRC→STD) model. Clearly, special attention ought to be paid to language varieties. Direct unsupervised translation from SRC to TGT performs poorly as well, confirming previously reported results of the ineffectiveness of such methods on unrelated languages (Guzmán et al., 2019).

[5]Additional ablation results are listed in Appendix C.

Translating SRC to TGT by pivoting through STD achieves much better performance owing to strong UNSUP(STD→TGT) models that leverage the similarities between STD and TGT. However, when resources are scarse (e.g., with 10K monolingual sentences as opposed to 1M), this performance gain considerably diminishes. We attribute this drop to overfitting during the pre-training phase on the small TGT monolingual data. Ablation results (Appendix C) also show that in such low-resource settings the learned embeddings are of low quality.

Finally, LANGVARMT consistently outperforms all baselines. Using 1M UK sentences, it achieves similar performance (for EN→UK) to the softmax ablation of our method, SOFTMAX, and small gains over unsupervised methods. However, in lower resource settings our approach is clearly better than the strongest baselines by over 4 BLEU points for UK (10K) and 3.9 points for BE (100K).

To identify potential sources of error in our proposed method, we lemmatize the generated translations and test sets and evaluate BLEU (Qi et al., 2020). Across all data sizes, both UK and BE achieve a substantial increase in BLEU (up to +6 BLEU; see Appendix D for details) compared to that obtained on raw text, indicating morphological errors in the translations. In future work, we will investigate whether we can alleviate this issue by considering TGT embeddings based on morphological features of tokens (Chaudhary et al., 2018).

Real-world Setup The effectiveness of LANGVARMT is pronounced in this setup with a dramatic improvement of more than 18 BLEU points over unsupervised baselines when translating into Doha Arabic. We hypothesize that during the pretraining phase of unsupervised methods, the extreme difference between the size of the MSA monolingual corpus (10M) and the varieties' corpora (10K) leads to overfitting. Additionally, compared to the synthetic setup, the Arabic varieties we consider are quite close to MSA, allowing for easy and effective adaptation of both word embeddings and

EN→MSA models. LANGVARMT also improves in all other Arabic varieties, although naturally some varieties remain challenging. For example, the Rabat and particularly the Tunis varieties are more likely to include French loanwords (Bouamor et al., 2018) which are not adequately handled as they are not part of our vocabulary. In future work, we will investigate whether we can alleviate this issue by potentially including French corpora (transliterated into Arabic) to our TGT language corpora. On average, our approach improves by 2.3 BLEU points over the softmax-based baseline (cf. 7.7 and 10.0 in Table 2 under $\mathbf{avg}_{\mathcal{L}}$) across the four Arabic dialects. For a population-weighted average ($\mathbf{avg}_{\mathbf{pop}}$), we associate the Doha variety with Gulf Arabic (ISO code: `afb`), the Beirut one with North Levantine Arabic (`apc`), Rabat with Moroccan (`ary`), and the Tunis variety with Tunisian Arabic (`aeb`). As before, LANGVARMT outperforms the baselines. The absolute BLEU scores in this highly challenging setup are admittedly low, but as we discuss in Appendix D, the translations generated by LANGVARMT are often fluent and input preserving, especially compared to the baselines.

Finally, due to high similarity between NO and NN, the SUP(EN→NO) model also performs well on NN with 11.3 BLEU, but our method yields further gains of over 4 points over the baselines.

5 Discussion

Fairness The goal of this work is to develop more equitable technologies, usable by speakers of diverse language varieties. Here, we evaluate the systems along the principles of *fairness*. We evaluate the fairness of our Arabic multi-dialect system's utility proportionally to the populations speaking those dialects. In particular, we seek to measure how much average benefit will the people of different dialects receive if their respective translation performance is improved. A simple proxy for fairness is the standard deviation (or, even simpler, a $\max - \min$ performance) of the BLEU scores across dialects (A higher value implies more unfairness across the dialects) Beyond that, we measure a system's *unfairness* with respect to the different dialect subgroups, using the adaptation of generalized entropy index (Speicher et al., 2018), which considers equities within and between subgroups in evaluating the overall unfairness of an algorithm on a population Faisal et al. (2021) (See Appendix F for details and additional discussion).

Table 2 shows that our proposed method is fairer across all dialects, compared to baselines where only MSA translation produces comprehensible outputs.

Model	$\mathbf{avg}_{\mathcal{L}}\uparrow$	$\mathbf{avg}_{\mathbf{pop}}\uparrow$	max−min↓	unfair↓
SUP(SRC→STD)	2.2	1.8	19.9	0.037
UNSUP(SRC→TGT)	0.1	0.1	21.1	0.046
PIVOT	1.7	1.8	20.1	0.037
SOFTMAX	7.7	5.7	17.3	0.020
LANGVARMT	**10.0**	**7.3**	**16.6**	**0.016**

Table 2: Average performance and fairness metrics across the four Arabic varieties. This evaluation includes MSA (with a BLEU score of 21.2 on the SUP(EN→MSA) model).

Negative Results Our proposed method relies on two components: (1) quality of TGT word embeddings which is dependent on STD and TGT shared (subword) vocabulary, and (2) the psuedo-parallel SRC–TGT obtained by back-translating TGT data through a STD→SRC model. If STD and TGT are not sufficiently closely related, the quality of both of these components can degrade, leading to a drop in the performance of our proposed method. We present results of two additional experiments to elucidate this phenomenon in Appendix E.

Related Work We provide an extensive discussion of related work in Appendix A.

6 Conclusion

We presented a transfer-learning framework for rapid and effective adaptation of MT models to different varieties of the target language without access to any source-to-variety parallel data. We demonstrated significant gains in BLEU scores across several language pairs, especially in highly resource-scarce scenarios. The improvements are mainly due to the benefits of continuous-output models over softmax-based generation. Our analysis highlights the importance of addressing morphological differences between language varieties, which will be in the focus of our future work.

A Related Work

Early work addressing translation involving language varieties includes rule-based transformations (Altintas and Cicekli, 2002; Marujo et al., 2011; Tan et al., 2012) which rely on language specific information and expert knowledge which can be expensive and difficult to scale. Recent work to address this issue only focuses on cases where parallel data do exist. They include a combination of word-level and character-level MT (Vilar et al., 2007; Tiedemann, 2009; Nakov and Tiedemann, 2012) between related languages or training multilingual models to translate to/from English to different varieties of a language (e.g., Lakew et al. (2018) work on Brazilian–European Portuguese and European–Canadian French). Such parallel data, however, are typically unavailable for most language varieties.

Unsupervised translation models, which require only monolingual data, can address this limitation (Artetxe et al., 2018; Lample et al., 2018a; Garcia et al., 2020, 2021). However, when even *mono*lingual corpora are limited, unsupervised models are challenging to train and are quite ineffective for translating between unrelated languages (Marchisio et al., 2020). Considering varieties of a language as writing styles, unsupervised style transfer (Yang et al., 2018; He et al., 2020) or deciphering methods (Pourdamghani and Knight, 2017) to translate between different varieties have also been been explored but have not been shown to perform well, often only reporting BLEU-1 scores since they obtain BLEU-4 scores which are closer to 0. Additionally, all of these approaches require simultaneous access to data in all varieties during training and must be trained from scratch when a new variety is added. In contrast, our presented method allows for easy adaptation of SRC→STD models to any new variety as it arrives.

Considering a new target variety as a new domain of STD, unsupervised domain adaptation methods can be employed, such as finetuning SRC→STD models using pseudo-parallel corpora generated from monolingual corpora in target varieties (Hu et al., 2019; Currey et al., 2017). Our proposed method is most related to this approach; but while these methods have the potential to adapt the decoder language model, for effective transfer, STD and TGT must have a shared vocabulary which is not true for most language varieties due to lexical, morphological, and at times orthographic differences. In contrast, our proposed method makes use of cross-variety word embeddings. While our examples only involve same-script varieties, augmenting our approach to work across scripts through a transliteration component is straightforward.

B Implementation Details

We modify the standard OpenNMT-py seq2seq models of PyTorch (Klein et al., 2017) to train our model with vMF loss (Kumar and Tsvetkov, 2019). We use the transformer-BASE model (Vaswani et al., 2017), with 6 layers in both encoder and decoder and with 8 attention heads, as our underlying architecture. We modify this model to predict pretrained `fasttext` vectors. We also initialize the decoder input embedding table with the pretrained vectors and do not update them during model training. All models are optimized using Rectified Adam (Liu et al., 2020) with a batch size of 4K tokens and dropout of 0.1. We train SRC→STD models for 350K steps with an initial learning rate of 0.0007 with linear decay. For finetuning, we reduce the learning rate to 0.0001 and train for up to 100K steps. We use early stopping in all models based on validation loss computed every 2K steps. We decode all the softmax-based models with a beam size of 5 and all the vMF-based models greedily.

We evaluate our methods using BLEU score (Papineni et al., 2002) based on the SacreBLEU implementation (Post, 2018). While we recognize the limitations of BLEU (Mathur et al., 2020), more sophisticated embedding-based metrics for MT evaluation (Zhang et al., 2020; Sellam et al., 2020) are simply not available for language varieties.

C Additional English-Ukrainian Experiments

On our resource-richest setup of EN→UK translation using 1M UK sentences and RU as STD, we compare our method with the following additional baselines. Table 3 presents these results.

LAMPLE-UNSUP(SRC→TGT): This is another unsupervised model, based on Lample et al. (2018a) which initializes the input and output embedding tables of both encoder and decoder using cross-lingual word embeddings trained on SRC and TGT monolingual corpora. The model is trained in a similar manner to Chronopoulou et al. (2020) (UNSUP(SRC→TGT)) with iterative backtranslation and autoencoding.

PIVOT:LAMPLE(STD→TGT): This baseline is

Method	BLEU (uk)
SUP(SRC-STD)	1.7
UNSUP(SRC→TGT)	0.9
PIVOT:	14.9
LAMPLE-UNSUP(SRC→TGT)	0.4
PIVOT:LAMPLE-UNSUP(STD→TGT)	9.0
PIVOT:DICTREPLACE(STD→TGT)	2.9
LANGVARMT	15.3
LANGVARMT w/ poor embeddings	4.6
LANGVARMT-RANDOM	13.1
SOFTMAX	15.4
LANGVARMT-RANDOM-SOFTMAX	14.1

Table 3: BLEU scores on EN-UK test corpus with 1M UK monolingual corpus.

similar to the PIVOT baseline, where we replace the unsupervised model with that of Lample et al. (2018a).

PIVOT:DICTREPLACE(STD→TGT): Here we first translate SRC to STD using SUP(SRC→STD), and then modify the STD output to get a TGT sentence as follows: We create a STD–TGT dictionary using the embedding map suggested by Lample et al. (2018b). This dictionary is created on words tokenized with Moses tokenizer (Hoang and Koehn, 2008) rather than BPE tokens. We replace each token in the generated STD sentence which is not in the TGT vocabulary using the dictionary (if available). We consider this baseline to measure lexical vs. syntactic/phrase level differences between Russian and Ukrainian.

In addition to baseline comparison, we report the following ablation experiments.

(1) To measure transfer from STD to TGT embeddings, we finetune the SUP(SRC→STD) model using TGT embeddings trained from scratch (as opposed to initialized with STD embeddings).

(2) To measure the impact of initialization during model finetuning, we compare with a randomly initialized model trained in a supervised fashion on the psuedo-parallel SRC–TGT data.

Baselines On the unsupervised models based on Lample et al. (2018a), we observe a similar trend as that of Chronopoulou et al. (2020), where the LAMPLE-UNSUP(SRC→TGT) model performing poorly (0.4) with substantial gains when pivoting through Russian (9.0 BLEU).

PIVOT:DICTREPLACE(STD→TGT) gains some improvement over considering the output of SUP(SRC→STD) as TGT, probably due to syntactic similarities between Russian and Ukrainian. This result can potentially be further improved with a human-curated RU–UK dictionary, but such resources are typically not available for the low-resource settings we consider in this paper.

Ablations As shown in Table 3, training the SRC→TGT model on a randomly initialized model (LANGVAR-RANDOM) results in a performance drop, confirming that transfer learning from a SRC→STD model is beneficial. Similarly, using TGT embeddings trained from scratch (LANGVARMT w/ poor embeddings) results in a drastic performance drop, providing evidence for essential transfer from STD embeddings.

D Analysis

To better understand the performance of our models, we perform additional analyses.

Lemmatized BLEU For UK and BE, we lemmatize each word in the test sets and the translations and evaluate BLEU scores. The results, depicted in Table 4, very likely indicate that our framework often generates correct lemmas, but may fail on the correct inflectional form of the target words. This highlights the importance of considering morphological differences between language varieties. The high BLEU scores also demonstrate that the resulting translations are quite likely understandable, albeit not always grammatical.

	EN→UK			EN→BE		
	10K	100K	1M	10K	100K	1M
raw	6.1	13.5	15.3	2.3	8.8	9.8
lemma	12.8	19.5	21.3	3.5	13.7	15.8

Table 4: BLEU scores on raw vs lemmatized text with LANGVARMT.

Translation of Rare Words On the outputs of the EN→UK model, trained with 100K UK sentences, we compute the translation accuracy of words based on their frequency in the TGT monolingual corpus for LANGVARMT, our best baseline SUP(SRC→STD)+UNSUP(SRC→TGT) and the best performing ablation SOFTMAX. These results, shown in Table 5, reveal that LANGVARMT is more accurate at translating rare words (with frequency less than 10) compared to the baselines.

Examples We provide some examples of EN-UK and EN-Beirut Arabic translations generated by the three models in Tables 6 and 7. As evaluated by native speakers of the Beirut Arabic, we find that

frequency	PIVOT	SOFTMAX	LANGVARMT
1	0.0429	0.1516	0.1812
2	0.0448	0.2292	0.2556
3	0.0597	0.2246	0.2076
4	0.0692	0.2601	0.2962
[5,10)	0.0582	0.2457	0.2722
[10,100)	0.1194	0.2881	0.2827
[100,1000)	0.2712	0.4537	0.4449

Table 5: Translation accuracies of words based on their frequencies on EN→UK with 100K UK sentences.

despite a BLEU score of only 8, in a majority of cases our baseline model is able to generate fluent translations of the input, preserving most of the content, whereas the baseline model ignores many of the content words. We also observe that in some cases, despite predicting in the right semantic space of the pretrained embeddings, it fails to predict the right token, resulting in surface form errors (e.g., predicting adjectival forms of verbs). This phenomenon is known and studied in more detail in Kumar and Tsvetkov (2019).

E Negative Results

We present results for the following experiments: (a) adapting an English to Thai (EN→TH) model to Lao (LO). We use a parallel corpus of around 10M sentences for training the supervised EN→TH model from the CCAligned corpus (El-Kishky et al., 2020), around 140K LO monolingual sentences from the OSCAR corpus (Ortiz Suárez et al., 2020) and TED2020 dev/tests for both TH and LO[6] (Reimers and Gurevych, 2020). (b) adapting an English to Amharic Model (EN→AM) to Tigrinya (TI). We use training, development and test sets from the JW300 corpus (Agić and Vulić, 2019) containing 500K EN–AM parallel corpus and 100K Tigrinya monolingual sentences.

As summarized in Table 8, our method fails to perform well on these sets of languages. Although Thai and Lao are very closely related languages, we attribute this result to little subword overlap in their respective vocabularies which degrade the quality of the embeddings. This is because Lao's writing system is developed phonetically whereas Thai writing contains many silent characters. Considering shared phonetic information while learning the embeddings can alleviate this issue and is an avenue for future work. On the other hand, Amharic and Tigrinya, while sharing a decent amount of vocabulary, use different constructs and function words (Kidane et al., 2021) leading to a very noisy psuedo-parallel corpus.

[6]Although Thai and Lao scripts look very similar, they use different Unicode symbols which are one-to-one mappable to each other: https://en.wikipedia.org/wiki/Lao_(Unicode_block)

Table 8: BLEU scores for English to Lao and English to Tigrinya translation

principle proposed by Rawls (1999), whose egalitarian approach proposes to narrow the gap between unequal accuracies.

A simple proxy for unfairness is the standard deviation (or, even simpler, a $\max - \min$ performance) of the scores across languages. Beyond that, we measure a system's *unfairness* with respect to the different subgroups using the adaptation of generalized entropy index described by Speicher et al. (2018), which considers equities within and between subgroups in evaluating the overall unfairness of an algorithm on a population. The generalized entropy index for a population of n individuals receiving benefits $b_1, b_2, \ldots, b_n$ with mean benefit μ is

$$\mathcal{E}^{\alpha}(b_1, \ldots, b_n) = \frac{1}{n\alpha(\alpha-1)} \sum_{i=1}^{n} \left[\left(\frac{b_i}{\mu} \right)^{\alpha} - 1 \right].$$

Using $\alpha = 2$ following Speicher et al. (2018), the generalized entropy index corresponds to half the squared coefficient of variation.[7]

If the underlying population can be split into $|G|$ disjoint subgroups across some attribute (e.g. gender, age, or language variety) we can decompose the total unfairness into individual and group-level unfairness. Each subgroup $g \in G$ will correspond to n_g individuals with corresponding benefit vector $\mathbf{b}^g = (b_1^g, b_2^g, \ldots, b_{n_g}^g)$ and mean benefit μ_g. Then, total generalized entropy can be re-written as:

$$\begin{aligned} \mathcal{E}^{\alpha}(b_1, \ldots, b_n) =& \sum_{g=1}^{|G|} \frac{n_g}{n} \left(\frac{\mu_g}{\mu} \right)^{\alpha} \mathcal{E}^{\alpha}(\mathbf{b}^g) \\ &+ \sum_{g=1}^{|G|} \frac{n_g}{n\alpha(\alpha-1)} \left[\left(\frac{\mu_g}{\mu} \right)^{\alpha} - 1 \right] \\ =& \mathcal{E}^{\alpha}(\mathbf{b}) + \mathcal{E}_{\beta}^{\alpha}(\mathbf{b}). \end{aligned}$$

The first term $\mathcal{E}^{\alpha}(\mathbf{b})$ corresponds to the weighted unfairness score that is observed *within* each subgroup, while the second term $\mathcal{E}_{\beta}^{\alpha}(\mathbf{b})$ corresponds to the unfairness score *across* different subgroups.

In this measure of unfairness, we define the benefit as being directly proportional to the system's accuracy. For a Machine Translation system, each user receives an average benefit equal to the BLEU score the MT system achieves on the user's dialect. Conceptually, if the system produces a perfect translation (BLEU=1) then the user will receive the highest benefit of 1. If the system fails to produce a meaningful translation (BLEU$\rightarrow$ 0) then the user receives no benefit ($b = 0$) from the interaction with the system.

[7]The coefficient of variation is simply the ratio of the standard deviation σ to the mean μ of a distribution.

Is Sparse Attention more Interpretable?

Clara Meister[ϟ] **Stefan Lazov**[★] **Isabelle Augenstein**[ↀ] **Ryan Cotterell**[★,ϟ]

Abstract

Sparse attention has been claimed to increase model interpretability under the assumption that it highlights influential inputs. Yet the attention distribution is typically over representations internal to the model rather than the inputs themselves, suggesting this assumption may not have merit. We build on the recent work exploring the interpretability of attention; we design a set of experiments to help us understand how sparsity affects our ability to use attention as an explainability tool. On three text classification tasks, we verify that only a weak relationship between inputs and co-indexed intermediate representations exists—under sparse attention and otherwise. Further, we do not find any plausible mappings from sparse attention distributions to a sparse set of influential inputs through other avenues. Rather, we observe in this setting that inducing sparsity may make it less plausible that attention can be used as a tool for understanding model behavior.

1 Introduction

Interpretability research in natural language processing (NLP) is becoming increasingly important as complex models are applied to more and more downstream decision making tasks. In light of this, many researchers have turned to the attention mechanism, which has not only led to impressive performance improvements in neural models, but has also been claimed to offer insights into how models make decisions. Specifically, a number of works imply or directly state that one may inspect the attention distribution to determine the amount of influence each input token has in a model's decision-making process (Xie et al., 2017; Mullenbach et al., 2018; Niculae et al., 2018, *inter alia*).

Many lines of work have gone on to exploit this assumption when building their own "interpretable" models or analysis tools (Yang et al., 2016; Tu et al., 2016; De-Arteaga et al., 2019); one subset has even tried to make models with attention *more* interpretable by inducing sparsity—a common attribute of interpretable models (Lipton, 2018; Rudin, 2019)—in attention weights, with the motivation that this allows model decisions to be mapped to a *limited* number of items (Martins and Astudillo, 2016; Malaviya et al., 2018; Zhang et al., 2019). Yet, there lacks concrete reasoning or evidence that sparse attention weights leads to more interpretable models: customarily, attention is not directly over the model's inputs, but rather over some representation *internal* to the model, e.g. the hidden states of a recurrent network or contextual embeddings of a Transformer (see Fig. 1). Importantly, these internal representations do not solely encode information from the input token they are co-indexed with (Salehinejad et al., 2017; Brunner et al., 2020), but rather from a range of inputs. This presents the question: if internal representations themselves may not be interpretable, can we actually deduce anything from "interpretable" attention weights?

We build on the recent line of work challenging the validity of attention-as-explanation methods (Jain and Wallace, 2019; Serrano and Smith, 2019; Grimsley et al., 2020, *inter alia*) and specifically examine how *sparsity* affects their observations. To this end, we introduce a novel entropy-based metric to measure the *dispersion* of inputs' influence, rather than just their magnitudes. Through experiments on three text classification tasks, utilizing both LSTM and Transformer-based models, we observe how sparse attention affects the results of Jain and Wallace (2019) and Wiegreffe and Pinter (2019), additionally exploring whether it allows us to identify a core set of inputs that are important to models' decisions. We find we are unable to identify such a set when using sparse attention; rather, it appears that encouraging sparsity may simultaneously encourage a higher degree of

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 122–129
August 1–6, 2021. ©2021 Association for Computational Linguistics

contextualization in intermediate representations. We further observe a decrease in the correlation between the attention distribution and input feature importance measures, which exacerbates issues found by prior works. The primary conclusion of our work is that we should not believe sparse attention enhances model interpretability until we have concrete reasons to believe so; in this preliminary analysis, we do not find any such evidence.

2 Attention-based Neural Networks

We consider inputs $\mathbf{x} = x_1 \cdots x_n \in \mathcal{V}^n$ of length n where the tokens from taken from an alphabet $\mathcal{V}$. We denote the embedding of $\mathbf{x}$, e.g., its one hot encoding or (more commonly) a linear transformation of its one-hot encoding with an embedding matrix $E \in \mathbb{R}^{d \times |\mathcal{V}|}$, as $X^{(e)} \in \mathbb{R}^{d \times n}$. Our embedded input $X^{(e)}$ is then fed to an encoder, which produces n intermediate representations $I = [\mathbf{h}_1; \ldots; \mathbf{h}_n] \in \mathbb{R}^{m \times n}$, where $\mathbf{h}_i \in \mathbb{R}^m$ and m is a hyperparameter of the encoder. This transformation is quite architecture dependent.

An alignment function $A(\cdot, \cdot)$ maps a **query** $\mathbf{q}$ and a **key** K to weights $\mathbf{a}^{(t)}$ for a decoding time step t; we subsequently drop t for simplicity. In colloquial terms, A chooses which values of K should receive the most attention based on $\mathbf{q}$, which is then represented in the vector $\mathbf{a}^{(t)} \in \mathbb{R}^n$. For the NLP tasks we consider, we have $K = I = [\mathbf{h}_1; \ldots; \mathbf{h}_n]$, the encoder outputs. A query $\mathbf{q}$ may be, e.g., a representation of the question in question answering.

The weights $\mathbf{a}$ are projected to sum to 1, which results in the **attention distribution** $\boldsymbol{\alpha}$. Mathematically, this is done via a projection onto the probability simplex using a projection function ϕ, e.g., softmax or sparsemax. We then compute the **context vector** as $\mathbf{c} = \sum_{i=1}^{n} \alpha_i \, \mathbf{h}_i$. This context vector is fed to a decoder, whose structure is again architecture dependent, which generates a (possibly unnormalized) probability distribution over the set of labels $\mathcal{Y}$, where $\mathcal{Y}$ is defined by the task.

Attention. We experiment with two methods of constructing an attention distribution: (1) additive attention, proposed by Bahdanau et al. (2015): $A(K, \mathbf{q})_i = \mathbf{v}^\top \tanh(W_1 K_i + W_2 \mathbf{q})$ and (2) the scaled dot product alignment function, as in the Transformer network: $A(K, \mathbf{q}) = \frac{K^\top \mathbf{q}}{\sqrt{m}}$ where $\mathbf{v} \in \mathbb{R}^l$ and $W_1, W_2 \in \mathbb{R}^{l \times m}$ are weight matrices. Note that the original (without attention) neural encoder–decoder architecture, as in Sutskever et al. (2014), can be recovered with alignment function $A(\cdot, \cdot) = [0, \ldots, 0, 1]$, i.e., only the last of the n intermediate representations is given to the decoder.

Projection Functions. A projection function ϕ takes the output of the alignment function and maps it to a valid probability distribution: $\phi : \mathbb{R}^n \to \Delta^{n-1}$. The standard projection function is softmax:

$$\phi_{\text{soft}}(\mathbf{z}) = \frac{\exp(\mathbf{z})}{\sum_{i \in [n]} \exp(z_i)} \tag{1}$$
$$= \operatorname*{argmin}_{\mathbf{p} \in \Delta^{n-1}} \left(\sum_{i \in [n]} p_i \log p_i - \mathbf{p}^\top \mathbf{z} \right)$$

However, softmax leads to non-sparse solutions as an entry $\phi_{\text{soft}}(\mathbf{z})_i$ can only be 0 if $x_i = -\infty$. Alternatively, Martins and Astudillo (2016) introduce **sparsemax**, which can output sparse distributions:

$$\phi_{\text{sparse}}(\mathbf{z}) = \operatorname*{argmin}_{\mathbf{p} \in \Delta^{n-1}} \|\mathbf{p} - \mathbf{z}\|_2^2 \tag{2}$$

In words, sparsemax directly maps $\mathbf{z}$ onto the probability simplex, which often leads to solutions on the boundary, i.e. where at least one entry of $\mathbf{p}$ is 0. One shortcoming of sparsemax is the lack of control over the degree of sparsity. **Sparsegen** (Laha et al., 2018) fills this gap:

$$\phi_{\text{sparseg}}(\mathbf{z}) = \operatorname*{argmin}_{\mathbf{p} \in \Delta^{n-1}} \|\mathbf{p} - g(\mathbf{z})\|_2^2 - \lambda \|\mathbf{p}\|_2^2 \tag{3}$$

where the degree of sparsity can be tuned via the hyperparameter $\lambda \in (-\infty, 1)$; a larger λ encourages more sparsity in the minimizing solution.

3 Model Interpretability

Model interpretability and explainability have been framed in different ways (Gehrmann et al., 2019)—as model understanding tasks, where (spurious) features learned by a model are identified, or as decision understanding tasks, where explanations for particular instances are produced. We consider the latter in this paper. Such tasks can be framed as generative, where models generate free text explanations (Camburu et al., 2018; Kotonya and Toni, 2020; Atanasova et al., 2020b), or as post-hoc interpretability methods, where salient portions of the input are highlighted (Lipton, 2018; DeYoung et al., 2020; Atanasova et al., 2020a).

As there does not exist a clearly superior choice for framing decision understanding for NLP tasks (Miller, 2019; Carton et al., 2020; Jacovi and

Goldberg, 2021), we follow a substantial body of prior work in considering the post-hoc definition of interpretability based on local methods proposed by Lipton (2018). This definition is naturally operationalized through feature importance metrics and meta models (Jacovi and Goldberg, 2020). Further, we acknowledge the specific requirement that an interpretable model obeys some set of structural constraints of the domain in which it is used, such as monotonicity or physical constraints (Rudin, 2019). For NLP tasks such as sentiment analysis or topic classification, such constraints may logically include the utilization of *only* a few key words in the input when making a decision, in which case, knowing the magnitude of the influence each input token has on a model's prediction through, e.g., feature importance metrics, may suffice to verify the model obeys such constraints. While this collective definition is limited (Doshi-Velez and Kim, 2017; Guidotti et al., 2018; Rudin, 2019), we posit that if attention cannot provide model interpretability at this level, then it would likewise not be able to under more rigorous constraints.

3.1 Measures of Feature Importance

Gradient-Based Methods. Gradient-based measures of feature importance (F1; Baehrens et al., 2010; Simonyan et al., 2014; Poerner et al., 2018) use the gradient of a function's output w.r.t. a feature to measure the importance of that feature. In the case of an attentional neural network for binary classification $f(\cdot)$, we can take the gradient of f w.r.t. the variable $\mathbf{x}$ and evaluate at a point $\mathbf{x} = \mathbf{x}'$ to gain a sense of how much influence each x'_i had on the outcome $\hat{y} = f(\mathbf{x}')$. These measures are not restricted to the relationship between inputs x_i and the outcome $f(\mathbf{x})$; they can also be adapted to measure for effects from and to intermediate representations $\mathbf{h}_p$. Formally, our measures are as follows:

$$\mathbf{g}_{\hat{y}}(x_i) = \frac{\left\| \frac{\partial f}{\partial X_i^{(e)}} \right\|_2}{\sum_{k=1}^{n} \left\| \frac{\partial f}{\partial X_k^{(e)}} \right\|_2} \tag{4}$$

$$\mathbf{g}_{\mathbf{h}_p}(x_i) = \frac{\left\| \frac{\partial ||\mathbf{h}_p||_2}{\partial X_i^{(e)}} \right\|_2}{\sum_{k=1}^{n} \left\| \frac{\partial ||\mathbf{h}_p||_2}{\partial X_k^{(e)}} \right\|_2} \tag{5}$$

where $\mathbf{g}_{\hat{y}}(x_i) \in [0, 1]$ and $\mathbf{g}_{x_i}(\mathbf{h}_p) \in [0, 1]$ represents the gradient-based FI of token x_i on $\hat{y}$ and intermediate representation $\mathbf{h}_p$, respectively. Gradient-based methods are often used in explainability techniques, as they have exhibited higher correlation with human judgement than others (Atanasova et al., 2020a). Note that we take gradients w.r.t. the embedding of token x_i and that in the latter metric, we measure the influence of x_i on the magnitude of $\mathbf{h}_p$—a decision we discuss in App. A.

Leave-One-Out (LOO)-based Methods. As a secondary FI metric, we observe how model predictions change when a specific input token is removed. For token x_i, this can be calculated as:

$$D_{\hat{y}}(x_i) = \frac{|\hat{y} - \hat{y}_{-i}|}{\sum_{k=1}^{n} |\hat{y} - \hat{y}_{-k}|} \tag{6}$$

where $\hat{y}_{-i}$ is the prediction of a model with input x_i removed. The formula can also be used for intermediate representations; we denote this as $D_{\hat{y}}(\mathbf{h}_i)$.

4 Experiments

Setup. We run experiments across several model architectures, attention mechanisms, and datasets in order to understand the effects of induced attentional sparsity on model interpretability. We use three binary classification datasets: ImDB and SST (sentiment analysis) and 20News (topic classification). We use the dataset versions provided by Jain and Wallace (2019), exactly following their pre-processing steps. We show a subset of representative results here, with additional results in App. C. Further details, including model architecture descriptions, dataset statistics and baselines accuracies may be found in App. B.

Inputs and Intermediate Representations are not Interchangeable. We first explore how strongly-related inputs are to their co-indexed intermediate representations. A strong relationship on its own may validate the use of sparse attention, as the ability to identify a subset of influential intermediate representations would then directly translate to a set of influential inputs. Previous works show that the "contribution" of a token x_i to its intermediate representation $\mathbf{h}_i$ is often quite low for various model architectures (Salehinejad et al., 2017; Ming et al., 2017; Brunner et al., 2020; Tutek and Snajder, 2020). In the context of attention, we find this property to be evinced by the adversarial experiments of Wiegreffe and Pinter (2019) (§4) and Jain and Wallace (2019) (§4), which we verify in App. C. They construct adversarial attention distributions by optimizing for divergence from a baseline

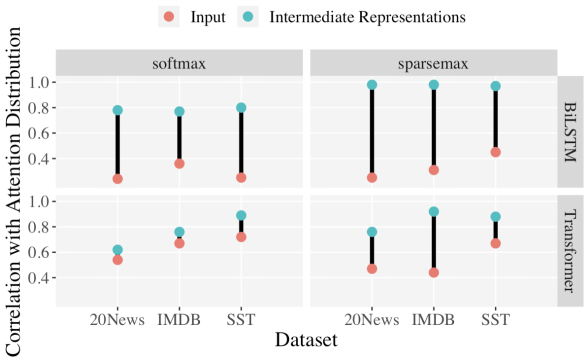

Figure 1: Correlation between the attention distribution and gradient-based FI measures. We see a notably stronger correlation between attention and FI of intermediate representation than of inputs across all models.

Table 1: Mean entropy of gradient-based FI of input to intermediate representations. Green numbers are std. deviations. Projection functions are parenthesized.

model's attention distribution by: (1) adopting all of the baseline model's parameters and directly optimizing for divergence and (2) training an entirely new model and optimizing for divergence as part of the training process. The former method leads to a large drop in performance (accuracy) while the latter does not. If we believe the model must encode the same information to achieve similar accuracy, this discrepancy implies that in the latter method, the model likely "redistributes" information across encoder outputs (i.e., intermediate representations $\mathbf{h}_p$), which would suggest token-level information is not tied to a particular $\mathbf{h}_p$.

As further verification of high degrees of contextualization in attentional models, we report a novel quantification, offering insights into whether individual intermediate representations can be linked primarily to *any* single input—i.e., perhaps not the co-indexed input; we measure the normalized entropy[1] of the gradient-based FI of inputs to intermediate representations $\tilde{\mathrm{H}}(\mathbf{g}_{\mathbf{h}_p}(\mathbf{x})) \in [0, 1]$ to gain a sense of how dispersed influence for intermediate representation is across inputs. A value of 1 would indicate all inputs are equally influential; a value of 0 would indicate solely a single input

[1]We use Shannon entropy $\tilde{\mathrm{H}}(p) := -\sum_x p(x) \log p(x)$ albeit normalized (i.e. divided) by maximum possible entropy of the distribution to control for dimension.

has influence on an intermediate representation. Results in Table 1 show consistently high entropy in the distribution of the influence of inputs x_i on an intermediate representation $\mathbf{h}_p$ across all datasets, model architectures, and projection functions, which suggests the relationship between intermediate representations and inputs is far from one-to-one in these tasks.

Sparse Attention $\neq$ Sparse Input Feature Importance. Our prior results demonstrated that—even when using sparse attention—we cannot identify a subset of influential inputs directly through intermediate representations; we explore whether a subset can still be identified through FI metrics. In the case where the normalized FI distribution highlights only a few key items, the distribution will, by definition, have low entropy. Thus, we explore whether sparse attention leads to lower entropy input FI distributions in comparison to standard attention. We find no such trend; Fig. 2 shows that across all models and settings, the entropy of the FI distribution is quite high. Further, we see a consistent *negative* correlation between this entropy and the sparsity parameter of the sparsegen projection (Table 2), implying that entropy of feature importance *increases* as we raise the degree of sparsity in $\boldsymbol{\alpha}$.

Correlation between Attention and Feature Importance. Finally, we follow the experimental setup of Jain and Wallace (2019), who postulate

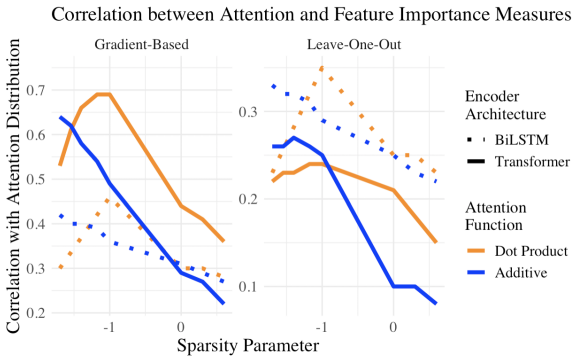

Figure 3: Correlation between the attention distribution and input FI measures as a function of the sparsity penalty λ used in the projection function ϕ_{sparseg}. x-axis is log-scaled for $\lambda < 0$ since $\lambda \in (-\infty, 1)$. Results are from the IMDb dataset.

that if the attention distribution indicates which inputs influence model behavior, then one may reasonably expect attention to correlate[2] with FI measures of the input. While they find only a weak correlation, we explore how inducing sparsity in the attention distribution affects this result. Surprisingly, Fig. 3 shows a downward trend in this correlation as the sparsity parameter λ of the sparsegen projection function is increased. As argued by Wiegreffe and Pinter (2019), a lack of this correlation does not indicate attention *cannot* be used as explanation; FI measures are not ground-truth indicators of critical inputs. However, the inverse relationship between input FI and attention is rather surprising. If anything, we may surmise sparsity in $\boldsymbol{\alpha}$ leads to *less* faithful explanations from $\boldsymbol{\alpha}$. From these results, we posit that promoting sparsity in attention distribution may simply lead to the dispersion of information to different intermediate representations, a behavior similar to that seen when constraining attention for divergence from another distribution, i.e., in the adversarial experiments of Wiegreffe and Pinter (2019) compared to those of Jain and Wallace (2019).

5 Related Work

The use of attention as an indication of inputs' influence on model decisions may at first seem natural; yet a large body of work has recently challenged this practice. Perhaps the first to do so was Jain and Wallace (2019), which revealed both a lack of correlation between the attention distribution and well established feature importance metrics and of unique optimal attention weights.[3] Subsequently, other studies arrived at similar results: Grimsley et al. (2020) found evidence that causal explanations are not attainable from attention layers over text data; Jacovi and Goldberg (2020) explored the faithfulness of attention heatmaps; Pruthi et al. (2020) showed that attention masks can be trained to give deceptive explanations. We view this work as another such study, exploring attention's innate interpretability on a different axis.

Further, this work fits into the context of a larger body of interpretability research in NLP, which has challenged the informal use of terms such as faithfulness, plausibility, and explainability (Lipton, 2018; Arrieta et al., 2020; Jacovi and Goldberg, 2021, *inter alia*) and tried to quantify the reliability of current definitions (Atanasova et al., 2020a). While we consider their findings in our experimental design—e.g., in our choice of feature importance metrics—we recognize that further experiments would be needed to address all of their concerns; for example, this work could be extended by using the benchmark created by DeYoung et al. (2020) as an additional metric of interpretability.

6 Conclusion

Prior work has cited interpretability as a driving factor for promoting sparsity in attention distributions. We explore how induced sparsity affects the ability to use attention as a tool for explaining model decisions. In our experiments on text classification tasks, we see that while sparse attention distributions may allow us to pinpoint influential intermediate representations, we are unable to find any plausible mapping from sparse attention to a small, critical set of influential inputs. Rather, we find evidence that inducing sparsity may make it even less plausible to use the attention distribution to interpret model behavior. We conclude that we need further reason to believe sparse attention increases model interpretability as our results do not support such claims.

[3] Serrano and Smith (2019) contemporaneously found similar results.

Ethical Considerations

Machine learning models are being deployed in an increasing number of sensitive situations. In these settings, it is critical that models are interpretable, so that we can avoid e.g., inadvertent racial or gender bias. Giving a false sense of interpretability can allow models with undesirable (i.e., unethical or unstable) behavior to fly under the radar. We view this work as another critique of interpretability claims and hope our results will encourage the more careful consideration of interpretability assumptions when using machine learning models in practice.

The Case for Translation-Invariant Self-Attention in Transformer-Based Language Models

Ulme Wennberg **Gustav Eje Henter**
Division of Speech, Music and Hearing, KTH Royal Institute of Technology, Sweden
{ulme, ghe}@kth.se

Abstract

Mechanisms for encoding positional information are central for transformer-based language models. In this paper, we analyze the position embeddings of existing language models, finding strong evidence of translation invariance, both for the embeddings themselves and for their effect on self-attention. The degree of translation invariance increases during training and correlates positively with model performance. Our findings lead us to propose translation-invariant self-attention (TISA), which accounts for the relative position between tokens in an interpretable fashion without needing conventional position embeddings. Our proposal has several theoretical advantages over existing position-representation approaches. Experiments show that it improves on regular ALBERT on GLUE tasks, while only adding orders of magnitude less positional parameters.

1 Introduction

The recent introduction of transformer-based language models by Vaswani et al. (2017) has set new benchmarks in language processing tasks such as machine translation (Lample et al., 2018; Gu et al., 2018; Edunov et al., 2018), question answering (Yamada et al., 2020), and information extraction (Wadden et al., 2019; Lin et al., 2020). However, because of the non-sequential and position-independent nature of the internal components of transformers, additional mechanisms are needed to enable models to take word order into account.

Liu et al. (2020) identified three important criteria for ideal position encoding: Approaches should be *inductive*, meaning that they can handle sequences and linguistic dependencies of arbitrary length, *data-driven*, meaning that positional dependencies are learned from data, and *efficient* in terms of the number of trainable parameters. Separately, Shaw et al. (2018) argued for *translation-invariant* positional dependencies that depend on the relative distances between words rather than their absolute positions in the current text fragment. It is also important that approaches be *parallelizable*, and ideally also *interpretable*. Unfortunately, none of the existing approaches for modeling positional dependencies satisfy all these criteria, as shown in Table 1 and in Sec. 2. This is true even for recent years' state-of-the-art models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), and ELECTRA (Clark et al., 2020), which require many positional parameters but still cannot handle arbitrary-length sequences.

This paper makes two main contributions: First, in Sec. 3, we analyze the learned position embeddings in major transformer-based language models. Second, in Sec. 4, we leverage our findings to propose a new positional-dependence mechanism that satisfies all desiderata enumerated above. Experiments verify that this mechanism can be used alongside conventional position embeddings to improve downstream performance. Our code is available.

2 Background

Transformer-based language models (Vaswani et al., 2017) have significantly improved modeling accuracy over previous state-of-the-art models like ELMo (Peters et al., 2018). However, the non-sequential nature of transformers created a need for other mechanisms to inject positional information into the architecture. This is now an area of active research, which the rest of this section will review.

The original paper by Vaswani et al. (2017) proposed summing each token embedding with a position embedding, and then used the resulting embedding as the input into the first layer of the model. BERT (Devlin et al., 2019) reached improved performance training data-driven d-dimensional em-

Table 1: Characteristics of position-representation approaches for different language-modeling architectures.

beddings for each position in text snippets of at most n tokens. A family of models have tweaked the BERT recipe to improve performance, including RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2020), where the latter has layers share the same parameters to achieve a more compact model.

All these recent data-driven approaches are restricted to fixed max sequence lengths of n tokens or less (typically $n = 512$). Longformer (Beltagy et al., 2020) showed modeling improvements by increasing n to 4096, suggesting that the cap on sequence length limits performance. However, the Longformer approach also increased the number of positional parameters 8-fold, as the number of parameters scales linearly with n; cf. Table 2.

Clark et al. (2019) and Htut et al. (2019) analyzed BERT attention, finding some attention heads to be strongly biased to local context, such as the previous or the next token. Wang and Chen (2020) found that even simple concepts such as word-order and relative distance can be hard to extract from absolute position embeddings. Shaw et al. (2018) independently proposed using relative position embeddings that depend on the signed distance between words instead of their absolute position, making local attention easier to learn. They reached improved BLEU scores in machine translation, but their approach (and refinements by Huang et al. (2019)) are hard to parallelize, which is unattractive in a world driven by parallel computing. Zeng et al. (2020) used relative attention in speech synthesis, letting each query interact with separate matrix transformations for each key vector, depending on their relative-distance offset. Raffel et al. (2020) directly model position-to-position interactions, by splitting relative-distance offsets into q bins. These relative-attention approaches all facilitate processing sequences of arbitrary length, but can only resolve linguistic dependencies up to a fixed predefined maximum distance.

Tay et al. (2020) directly predicted both word and position contributions to the attention matrix without depending on token-to-token interactions. However, the approach is not inductive, as the size of the attention matrix is a fixed hyperparameter.

Liu et al. (2020) used sinusoidal functions with learnable parameters as position embeddings. They obtain compact yet flexible models, but use a neural ODE, which is computationally unappealing.

Ke et al. (2021) showed that self-attention works better if word and position embeddings are untied to reside in separate vector spaces, but their proposal is neither inductive nor parameter-efficient.

Su et al. (2021) propose rotating each embedding in the self-attention mechanism based on its absolute position, thereby inducing translational invariance, as the inner product of two vectors is conserved under rotations of the coordinate system. These rotations are, however, not learned.

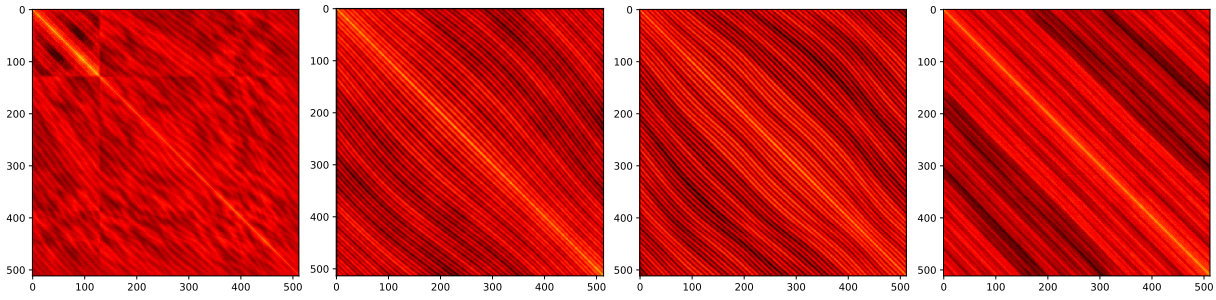
The different position-representation approaches are summarized in Table 1. None of them satisfy all design criteria. In this article, we analyze the position embeddings in transformer models, leading us to propose a new positional-scoring mechanism that combines all desirable properties (final row).

3 Analysis of Existing Language Models

In this section, we introspect selected high-profile language models to gain insight into how they have learned to account for the effect of position.

3.1 Analysis of Learned Position Embeddings

First, we stack the position embeddings in the matrix $E_P \in \mathbb{R}^{n \times d}$, and inspect the symmetric matrix $P = E_P E_P^T \in \mathbb{R}^{n \times n}$, where $P_{i,j}$ represents the inner product between the ith and jth embedding vectors. If inner products are translation invariant, $P_{i,j}$ will only depend on the difference between the indices, $j - i$, giving a *Toeplitz matrix*, a matrix where each diagonal is constant.



(a) BERT base (b) RoBERTa base (c) ALBERT base v1 (d) ALBERT xxlarge v2

Figure 1: Heatmaps visualizing the matrix $P = E_P E_P^T$ of position-embedding inner products for different models. The greater the inner product between the embeddings, the brighter the color. See appendix Figs. 4, 5 for more.

Fig. 1 visualizes the P-matrices for the position embeddings in a number of prominent transformer models, listed from oldest to newest, which also is in order of increasing performance. We note that a clear Toeplitz structure emerges from left to right. Translation invariance is also seen when plotting position-embedding cosine similarities, as done by Wang and Chen (2020) for transformer-based language models and by Dosovitskiy et al. (2020) for 2D transformers modeling image data.

In Fig. 2 we further study how the degree of Toeplitzness (quantified by R^2, the amount of the variance among matrix elements $P_{i,j}$ explained by the best-fitting Toeplitz matrix) changes for different ALBERT models. With longer training time (i.e., going from ALBERT v1 to v2), Toeplitzness increases, as the arrows show. This is associated with improved mean dev-set score. Such evolution is also observed in Wang and Chen (2020, Fig. 8).

3.2 Translation Invariance in Self-Attention

Next, we analyze how this translation invariance is reflected in self-attention. Recall that Vaswani et al. (2017) self-attention can be written as

$$\mathrm{att}(Q, K, V) = \mathrm{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V, \quad (1)$$

and define position embeddings E_P, word embeddings E_W, and query and key transformation weight matrices W_Q and W_K. By taking

$$QK^T = (E_W + E_P) W_Q W_K^T (E_W + E_P)^T \quad (2)$$

and replacing each row of E_W by the average word embedding across the entire vocabulary, we obtain a matrix we call $\widehat{F}_P$ that quantifies the average effect of E_P on the softmax in Eq. (1). Plots of the resulting $\widehat{F}_P$ for all 12 ALBERT-base attention heads in the first layer are in appendix Fig. 8. Importantly, these matrices also exhibit Toeplitz structure. Fig. 3 graphs sections through the main diagonal for selected heads, showing peaks at short relative distances, echoing Clark et al. (2019) and Htut et al. (2019). In summary, we conclude that position encodings, and their effect on softmax attention, have an approximately translation-invariant structure in successful transformer-based language models.

4 Proposed Self-Attention Mechanism

We now introduce our proposal for parameterizing the positional contribution to self-attention in an efficient and translation-invariant manner, optionally removing the position embeddings entirely.

4.1 Leveraging Translation Invariance for Improved Inductive Bias

Our starting point is the derivation of Ke et al. (2021). They expand QK^T while ignoring cross terms, yielding

$$QK^T \approx E_W W_Q W_K^T E_W^T + E_P W_Q W_K^T E_P^T, \quad (3)$$

an approximation they support by theory and empirical evidence. They then "untie" the effects of words and positions by using different W-matrices for the two terms in Eq. (3). We agree with sepa-

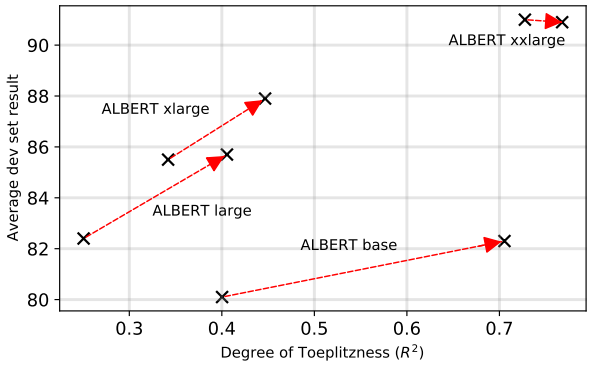


Figure 2: Scatterplot of the degree of Toeplitzness of P for different ALBERT models (v1→v2) against average performance numbers (from Lan et al.'s GitHub) over SST-2, MNLI, RACE, and SQuAD 1.1 and 2.0.

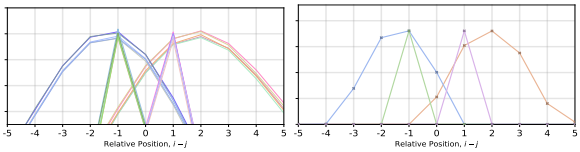

Figure 3: Positional responses of select attention heads. Left: Sections $(\widehat{F}_P)_{i,j}$ through $\widehat{F}_P$ of ALBERT base v2, varying j for 5 different i, keeping $j = i$ centered. The sections are similar regardless of i since $\widehat{F}_P$ is close to Toeplitz. Colors distinguish different heads. Right: TISA scoring functions, attending to similar positions as heads on the left. Larger plots in Figs. 6, 7.

rating these effects, but also see a chance to reduce the number of parameters.

Concretely, we propose to add a second term $F_P \in \mathbb{R}^{n\times n}$, a Toeplitz matrix, inside the parentheses of Eq. (1). F_P can either a) supplement or b) replace the effect of position embeddings on attention in our proposed model. For case a), we simply add F_P to the existing expression inside the softmax, while for case b) a term $\sqrt{d_k}F_P$ is inserted in place of the term $E_P W_Q W_K^T E_P^T$ in Eq. (3). This produces two new self-attention equations:

$$\text{att} = \begin{cases} \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}} + F_P\right)V & \text{a)} \\ \text{softmax}\left(\frac{Q_W K_W^T}{\sqrt{d_k}} + F_P\right)V_W & \text{b)} \end{cases} \quad (4)$$

where the inputs Q_W, K_W, and V_W (defined by $Q_W = E_W W_Q$, and similarly for K_W and V_W) do not depend on the position embeddings E_P. Case a) is not as interpretable as TISA alone (case b), since the resulting models have two terms, E_P and F_P, that share the task of modeling positional information. Our two proposals apply to any sequence model with a self-attention that follows Eq. (1), where the criteria in Table 1 are desirable.

4.2 Positional Scoring Function

Next, we propose to parameterize the Toeplitz matrix F_P using a *positional scoring function* $f_\theta(\cdot)$ on the integers $\mathbb{Z}$, such that $(F_P)_{i,j} = f_\theta(j-i)$. f_θ defines F_P-matrices of any size n. The value of $f_\theta(j-i)$ directly models the positional contribution for how the token at position i attends to position j. We call this *translation-invariant self-attention*, or TISA. TISA is inductive and can be simplified down to arbitrarily few trainable parameters.

Let $k = j - i$. Based on our findings for $\widehat{F}_P$ in Sec. 3, we seek a parametric family $\{f_\theta\}$ that allows both localized and global attention, without diverging as $|k| \to \infty$. We here study one family

	Standard	Ke et al. (2021)	TISA
General formula	nd	$nd + 2d^2$	$3SHL$
Longformer	3,145,728	4,325,376	**2,160**
BERT/RoBERTa	393,216	1,572,864	**2,160**
ALBERT	65,536	98,304	**2,160**

Table 2: Number of positional parameters for base models of different language-model architectures and different positional information processing methods, with max sequence length $n \in (512, 4096)$, position embeddings of dimension $d \in (128, 768)$, $S = 5$ kernels, $H = 12$ attention heads, and $L = 12$ layers with distinct TISA positional scoring functions. Parameter sharing gives ALBERT lower numbers. TISA can be used alone or added to the counts in other columns.

that satisfies the criteria: the radial-basis functions

$$f_\theta(k) = \sum_{s=1}^{S} a_s \exp\left(-|b_s|(k - c_s)^2\right). \quad (5)$$

Their trainable parameters are $\theta = \{a_s, b_s, c_s\}_{s=1}^S$, i.e., 3 trainable parameters per kernel s. Since these kernels are continuous functions (in contrast to the discrete bins of Raffel et al. (2020)), predictions change smoothly with distance, which seems intuitively meaningful for good generalization.

Lin et al. (2019) found that word-order information in BERTs position embeddings gets increasingly washed out from layer 4 onward. As suggested by Dehghani et al. (2019) and Lan et al. (2020), we inject positional information into each of the H heads at all L layers, resulting in one learned function $f_{\theta^{(h,l)}}$ for each head and layer. The total number of positional parameters of TISA is then $3SHL$. As seen in Table 2, this is several orders of magnitude less than the embeddings in prominent language models.

The inductivity and localized nature of TISA suggests the possibility to rapidly pre-train models on shorter text excerpts (small n), scaling up to longer n later in training and/or at application time, similar to the two-stage training scheme used by Devlin et al. (2019), but without risking the undertraining artifacts visible for BERT at $n > 128$ in Figs. 1 and 4. However, we have not conducted any experiments on the performance of this option.

5 Experiments

The main goal of our experiments is to illustrate that TISA can be added to models to improve their performance (Table 3a), while adding a minuscule amount of extra parameters. We also investigate the performance of models without position em-

beddings (Table 3b), comparing TISA to a bag-of-words baseline ($S = 0$). All experiments use pretrained ALBERT base v2 implemented in Huggingface (Wolf et al., 2020). Kernel parameters $\theta^{(h)}$ for the functions in Eq. (5) were initialized by regression to the $\widehat{F}_P$ profiles of the pretrained model, (see Appendix C for details); example plots of resulting scoring functions are provided in Fig. 3. We then benchmark each configuration with and without TISA for 5 runs on GLUE tasks (Wang et al., 2018), using jiant (Phang et al., 2020) and standard dataset splits to evaluate performance.

Our results in Table 3a show relative error reductions between 0.4 and 6.5% when combining TISA and conventional position embeddings. These gains are relatively stable regardless of S. We also note that Lan et al. (2020) report 92.9 on SST-2 and 84.6 on MNLI, meaning that our contribution leads to between 1.3 and 2.8% relative error reductions over their scores. The best performing architecture ($S=5$), gives improvements over the baseline on 7 of the 8 tasks considered and on average increases the median F1 score by 0.4 points. All these gains have been realized using a very small number of added parameters, and without pre-training on any data after adding TISA to the architecture. The only joint training happens on the training data of each particular GLUE task.

Results for TISA alone, in Table 3b, are not as strong. This could be because these models are derived from an ALBERT model pretrained using conventional position embeddings, since we did not have the computational resources to tune from-scratch pretraining of TISA-only language models.

Figs. 3 and 6 plot scoring functions of different attention heads from the initialization described in Appendix C. Similar patterns arose consistently and rapidly in preliminary experiments on pretraining TISA-only models from scratch. The plots show heads specializing in different linguistic aspects, such as the previous or next token, or multiple tokens to either side, with other heads showing little or no positional dependence. This mirrors the visualizations of ALBERT base attention heads in Figs. 3, 6, 7, 8 and the findings of Htut et al. (2019) and Clark et al. (2019) on BERT, but TISA makes this directly visible in an interpretable model, without having to probe correlations in a black box.

Interestingly, the ALBERT baseline on STS-B in Table 3a is only 1.3 points ahead of the bag-of-words baseline in Table 3b. This agrees with experiments shuffling the order of words (Pham et al., 2020; Sinha et al., 2021) finding that modern language models tend to focus mainly on higher-order word co-occurrences, rather than word order, and suggests that word-order information is underutilized in state-of-the-art language models.

6 Conclusion

We have analyzed state-of-the-art transformer-based language models, finding that translation-invariant behavior emerges during training. Based on this we proposed TISA, the first positional information processing method to simultaneously satisfy the six key design criteria in Table 1. Experiments demonstrate competitive downstream performance. The method is applicable also to transformer models outside language modeling, such as modeling time series in speech or motion synthesis, or to describe dependencies between pixels in computer vision.

Acknowledgments

A Visualizing $E_P E_P^T$ for Additional Language Models

Fig. 1 shows the inner product between different position embeddings for the models BERT base uncased, RoBERTa base, ALBERT base v1 as well as ALBERT xxlarge v2. Leveraging our analysis findings of translation invariance in the matrix of $E_P E_P^T$ in these pretrained networks, we investigate the generality of this phenomenon by visualizing the same matrix for additional existing large language models. We find that similar Toeplitz patterns emerge for all investigated networks.

B Coefficient of Determination R^2

The coefficient of determination, R^2, is a widely used concept in statistics that measures what fraction of the variance in a dependent variable that can be explained by an independent variable. Denoting the Residual Sum of Squares, RSS, and Total Sum of Squares, TSS, we have that

$$R^2 = 1 - \frac{RSS}{TSS}, \tag{6}$$

where $R^2 = 0$ means that the dependent variable is not at all explained, and $R^2 = 1$ means that the variance is fully explained by the independent variable.

Applied to a matrix, $A \in \mathbb{R}^{n \times n}$, to determine its degree of Toeplitzness, we get RSS by finding the Toeplitz matrix, $A_T \in \mathbb{R}^{n \times n}$, that minimizes the following expression:

$$RSS = \min_{A_T} \sum_{i=1}^{n} \sum_{j=1}^{n} (A - A_T)_{i,j}^2 \tag{7}$$

Furthermore, we can compute TSS as:

$$TSS = \sum_{i=1}^{n} \sum_{j=1}^{n} \left(A_{i,j} - \left(\frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} A_{i,j} \right) \right)^2 \tag{8}$$

C Extracting ALBERT positional scores

In order to extract out the positional contributions to the attention scores from ALBERT, we disentangle the positional and word-content contributions from equation (3), and remove any dependencies on the text sequence through E_W. We exchange $E_W \approx E_{\overline{W}}$, with the average word embedding over the *entire vocabulary*, which we call $E_{\overline{W}}$.

$$F_P \approx \frac{1}{\sqrt{d_k}} (E_W W_Q W_K^T E_P^T + \tag{9}$$

$$+ E_P W_Q W_K^T E_W^T + E_P W_Q W_K^T E_P^T) \tag{10}$$

$$\approx \frac{1}{\sqrt{d_k}} (E_{\overline{W}} W_Q W_K^T E_P^T + \tag{11}$$

$$+ E_P W_Q W_K^T E_{\overline{W}}^T + E_P W_Q W_K^T E_P^T) \tag{12}$$

This way, we can disentangle and extract the positional contributions from the ALBERT model.

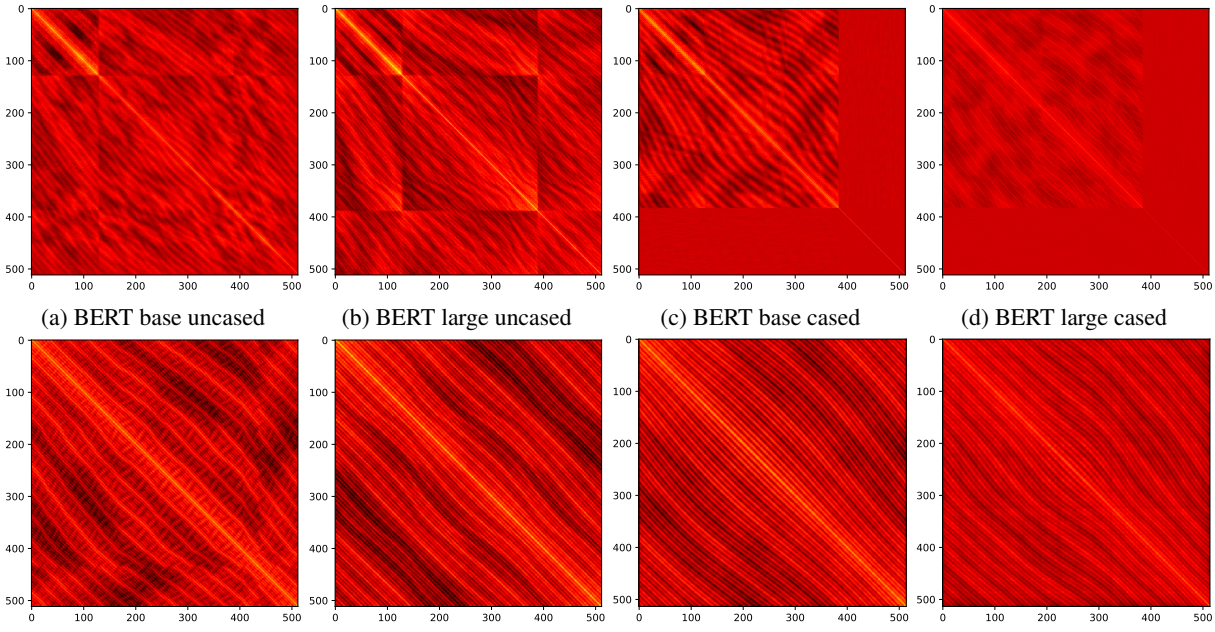
Initialization of Position-Aware Self-Attention Using this trick, we initialize F_P with formula (12). Since F_P is only generating the positional scores, which are independent of context, it allows for training a separate positional scorer neural network to predict the positional contributions in the ALBERT model. Updating only 2,160 parameters (see Table 2) significantly reduces the computational load. This pretraining initialization scheme converges in less than 20 seconds on a CPU.

Removing Position Embeddings When removing the effect of position embeddings, we calculate the average position embedding and exchange all position embeddings for it. This reduces the variation between position embeddings, while conserving the average value of the original input vectors $E_W + E_P$.

Extracted Attention Score Contributions Leveraging our analysis findings of translation invariance in large language models, we visualize the scoring functions as a function of relative distance offset between tokens. Fig. 3 shows the implied scoring functions for 4 attention heads for 5 different absolute positions. Figs. 6, 7 show all 12 attention heads of ALBERT base v2 with TISA.

D Number of Positional Parameters of Language Models

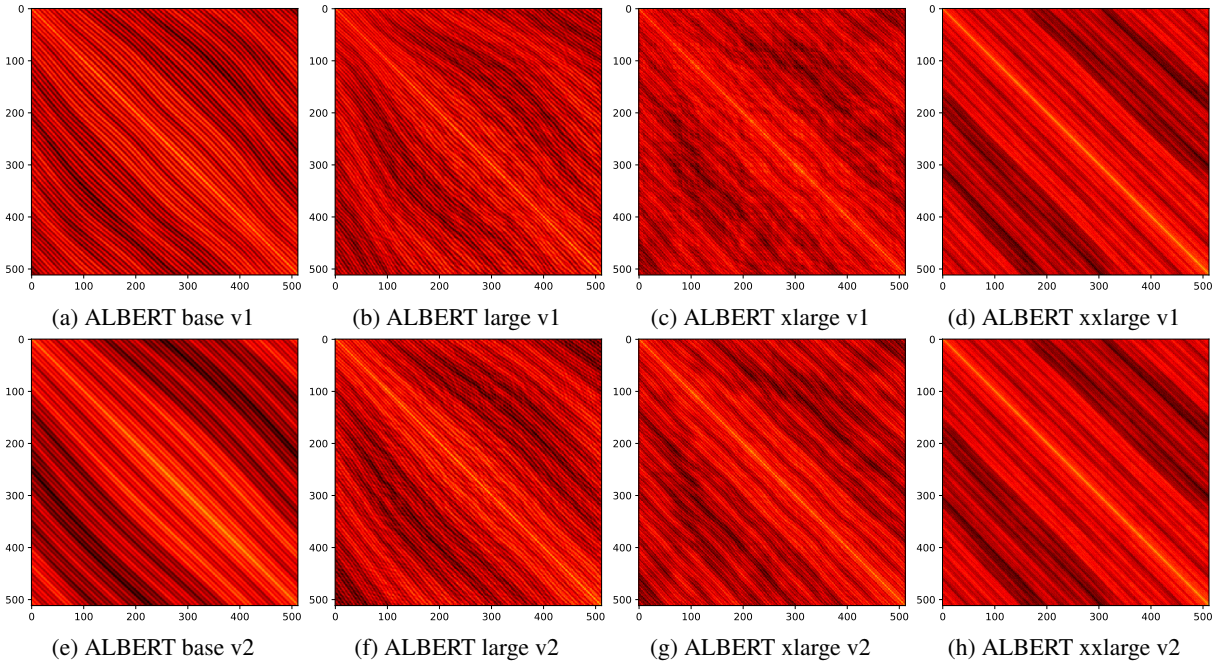
In the paper, define positional parameters as those modeling only positional dependencies. In most BERT-like models, these are the position embeddings only (typically $n \times d$ parameters). Ke et al. (2021) propose to separate position and content embeddings, yielding more expressive models with separate parts of the network for processing separate information sources. In doing so, they introduce two weight matrices specific to positional information processing, $U_Q \in \mathbb{R}^{d \times d}$ and $U_K \in \mathbb{R}^{d \times d}$, totaling $nd + 2d^2$ positional parameters.



(a) BERT base uncased (b) BERT large uncased (c) BERT base cased (d) BERT large cased

(e) ELECTRA small (f) ELECTRA large (g) RoBERTa base (h) RoBERTa large

Figure 4: Visualizations of the inner-product matrix $P = E_P E_P^T \in \mathbb{R}^{n \times n}$ for different BERT, ELECTRA, and RoBERTa models. We see that ELECTRA and RoBERTa models show much stronger signs of translational invariance than their BERT counterparts. Most BERT models follow the pattern noted by Wang and Chen (2020), where the Toeplitz structure is much more pronounced for the first 128×128 submatrix, reflecting how these models mostly were trained on 128-token sequences, and only scaled up to $n = 512$ for the last 10% of training (Devlin et al., 2019). Position embeddings 385 through 512 of the BERT cased models show a uniform color, suggesting that these embeddings are almost completely untrained.



(a) ALBERT base v1 (b) ALBERT large v1 (c) ALBERT xlarge v1 (d) ALBERT xxlarge v1

(e) ALBERT base v2 (f) ALBERT large v2 (g) ALBERT xlarge v2 (h) ALBERT xxlarge v2

Figure 5: Visualizations of the inner-product matrix $P = E_P E_P^T \in \mathbb{R}^{n \times n}$ for different ALBERT models (Lan et al., 2020). We plot both v1 and v2 to show the progression towards increased Toeplitzness during training.

Hyperparameter Selection We performed a manual hyperparameter search starting from the hyperparameters that the Lan et al. (2020) report in https://github.com/google-research/albert/blob/master/run_glue.sh. Our hyperparameter config files can be found with our code.

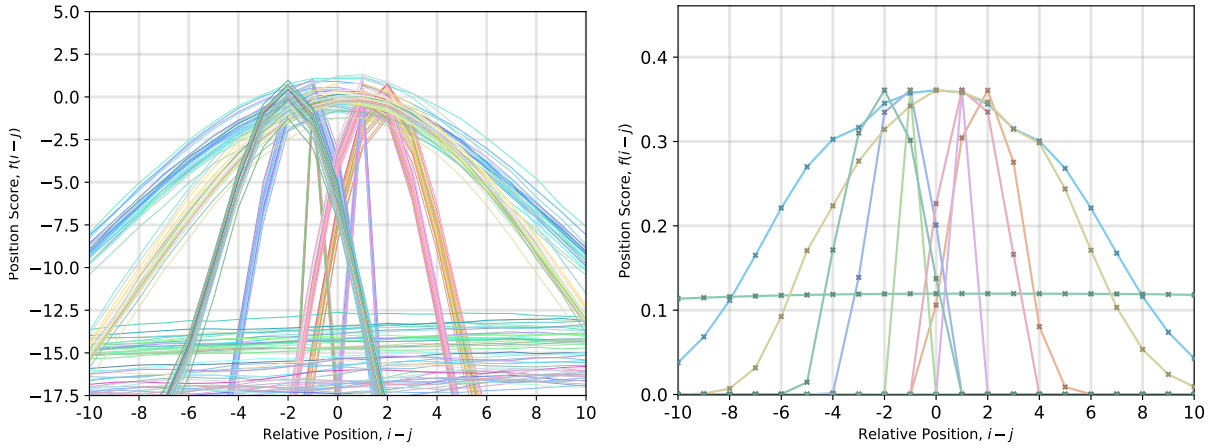


Figure 6: Positional responses of all attention heads. Sections through $\widehat{F}_P$ of ALBERT base v2, aligned to the main diagonal, (left) show similar profiles as the corresponding TISA scoring functions (right). Vertical axes differ due to 1) the scaling factor $\sqrt{d_k}$ and 2) softmax being invariant to vertical offset.

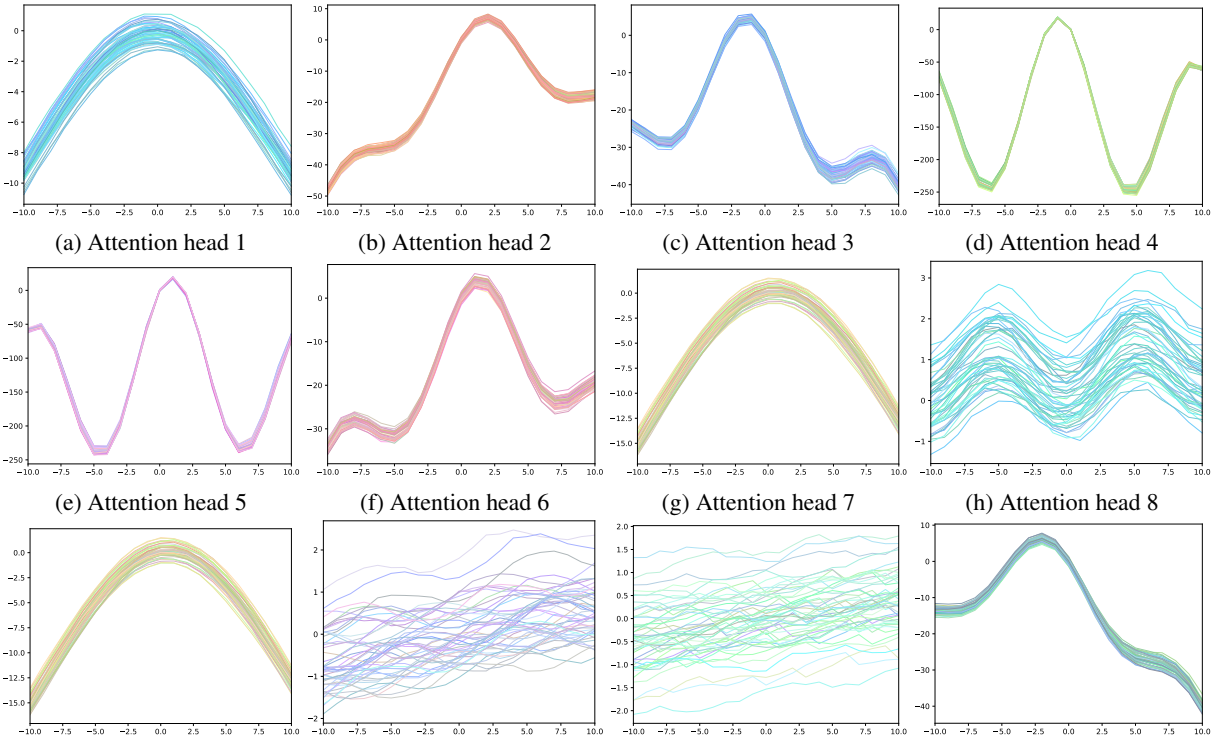

(a) Attention head 1 (b) Attention head 2 (c) Attention head 3 (d) Attention head 4

(e) Attention head 5 (f) Attention head 6 (g) Attention head 7 (h) Attention head 8

(i) Attention head 9 (j) Attention head 10 (k) Attention head 11 (l) Attention head 12

Figure 7: Rows from the positional attention matrices $\widehat{F}_P$ for all ALBERT base v2 attention heads, centered on the main diagonal. Note that the vertical scale generally differs between plots. The plots are essentially aligned sections through the matrices in Fig. 8, but zoomed in to show details over short relative distances since this is where the main peak(s) are located, and the highest values are by far the most influential on softmax attention.

E Reproducibility

Experiments were run on a GeForce RTX 2080 machine with 8 GPU-cores. Each downstream experiment took about 2 hours to run. Datasets and code can be downloaded from https://github.com/nyu-mll/jiant/blob/master/guides/tasks/supported_tasks.md and https://github.com/ulmewennberg/tisa.

Abstract

Determining the relative importance of the elements in a sentence is a key factor for effortless natural language understanding. For human language processing, we can approximate patterns of relative importance by measuring reading fixations using eye-tracking technology. In neural language models, gradient-based saliency methods indicate the relative importance of a token for the target objective. In this work, we compare patterns of relative importance in English language processing by humans and models and analyze the underlying linguistic patterns. We find that human processing patterns in English correlate strongly with saliency-based importance in language models and not with attention-based importance. Our results indicate that saliency could be a cognitively more plausible metric for interpreting neural language models. The code is available on github: https://github.com/beinborn/relative_importance.

1 Introduction

When children learn to read, they first focus on each word individually and gradually learn to anticipate frequent patterns (Blythe and Joseph, 2011). More experienced readers are able to completely skip words that are predictable from the context and to focus on the more *relevant* words of a sentence (Schroeder et al., 2015). Psycholinguistic studies aim at unraveling the characteristics that determine the relevance of a word and find that lexical factors such as word class, word frequency, and word complexity play an important role, but that the effects vary depending on the sentential context (Rayner and Duffy, 1986).

In natural language processing, the relative importance of words is usually interpreted with respect to a specific task. Emotional adjectives are most relevant in sentiment detection (Socher et al., 2013), relative frequency of a term is an indicator for information extraction (Wu et al., 2008), the relative position of a token can be used to approximate novelty for summarisation (Chopra et al., 2016), and function words play an important role in stylistic analyses such as plagiarism detection (Stamatatos, 2011). Neural language models are trained to be a good basis for any of these tasks and are thus expected to represent a more general notion of relative importance (Devlin et al., 2019).

Relative importance of the input in neural networks can be modulated by the so-called "attention" mechanism (Bahdanau et al., 2014). Analyses of image processing models indicate that attention weights reflect cognitively plausible patterns of visual saliency (Xu et al., 2015; Coco and Keller, 2012). Recent research in language processing finds that attention weights are not a good proxy for relative importance because different attention distributions can lead to the same predictions (Jain and Wallace, 2019). Gradient-based methods such as saliency scores seem to better approximate the relative importance of input words for neural processing models (Bastings and Filippova, 2020).

In this work, we compare patterns of relative importance in human and computational English language processing. We approximate relative importance for humans as the relative fixation duration in eye-tracking data collected in naturalistic language understanding scenarios. In related work, Sood et al. (2020a) measure the correlation between attention in neural networks trained for a document-level question-answering task and find that the attention in a transformer language model deviates strongly from human fixation patterns. In this work, we instead approximate relative importance in computational models using gradient-based saliency and find that it correlates much better with human patterns.

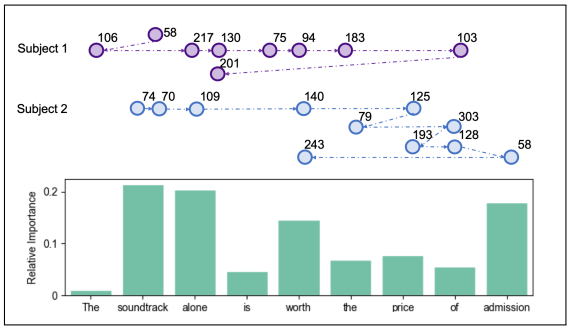

Figure 1: Example fixations for two subjects in the ZuCo dataset for the sentence "The soundtrack alone is worth the price of admission". The numbers indicate the fixation duration and the circles represent the approximate horizontal position of the fixation (positions are simplified for better visualization). The plot at the bottom indicates the relative importance of each token averaged over all subjects.

2 Determining Relative Importance

The concept of relative importance of a token for sentence processing encompasses several related psycholinguistic phenomena such as relevance for understanding the sentence, difficulty and novelty of a token within the context, semantic and syntactic surprisal, or domain-specificity of a token. We take a data-driven perspective and approximate the relative importance of a token by the processing effort that can be attributed to it compared to the other tokens in the sentence.

2.1 In Human Language Processing

The sentence processing effort can be approximated indirectly using a range of metrics such as response times in reading comprehension experiments (Su and Davison, 2019), processing duration in self-paced reading (Linzen and Jaeger, 2016), and voltage changes in electroencephalography recordings (Frank et al., 2015). In this work, we approximate relative importance using eye movement recordings during reading because they provide online measurements in a comfortable experimental setup which is more similar to a normal, uncontrolled reading experience. Eye-tracking technology can measure with high accuracy how long a reader fixates each word. The fixation duration and the relative importance of a token for the reader are strongly correlated with reading comprehension (Rayner, 1977; Malmaud et al., 2020).

Language models that look ahead and take both the left and right context into account are often considered cognitively less plausible because humans process language incrementally from left to right (Merkx and Frank, 2020). However, in human reading, we frequently find regressions: humans fixate relevant parts of the left context again while already knowing what comes next (Rayner, 1998). In Figure 1, subject 1 first reads the entire sentences and then jumps back to the token "alone". Subject 2 performs several regressions to better understand the second half of the sentence. The fixation duration is a cumulative measure that sums over these repeated fixations. Absolute fixation duration can vary strongly between subjects due to differences in reading speed but the relative fixation duration provides a good approximation for the relative importance of a token as it abstracts from individual differences. We average the relative fixation duration over all subjects to obtain a more robust signal (visualized in the plot at the bottom of Figure 1).

2.2 In Computational Language Processing

In computational language models, the interpretation of a token depends on the tokens in its context but not all tokens are equally important. To account for varying importance, so-called attention weights regulate the information flow in neural networks (Bahdanau et al., 2014). These weights are optimized with respect to a target objective and higher attention for an input token has been interpreted as higher importance with respect to the output (Vig, 2019). Recent research indicates that complementary attention distributions can lead to the same model prediction (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019) and that the removal of input tokens with large attention weights often does not lead to a change in the model's prediction (Serrano and Smith, 2019). In transformer models, the attention weights often approximate an almost uniform distribution in higher model layers (Abnar and Zuidema, 2020). Bastings and Filippova (2020) argue that saliency methods are more suitable for assigning importance weights to input tokens.

Saliency methods calculate the gradient of the output corresponding to the correct prediction with respect to an input element to identify those parts of the input that have the biggest influence on the prediction (Lipton, 2018). Saliency maps were first developed for image processing models to highlight the areas of the image that are discriminative with respect to the tested output class (Simonyan et al., 2014). Li et al. (2016) adapt this method to calculate the relative change of the output probabilities with respect to individual input tokens in

text classification tasks and Ding et al. (2019) calculate saliency maps for interpreting the alignment process in machine translation models.

In general-purpose language models such as BERT (Devlin et al., 2019), the objective function tries to predict a token based on its context. A saliency vector for a masked token thus indicates the importance of each of the tokens in the context of correctly predicting the masked token (Madsen, 2019).

We iterate over each token vector $\mathbf{x}_i$ in our input sequence $x_1, x_2, ... x_n$. Let $\mathbf{X}_i$ be the input matrix with $\mathbf{x}_i$ being masked. The saliency s_{ij} for input token $\mathbf{x}_j$ for the prediction of the correct token $\mathbf{t}_i$ is then calculated as the Euclidean norm of the gradient of the logit for x_i.

$$s_{ij} = \|\nabla_{\mathbf{x}_j} f_{t_i}(\mathbf{X}_i)\|_2 \quad (1)$$

The saliency vector $\mathbf{s}_i$ indicates the relevance of each token for the correct prediction of the masked token t_i.[1] The saliency scores are normalized by dividing by the maximum. We determine the relative importance of a token by summing over the saliency scores for each token. For comparison, we also approximate importance using attention values from the last layer of each model as Sood et al. (2020a).

2.3 Patterns of Relative Importance

Relative importance in human processing and in computational models is sensitive to linguistic properties. Rayner (1998) provides a detailed overview of token-level features that have been found to correlate with fixation duration such as length, frequency, and word class. On the contextual level, lexical and syntactic disambiguation processes cause regressions and thus lead to longer fixation duration (Just and Carpenter, 1980; Lowder et al., 2018). Computational models are also highly susceptible to frequency effects and surprisal metrics calculated using language models can predict the human processing effort (Frank et al., 2013).

The inductive bias of language processing models can be improved using the eye-tracking signal (Barrett et al., 2018; Klerke and Plank, 2019) and the modification leads to more "human-like" output in generative tasks (Takmaz et al., 2020; Sood et al., 2020b). This indicates that patterns of relative importance in computational representations differ from human processing patterns. Previous work focused on identifying links between the eye-tracking signal and attention (Sood et al., 2020a). To our knowledge, this is the first attempt to correlate fixation duration with saliency metrics.

	Dataset	BERT	Distil	ALBERT	Rand
Saliency	GECO	**.54**	.51	.48	.00
	ZuCo	**.68**	.64	.62	.00
Attention	GECO	.18	.06	.26	.00
	ZuCo	.11	.03	.37	.00

Table 1: Spearman correlation between relative fixation duration by humans and attention and saliency in the language models. Correlation values are averaged over all sentences. *Rand* is a permutation baseline.

The eye-tracking signal represents human reading processes aimed at language understanding. In previous work, we have shown that contextualized language models can predict eye patterns associated with human reading (Hollenstein et al., 2021), which indicates that computational models and humans encode similar linguistic patterns. It remains an open debate to which extent language models are able to approximate language understanding (Bender and Koller, 2020). We are convinced that language needs to be cooperatively grounded in the real world (Beinborn et al., 2018). Purely text-based language models clearly miss important aspects of language understanding but they can approximate human performance in an impressive range of processing tasks. We aim to gain a deeper understanding of the similarities and differences between human and computational language processing to better evaluate the capabilities of language models.

3 Methodology

We extract relative importance values for tokens from eye-tracking corpora and language models as described in section 2 and calculate the Spearman correlation for each sentence.[2] We first average the correlation over all sentences to analyze whether the importance patterns of humans and models are comparable and then conduct token-level analyses.

3.1 Eye-tracking Corpora

We extract the relative fixation duration from two eye-tracking corpora and average it over all readers for each sentence. Both corpora record natural reading and the text passages were followed by

[1] Our implementation adapts code from https://pypi.org/project/textualheatmap/. An alternative would be to multiply saliency and input (Alammar, 2020).

[2] Kendall's τ and KL divergence yield similar results.

multiple-choice questions to test the readers' comprehension.

GECO contains eye-tracking data from 14 native English speakers reading the entire novel *The Mysterious Affair at Styles* by Agatha Christie (Cop et al., 2017). The text was presented on the screen in paragraphs.

ZuCo contains eye-tracking data of 30 native English speakers reading full sentences from movie reviews and Wikipedia articles (Hollenstein et al., 2018, 2020).[3]

3.2 Language Models

We compare three state-of-the-art language models trained for English: BERT, ALBERT, and DistilBERT.[4] BERT was the first widely successful transformer-based language model and remains highly influential (Devlin et al., 2019). ALBERT and DistilBERT are variants of BERT that require less training time due to a considerable reduction of the training parameters while maintaining similar performance on benchmark datasets (Lan et al., 2019; Sanh et al., 2019).[5] We analyze if the lighter architectures have an influence on the patterns of relative importance that the models learn.

4 Results

The results in Table 1 show that relative fixation duration by humans strongly correlates with the saliency values of the models. In contrast, attention-based importance does not seem to be able to capture the human importance pattern. A random permutation baseline that shuffles the importance assigned by the language model yields no correlation (0.0) in all conditions.[6] As the standard deviations of the correlation across sentences are quite high (ZuCo: ∼0.22, GECO: ∼0.39), the small differences between models can be neglected (although they are consistent across corpora). For the subsequent analyses, we focus only on the BERT model which yields the best results. The differences between the corpora might be related to the number of sentences and the differences in average sentence length (ZuCo: 924, 19.5, GECO: 4,926, 12.7).

		Length		Frequency	
		Sent	Tok	Sent	Tok
GECO	Human	.69	.31	-.36	-.25
	BERT	.65	.27	-.48	-.28
ZuCO	Human	.75	.47	-.52	-.36
	BERT	.72	.36	-.65	-.40

Table 2: Spearman correlation between relative importance and word length and frequency. For the *Sent* condition, correlation is calculated per sentence and averaged. For *Tok*, importance is normalized by sentence length and correlation is calculated over all tokens.

Length and Frequency In eye-tracking data, word length correlates with fixation duration because it takes longer to read all characters. The correlation for frequency is inverse because high-frequency words (e.g. "the", "has") are often skipped in processing as they carry (almost) no meaning (Rayner, 1998). For English, word frequency and word length are both closely related to word complexity (Beinborn et al., 2014). Language models do not directly encode word length but they are sensitive to word frequency.

Our results in Table 2 show that both token length and frequency are strongly correlated with relative importance on the sentence level. Interestingly, the correlation decreases when it is calculated directly over all tokens indicating that the token-level relation between length and importance is more complex than the correlation might suggest.

Word Class Figure 2 shows the average relative importance of all tokens belonging to the same word class (normalized by sentence length). We see that both humans and BERT clearly assign higher importance to content words (left) than to function words (right). Interjections such as "Oh" in figure 3 receive the highest relevance which is understandable because they interrupt the reading flow. When we look at individual sentences, we note that the differences in importance are more pronounced in the model saliency while human fixation duration yields a smoother distribution over the tokens.

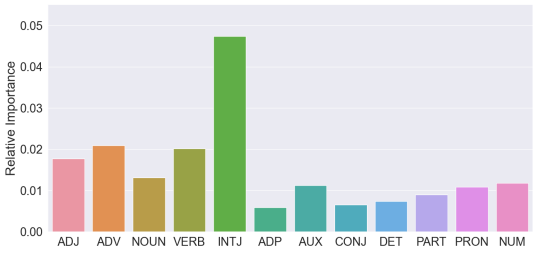
Novelty We extract the language model representations for each sentence separately whereas the readers processed the sentences consecutively. If tokens are mentioned repeatedly such as "Sherlock

[3] We combine ZuCo 1.0 (T1, T2) and ZuCo 2.0. (T1).

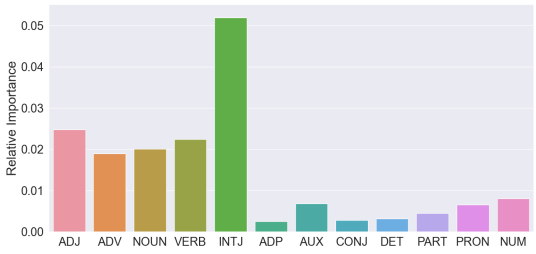
[4] We use the *Huggingface* transformers implementation (Wolf et al., 2020) and the models `bert-based-uncased`, `albert-base-v2`, and `distilbert-base-uncased`.

[5] Reduction is achieved by parameter sharing across layers (ALBERT) and by distillation which approximates the output distribution of the original BERT model using a smaller network (DistilBERT). See model references for details.

[6] We repeat the permutation 100 times and average the correlation over all iterations.



(a) Human Fixation



(b) Model saliency

Figure 2: Relative importance of tokens with respect to word class. Relative importance is measured as relative fixation duration for humans in GECO (left) and as relative gradient-based saliency in the BERT model (right).

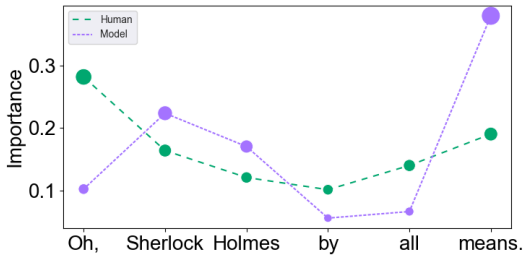


Figure 3: Relative importance values for an example sentence from the GECO corpus for the BERT model and the human values.

Holmes" which also occurred in the sentence preceding the example in Figure 3), processing ease increases for the reader, and not for the model. Some language models are able to process multiple sentences, but establishing semantic links across sentences remains a challenge.

5 Conclusion

We find that human sentence processing patterns in English correlate strongly with saliency-based importance in language models and not with attention-based importance. Our results indicate that saliency could be a cognitively more plausible metric for interpreting neural language models. In future work, it would be interesting to test the robustness of the approach with different variants for calculating saliency (Bastings and Filippova, 2020; Ding and Koehn, 2021). As we conducted our analyses only for English data, it is not yet clear whether our results generalize across languages. We will address this in future work using eye-tracking data from non-English readers (Makowski et al., 2018; Laurinavichyute et al., 2019) and comparing mono- and multilingual models (Beinborn and Choenni, 2020). We want to extend the token-level analyses to syntactic phenomena and cross-sentence effects. For example, it would be interesting to see how a language model encodes relative importance for sentences that are syntactically correct but not semantically meaningful (Gulordava et al., 2018).

Previous work has shown that the inductive bias of recurrent neural networks can be modified to obtain cognitively more plausible model decisions (Bhatt et al., 2020; Shen et al., 2019). In principle, our approach can also be applied to left-to-right models such as GPT-2 (Radford et al., 2019). In this case, the tokens at the beginning of the sentence would be assigned disproportionately high importance as the following tokens cannot contribute to the prediction of preceding tokens in incremental processing. It might thus be more useful to only use the first fixation duration of the gaze signal for analyzing importance in left-to-right models. However, we think that the regressions by the readers provide valuable information about sentence processing.

6 Ethical Considerations

Data from human participants were leveraged from freely available datasets (Hollenstein et al., 2018, 2020; Cop et al., 2017). The datasets provide anonymized records in compliance with ethical board approvals and do not contain any information that can be linked to the participants.

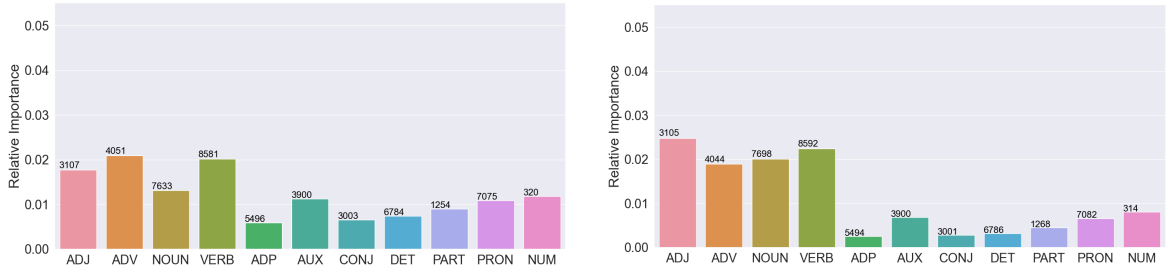
A Additional Results



(a) Human Fixation (b) Model saliency

Figure 4: Relative importance of tokens with respect to word class in the GECO dataset. Relative importance is measured as relative fixation duration for humans (top) and as relative gradient-based saliency in the BERT model (bottom). This is the same figure as Figure 2 in the paper but it includes the number of instances per word class on top of the respective bar.

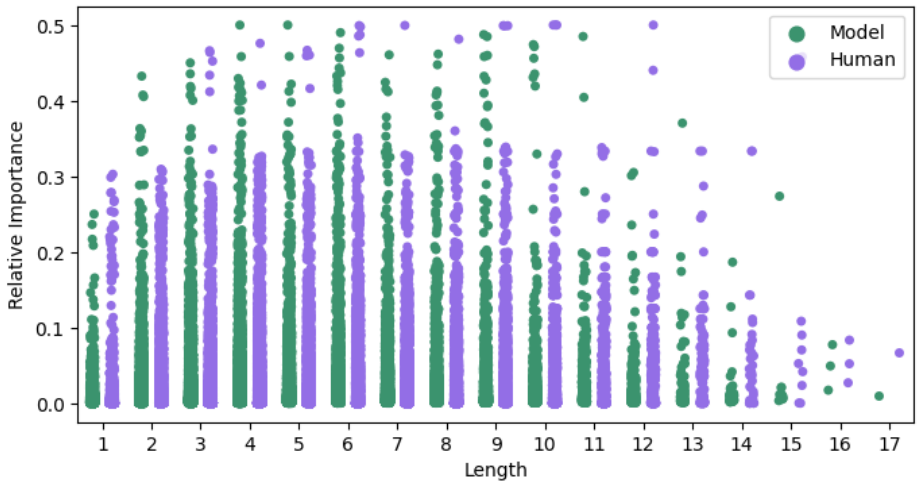


Figure 5: Relative importance values with respect to word length from human readers and from the BERT model for the GECO corpus.

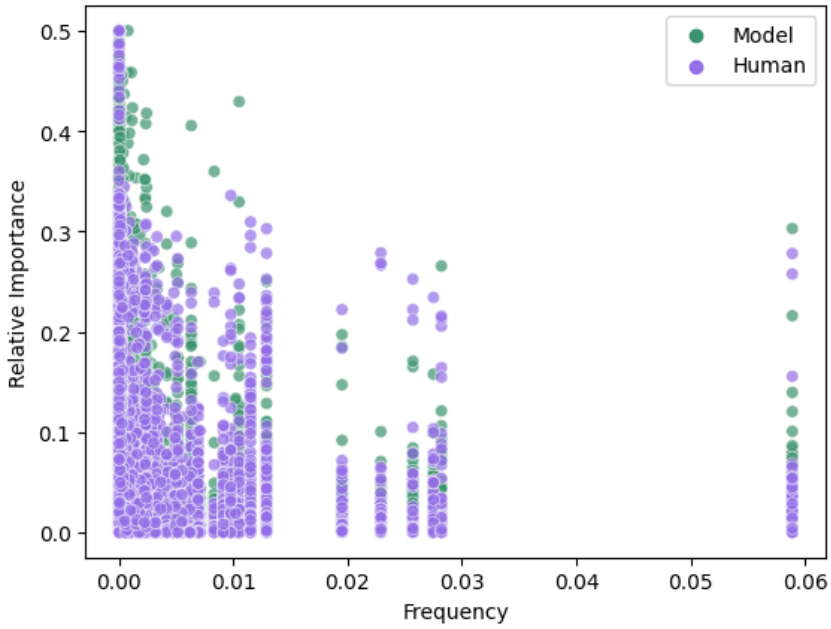

Figure 6: Relative importance values with respect to word frequency from human readers and from the BERT model for the GECO corpus.

Doing Good or Doing Right?
Exploring the Weakness of Commonsense Causal Reasoning Models

Abstract

Pretrained language models (PLM) achieve surprising performance on the Choice of Plausible Alternatives (COPA) task. However, whether PLMs have truly acquired the ability of causal reasoning remains a question. In this paper, we investigate the problem of semantic similarity bias and reveal the vulnerability of current COPA models by certain attacks. Previous solutions that tackle the superficial cues of unbalanced token distribution still encounter the same problem of semantic bias, even more seriously due to the utilization of more training data. We mitigate this problem by simply adding a regularization loss and experimental results show that this solution not only improves the model's generalization ability, but also assists the models to perform more robustly on a challenging dataset, BCOPA-CE, which has unbiased token distribution and is more difficult for models to distinguish cause and effect.

1 Introduction

Supervised learning algorithms recklessly absorbing all the correlations found in training data is statistically correct but might have missed the point (Ahuja et al., 2020). Hence, recent work has focused more on spurious correlations in datasets in computer vision and NLP (Jia and Liang, 2017; McCoy et al., 2019). In inference tasks over natural language, spurious correlation has been identified a lot, such as lexical and grammatical constructs, word overlap, sentence length (Gururangan et al., 2018), and unbalanced token distribution (Poliak et al., 2018; Kavumba et al., 2019). COPA (Roemmele et al., 2011) is a natural language understanding task, which requires a system to choose either a cause or effect of a given story event. It is one of the natural language understanding tasks in SuperGlue benchmark (Wang et al., 2019). Pretrained language models gain a great improvement on COPA, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020). The recent state-of-the-art model on COPA, DeBERTa (He et al., 2020), reached a surprising accuracy of 98.4%. However, the complexity of causal reasoning and the requirements of world knowledge imply that the ability of causal reasoning in PLMs might be overestimated. It is worth exploring whether the models have acquired the ability of causal reasoning.

A Sample from development dataset
Premise: The woman banished the children from her property.
ask-for: "cause"
Alt1: The children hit a ball into her yard. × **(effect)**
Alt2: The children trampled through her garden. √ **(cause)**

Table 1: A challenging case where BERT predicts wrongly

We observe that 66.8% accuracy can be reached by a text semantic similarity model (Mulyar, 2020) based on BERT which is close to the performance (69.5%) of fine−tuning BERT on COPA training set. It indicates BERT is over-dependent on semantic similarity. Since the *cause* and *effect* of

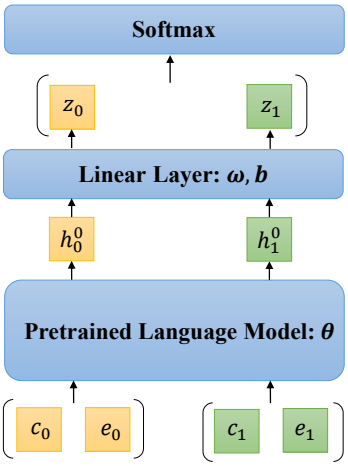

Figure 1: The general architecture of the PLMs on COPA task.

the same event often share the similar context, can PLMs really discriminate what we are asking for? A special case where BERT made mistakes on COPA development set in Table 1 seems to confirm our conjecture. BERT is more likely to fail in these challenging samples where the wrong alternative is the answer of its reverse question type. These investigations imply the models with satisfactory performance might have focused excessively on the topic semantic similarity instead of understanding cause and effect more finely. For this purpose, we design several probing experiments (Section 2) to verify our conjecture: (1) perturbation with distractors, (2) masking question type.

The main work on exploring bias in COPA is from Kavumba et al. (2019). They investigate unbalanced token distributions in correct answers in COPA training set and show that the good performance brought by BERT can be explained by its ability to exploit token distribution in alternatives. They augment the training set with a mirrored-COPA set to prevent the models from predicting with token distribution imprudently. However, we observed this improved model relies on semantic bias more seriously than the original PLMs. We further test the models on a new dataset, BCOPA-CE, which evaluates the ability of a system to distinguish the *cause* and *effect* and to reason without the clues of token distribution. For alleviating the semantic bias problem, we propose to add a regularization loss to the original objective (Section 3). Experimental results show that this solution is not only effective in our challenging test set, but improves the generalization ability of the model on the original test set. It also performs more robustly than the original PLMs in COPA-test *hard* set proposed by Kavumba et al. (2019).

In sum, our contributions are as follows:

(1) We explore the vulnerability of different COPA models by perturbing them with distractive alternatives. (2) We mitigate the weakness of COPA models by adding a regularization loss while maintaining their generalization ability. Our improved models also perform more robustly on the COPA-test hard set. (3) We introduce the BCOPA-CE dataset, which can evaluate the ability of a system to distinguish the cause and effect and to choose cause or effect under unbiased token distribution.

2 Probing Experiments

Unlike bias about token distribution or sentence length, indirect semantic cues cannot be analyzed statistically. We explore whether PLMs rely excessively on semantic similarity with special probing experiments. Firstly, we observe whether the model has dropped to a great extent if they see a distractive alternative, like a ***premise***. This distractor cannot be the correct answer, but it has a higher similarity score than the correct alternative. Moreover, inspired by Table 1, we investigate whether the model is aware of the question type during prediction. This is achieved by evaluating the model's performance while removing/masking the question type. We observe whether they still keep good performance without seeing the question type. We describe the model implementation details in Appendix A.

2.1 Exp1: Perturbation with Distractors

Model architecture: General PLMs assume that the first sentence and the second sentence describe a cause and an effect, respectively. For example, BERT take as input {cause, [SEP], effect}, which entails the question type in its formation. The general architecture in our experiment is shown in Figure 1. The shared parameters θ, ω, b are learned to classify each choice independently with the premise, where (c_i, e_i) is the i-th cause-effect pair, taking the first hidden vector in the final PLM layer:

$$h_i^0 = \theta(c_i, e_i) \quad (1)$$

yielding the logits for each cause-effect pair:

$$z_i = \omega^T h_i^0 + b \quad (2)$$

For training, we pass the logits $[z_0; z_1]$ through a softmax function to determine a probability

distribution and minimize the cross-entropy loss with the labels. For prediction, we choose the answer with the highest score by $i^* = argmax_{i\in\{0,1\}} z_i$. If we evaluate the trained models on ternary-choice test set, the prediction is then $i^* = argmax_{i\in\{0,1,2\}} z_i$.

Perturbation: We perturb models by adding a third choice, which does not affect human judgment. The "*premise*" is a good candidate since it is highly semantically related to itself while it cannot be the cause or effect of itself due to the non-reflexive trait of causality. We anticipate that the model will change its prediction when it meets the added choice. Meanwhile, we need to make sure that the performance drop is not from the increased difficulty of the problem since it becomes a ternary choice from a binary choice, hence we compare the results with a control experiment, where we add a choice randomly sampled from the COPA-test set.

- **COPA-random**: We control the difficulty of perturbation test by taking a wrong choice randomly sampled from the COPA-test set as the third alternative for each sample. We refer to COPA-random as "**Rand**" in Table 2.
- **COPA-premise:** we take the premise as the third alternative. We refer to COPA-premise as "**Prem**" in Table 2.

2.2 Exp2: Masking Question Type

As mentioned above, models are likely to ignore the question information (*cause* or *effect*, often share the same context) if they rely excessively on the semantic similarity. We mask the "*ask-for*" for each sample in COPA-test set by inputting the models with an arbitrary question type. The order of the alternative and the premise is determined by the question type. In masking setting, we randomly input [alternative; premise] or [premise; alternative] for each instance in spite of the question. In this way, half of the samples will keep the original question type, and the other samples get the wrong question type, which do not have the real correct answer. We observe whether these models still keep good performance without seeing the question type. If they do, the question type is ignored for the prediction of the models. We refer to this experimental setting as "**Mask**" in Table 2. The lower accuracy on "Mask" setting, the more robust the models are.

2.3 Baseline models

We conduct the aforementioned experiments with both traditional and SOTA COPA models.

- **CS:** Sasaki et al. (2017) handled the COPA task by statistically estimating causality scores using causal knowledge extracted from a corpus with causal templates.
- **PLMs:** We take BERT-large, RoBERTa-large, ALBERT-xxlarge-v1, and DeBERTa-large as baseline models (referred to as b-l, rb-l, alb, and db-l, respectively), and fine-tune them on the COPA-dev set, using the implementation from hugging face[1].
- **PLMs-aug (**b-l-aug, rb-l-aug, alb-aug and db-l-aug**):** PLMs are fine-tuned on BCOPA, a dataset with unbiased token distribution between the correct alternatives and the wrong alternatives proposed by Kavumba et al. (2019). The BCOPA dataset was constructed by mirroring the original training set with a modified premise.

2.4 Results and analysis

As is shown in Table 2, The CS method based on causal knowledge is the most robust system, barely affected by the added alternative. PLMs show different degrees of weakness when they are disturbed by the added alternative. The defensive

Model	Exp1: Perturbation			Exp2: Masking	
	Rand ↑	Prem ↑	Δ ↓	Test ↑	Mask ↓
CS	70.1	70.5	-0.4	70.8	61.1
b-l	59.3	11.6	47.6	69.5	69.0
b-l-aug	63.3	13.0	50.3	70.0	69.6
rb-l	83.3	66.7	16.6	86.3	82.8
rb-l-aug	85.6	65.7	19.9	87.3	83.5
alb	86.7	71.9	14.7	88.0	80.2
alb-aug	86.4	61.2	25.2	87.9	84.1
db-l	90.8	77.9	12.9	91.6	87.8
db-l-aug	91.1	78.9	12.2	91.8	88.8

Table 2. The accuracy of models in probing experiments. "↓" denotes a negative indicator (the lower, the better) and "↑" denotes a positive indicator (the higher, the better).

A Sample in COPA-test set	New Samples in BCOPA-CE test set	
Premise: The accident was my fault. *ask-for:* "effect" *Alt1:* I felt guilty. √ *Alt2:* I pressed charges. ×	*Premise:* The accident was my fault. *ask-for:* "effect" *Alt1:* I felt guilty. √ *Alt2:*I was absent-minded. ×	*Premise:* The accident was my fault. *ask-for:* "cause" *Alt1:* I felt guilty. × *Alt2:* I was absent-minded. √

Table 3 The samples in COPA-test set and BCOPA-CE test set.

ability of BERT is the weakest, which is almost completely fooled by distractor and remains the original accuracy without seeing the questions. RoBERTa, ALBERT, and DeBERTa also drop 16.6%, 14.7%, 12.9% respectively compared with the performance of "**Rand**" setting. The fact that the systems perform worse on "**Prem**" (*premise* as a distractor) supports our hypothesis that PLMs have semantic similarity bias. This is because the *premise* is 100% similar to itself, being much more similar than a random distractor. For masking experiments, the theoretical accuracy of a perfectly robust model should be half of the chance-level (i.e., 50%) plus half of the original accuracy. The CS method achieves an accuracy of 61.1% and pays attention to the question type. On the contrary, PLMSs seem not to be aware of the question type and perform similarly without this information as original model setting. However, PLMs do not completely ignore the question type since they do not keep the same performance as the original test set.

We also investigate the robustness of the debiased methods of augmenting training data which focus on the unbalanced token distributions proposed by Kavumba et al. (2019). They suffer from the same issue even more seriously than the original PLMs except DeBERTa. This might be due to the fact that the models are more likely to capture the semantic similarity since each alternative pair in BCOPA appears twice.

3 Model-improving Method

3.1 BCOPA-CE Test

As is shown in Table 3, we introduce a balanced COPA test set, BCOPA-CE, by taking cause event and effect event as two alternatives for each premise. Specifically, for each premise of the 500 samples in COPA-test set, we generate one event manually which is a plausible answer to the opposite question type of the original sample, In the sample in Table 3, for the premise: "*The accident was my fault.*", we generate the *cause* of it: "*I was absent-minded.*", since the original question is asking for "*effect*". After this process, we obtain 500 triplets of <*premise*, *cause*, *effect*>. Then, we construct 1000 samples by giving two different questions (*cause* or *effect*) to each triplet. This guarantees the balanced token distribution between the correct and the wrong alternatives. The dataset generation details are described in Appendix B. Human evaluation has been conducted to ensure the quality of the new dataset in Appendix C.

3.2 Regularization Loss

We expect the model to make good choices while paying attention to the question type. For a sample in the COPA training set, the proposed loss includes two parts: The CrossEntropy loss and a regularization loss. The first part prompts the model to answer correctly given the question type. The extra regularization loss requires that a model should be neutral when it sees the opposite question type for the same premise and same alternatives, since neither alternative is the correct answer.

General PLMs take the first input sentence as the cause, and the second sentence as the effect. Mathematically, the logits of two input sentences in reverse cause-effect order should be as close as possible, even if one of two alternatives is semantically similar to the premise (the correct answer of the original question).

$$L = (1-\lambda) * L_{CE} + \lambda * L_{Reg} \quad (3)$$

$$L_{Reg} = \|z_0^r - z_1^r\|_2^2 \quad (4)$$

z_i^r is the logit of input $[e_i; c_i]$ computed by equation (1), which reverses the order of cause and effect of choice i. We set $\lambda = 0.01$ in all experiments corresponding to regularization loss.

3.3 Result and Analysis

Table 4 demonstrates the performance of our improved models on the COPA-test set, the BCOPA-CE set and the COPA-hard set. It's noted that the models with a regularization loss not only have improved performance on BCOPA-CE set,

Model	Test ↑	BCOPA-CE ↑	Δ ↓	Test-hard ↑
b-l	69.5	51.5	18.0	61.6
b-l-reg	**71.1**	**64.1**	**7.0**	63.6
b-l-aug	70.0	51.1	18.9	**69.7**
rb-l	86.3	73.0	13.3	83.1
rb-l-reg	**87.7**	**83.9**	**3.8**	84.5
rb-l-aug	87.3	69.2	18.2	**87.0**
alb	88.0	80.5	7.6	86.9
alb-reg	**89.4**	**86.7**	**2.7**	**88.6**
alb-aug	87.9	71.4	16.5	88.0
db-l	91.6	72.3	19.3	88.6
db-l-reg	**92.2**	**86.3**	**5.9**	89.7
db-l-aug	91.8	69.8	21.9	**90.5**

Table 4 The performance of PLMs and their variants on challenging set. Bold represents the best model setting in the same PLM.

but also perform better than the original PLMs on COPA-test set. Previous debiased models on token distribution perform worse than the original model, which is consistent with our conjecture that they amplify the semantic bias. Our solution also performs better on COPA-test-hard than the original PLMs, which has balanced token distribution as Kavumba et al. (2019) introduced. Regularization in our method considers debiasing token distribution as well, because we tend to stop the models from capturing any cues when it reverses the input order.

3.4 Error Analysis

We conduct an error analysis for the SOTA model, DeBERTa, using the run that is closest to the average of 20 runs. We give an example (the second row) from the BCOPA-CE dataset in Table 5 where DeBERTa predicts wrongly but the regularized DeBERTa model succeeds. Interestingly, both models make a correct prediction on the original sample (the first row) from COPA-test set, which indicates that the new alternative we generate perturbs the choice of the original DeBERTA model.

We calculate the word importance of all tokens in correct answer through erasure (Li et al., 2017). The importance score is computed by the relative difference in log likelihood on gold-standard labels while replacing the token with [MASK]. We observe two models predict correctly in this original sample but with different attention on tokens. As is shown in Figure 2, DeBERTa chooses Alt2 by focusing on "*He*" and "*spoke*", but DeBERTa-reg pays the most attention to

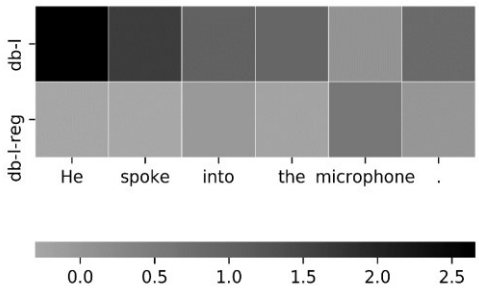

Figure 2: Heatmap of importance of each token in correct answer for the db-l model and db-l-reg model.

Original sample	*Premise:* The man's voice projected clearly throughout the auditorium. *Ask-for:* cause *Alt1:* He greeted the audience. × *Alt2:* He spoke into the microphone. √
New sample	*Premise:* The man's voice projected clearly throughout the auditorium. *Ask-for:* cause *Alt1:* Everyone heard him. × *Alt2:* He spoke into the microphone. √

Table 5 The case where DeBERTa is perturbed but regularized DeBERTa not.

"*microphone*", which is more in line with human causal intuition. When people make such inference, the causal relation between "*microphone*" and "*projected clearly throughout the auditorium*" should be more important than the co-reference relationship.

4 Conclusion

In this paper, we explore whether COPA models rely excessively on semantic similarity for prediction. We add the regularization loss to the training objective to alleviate this weakness. Results show that our solution is effective in our adversarial test, and improve the generalization ability and the robustness of models on previous COPA-hard dataset. Moreover, previous debiased models on token distribution rely on semantic bias more seriously than the original models, which reminds us if debiasing bring more other bias.

Appendix

A Implementation Details

PLMs: We randomly split the training set (COPA-dev, or BCOPA) into training set and development set with a ratio of 9:1, and finetune our model up to 20 epochs by implementing an early-stopping strategy with a patience of 5 epochs and using AdamW optimizer. We run 20 different random seeds for each supervised model and report the mean of the non-degenerate runs for each model, which have higher than 80% of accuracy in the training set as in previous work (Niven and Kao, 2019).

CS: We reproduce the preprocessing of their work and achieve 70.8% accuracy, which is slightly lower than the reported accuracy of 71.4%.

All parameters are learned from the development set by manual tuning. The best-performing parameter is determined by the accuracy of the model in the development set. The final parameters in our experiments are shown in Table 6.

Model	LR	BS	WD	WP	λ
b-l	1e-4	32	0.01	0.1	-
b-l-aug					
b-l-reg	8e-5				0.01
rb-l	8e-6	32	0.01	0.06	-
rb-l-aug					
rb-l-reg	1.2e-5				0.01
alb	1.1e-4	48	0	0	-
alb-aug					
alb-reg	6e-5				0.01
db-l	5e-6	32	0.01	0.06	-
db-l-aug					
db-l-reg	1e-5				0.01

Table 6. The best Batch Size (BS), Learning Rate (LR), Warm up rate (WP)， and Weight Decay value (WD) we used in our experiments.

B Construction Details of BCOPA-CE

We asked five fluent English speakers who have background knowledge of NLP to create the new alternative with the specific guidelines. We instructed creators with requirements of sentence length, overlap rules, and expressions similar to Kavumba et al. (2019).

C Human Evaluation on BCOPA-CE

We have 1000 samples in BCOPA-CE set, which consist of. 500 samples whose answers are same with original COPA-test set (the left sample in the second column in Table 3, referred to as COPA-CE-ori) and 500 samples whose answers are the choices that we generate (the right sample in the second column in Table 3, referred to as COPA-CE-opp). To ensure the quality of generated dataset, we conduct a quality evaluation with two questions:

- ***Q1****: Are the instances in* BCOPA-CE dataset *comparable in difficulty to the COPA-test instances?*
- ***Q2****: Is the new alternative we collect plausible for the opposite question type?*

	COPA-test	COPA-CE-ori	COPA-CE-opp
Accuracy	0.980	0.990	1.000
Fleiss' Kappa	0.919	0.893	0.890

Table 7: Human evaluation result of generated dataset.

We evaluate the accuracy of human on both COPA-CE-ori dataset and COPA-CE-opp dataset to answer the Q1 and evaluate the human performance on COPA-CE-opp set for Q2. The COPA-CE-opp set changes the question type and takes the generated event as gold answers, hence it can be evaluated for the plausibility of generated alternatives. We asked 9 people to make choices, each group of 3 people for one dataset. We determine the final choice by majority voting. The inter-annotator agreement is calculated by Fleiss' Kappa. As is shown in Table 7, the BCOPA-CE set has comparable difficulty with COPA-test. The performance on COPA-CE-opp shows that the new alternatives we create are plausible.

AND does not mean OR: Using Formal Languages to Study Language Models' Representations

Abstract

A current open question in natural language processing is to what extent language models, which are trained with access only to the *form* of language, are able to capture the *meaning* of language. In many cases, meaning constrains form in consistent ways. This raises the possibility that some kinds of information about form might reflect meaning more transparently than others. The goal of this study is to investigate under what conditions we can expect meaning and form to covary sufficiently, such that a language model with access only to form might nonetheless succeed in emulating meaning. Focusing on propositional logic, we generate training corpora using a variety of motivated constraints, and measure a distributional language model's ability to differentiate logical symbols ($\neg$, $\wedge$, $\vee$). Our findings are largely negative: none of our simulated training corpora result in models which definitively differentiate meaningfully different symbols (e.g., $\wedge$ vs. $\vee$), suggesting a limitation to the types of semantic signals that current models are able to exploit.

1 Introduction

A current open question in natural language processing is to what extent language models (LMs; neural networks trained to predict the likelihood of word forms given textual context) are capable of truly understanding language. Bender and Koller (2020) argue that, since such models are trained exclusively on the *form* of language, they cannot possibly learn the *meaning* of language. We argue that the question of whether language models can learn meaning cannot be settled *a priori*. While language models only have direct access to form, linguistic form often correlates with meaning. The strength of the correlation varies across both different aspects of language and different tests of linguistic competence. While several intuitive tests of understanding (e.g., demonstrating knowledge of the word *dog* by identifying pictures of dogs) are out of scope for LMs, many tasks which NLP aspires to solve (e.g., question answering, machine translation) operate entirely on natural language input and output. Thus, a relevant question is whether models which operate only on the forms of language can nonetheless learn to differentiate meanings.

Our goal is to focus on a tractable subproblem in order to improve our intuitions about the types of distributional signals that LMs can use to extract information relevant to meaning. We simulate a language modeling setup using propositional logic, in which we can naturally operationalize *form* to be strings of symbols in the language and *meaning* to be truth conditions. We define the *semantic transparency* of a text-only training corpus to be the degree to which an LM trained on that corpus learns to differentiate between aspects of form that affect truth conditions and aspects of form that do not. We have two primary research questions. First, what constraints on corpus generation produce greater semantic transparency? And second, are any such constraints sufficient for an LM to adequately differentiate meanings?

2 Experimental Design

2.1 Dataset Generation

We consider the *form* of a sentence to be simply the observed, syntactically-valid strings of characters and the *meaning* to be the truth conditions. Propositional logic is a simple language in which we can characterize both form and meaning. We use the grammar in Table 1, with standard semantics.

We focus our analysis on whether the representations of logical operators ($\wedge$, $\vee$, $\neg$) are influenced by distributional patterns that go beyond their superficial syntactic similarity evident in the grammar. That is, if a trained LM identifies that the meanings

$S \rightarrow$	$(S \wedge S) \mid (S \vee S) \mid (\neg S) \mid (\texttt{sym})$
$\wedge \rightarrow$	$\wedge_1 \mid \wedge_2 \cdots \mid \wedge_K$
$\vee \rightarrow$	$\vee_1 \mid \vee_2 \cdots \mid \vee_L$
$\neg \rightarrow$	$\neg_1 \mid \neg_2 \cdots \mid \neg_M$
$\texttt{sym} \rightarrow$	$\texttt{sym}_1 \mid \texttt{sym}_2 \cdots \mid \texttt{sym}_N$

Table 1: Propositional logic grammar.

of $\wedge_1 \cdots \wedge_k$ are identical to one another, and different from the meanings of $\vee_1 \cdots \vee_l$, we expect the embeddings for the $\wedge_i$ to be more similar to one another than they are to any of the $\vee_i$ or the $\neg_i$. We consider a corpus to be *semantically transparent* if an LM trained on the corpus learns semantically-clustered representations of the logical operators.

We generate four different training corpora, motivated by different assumptions one might make about how natural language corpora arise. These constraints are as follows, ordered roughly from weakest to strongest:

1. Syntactic Constraint. Speakers only generate sentences which are syntactically well-formed (that can be parsed by a syntactic parser). Here, this amounts to sampling from the grammar without additional constraints.

2. Truthfulness Constraint. Speakers of the language are constrained to generate sentences that are true in some context, i.e., that evaluate to `True` in at least one possible world. To implement this, we again sample from the grammar but additionally check with a satisfiability checker and omit sentences which are not satisfiable. E.g., $(\texttt{sym}_1 \wedge (\neg(\texttt{sym}_1)))$ would not appear.

3. Informativity Constraint. Speakers generate sentences not just to state true facts, but to provide listeners with information about a particular state of affairs. To simulate such a constraint, we randomly sample a set of "target worlds" T and a set of "alternative worlds" A such that $T \cap A = \emptyset$. We then generate the shortest sentence s such that s is true in every world in T and s is false in every world in A. We experiment with several sizes of T and A, but report only on $|T| = |A| = 2$ as this provides the right balance of contextual diversity. See Appendix for additional discussion.

4. Explicit Grounding. We consider a setting in which speakers explicitly dictate the full state of affairs, without ambiguity. This is not intended as a realistic model of how corpora are generated, but rather to provide an upper bound on semantic transparency by giving models a corpus in which form is perfectly correlated with meaning. We generate this corpus in the same way as the Truthfulness corpus, but append an explicit marker of the truth values[1] of the variables in the sentence, e.g.: $(\texttt{sym}_1 \wedge (\neg(\texttt{sym}_2)))$ `<sep>` $\texttt{sym}_1$ `T` $\texttt{sym}_2$ `F`.

Sampling Parameters. Each dataset consists of 100K training and 1K validation sentences. We set the number of non-reserved symbols (N in the above grammar) to 5,000, and the number of "synonyms" of each logical symbol (K,L,M) to be 5. Thus, a sentence in one of our datasets might look like $(\texttt{sym}_1 \wedge_3 (\neg_4(\texttt{sym}_{85})))$, and would be true if and only if $\texttt{sym}_1$ is true and $\texttt{sym}_{85}$ is false [2].

We generate sentences using a probabilistic context-free grammar with the rules shown above. The tree depth d of a generated sentence is controlled by a parameter γ such that $P(d|d-1) = \gamma^d$. The number of unique variables in a sentence[3] is sampled from a non-zero Poisson distribution parameterized by λ. We set $\lambda = 2$ and $\gamma = .85$ in the reported experiments, but don't find parameter choice affects our conclusions. Note that the Informativity dataset is generated deterministically, and thus sampling parameters do not apply and sentences in that dataset are shorter. Dataset statistics and data generation parameter sensitivity are in the Appendix.

2.2 Models and Training

We consider LSTM and Transformer LMs of differing sizes, shown in Table 2. Each model is trained on one of the above four datasets until convergence on the associated validation set using early stopping with a patience of 15 epochs. The LMs were implemented in PyTorch (Paszke et al., 2019) and took roughly 5 hours to converge on TitanV, TitanRTX, and QuadroRTX GPUs [4]. We randomly initialize the embedding layer. Hyperparameter details can be found in the Appendix. We train 5 random restarts of each setting. Due to the regular nature of our synthetic data, we found larger mod-

[1] Sampled from the set of satisfying variable assignments.

[2] We began by experimenting with many different dataset sizes and vocab counts. However, we did not find that models behaved differently on larger datasets and so focused on the smaller ones for convenience. See Appendix for results with different model sizes.

[3] We set a maximum number of variables per sentence in order to bound the number of possible variable assignments.

Model	Syntactic	Truthfulness	Informativity	Grounded
Small LSTM (192K)	21.2 / 87.7 / 87.7	17.6 / 88.7 / 88.6	21.5 / 99.6 / 99.5	21.2 / 87.5 / 87.5
Medium LSTM (545K)	17.6 / 90.2 / 90.1	17.5 / 89.6 / 89.5	20.9 / 99.9 / 99.8	8.3 / 89.3 / 86.8
Small Trans. (311K)	11.8 / 86.9 / 84.6	12.4 / 87.2 / 85.4	21.7 / 98.4 / 98.2	10.3 / 86.2 / 83.1
Medium Trans. (377K)	11.4 / 91.3 / 90.6	9.9 / 92.0 / 91.3	18.1 / 99.5 / 99.5	9.1 / 91.7 / 89.8

Table 2: Summary of language modeling performance. For each model, on each training dataset, we report **PPL / %Syn / %Sem** where PPL is the perplexity on heldout data (drawn from the same distribution as the training corpus), %Syn is the percentage of generated sentences that are syntactically well formed (i.e., parseable), estimated on a set of 1,000 generations sampled from the trained model, and % Sem is the percentage of generated sentences that are semantically well formed (i.e., satisfiable), estimated on the same set of 1,000.

els overfit the training data quickly, and thus focus on smaller models.

3 Results and Discussion

Language Modeling Performance. We first sanity check that the trained models indeed function as LMs before evaluating the lexical representations. We compute the models' perplexity on heldout data. However, since perplexity is not comparable across conditions (since each constraint leads to differently distributed corpora) we also sample 1,000 generated sentences from each model and compare by measuring whether the sentences are 1) syntactically well-formed (i.e., parseable) and 2) semantically well-formed (i.e., satisfiable). Even in the case of models trained with the Syntactic constraint, as seen in Table 2, most of the sentences produced are nonetheless satisfiable. We see no difference between the Syntactic, Truthfulness, and Explicit Grounding conditions on these metrics. (The Informativity numbers are likely higher due to the shorter sentences that result from that generative process.) The fact that models trained only on satisfiable sentences nonetheless generate sentences which do not abide by such constraints suggests the models fail to encode less overt distributional patterns, which depend, for example, on recognizing abstract relations such as "sameness" of symbols in order to recognize violations (e.g., (A $\wedge$($\neg$ A)). The failure to capture such properties of the data even in this simplified setting might have negative implications for the models' ability to infer abstract semantic relationships from more complex natural language corpora.

Representations of Logical Symbols. Again, our first question is: What constraints on corpus generation yield the greatest amounts of semantic transparency? We quantify this by measuring how well the embeddings learned by the trained LMs correspond to our truth-theoretic notions of semantic equivalence: e.g., are $\wedge_1$ and $\wedge_2$ more similar to one another than $\wedge_1$ and $\vee_1$? We use a nearest neighbors probing classifier to evaluate whether models distinguish the operators at the lexical level. We run k-fold cross validation, in each iteration choosing one symbol per class (i.e., one $\wedge$, one $\vee$, one $\neg$) as the class exemplars, and then classifying the remaining points using cosine similarity. We set k to 125, so that we observe every symbol combination as exemplars. We report accuracy averaged across folds and random restarts.

Probing classifier results are shown in Figure 1. Figure 2 shows an embedding visualization for one model (Medium Transformer). We find that training on the Syntactic and on the Explicit Grounding dataset leads to the least and the most distinguishable operators respectively for all models, and the other conditions end up between these values.

These results address our first question: there is some difference in semantic transparency between differently constrained datasets. Interestingly, the Transformer models perform better in the Truthfulness condition than in the Syntactic condition, which the LSTMs fail to differentiate. This suggests that, even if it does not necessarily manifest in the models' generations (Table 2), the Transformer architecture may nonetheless be capable of picking up on some of the more abstract distributional patterns via which syntax and semantics are correlated. Further work on larger models would be required to explore this in depth.

In addition, we observe little difference between the quality of the representations learned in the Informativity condition and those learned in the Truthfulness condition; one exception might be in the Medium LSTM, though we cannot confirm that this difference is robustly reproducible. Thus,

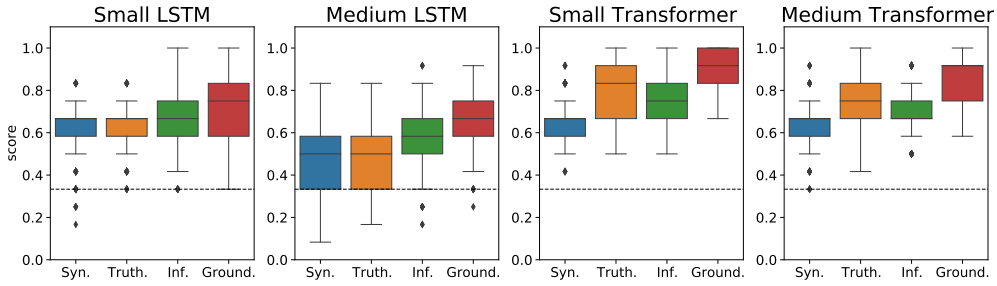

Figure 1: Each value in this graph represents average classification score across 125 iterations of a simple nearest neighbor probing classifier averaged across 5 random seeds of the model (625 accuracy numbers per box and whiskers plot). The dotted line is random chance / maximum class accuracy (33%).

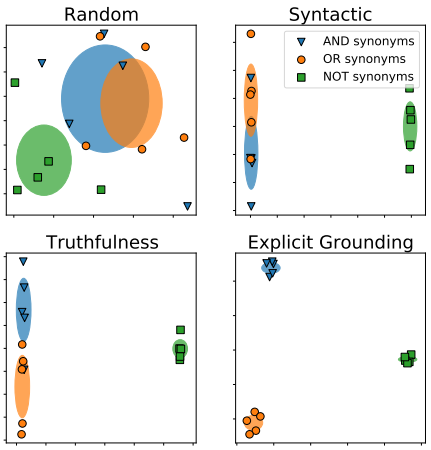

Figure 2: PCA of the representations created by the Medium Transformer model.

based on our experiments, there is no evidence that Informativity alone yields greater semantic transparency. However, we note that the experimental setup for Informativity is not directly comparable to the others (e.g., sentences are shorter and less diverse than in Truthfulness) and thus further study would be needed to make strong claims, positive or negative.

Finally, we note that in nearly all cases, models are able to differentiate $\neg$ from the other operators, likely because it is a unary operator and thus syntactically different from the binary operators. Thus the difference in accuracy is almost entirely due to whether the representations of $\wedge$ and $\vee$ are differentiated (as shown in Figure 2). This gives a negative answer to our second question concerning whether any constraints are sufficient for an LM to adequately differentiate meaning. Apart from the Small Transformer on the Explicit Grounding condition, none of the models can completely distinguish between symbols that are similar in form but different in meaning.

4 Related Work

It is an open question whether neural models can learn abstract functions (Marcus, 2001). Our work builds upon a large body of research intended to probe which aspects of language and meaning are being captured by large LMs. Most closely related is work that assesses whether models can perform symbolic reasoning about language (Kassner et al., 2020) e.g., quantifiers or negation (Talmor et al., 2020; Ettinger, 2020; Kassner and Schütze, 2020; Wang et al., 2018) or by measuring the systematicity of models' inferences (Goodwin et al., 2020; Kim and Linzen, 2020; Yanaka et al., 2020; Warstadt et al., 2019). Such work has tended to find that LMs reason primarily contextually as opposed to abstractly. Our evaluation method– which asks whether word embeddings cluster according to their truth-conditional meaning– is related to recent work which defines text-only models as "grounded" if the learned embedding space is isomorphic to the similarity function defined over a ground-truth meaning representation (Merrill et al., 2021). More distantly related is work on LMs' ability to reason about numbers (Wallace et al., 2019) or perform multi-hop reasoning (Yang et al., 2018). Prior work that examines neural networks' ability to perform logical reasoning is superficially related (Evans et al., 2018). In this way, our work builds on past work that uses synthetic rather than natural language datasets in order to probe model behavior in the absence of confounds. Notable examples are SCAN for measuring compositionality and generalization (Lake and Baroni, 2018) and Kassner et al. (2020) which investigates LM knowledge acquisition and fact memorization using a synthetic dataset of entity-relation tuples.

5 Conclusion

Using propositional logic corpora to simulate a controlled language modeling setting, we ask: 1) Do properties of the training corpus affect LMs' abilities to differentiate the meanings of logical operators? and 2) Do any training corpora lead to models that differentiate these meanings to a satisfactory degree? Our results imply a positive answer to (1): Models trained on corpora generated with different constraints appear to perform differently at the task of separating $\wedge$ from $\vee$. However, these differences are a function of both data and model. For example, the Transformer architecture seems better able to learn from weaker signal (corpora generated only with a Truthfulness constraint), while LSTMs require more explicit signal (direct access to truth values). On question (2), our results are largely negative for the syntactically similar operators. Even the most semantically transparent training data did not enable models to separate the representations of symbols with similar form but different meaning. Only the Small Transformer trained on the Explicit Grounding condition can perfectly differentiate $\wedge$ from $\vee$ at the lexical level, despite the task's controlled nature. However, every model did separate $\neg$ from both $\wedge$ and $\vee$, illustrating how syntactic differences can support differentiation of meaning.

Overall, we contribute a novel framework, based on syntax and semantics of propositional logic, via which we can explore questions of the linguistic capabilities and weaknesses of neural LMs. Our experiments represent a first step in this line of work, but further work is needed to fully appreciate the implications of these results in natural language settings, in particular, how closely the constraints explored here mirror real corpora, and how such learning is influenced by noise and ambiguity found in human language. One specific limitation of our experiments is that we constrain our analysis to the lexical representations– i.e., we assume that differences between the meanings of $\wedge$ and $\vee$ should be encoded in the lexicon, via context-invariant type embeddings. While this assumption is commonplace in formal semantics, neural LMs open the possibility of alternative representations of lexical and compositional semantics. Our results do not rule out the possibility that the relevant semantic distinctions are encoded elsewhere in the model, above the lexical layer. However, we take the combination of the lexical probing results and LM generation results as suggestive but not confirmational evidence of a more general negative finding.

7 Appendix

7.1 Dataset generation parameters

There are several parameters involved in the creation of our synthetic propositional logic datasets:

- Number of sentences in the training set
- Number of unique non-reserved variables (N)
- Number of each operator (K, L, M)
- Sentence depth parameter (γ)
- Poisson distribution parameter for unique non-reserved variables in sentence (λ)

In comparison to dataset sizes for large language models in modern natural language processing, the dataset size (100k training examples) and vocabulary size (5k symbols + 5 of each operator) of our main experimental results (Figure 1) are rather small. We sought to determine whether our choice for dataset size and non-restricted variable count greatly changed the final results– do our conclusions change based on these parameters? We trained models on different variations of our initial parameters.

First, we swept across training set sizes (20k, 100k, and 500k examples) and number of symbols (500, 5k, 50k) while holding all other parameters constant (γ = .85, λ = 2, K, L, M = 5). We used the Medium Transformer model, which performed the best across our four models, and observed the results of the probing classifier on the embeddings after training separately on each model.

The results of the above sweep are shown in Figure 3. We do not find that the models perform dramatically differently on any of the datasets when dataset size and number of non-reserved symbols are varied.

We also experimented with changing the number of operator synonyms (e.g. $\wedge_1, \wedge_2, ...\wedge_K$) We experimented with three different sizes– (K, L, M) = 5, 25, 100– for each of our 4 datasets. Those results are shown in Figure 5, and average frequency is shown in Table 3. We found that adding additional synonyms of each operator hurt performance– likely because adding additional synonyms of $\wedge$ and $\vee$ made generalization more challenging, causing the models' performance to drop.

In a set of earlier experiments, to choose the sentence depth (γ) and Poisson distribution (λ) parameters, we hyperparameter searched on the Explicit Grounding condition across three values of each (nine datasets in total). Specifically, we tested $\lambda = 2, 3, 5$ and $\gamma = .7, .8, .85$. We then trained the transformer model once on each of the nine datasets, and the results are shown in Figure 6. We chose $\lambda = 2$ and $\gamma = .85$.

K, L, M	Syn.	Tru.	Inf.	Grd.
5	49.7k	49.2k	16.3k	49k
25	9.94k	9.84k	3.25k	9.81k
100	2.49k	2.46k	0.81k	2.45k

Table 3: Average count of each operator across each of the datasets.

7.2 Informativity dataset information

We tested different settings of $|T|$ (number of target worlds) and $|A|$ (number of alternative worlds). For $|T| = 1, |A| = 1$, the best choice of s will always be a single $\texttt{sym}$ or its negation. For example, with variables $\texttt{sym}_1, \texttt{sym}_2$, we might sample max variables = 2 and thus $T = (\texttt{sym}_1 = \texttt{T}, \texttt{sym}_2 = \texttt{F}), A = (\texttt{sym}_1 = \texttt{F}, \texttt{sym}_2 = \texttt{F})$. The shortest sentence would then be $\texttt{sym}_1$, as it sufficiently distinguishes T from A. However, with $|T| = 1, |A| = 2$, we might generate $T = (\texttt{sym}_1 = \texttt{T}, \texttt{sym}_2 = \texttt{F}), A = ((\texttt{sym}_1 = \texttt{F}, \texttt{sym}_2 = \texttt{F}), (\texttt{sym}_1 = \texttt{T}, \texttt{sym}_2 = \texttt{T}))$. Now the shortest sentence that can be generated is $(\texttt{sym}_1 \wedge_1 \neg_1(\texttt{sym}_2))$.

$|T| = 1, |A| = 2$ and $|T| = 2, |A| = 1$ result in sentences that are both short and structurally nearly identical, although inverted. This is due to the truth conditions allowed by each operator. We generate the datasets for each combination and report the results in Table 4. We excluded these datasets because of the simplicity and similarity of the sentences. We found that $|T| = 2, |A| = 2$ allows for sentences that are much more varied.

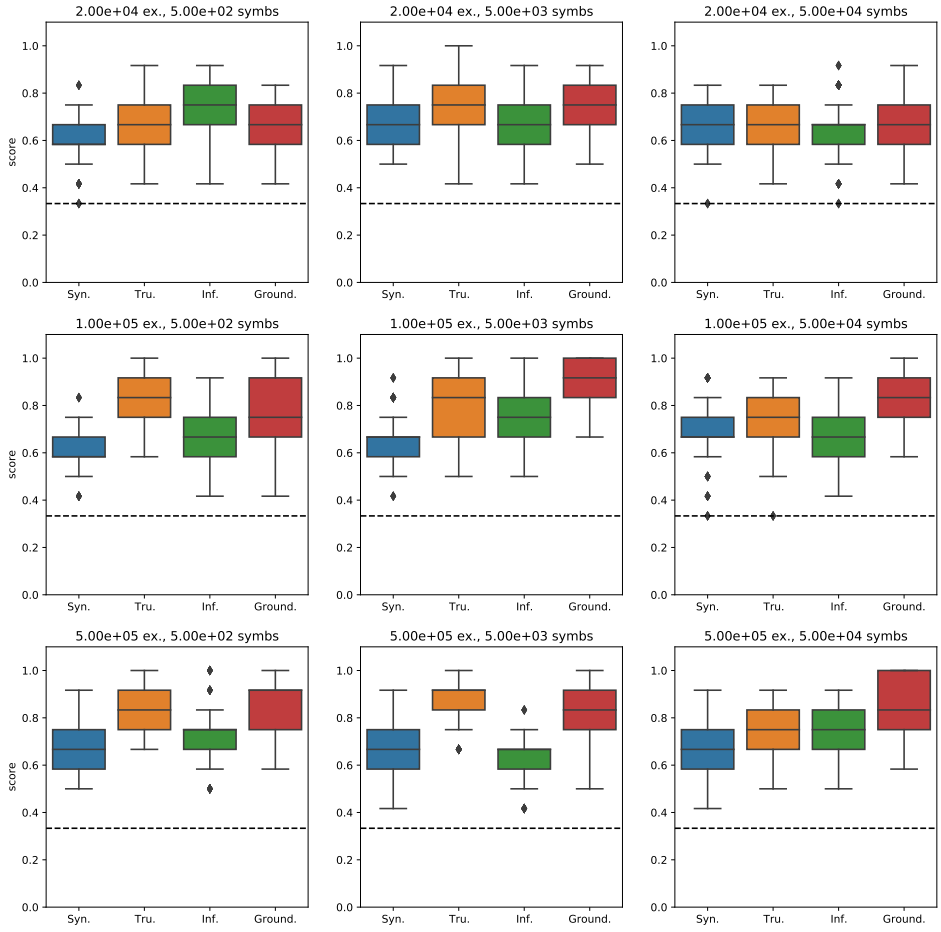

Figure 3: Average probing classifier score across example count / number of unique non-variable symbols for the Medium Transformer model.

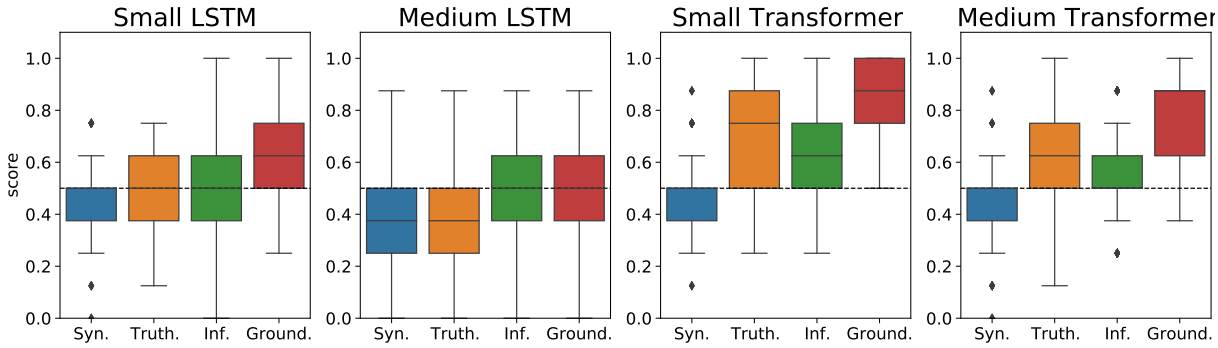

Figure 4: This graph contains the same experiments as Figure 1, but is only the accuracy on $\wedge$ and $\vee$, excluding the results of the negation operator.

Abstract

The predominant challenge in weakly supervised semantic parsing is that of *spurious programs* that evaluate to correct answers for the wrong reasons. Prior work uses elaborate search strategies to mitigate the prevalence of spurious programs; however, they typically consider only one input at a time. In this work we explore the use of consistency between the output programs for related inputs to reduce the impact of spurious programs. We bias the program search (and thus the model's training signal) towards programs that map the same phrase in related inputs to the same sub-parts in their respective programs. Additionally, we study the importance of designing logical formalisms that facilitate this kind of consistency-based training. We find that a more consistent formalism leads to improved model performance even without consistency-based training. When combined together, these two insights lead to a 10% absolute improvement over the best prior result on the Natural Language Visual Reasoning dataset.

1 Introduction

Semantic parsers map a natural language utterance into an executable meaning representation, called a logical form or program (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005). These programs can be executed against a context (e.g., database, image, etc.) to produce a denotation (e.g., answer) for the input utterance. Methods for training semantic parsers from only (utterance, denotation) supervision have been developed (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013); however, training from such weak supervision is challenging. The parser needs to search for the correct program from an exponentially large space, and the presence of *spurious programs*—incorrect representations that evaluate to the correct denotation—greatly hampers learning. Several strategies have been proposed to mitigate this issue (Guu et al., 2017; Liang et al., 2018; Dasigi et al., 2019). Typically these approaches consider a single input utterance at a time and explore ways to score programs.

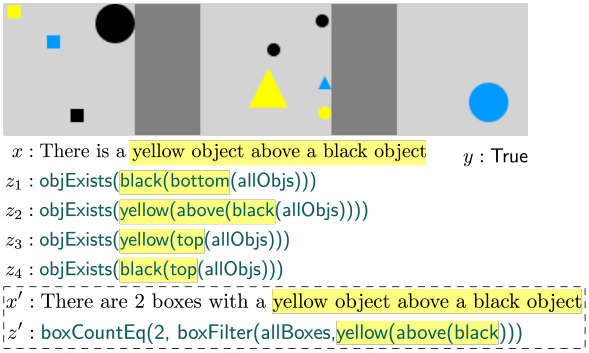

Figure 1: Utterance x and its program candidates z_1-z_4, all of which evaluate to the correct denotation (True). z_2 is the correct interpretation; other programs are *spurious*. Related utterance x' shares the phrase *yellow object above a black object* with x. Our consistency reward would score z_2 the highest since it maps the shared phrase most similarly compared to z'.

In this work we encourage consistency between the output programs of related natural language utterances to mitigate the issue of spurious programs. Consider related utterances, *There are two boxes with three yellow squares* and *There are three yellow squares*, both containing the phrase *three yellow squares*. Ideally, the correct programs for the utterances should contain similar sub-parts that corresponds to the shared phrase. To incorporate this intuition during search, we propose a consistency-based reward to encourage programs for related utterances that share sub-parts corresponding to the shared phrases (§3). By doing so, the model is provided with an additional training signal to distinguish between programs based on their consistency with programs predicted for related utterances.

We also show the importance of designing the logical language in a manner such that the ground-truth programs for related utterances are consistent with each other. Such consistency in the logical language would facilitate the consistency-based training proposed above, and encourage the semantic parser to learn generalizable correspondence between natural language and program tokens. In the previously proposed language for the Natural Language Visual Reasoning dataset (NLVR; Suhr et al., 2017), we notice that the use of macros leads to inconsistent interpretations of a phrase depending on its context. We propose changes to this language such that a phrase in different contexts can be interpreted by the same program parts (§4).

We evaluate our proposed approaches on NLVR using the semantic parser of Dasigi et al. (2019) as our base parser. On just replacing the old logical language for our proposed language we see an 8% absolute improvement in consistency, the evaluation metric used for NLVR (§5). Combining with our consistency-based training leads to further improvements; overall 10% over the best prior model, reporting a new state-of-the-art on the NLVR dataset.

2 Background

In this section we provide a background on the NLVR dataset (Suhr et al., 2017) and the semantic parser of Dasigi et al. (2019).

Natural Language Visual Reasoning (NLVR) dataset contains human-written natural language utterances, where each utterance is paired with 4 synthetically-generated images. Each (utterance, image) pair is annotated with a binary truth-value denotation denoting whether the utterance is true for the image or not. Each image is divided into three *boxes*, where each box contains 1-8 *objects*. Each object has four properties: *position* (x/y coordinates), *color* (black, blue, yellow), *shape* (triangle, square, circle), and *size* (small, medium, large). The dataset also provides a structured representation of each image which we use in this paper. Figure 1 shows an example from the dataset.

Weakly supervised iterative search parser We use the semantic parser of Dasigi et al. (2019) which is a grammar-constrained encoder-decoder with attention model from Krishnamurthy et al. (2017). It learns to map a natural language utterance x into a program z such that it evaluates to the correct denotation $y = [\![z]\!]^r$ when executed against the structured image representation r. Dasigi et al. (2019) use a manually-designed, typed, variable-free, functional query language for NLVR, inspired by the GeoQuery language (Zelle and Mooney, 1996).

Given a dataset of triples (x_i, c_i, y_i), where x_i is an utterance, c_i is the set of images associated to it, and y_i is the set of corresponding denotations, their approach iteratively alternates between two phases to train the parser: Maximum marginal likelihood (MML) and a Reward-based method (RBM). In MML, for an utterance x_i, the model maximizes the marginal likelihood of programs in a given set of logical forms Z_i, all of which evaluate to the correct denotation. The set Z_i is constructed either by performing a heuristic search, or generated from a trained semantic parser.

The reward-based method maximizes the (approximate) expected value of a reward function $\mathcal{R}$.

$$\max_{\theta} \sum_{\forall i} \mathbb{E}_{\tilde{p}(z_i|x_i;\theta)} \mathcal{R}(x_i, z_i, c_i, y_i) \qquad (1)$$

Here, $\tilde{p}$ is the *re-normalization* of the probabilities assigned to the programs on the beam, and the reward function $\mathcal{R} = 1$ if z_i evaluates to the correct denotation for all images in c_i, or 0 otherwise. Please refer Dasigi et al. (2019) for details.

3 Consistency reward for programs

Consider the utterance x = *There is a yellow object above a black object* in Figure 1. There are many program candidates decoded in search that evaluate to the correct denotation. Most of them are *spurious*, i.e., they do not represent the meaning of the utterance and only coincidentally evaluate to the correct output. The semantic parser is expected to distinguish between the correct program and spurious ones by identifying correspondence between parts of the utterance and the program candidates. Consider a related utterance x' = *There are 2 boxes with a yellow object above a black object*. The parser should prefer programs for x and x' which contain similar sub-parts corresponding to the shared phrase p = *yellow object above a black object*. That is, the parser should be consistent in its interpretation of a phrase in different contexts. To incorporate this intuition during program search, we propose an additional reward to programs for an utterance that are consistent with programs for a related utterance.

Specifically, consider two related utterances x and x' that share a phrase p. We compute a reward for a program candidate z of x based on how similarly it maps the phrase p as compared to a program candidate z' of x'. To compute this reward we need (a) *relevant program parts* in z and z' that correspond to the phrase p, and (b) a *consistency reward* that measures consistency between those parts.

(a) Relevant program parts Let us first see how to identify relevant parts of a program z that correspond to a phrase p in the utterance.

Our semantic parser (from Krishnamurthy et al. (2017)) outputs a linearized version of the program $z = [z^1, \ldots, z^T]$, decoding one action at a time from the logical language. At each time step, the parser predicts a normalized attention vector over the tokens of the utterance, denoted by $[a_1^t, \ldots, a_N^t]$ for the z^t action. Here, $\sum_{i=1}^{N} a_i^t = 1$ and $a_i^t \geq 0$ for $i \in [1, N]$. We use these attention values as a relevance score between a program action and the utterance tokens. Given the phrase p with token span $[m, n]$, we identify the relevant actions in z as the ones whose total attention score over the tokens in p exceeds a heuristically-chosen threshold $\tau = 0.6$.

$$A(z, p) = \left\{ z^t \;\middle|\; t \in [1, T] \text{ and } \sum_{i=m}^{n} a_i^t \geq \tau \right\} \quad (2)$$

This set of program actions $A(z, p)$ is considered to be generated due to the phrase p. For example, for utterance *There is a yellow object above a black object*, with program objExists(yellow(above(black(allObjs)))), this approach could identify that for the phrase *yellow object above a black object* the actions corresponding to the functions yellow, above, and black are relevant.

(b) Consistency reward Now, we will define a reward for the program z based on how consistent its mapping of the phrase p is w.r.t. the program z' of a related utterance. Given a related program z' and its relevant action set $A(z', p)$, we define the consistency reward $S(z, z', p)$ as the F1 score for the action set $A(z, p)$ when compared to $A(z', p)$. If there are multiple shared phrases p_i between x and x', we can compute a weighted average of different $S(z, z', p_i)$ to compute a singular consistency reward $S(z, z')$ between the programs z and z'. In this work, we only consider a single shared phrase p between the related utterances, hence $S(z, z', p) = S(z, z', p)$ in our paper.

As we do not know the gold program for x', we decode top-K program candidates using beam-search and discard the ones that do not evaluate to the correct denotation. We denote this set of programs by Z'_c. Now, to compute a consistency reward $\mathcal{C}(x, z, x')$ for the program z of x,we take a weighted average of $S(z, z')$ for different $z' \in Z'_c$ where the weights correspond to the probability of the program z' as predicted by the parser.

$$\mathcal{C}(x, z, x') = \sum_{z' \in Z'_c} \tilde{p}(z'|x'; \theta) S(z, z') \quad (3)$$

Consistency reward based parser Given x and a related utterance x', we use $\mathcal{C}(x, z, x')$ as an additional reward in Eq. 1 to upweight programs for x that are consistent with programs for x'.

$$\max_{\theta} \sum_{\forall i} \mathbb{E}_{\tilde{p}(z_i|x_i;\theta)} \left[\mathcal{R}(x_i, z_i, c_i, y_i) + \mathcal{C}(x_i, z_i, x'_i) \right]$$

This consistency-based reward pushes the parser's probability mass towards programs that have consistent interpretations across related utterances, thus providing an additional training signal over simple denotation accuracy. The formulation presented in this paper assumes that there is a single related utterance x' for the utterance x. If multiple related utterances are considered, the consistency reward $\mathcal{C}(x, z, x'_j)$ for different related utterances x'_j can be summed/averaged to compute a single consistency reward $\mathcal{C}(x, z)$ the program z of utterance x based on all the related utterances.

4 Consistency in Language

The consistency reward (§3) makes a key assumption about the logical language in which the utterances are parsed: that the gold programs for utterances sharing a natural language phrase actually correspond to each other. For example, that the phrase *yellow object above a black object* would always get mapped to yellow(above(black)) irrespective of the utterance it occurs in.

On analyzing the logical language of Dasigi et al. (2019), we find that this assumption does not hold true. Let us look at the following examples:

x_1: *There are items of at least two different colors*
z_1: objColorCountGrtEq(2, allObjs)
x_2: *There is a box with items of at least two different colors*
z_2: boxExists(
memberColorCountGrtEq(2, allBoxes))

Here the phrase *items of at least two different colors*

Model	Dev		Test-P		Test-H	
	Acc.	Cons.	Acc.	Cons.	Acc.	Cons.
ABS. SUP. (Goldman et al., 2018)	84.3	66.3	81.7	60.1	-	-
ABS. SUP. + RERANK (Goldman et al., 2018)	85.7	67.4	84.0	65.0	82.5	63.9
ITERATIVE SEARCH (Dasigi et al., 2019)	85.4	64.8	82.4	61.3	82.9	64.3
+ Logical Language Design (ours)	88.2	73.6	86.0	69.6	-	-
+ Consistency Reward (ours)	**89.6**	**75.9**	**86.3**	**71.0**	**89.5**	**74.0**

Table 1: **Performance on NLVR:** Design changes in the logical language and consistency-based training, both significantly improve performance. Larger improvements in consistency indicate that our approach efficiently tackles spurious programs.

is interpreted differently in the two utterances. In x_2, a macro function memberColorCountGrtEq is used, which internally calls objColorCountGrtEq for each *box* in the image. Now consider,
x_3: *There is a tower with exactly one block*
z_3: boxExists(memberObjCountEq(1,allBoxes))
x_4: *There is a tower with a black item on the top*
z_4: objExists(black(top(allObjs)))
Here the phrase *There is a tower* is interpreted differently: z_3 uses a macro for filtering boxes based on their object count and interprets the phrase using boxExists. In the absence of a complex macro for checking *black item on the top*, z_4 resorts to using objExists making the interpretation of the phrase inconsistent. These examples highlight that these macros, while they shorten the search for programs, make the language inconsistent.

We make the following changes in the logical language to make it more consistent. Recall from §2 that each NLVR image contains 3 boxes each of which contains 1-8 objects. We remove macro functions like memberColorCountGrtEq, and introduce a generic boxFilter function. This function takes two arguments, a set of *boxes* and a filtering function f: Set[Obj] → bool, and prunes the input set of boxes to the ones whose objects satisfies the filter f. By doing so, our language is able to reuse the same object filtering functions across different utterances. In this new language, the gold program for the utterance x_2 would be
z_2: boxCountEq(1, boxFilter(allBoxes, objColorCountGrtEq(2)))
By doing so, our logical language can now consistently interpret the phrase *items of at least two different colors* using the object filtering function f: objColorCountGrtEq(2) across both x_1 and x_2. Similarly, the gold program for x_4 in the new logical language would be
z_4: boxExists(boxFilter(allBoxes, black(top)))
making the interpretation of *There is a box* consistent with x_3. Please refer appendix §A for details.

5 Experiments

Dataset We report results on the standard development, public-test, and hidden-test splits of NLVR. The training data contains 12.4k (utterance, image) pairs where each of 3163 utterances are paired with 4 images. Each evaluation set roughly contains 270 unique utterances.

Evaluation Metrics (1) *Accuracy* measures the proportion of examples for which the correct denotation is predicted. (2) Since each utterance in NLVR is paired with 4 images, a *consistency* metric is used, which measures the proportion of utterances for which the correct denotation is predicted for all associated images. Improvement in this metric is indicative of correct program prediction as it is unlikely for a spurious program to correctly make predictions on multiple images.

Experimental details We use the same parser, training methodology, and hyper-parameters as Dasigi et al. (2019). For discovering related utterances, we manually identify ∼10 sets of equivalent phrases that are common in NLVR. For example, *there are* NUM *boxes*, COLOR1 *block on a* COLOR2 *block*, etc. For each utterance that contains a particular phrase, we pair it with one other randomly chosen utterance that shares the phrase. We make 1579 utterance pairs in total. Refer appendix §B for details about data creation.[1]

Baselines We compare against the state-of-the-art models; ABS. SUP. (Goldman et al., 2018) that

[1]We release the data and code at https://www.github.com/nitishgupta/allennlp-semparse/tree/nlvr-v2/scripts/nlvr_v2

uses abstract examples, ABS. SUP. + RERANK that uses additional data and reranking, and the iterative search parser of Dasigi et al. (2019).

Results Table 1 compares the performance of our two proposed methods to enforce consistency in the decoded programs with the previous approaches. We see that changing the logical language to a more consistent one (§4) significantly improves performance: the accuracy improves by 2-4% and consistency by 4-8% on the dev. and public-test sets. Additionally, training the parser using our proposed consistency reward (§3) further improves performance: accuracy improves by 0.3-0.4% but the consistency significantly improves by 1.4-2.3%.[2] On the hidden-test set of NLVR, our final model improves accuracy by 7% and consistency by 10% compared to previous approaches. Larger improvements in consistency across evaluation sets indicates that our approach to enforce consistency between programs of related utterances greatly reduces the impact of spurious programs.

6 Conclusion

We proposed two approaches to mitigate the issue of spurious programs in weakly supervised semantic parsing by enforcing consistency between output programs. First, a consistency based reward that biases the program search towards programs that map the same phrase in related utterances to similar sub-parts. Such a reward provides an additional training signal to the model by leveraging related utterances. Second, we demonstrate the importance of logical language design such that it facilitates such consistency-based training. The two approaches combined together lead to significant improvements in the resulting semantic parser.

Acknowledgement

We would like to thank Pradeep Dasigi for helping us with the code for preprocessing NLVR and the Iterative Search model, Alane Suhr for getting us our model's evaluation results on the hidden test set in a timely manner, and the anonymous reviewers for their helpful comments. This work is supported in part by NSF award #IIS-1817183.

[2]We report average performance across 10 runs trained with different random seeds. All improvements in consistency are statistically significant (p-value < 0.05) based on the stochastic ordering test (Dror et al., 2019).

A Logical language details

In Figure 2, we show an example utterance with its gold program according to our proposed logical language. We use function composition and function currying to maintain the variable-free nature of our language. For example, action z^7 uses function composition to create a function from Set[Object] → bool by composing two functions, from Set[Object] → bool and Set[Object] → Set[Object]. Similarly, action z^{11} creates a function from Set[Object] → Set[Object] by composing two functions with the same signature.

Actions z^8 - z^{10} use function currying to curry the 2-argument function objectCountGtEq by giving it one int=2 argument. This results in a 1-argument function objectCountGtEq(2) from Set[Object] → bool.

B Dataset details

To discover related utterance pairs within the NLVR dataset, we manually identify 11 sets of phrases that commonly occur in NLVR and can be interpreted in the same manner:

1. { COLOR block at the base, the base is COLOR }
2. { COLOR block at the top, the top is COLOR }
3. { COLOR1 object above a COLOR2 object }
4. { COLOR1 block on a COLOR2 block, COLOR1 block over a COLOR2 block }
5. { a COLOR tower }
6. { there is one tower, there is only one tower, there is one box, there is only one box }
7. { there are exactly NUMBER towers, there are exactly NUMBER boxes }
8. { NUMBER different colors }
9. { with NUMBER COLOR items, with NUMBER COLOR blocks, with NUMBER COLOR objects }
10. { at least NUMBER COLOR items, at least NUMBER COLOR blocks, at least NUMBER COLOR objects }
11. { with NUMBER COLOR SHAPE, are NUMBER COLOR SHAPE, with only NUMBER COLOR SHAPE, are only NUMBER COLOR SHAPE }

In each phrase, we replace the abstract COLOR, NUMBER, SHAPE token with all possible options from the NLVR dataset to create grounded phrases. For example, *black block at the top*, *yellow object above a blue object*. For each set of equivalent grounded phrases, we identify the set of utterances that contains any of the phrase. For each utterance in that set, we pair it with 1 randomly chosen utterance from that set. Overall, we identify related utterances for 1420 utterances (out of 3163) and make 1579 pairings in total; if an utterance contains two phrases of interest, it can be paired with more than 1 utterance.

x: *There is one box with at least 2 yellow squares*
z: boxCountEq(1, boxFilter(allBoxes, objectCountGtEq(2)(yellow(square))))

Program actions for z:
z^1: bool → [<int,[Set[Box]:bool>, int, Set[Box]]
z^2: <int,[Set[Box]:bool> → boxCountEq
z^3: int → 1
z^4: Set[Box] → [<Set[Box],<Set[Object]:bool>:Set[Box]>, Set[Box], <Set[Object]:bool>]
z^5: <Set[Box],<Set[Object]:bool>:Set[Box]> → boxFilter
z^6: Set[Box] → allBoxes
z^7: <Set[Object]:bool> → [*, <Set[Object]:bool>, <Set[Object]:Set[Object]>]
z^8: <Set[Object]:bool> → [<int,Set[Object]:bool>, int]
z^9: <int,Set[Object]:bool> → objectCountGtEq
z^{10}: int → 2
z^{11}: <Set[Object]:Set[Object]> → [*, <Set[Object]:Set[Object]>, <Set[Object]:Set[Object]>]
z^{12}: <Set[Object]:Set[Object]> → yellow
z^{13}: <Set[Object]:Set[Object]> → square

An Improved Model for Voicing Silent Speech

David Gaddy and **Dan Klein**
University of California, Berkeley
{dgaddy,klein}@berkeley.edu

Abstract

In this paper, we present an improved model for voicing silent speech, where audio is synthesized from facial electromyography (EMG) signals. To give our model greater flexibility to learn its own input features, we directly use EMG signals as input in the place of hand-designed features used by prior work. Our model uses convolutional layers to extract features from the signals and Transformer layers to propagate information across longer distances. To provide better signal for learning, we also introduce an auxiliary task of predicting phoneme labels in addition to predicting speech audio features. On an open vocabulary intelligibility evaluation, our model improves the state of the art for this task by an absolute 25.8%.

1 Introduction

EMG-based voicing of silent speech is a task that aims to synthesize vocal audio from muscular signals captured by electrodes on the face while words are silently mouthed (Gaddy and Klein, 2020; Toth et al., 2009). While recent work has demonstrated a high intelligibility of generated audio when restricted to a narrow vocabulary (Gaddy and Klein, 2020), in a more challenging open vocabulary setting the intelligibility remained low (68% WER). In this work, we introduce an new model for voicing silent speech that greatly improves intelligibility.

We achieve our improvements by modifying several different components of the model. First, we improve the input representation. While prior work on EMG speech processing uses hand-designed features (Jou et al., 2006; Diener et al., 2015; Meltzner et al., 2018; Gaddy and Klein, 2020) which may throw away some information from the raw signals, our model learns directly from the complete signals with minimal pre-processing by using a set of convolutional neural network layers as feature extractors. This modification follows recent work in speech processing from raw waveforms (Collobert et al., 2016; Schneider et al., 2019) and gives our model the ability to learn its own features for EMG.

Second, we improve the neural architecture of the model. While other silent speech models have been based around recurrent layers such as LSTMs (Janke and Diener, 2017; Gaddy and Klein, 2020), we use the self-attention-based Transformer architecture (Vaswani et al., 2017), which has been shown to be a more powerful replacement across a range of tasks.

Finally, we improve the signal used for learning. Since the relatively small data sizes for this task creates a challenging learning problem, we introduce an auxiliary task of predicting phoneme labels to provide additional guidance. This auxiliary loss is inspired by prior work on the related problem of generating speech from ECoG sensors on the brain, which greatly benefited from intermediate prediction of phonemic information (Anumanchipalli et al., 2019).

We evaluate intelligibility of audio synthesized by our model on the single-speaker data from Gaddy and Klein (2020) in the most challenging open-vocabulary setting. Our results reflect an absolute improvement in error rate of 25.8% over the state of the art, from 68.0% to 42.2%, as measured by automatic transcription. Evaluation by human transcription gives an even lower error rate of 32%.

2 Model

At a high level, our system works by predicting a sequence of speech features from EMG signals and using a WaveNet vocoder (van den Oord et al., 2016) to synthesize audio from those predicted features, as was done in Gaddy and Klein (2020). The first component, dubbed the transduction model, takes in EMG signals from eight electrodes around

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 175–181

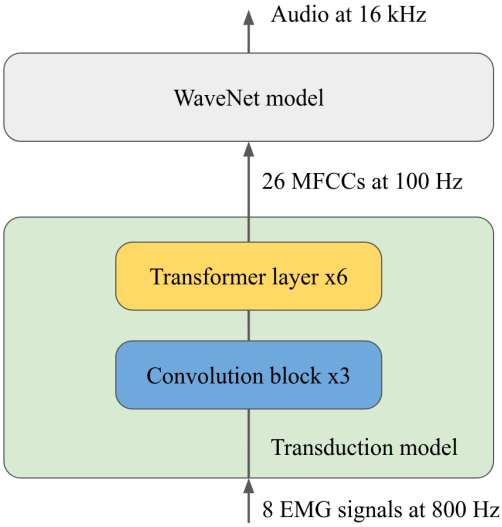

Figure 1: Model overview

the face and outputs a sequence of speech features represented as Mel-frequency cepstral coefficients (MFCCs). The final step of vocoding audio from MFCCs is unchanged in our work, so we defer to Gaddy and Klein (2020) for the details of the WaveNet model.

The neural architecture for our transduction model is made up of a set of residual convolution blocks followed by a transformer with relative position embeddings, as shown in Figure 1. We describe these two components in Sections 2.1 and 2.2 below. Next, in Section 2.3 we describe our training procedure, which aligns each silent utterance to a corresponding vocalized utterance as in Gaddy and Klein (2020) but with some minor modifications. Finally, in Section 2.4 we describe the auxiliary phoneme-prediction loss that provides additional signal to our model during training.[1]

2.1 Convolutional EMG Feature Extraction

The convolutional layers of our model are designed to directly take in EMG signals with minimal preprocessing. Prior to use of the input EMG signals, AC electrical noise is removed using band stop filters at harmonics of 60 Hz, and DC offset and drift are removed with a 2 Hz high-pass filter. The signals are then resampled from 1000 Hz to 800 Hz, and the magnitudes are scaled down by a factor of 10.

Our convolutional architecture uses a stack of 3 residual convolution blocks inspired by ResNet (He et al., 2016), but modified to use 1-dimensional

[1]Code for our model is available at https://github.com/dgaddy/silent_speech.

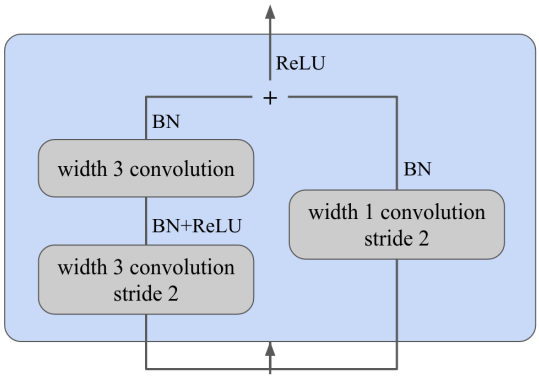

Figure 2: Convolution block architecture

convolutions. The architecture used for each convolution block is shown in Figure 2, and has two convolution-over-time layers along the main path as well as a shortcut path that does not do any aggregation over the time dimension. Each block downsamples the signal by a factor of 2, so that the input signals at 800 Hz are eventually transformed into features at 100Hz to match the target speech feature frame rate. All convolutions have channel dimension 768.

Before passing the convolution layer outputs to the rest of the model, we include an embedding of the session index, which helps the model account for differences in electrode placement after electrodes are reattached for each session. Each session is represented with a 32 dimensional embedding, which is projected up to 768 dimensions with a linear layer before adding to the convolution layer outputs at each timestep.

2.2 Transformer with Relative Position Embeddings

To allow information to flow across longer time horizons, we use a set of bidirectional Transformer encoder layers (Vaswani et al., 2017) on top of the convolution layers in our model. To capture the time-invariant nature of the task, we use relative position embeddings as described by Shaw et al. (2018) rather than absolute position embeddings. In this variant, a learned vector p that depends on the relative distance between the query and key positions is added to the key vectors when computing attention weights. Thus, the attention logits are computed with

$$e_{ij} = \frac{(W_K x_j + p_{ij})^\top (W_Q x_i)}{\sqrt{d}}$$

where p_{ij} is an embedding lookup with index $i - j$, up to a maximum distance k in each direction (x are inputs to the attention module, W_Q and W_K are query and key transformations, and d is the dimension of the projected vectors $W_Q x_i$). For our model, we use $k = 100$ (giving each layer a 1 second view in each direction) and set all attention weights with distance greater than k to zero. We use six of these Transformer layers, with 8 heads, model dimension 768, feedforward dimension 3072, and dropout 0.1.

The output of the last Transformer layer is passed through a final linear projection down to 26 dimensions to give the MFCC audio feature predictions output by the model.

2.3 Alignment and Training

Since silent EMG signals and vocalized audio features must be recorded separately and so are not time-aligned, we must form an alignment between the two recordings to calculate a loss on predictions from silent EMG. Our alignment procedure is similar to the predicted-audio loss used in Gaddy and Klein (2020), but with some minor aspects improved.

Our loss calculation takes in a sequence of MFCC features $\hat{A}_S$ predicted from silent EMG and another sequence of target features A_V from a recording of vocalized audio for the same utterance. We compute a pairwise distance between all pairs of features

$$\delta[i, j] = \left\| A_V[i] - \hat{A}_S[j] \right\|_2$$

and run dynamic time warping (Rabiner and Juang, 1993) to find a minimum-cost monotonic alignment path through the δ matrix. We represent the alignment as $a[i] \rightarrow j$ with a single position j in $\hat{A}_S$ for every index i in A_V, and take the first such position when multiple are given by dynamic time warping. The loss is then the mean of aligned pairwise distances:

$$L = \frac{1}{N_V} \sum_{i=1}^{N_V} \delta[i, a[i]]$$

In addition to the silent-EMG training, we also make use of EMG recordings during vocalized speech which are included in the data from Gaddy and Klein (2020). Since the EMG and audio targets are recorded simultaneously for these vocalized examples, we can calculate the pairwise distance loss directly without any dynamic time warping. We train on the two speaking modes simultaneously.

To perform batching across sequences of different lengths during training, we concatenate a batch of EMG signals across time then reshape to a batch of fixed-length sequences before feeding into the network. Thus if the fixed batch-sequence-length is l, the sum of sample lengths across the batch is N_S, and the signal has c channels, we reshape the inputs to size $(\lceil N_S / l \rceil, l, c)$ after zero-padding the concatenated signal to a multiple of l. After running the network to get predicted audio features, we do the reverse of this process to get a set of variable-length sequences to feed into the alignment and loss described above. This batching strategy allows us to make efficient use of compute resources and also acts as a form of dropout regularization where slicing removes parts of the nearby input sequence. We use a sequence length $l = 1600$ (2 seconds) and select batches dynamically up to a total length of $N_{Smax} = 204800$ samples (256 seconds).

We train our model for 80 epochs using the AdamW optimizer (Loshchilov and Hutter, 2017). The peak learning rate is 10^{-3} with a linear warm-up of 500 batches, and the learning rate is decayed by half after 5 consecutive epochs of no improvement in validation loss. Weight decay 10^{-7} is used for regularization.

2.4 Auxiliary Phoneme Loss

To provide our model with additional training signal and regularize our learned representations, we introduce an auxiliary loss of predicting phoneme labels at each output frame.

To get phoneme labels for each feature frame of the vocalized audio, we use the Montreal Forced Aligner (McAuliffe et al., 2017). The aligner uses an acoustic model trained on the LibriSpeech dataset in conjunction with a phonemic dictionary to get time-aligned phoneme labels from audio and a transcription.

We add an additional linear prediction layer and softmax on top of the Transformer encoder to predict a distribution over phonemes. For training, we modify the alignment and loss cost δ by appending a term for phoneme negative log likelihood:

$$\delta'[i, j] = \left\| A_V[i] - \hat{A}_S[j] \right\|_2 - \lambda P_V[i]^\top \log \hat{P}_S[j]$$

where $\hat{P}_S$ is the predicted distribution from the model softmax and P_V is a one-hot vector for the target phoneme label. We use $\lambda = .1$ for the phoneme loss weight. After training, the phoneme prediction layer is discarded.

Ablation: Replace convolution features with hand-designed features	45.2
Ablation: Replace Transformer with LSTM	46.0
Ablation: Remove phoneme loss	51.7

Table 1: Open vocabulary word error rate results from an automatic intelligibility evaluation.

3 Results

We train our model on the open-vocabulary data from Gaddy and Klein (2020). This data contains 19 hours of facial EMG data recordings from a single English speaker during silent and vocalized speech. Our primary evaluation uses the automatic metric from that work, which transcribes outputs with an automatic speech recognizer[2] and compares to a reference with a word error rate (WER) metric. We also evaluate human intelligibility in Section 3.1 below.[3]

The results of the automatic evaluation are shown in Table 1. Overall, we see that our model improves intelligibility over prior work by an absolute 25.8%, or 38% relative error reduction. Also shown in the table are ablations of our three primary contributions. We ablate the convolutional feature extraction by replacing those layers with the hand-designed features used in Gaddy and Klein (2020), and we ablate the Transformer layers by replacing with LSTM layers in the same configuration as that work (3 bidirectional layers, 1024 dimensions). To ablate the phoneme loss, we simply set its weight in the overall loss to zero. All three of these ablations show an impact on our model's results.

3.1 Human Evaluation

In addition to the automatic evaluation, we performed a human intelligibility evaluation using a similar transcription test. Two human evaluators without prior knowledge of the text were asked to listen to 40 synthesized samples and write down the words they heard (see Appendix A for full instructions given to evaluators). We then compared these transcriptions to the ground-truth reference with a WER metric.

The resulting word error rates from the two human evaluators' transcriptions are 36.1% and 28.5% (average: 32.3%), compared to 42.2% from automatic transcriptions. These results validate the improvement shown in the automatic metric, and indicate that the automatic metric may be underestimating intelligibility to humans. However, the large variance across evaluators shows that the automatic metric may still be more appropriate for establishing consistent evaluations across different work on this task.

4 Phoneme Error Analysis

One additional advantage to using an auxiliary phoneme prediction task is that it provides a more easily interpretable view of model predictions. Although the phoneme predictions are not directly part of the audio synthesis process, we have observed that mistakes in audio and phoneme prediction are often correlated. Therefore, to better understand the errors that our model makes, we analyze the errors of our model's phoneme predictions. To analyze the phoneme predictions, we align predictions on a silent utterance to phoneme labels of a vocalized utterance using the procedure described above in Sections 2.3 and 2.4, then evaluate the phonemes using the measures described in Sections 4.1 and 4.2 below.

4.1 Confusion

First, we measure the confusion between each pair of phonemes. We use a frequency-normalized metric for confusion: $(e_{p1,p2} + e_{p2,p1})/(f_{p1} + f_{p2})$, where $e_{p1,p2}$ is the number of times $p2$ was predicted when the label was $p1$, and f_{p1} is the number of times phoneme $p1$ appears as a target label. Figure 3 illustrates this measure of confusion using darkness of lines between the phonemes, and Appendix B lists the values of the most confused pairs.

We observe that many of the confusions are be-

[2] An implementation of DeepSpeech (Hannun et al., 2014) from Mozilla (https://github.com/mozilla/DeepSpeech)

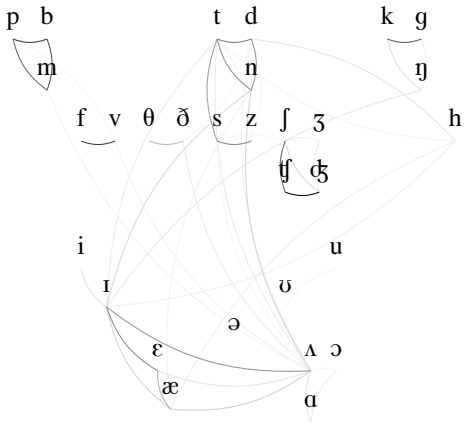

Figure 3: Phoneme confusability (darker lines indicate more confusion - maximum darkness is 13% confusion)

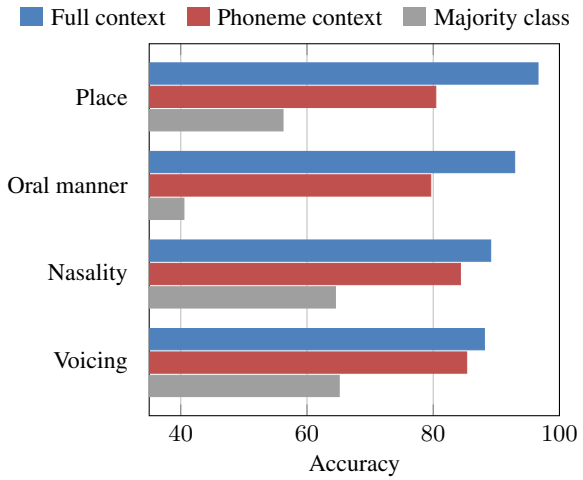

Figure 4: Accuracy of selecting phonemes along articulatory feature dimensions. We compare our full EMG model (full context) with a majority class baseline and a model given only phoneme context as input.

tween pairs of consonants that differ only in voicing, which is consistent with the observation in Gaddy and Klein (2020) that voicing signals appear to be subdued in silent speech. Another finding is a confusion between nasals and stops, which is challenging due to the role of the velum and its relatively large distance from the surface electrodes, as has been noted in prior work (Freitas et al., 2014). We also see some confusion between vowel pairs and between vowels and consonants, though these patterns tend to be less interpretable.

4.2 Articulatory Feature Accuracy

To better understand our model's accuracy across different consonant articulatory features, we perform an additional analysis of phoneme selection across specific feature dimensions. For this analysis, we define a confusion set for an articulatory feature as a set of English phonemes that are identical across all other features. For example, one of the confusion sets for the place feature is $\{p, t, k\}$, since these phonemes differ in place of articulation but are the same along other axes like manner and voicing (a full listing of confusion sets can be found in Appendix C). For each feature of interest, we calculate a forced-choice accuracy within the confusion sets for that feature. More specifically, we find all time steps in the target sequence with labels belonging in a confusion set and restrict our model output to be within the corresponding set for those positions. We then compute an accuracy across all those positions that have a confusion set.

To evaluate how much of the articulatory feature accuracies can be attributed to contextual inferences rather than information extracted from EMG, we compare our results to a baseline model that is trained to make decisions for a feature based on nearby phonemes. In the place of EMG feature inputs, this baseline model is given the sequence of phonemes predicted by the full model, but with information about the specific feature being tested removed by collapsing phonemes in each of its confusion sets to a single symbol. Additional details on this baseline model can be found in Appendix C.

The results of this analysis are shown in Figure 4. By comparing the gap in accuracy between the full model and the phoneme context baseline, we again observe trends that correspond to our prior expectations. While place and oral manner features can be predicted much better by our EMG model than from phonemic context alone, nasality and voicing are more challenging and have a smaller improvement over the contextual baseline.

5 Conclusion

By improving several model components for voicing silent speech, our work has achieved a 38% relative error reduction on this task. Although the problem is still far from solved, we believe the large rate of improvement is a promising sign for continued progress.

A Instructions to Human Evaluators

The following instructions were given to human evaluators for the transcription test described in Section 3.1:

Please listen to each of the attached sound files and write down what you hear. There are 40 files, each of which will contain a sentence in English. Write your transcriptions into a spreadsheet such as Excel or Google sheets so that the row numbers match the numbers in the file names. Many of the clips may be difficult to hear. If this is the case, write whatever words you are able to make out, even if it does not form a complete expression. If you are not entirely sure about a word but can make a strong guess, you may include it in your transcription, but only do so if you beleive it is more likely than not to be the correct word. If you cannot make out any words, leave the corresponding row blank.

B Phoneme Confusability

This section provides numerical results for phoneme confusions to complement the illustration given in Section 4.1 of the main paper. We compare the frequency of errors between two phonemes to the frequency of correct predictions on those phonemes. We define the following two quantities:

$$\text{Confusion: } (e_{p1,p2} + e_{p2,p1})/(f_{p1} + f_{p2})$$

$$\text{Accuracy: } (e_{p1,p1} + e_{p2,p2})/(f_{p1} + f_{p2})$$

where $e_{p1,p2}$ is the number of times $p2$ was predicted when the label was $p1$, and f_{p1} is the number of times phoneme $p1$ appears as a target label. Results for the most confused pairs are shown in the table below.

Phonemes		Confusion (%)	Accuracy (%)
ʤ	ʧ	13.2	49.4
v	f	10.4	72.0
p	b	10.3	64.3
m	b	9.3	74.3
k	ɡ	8.9	77.2
ʃ	ʧ	8.3	59.8
p	m	8.1	73.0
t	d	7.2	64.0
z	s	6.6	80.0
ɪ	ɛ	6.5	60.6
t	n	6.3	67.1
n	d	6.0	66.8
ɪ	ʌ	6.0	65.8
ɹ	ɚ	5.7	78.2
t	s	5.5	72.8
ɛ	æ	4.7	70.9
u	oʊ	4.3	77.4
θ	ð	4.1	76.9
ʌ	æ	3.2	72.1
ɪ	æ	3.1	64.9

C Articulatory Feature Analysis Details

The following table lists all confusion sets used in our articulatory feature analysis in Section 4.2.

Feature	Confusion Sets
Place	{p,t,k} {b,d,g} {m,n,ŋ} {f,θ,s,ʃ,h} {v,ð,z,ʒ}
Oral manner	{t,s} {d,z,l,r} {ʃ,ʧ} {ʒ,ʤ}
Nasality	{b,m} {d,n} {g,ŋ}
Voicing	{p,b} {t,d} {k,g} {f,v} {θ,ð} {s,z} {ʃ,ʒ} {ʧ,ʤ}

The phoneme context baseline model uses a Transformer architecture with dimensions identical to our primary EMG-based model, but is fed phoneme embeddings of dimension 768 in the place of the convolutional EMG features. The phonemes input to this model are the maximum-probability predictions output by our primary model at each frame, but with all phonemes from a confusion set replaced with the same symbol. We train a separate baseline model for each of the four articulatory feature types to account for different collapsed sets in the input. During training, a phoneme likelihood loss is applied to all positions and no restrictions are enforced on the output. Other training hyperparameters are the same between this baseline and the main model.

D Additional Reproducability Information

All experiments were run on a single Quadro RTX 6000 GPU, and each took approximately 12 hours. Hyperparameters were tuned manually based on automatic transcription WER on the validation set. The phoneme loss weight hyperparameter λ was chosen from $\{1, .5, .1, .05, .01, .005\}$. We report numbers on the same test split as Gaddy and Klein (2020), but increase the size of the validation set to 200 examples to decrease variance during model exploration and tuning. Our model contains approximately 40 million parameters.

What's in the Box? A Preliminary Analysis of Undesirable Content in the Common Crawl Corpus

Abstract

Whereas much of the success of the current generation of neural language models has been driven by increasingly large training corpora, relatively little research has been dedicated to analyzing these massive sources of textual data. In this exploratory analysis, we delve deeper into the Common Crawl, a colossal web corpus that is extensively used for training language models. We find that it contains a significant amount of undesirable content, including hate speech and sexually explicit content, even after filtering procedures. We discuss the potential impacts of this content on language models and conclude with future research directions and a more mindful approach to corpus collection and analysis.

1 Introduction

In recent years, much of the progress in Natural Language Processing (NLP) research has been largely driven by Transformer-based language models, which have pushed forward the state-of-the-art in tasks such as question answering (Rajpurkar et al., 2018) and natural language inference (Bowman et al., 2015). However, these increasingly complex models also require increasingly large amounts of data to train them, which is often a combination of curated, high-quality datasets such as encyclopedic articles and books and non-curated content from the Web (Radford et al., 2018, 2019). This second category of large, non-curated dataset is becoming increasingly popular as they are required to train large language models.

The current largest dataset used for training neural language models, the Common Crawl, is a non-curated corpus consisting of multilingual snapshots of the web. New versions of the Common Crawl are released monthly, with each version containing 200 to 300 TB of textual content scraped via automatic web crawling. This dwarfs other commonly used corpora such as English-language Wikipedia, which adds up to roughly 5.6 TB of data, and the BookCorpus, which only represents around 6 GB (Zhu et al., 2015). The Common Crawl has been used to train many of the recent neural language models in recent years, including the GPT model series (Radford et al., 2018; Brown et al., 2020), BERT (Devlin et al., 2018) and FastText (Grave et al., 2018) and, given its size, often represents the majority of data used to train these architectures.

In the current article, we present an initial analysis of the Common Crawl, highlighting the presence of several types of explicit and abusive content even after filtering. We discuss our findings and, given the potential downstream impact of this content on language models, we discuss the importance of ensuring that the corpora we use for training language models are extracted more mindfully and with more emphasis on their quality and propose avenues of research to achieve this goal.

2 Related Work

In recent years, a growing body of research in NLP has unearthed biases in common language models (Bolukbasi et al., 2016; Sheng et al., 2019; Zhao et al., 2019; Bordia and Bowman, 2019; Hutchinson et al., 2020). This work has raised important questions regarding the impact of these embedded biases on downstream decision-making, given the increasing usage of these models in various applications. Consequently, much work has also been dedicated to creating standardized diagnostic tests to detect these biases (Caliskan et al., 2017; May et al., 2019; Nadeem et al., 2020; Sweeney and Najafian, 2019) and to remove them (Bolukbasi et al., 2016; Zhao et al., 2018; Manzini et al., 2019), although the extent to which this is possible is still under debate (Gonen and Goldberg, 2019). In fact, research has found that *"The biases found in Internet-scale language models like GPT-2 are representative of the data on which the model was trained"* (So-

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 182–189
August 1–6, 2021. ©2021 Association for Computational Linguistics

laiman et al., 2019), which can be directly linked to the presence of hate speech on the Internet (Abid et al., 2021).

However, given the importance of this research, comparatively little attention has been dedicated to analyzing the corpora used to train language models. This is understandable because frequently used datasets such as the Common Crawl contain truly massive amounts of data, making it challenging to mine it for meaningful insights. In fact, a recent survey on automatic web page classification has deemed the task difficult not only due to the complexity and heterogeneity of web content, but also due its the high computational cost, suggesting that machine learning (ML) approaches have much to contribute to it (Hashemi, 2020). While certain notable endeavors have indeed analyzed specific aspects of corpora such as the Common Crawl (Kolias et al., 2014; Caswell et al., 2021) and Wikipedia (Hube, 2017), they have only scratched the surface of what these bodies of text contain. For instance, recent work has found that the Common Crawl contained over 300,000 documents from unreliable news sites and banned subReddit pages containing hate speech and racism (Gehman et al., 2020), while complementary research has shown that individual training examples can be extracted by querying language models (Carlini et al., 2020), together illustrating that the presence of questionable content is a significant issue for statistical language models. In the current work, we endeavor to understand the content and quality of the Common Crawl as a first step towards establishing more consistent approaches to filtering and refining it.

3 Analyzing the Common Crawl

Given its size, both downloading and analyzing the Common Crawl are time-consuming and costly endeavors. The most recent version of the Common Crawl, dating from November/December 2020, has 2.6 billion web pages in raw text format, saved in 'shards' each containing of tens of thousands of pages. Given our hardware constraints, we chose to focus on a subset of the corpus, randomly sampling 1% of the files it contains, which after filtering by language amounts to roughly 115 GB of textual content or 5,835,339 web pages in total, which we analyzed in terms of hate speech, adult content, and efficacy of perplexity-based filtering [1]. In this work, we focus on detecting sexually-explicit and hate speech, since they represent common examples of "undesirable" content that can be generally seen as inappropriate for a language model to generate in most situations. We acknowledge that desirable model behaviour is application specific, and believe our findings can extend to any other "undesirable" topic that might be present in available language corpora. We present our results in the sections below.

3.1 Detecting Hate Speech

The existence of hate speech on the internet has been described as "an important societal problem of our time", with "profound and lasting" psychological effects on its victims (Mishra et al., 2019). As such, a substantial amount of NLP research dedicated to automating hate speech detection, with several datasets and approaches being proposed in recent years (Schmidt and Wiegand, 2017; Mishra et al., 2019; Vidgen and Derczynski, 2020; Kiritchenko and Mohammad, 2018). Most of this research is carried out on data extracted from social media sources such as Twitter (Founta et al., 2018; Basile et al., 2019; Waseem and Hovy, 2016) and Reddit (Tadesse et al., 2019; Farrell et al., 2019), with both ML-based (Badjatiya et al., 2017) and count-based approaches (Davidson et al., 2017) achieving comparable results (Fortuna and Nunes, 2018). In order to estimate the quantity of hate speech in the Common Crawl, we endeavored to compare 3 approaches: DELIMIT, a recent BERT-based model trained on social media data (Aluru et al., 2020), Hate Sonar, a Logistic Regression approach trained on data from Web fora and Twitter (Davidson et al., 2017) and a n-gram-based approach using a list of n-grams extracted from Hate Base. We present samples of text flagged by all of these approaches in Table 1, below.

We found that the three approaches compared suggest similar proportions of websites containing hate speech : 5.24% of websites from our sample were flagged by DELIMIT, 4.02% by HateSonar, and 6.38% by the n-gram approach [2]. Qualitative analysis of a sample of sites flagged by each approach showed that while n-grams picked up on racial slurs, HateSonar also detected debates about racial supremacy and racially-charged conspiracy theories. Many of the sites that DELIMIT

[1] All code used in these analysis are publicly available: https://github.com/josephdviviano/whatsinthebox

[2] We are conscious of the high false positive rate of n-gram approaches and therefore only consider sites to be flagged if they contain 3 or more n-grams from the list.

Approach	Text
HateSonar	Their US/Euro plan put in your face: demonic jews hate white goyim!
	Such sick and twisted people, white people are.
Delimit	they are only stupid arab from wp-ar haha
	Yeah, dumb ass n*gger †
N-gram	nude attention whore asian bastards
	In America all male look like this homo

Table 1: Examples of hate speech found by the approaches tested. Examples with † have been censored by the authors.

Page URL (`http://` removed)

Table 2: Sample of URLs of adult content websites identified by the n-gram approach. Protocol removed to prevent URL generation.

flagged were adult content with mentions of violent acts towards specific ethnic groups, illustrating the fine line between sexual violence and hate speech, which we elaborate further in the following subsection. Generally speaking, the presence of even a small fraction of websites that incite hate in training corpora is worrisome since it can result in models that replicate this kind of discourse when prompted (Wolf et al., 2017; Carlini et al., 2020).

3.2 Sexually Explicit Content

Compared to hate speech, the detection of sexually explicit content has received less attention from the NLP community, with existing ML approaches focusing mainly on the detection of explicit images (Wehrmann et al., 2018; Rowley et al., 2006) and URLs (Matic et al., 2020), whereas n-gram-based approaches remain predominantly used in practice by web providers (Hammami et al., 2003; Polpinij et al., 2006; Ho and Watters, 2004). In our analysis, we used a list of n-grams extracted from adult websites in order to establish the percentage of websites from our sample that contained sexually explicit content; however, we found no available statistical or ML-based approach that we could use to compare our count-based approach with. The n-gram approach detected that 2.36% of the web pages that we analyzed contained at least one of the words from our list, with 1.36% containing 3 or more and 0.73% containing 10 or more (see Table 3 for results). We show a sample of the URLs flagged by our approach in Table 2, below.

While a few percent of sexually explicit content may not seem like much, the type of language and content contained on adult websites can have harmful repercussions. For instance, the prevalence of sexual violence towards women, especially towards women of color, on adult websites (Foubert et al., 2019; Shim et al., 2015; Fritz et al., 2020) may contribute to further dissemination and amplification of these biases in downstream models. As modern language models have no way to evaluate generation appropriateness, models trained with even a small proportion of these undesirable inputs cannot be guaranteed to avoid generating outputs with similar biases if presented with a specific context or prompt. This is a risk that is important to mitigate in applications, where the general-purpose language models can end up being used in applications used by sensitive groups in professional contexts or minors, such as chatbots and toys.

3.3 Filtering by Perplexity Score

While the analyses described above were carried out on unfiltered web pages from the Common Crawl, the training pipeline of many large-scale NLP models involves some type of filtering and cleaning, from excluding low-quality content (Grave et al., 2018) to fuzzy deduplication (Brown et al., 2020). One such popular filtering approach is based on training a language model on a target, high-quality domain such as Wikipedia, and using it to calculate the perplexity score of web pages using this model (Wenzek et al., 2020). To test the efficacy of this scoring procedure, we calculated the perplexity score of each web page from our sample of the Common Crawl and used it to separate pages into 3 equal buckets (high, middle and low-quality) based on their perplexity. We compare the percentages of hate speech and sexually explicit content for the entire sample, as well as the high- and low-quality documents, in Table 3.

While filtering by perplexity does seem to filter out many websites containing sexual content, it does not detect much of the hate speech that is flagged by the count-based or statistical methods. In fact, perplexity scores had low correlations with all detection methods tested (Figure 1). This supports the methodology of Wenzek et al. (2020),

	Entire Sample	High Quality	Low Quality
1+ sexual n-grams	2.36%	1.81%	3.97%
3+ sexual n-grams	1.36%	0.42%	3.11%
10+ sexual n-grams	0.73%	0.08%	1.98%
1+ hate n-grams	17.78%	18.95%	17.19%
3+hate n-grams	6.38%	6.19%	8.26%
10+ hate n-grams	1.16%	1.17%	1.70%
Hate speech (Sonar)	4.02%	3.47%	5.09%
Hate speech (Delimit)	5.24%	5.77%	5.66%

Table 3: Comparison of hate speech and sexual content detected in the entire corpus, as well as high- and low-quality sites.

who noted that while *"perplexity was a relative good proxy for quality"*, also argued that some of the lower-quality texts could still be useful for specific applications, and therefore did not use it to exclude documents from the training set of their language model. While we are exploring ways of modifying the original approach in order to be more discerning, we believe that there more nuanced metrics that can be used for estimating and filtering documents based on text, potentially coupling embedding-based approaches with statistical ones.

3.4 Behaviour of Different Detection Methods

The approaches that we compared in the current study are different in the features that they use and techniques employed for detecting particular types of content. HateSonar employs classical NLP techniques for hate speech detection, constructing features from Penn Part-of-Speech N-grams with TF-IDF weighting based on a hand-crafted hate speech dataset, training simple classifier ensembles using Support Vector Machines, random forests, naive Bayes, and linear models. Delimit, on the other hand, is A BERT-based model trained on Twitter and Reddit posts, not relying on any handcrafted features. Our simple n-gram approach unsurprisingly was more in agreement with HateSonar than Delimit, given that both rely on count-based features. The fact that all methods identified different instances of clear hate speech implies that we are far from a general purpose dataset-filtering approach. These results also imply that deep learning models learn very different features to classify hate speech than other methods, and given their sensitivity to the specific composition of the dataset used to train them (as exposed by the propensity of large models to memorize training examples (Carlini et al., 2020)), the presence of undesirable content in the corpora used to train them should be taken seriously.

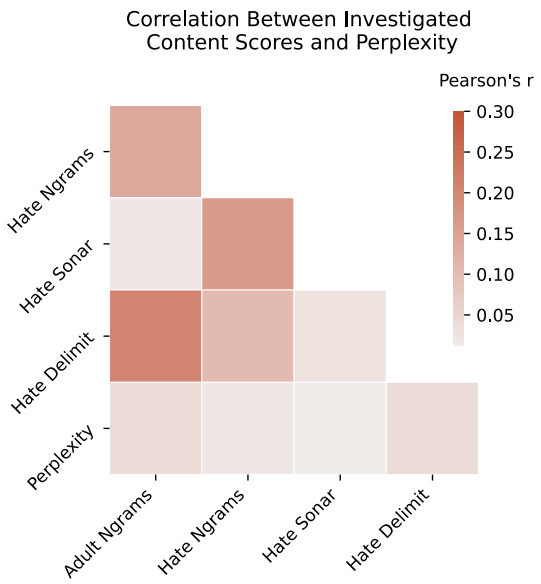

Figure 1: Correlation coefficients (Pearson's r) calculated between all content metrics investigated and perplexity, a commonly-used text quality metric.

4 Discussion

4.1 Summary of Results

We recognize that the exploratory work presented above is only the tip of the iceberg in terms of the analyses that can be done on the massive web corpora that are feeding our language models. However, analyzing the Common Crawl would require computational resources far in excess of what is available to most research institutions. We therefore hope that this initial analysis will inspire our fellow researchers to continue to dig deeper into this topic, and to propose more scalable, thorough, and nuanced approaches for analyzing the massive corpora used to train language models. We also recognize this analysis would have been more comprehensive on a small curated dataset, but given the

amount of data needed to train modern language models, we believe the community needs to move beyond analysis techniques only compatible with small-data, toward something that will scale to the datasets used to train these large models.

Also, while we have currently adopted a purely descriptive approach, we feel that it is worth discussing and debating the consequences of our analysis, and those of our peers, within the NLP community. While it can be argued that the Common Crawl corpus is an accurate portrayal of the discourse of modern society – which includes sexual content, hate speech, and racial and gender biases – we believe that it is up for debate whether this discourse is the one that we, as a community, want to use to train the models that translate our texts, influence our search results and answer our questions. Notably, the Common Crawl over-represents those populations that are avid users of the internet: younger, English-speaking individuals from developed countries, who are those who have the most access to the internet globally (World Bank, 2018). Furthermore, internet communities supported by anonymity and and particular norms can amplify toxic discourse that would not be found in mainstream corpora (Massanari, 2017) often exacerbated by the well-documented 'online disinhibition' phenomenon where users find themselves more likely to engage in anti-social behaviours due to the lack of immediate social feedback (Wachs et al., 2019; Mathew et al., 2019; de Lima et al., 2021). This can further perpetuate the lack of diverse, representative language models that can adequately mirror society beyond the boundaries of internet communities.

4.2 Future Work

Given the general superior performance of large language models on common benchmarks, and that they require ever larger datasets to train them, we believe it is important that for the ML community to carry out a more extensive analysis of: 1) the impact of undesirable content in the datasets used to train these models on downstream performance; 2) the effect of properly filtering these examples out of the dataset *before* model training, and 3) approaches for regularizing model outputs to be acceptable regardless of the data used to train the model. All three directions require a better understanding of the contents of the datasets, which we believe requires new tools that are scalable to the Common Crawl (or similarly large and diverse corpora) to identify such examples. Models trained to detect undesirable examples, like the ones used in this paper, need to be improved such that they can reliably generalize to the Common Crawl, which constitutes a significant undertaking. Additionally, future work could explore the utility of controlling model generation using labelled "undesirable" examples (Zhang et al., 2020; Engel et al., 2017), or human-in-the-loop learning methods (Wang et al., 2021) for fine-tuning a language model trained using undesirable examples. It will also be important to evaluate whether curation is sufficient: it remains possible that a model could create an undesirable generation from multiple distinct innocuous examples (Bender et al., 2021; Gehman et al., 2020). It is also worth considering that for some applications, task-focused models with curated training examples may perform better than large models trained on unfiltered corpora, so that their behaviour can be more reliably guaranteed: these are all interesting avenues for future work.

Finally, while larger corpora generally result in better models (Kaplan et al., 2020; Sun et al., 2017), data quality and corpora content also plays a major role in the caliber and appropriateness of these models for the various downstream applications (Florez, 2019; Abid et al., 2021; Bhardwaj et al., 2021). To produce high quality and safe neural language models will likely require the community to adopt more mindful data collection practices (Gehman et al., 2020; Bender and Friedman, 2018; Gebru et al., 2018; Jo and Gebru, 2020; Paullada et al., 2020; Bender et al., 2021), establish standardized filtering pipelines for corpora (Roziewski and Stokowiec, 2016; Ortiz Suarez et al., 2019; Wenzek et al., 2020), and develop methods for evaluating the bias in trained models (Schick et al., 2021). We recognize that this is not a straightforward task with a one-size-fits all solution, but we propose that as much attention should be dedicated to the corpora used for training language models as to the models themselves, and that corpora transparency is a prerequisite for language model accountability.

Continual Quality Estimation with Online Bayesian Meta-Learning

Abstract

Most current quality estimation (QE) models for machine translation are trained and evaluated in a static setting where training and test data are assumed to be from a fixed distribution. However, in real-life settings, the test data that a deployed QE model would be exposed to may differ from its training data. In particular, training samples are often labelled by one or a small set of annotators, whose perceptions of translation quality and needs may differ substantially from those of end-users, who will employ predictions in practice. To address this challenge, we propose an online Bayesian meta-learning framework for the continuous training of QE models that is able to adapt them to the needs of different users, while being robust to distributional shifts in training and test data. Experiments on data with varying number of users and language characteristics validate the effectiveness of the proposed approach.

1 Introduction

Quality Estimation (QE) models aim to evaluate the output of Machine Translation (MT) systems at run-time, when no reference translations are available (Blatz et al., 2004; Specia et al., 2009). QE models can be applied for instance to improve translation productivity by selecting high-quality translations amongst several candidates. A number of approaches have been proposed for this task (Specia et al., 2009, 2015; Kim et al., 2017; Kepler et al., 2019; Ranasinghe et al., 2020), and a shared task yearly benchmarks proposed approaches (Fonseca et al., 2019; Specia et al., 2020).

Different users of MT output have varying quality needs and standards, depending for instance on the downstream task at hand, or the level of their knowledge of the languages involved, and training for the task. Thus, the perception of the quality of MT output can be subjective, and therefore the quality estimates obtained from a model trained on data from one set of users may not serve the needs of a different set users. However, most existing QE models are trained and evaluated in a static setting which assumes a fixed distribution of train and test data. This consequently leads to suboptimal performance when faced with test data from a different set of users in practice.

The few previous approaches to develop QE models that are able to learn from a continuous stream of data suffer from the following limitations: they do not have an explicit objective that encourages the model to exploit common structures shared among different users to continually adapt efficiently for new users (Turchi et al., 2014), or assume a fixed number of users, and that the identity of each user is known in advance (de Souza et al., 2015). In addition, these previous approaches do not explicitly account for the underlying uncertainties in the data in order to improve performance.

In contrast, we propose a continual meta-learning framework that makes none of the aforementioned assumptions, but instead considers each user as a task and explicitly meta-learns the common structure shared among different users. This approach further exploits the underlying uncertainties in the streaming data through Bayesian inference to improve performance. In addition, the proposed approach is applicable even in a setting where no user identities are available, for instance due to privacy concerns, but where we still want to learn and adapt as efficiently as possible from supervision data that arrives incrementally.

2 Background

2.1 Continual Learning

Continual learning (Ring, 1994; Thrun, 1996; Zhao and Schmidhuber, 1996) aims to develop mod-

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 190–197
August 1–6, 2021. ©2021 Association for Computational Linguistics

els that are capable of learning from a continuous stream of sequential tasks, $\mathcal{T}_1, \mathcal{T}_2, .., \mathcal{T}_T$, with each task $\mathcal{T}_t$ having its associated train $\mathcal{D}_t^{train}$, validation $\mathcal{D}_t^{val}$ and test $\mathcal{D}_t^{test}$ splits. A major challenge associated with learning in this setting is the issue of *catastrophic forgetting*, where a model forgets knowledge of how to perform previous tasks as new tasks are encountered. Most recent work in lifelong learning has focused on ways of mitigating catastrophic forgetting, and approaches proposed include replay-based methods (Rebuffi et al., 2017; Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2019), which replay either stored or generated samples to remind the model of how to perform previous tasks; regularization-based methods (Kirkpatrick et al., 2017; Zenke et al., 2017), which utilize an additional regularization term to enforce retaining knowledge learned from previous tasks; and parameter-isolation methods, which make use of dedicated parameters for each task to prevent interference among tasks (Rusu et al., 2016; Fernando et al., 2017). Lange et al. (2019) presents an overview of recent continual learning methods. Research in continual learning can generally be carried in one of two settings (Aljundi et al., 2019): in a *task-incremental* continual learning setting, where the learner is sequentially given access to all the data of each task and is allowed to make multiple passes over it, with task boundaries and identities known to the learner; or in an *online continual learning* setting, where the learner is only allowed a single pass over the data of each task, and with no task identities or boundaries known to the learner. In this work we conduct experiments in the online continual learning setting.

2.2 Meta-Learning

The goal of meta-learning, also known as learning to learn (Schmidhuber, 1987; Thrun and Pratt, 1998), is to develop models that can learn more efficiently over time, by generalizing from knowledge of how to solve related tasks from a given distribution of tasks. Given a learner model $f_{\boldsymbol{w}}$, for instance a neural network parametrized by $\boldsymbol{w}$, and a distribution $p(\mathcal{T})$ over tasks $\mathcal{T}$, gradient-based meta-learning approaches such as MAML (Finn et al., 2017) seek to learn the parameters of the learner model which can be quickly adapted to new tasks sampled from the same distribution of tasks. In formal terms, these approaches seek parameters that optimize the meta-objective:

$$\min_{\boldsymbol{w}} \mathbb{E}_{\mathcal{T}\sim p(\mathcal{T})} \left[\mathcal{L}_{\mathcal{T}} \left(\mathcal{U}_k \left(\boldsymbol{w}; \mathcal{D}_{\mathcal{T}}\right)\right)\right] \quad (1)$$

where $\mathcal{L}_{\mathcal{T}}$ is the loss and $\mathcal{D}_{\mathcal{T}}$ is training data from task $\mathcal{T}$, and $\mathcal{U}_k$ denotes k steps of a gradient descent learning rule such as SGD.

In order to account for uncertainty and improve robustness, Bayesian approaches to meta-learning have also been proposed (Kim et al., 2018; Finn et al., 2018; Ravi and Beatson, 2019; Wang et al., 2020; Nguyen et al., 2020).

2.3 Meta-Learning for Continual Learning

Meta-learning for continual learning methods generally make use of the meta-learning objective one task at a time to ensure that learning on the current task does not lead to catastrophic forgetting on previous tasks. For instance, both Riemer et al. (2019) and Obamuyide and Vlachos (2019) propose to combine REPTILE (Nichol and Schulman, 2018), a first order meta-learning algorithm, together with experience replay to improve performance during continual learning. Javed and White (2019) proposed an online-aware meta-learning (OML) objective for learning representations that are less prone to catastrophic forgetting during continual learning. Holla et al. (2020) proposed to combine the OML objective together with experience replay for improved continual learning performance. Recently, Gupta et al. (2020) proposed Look-Ahead MAML (LA-MAML), which meta-learns per-parameter learning rates to help adapt to changing data distributions during continual learning.

These approaches have demonstrated that meta-learning can yield performance improvements for continual learning. Our work builds on these approaches and additionally demonstrates that the performance of meta-learning for continual learning can be further improved with the combination of an adaptive learning rate and Bayesian inference.

2.4 Bayesian Inference with Stein Variational Gradient Descent

Stein Variational Gradient Descent (SVGD) (Liu and Wang, 2016) is a Bayesian inference method which works by initializing a set of samples, also known as particles, from a simple distribution and iteratively updating the particles to match samples from a target distribution. Because its particle update rule is deterministic and differentiable, it can

be used to perform Bayesian inference in the meta-learning inner loop, since the entire update process can still be differentiated through for gradient-based updates from the outer loop.

In order to obtain N samples from a posterior $P(\boldsymbol{w})$, SVGD maintains N samples of model parameters, and iteratively transports the samples to match samples from the target distribution. Let the samples be represented by $\boldsymbol{W} = \{\boldsymbol{w}^n\}_{n=1}^N$. At each successive iteration t, SVGD updates each sample with the following update rule:

$$\boldsymbol{w}_{t+1} \leftarrow \boldsymbol{w}_t + \alpha_t \phi(\boldsymbol{w}_t) \tag{2}$$

where $\phi(\boldsymbol{w}_t) =$

$$\frac{1}{N}\sum_{n=1}^{N}\left[k(\boldsymbol{w}_t^n, \boldsymbol{w}_t)\nabla_{\boldsymbol{w}_t^n}\log p(\boldsymbol{w}_t^n) + \nabla_{\boldsymbol{w}_t^n} k(\boldsymbol{w}_t^n, \boldsymbol{w}_t)\right] \tag{3}$$

α_t is a step-size parameter and $k(.,.)$ is a positive-definite kernel, such as the RBF kernel.

Intuitively, the first term in Equation 3 implies that a particle determines its update direction through a weighted aggregate of the gradients from the other particles, with the kernel distance between the particles serving as the weight. Thus, closer particles have more weight in the aggregate. The second term of the equation can be understood as a repulsive force that prevents the particles from collapsing to a single point. For the case when the number of particles is one, the SVGD update procedure reduces to standard gradient ascent on the objective $p(\boldsymbol{w})$ for any kernel with the property $\nabla_{\boldsymbol{w}} k(\boldsymbol{w}, \boldsymbol{w}) = 0$, such as the RBF kernel. SVGD has been applied in a wide range of settings, including reinforcement learning (Liu et al., 2017; Haarnoja et al., 2017), uncertainty quantification (Zhu and Zabaras, 2018) and to improve performance in an offline meta-learning setup (Kim et al., 2018) which requires all tasks ahead of training. In this work we adapt SVGD to an online continual meta-learning setting for a natural language task.

3 Meta-Learning for Continual Learning with Adaptive SVGD

Learning continually from a stream of observations with varying underlying distributions involves dealing with various sources of uncertainty, which a model should properly account for in order to enhance its continual learning performance. One source of uncertainty is in the learning rate, that is, how fast learning should proceed on new data in order to both reduce catastrophic forgetting and enhance performance on the current task. Another source is the inherent uncertainty in the values of the model's parameters themselves. Learning an adaptive learning rate, for instance as proposed in Gupta et al. (2020), can help account for the first source of uncertainty, and Bayesian inference can be used to help a model account for the other source of uncertainty. In order to properly model both sources of uncertainty during continual learning, we propose to both perform inference of model parameters with SVGD, and meta-learn an adaptive per-parameter learning rate for SVGD updates. Thus, the SVGD update in Equation 2 now becomes:

$$\boldsymbol{w}_{t+1} \leftarrow \boldsymbol{w}_t + \boldsymbol{\alpha}_t \cdot \phi(\boldsymbol{w}_t) \tag{4}$$

where $\boldsymbol{\alpha}_t$ is a learnable parameter containing per-parameter learning rates, and $\cdot$ is the dot product.

The aim is then to meta-learn both the parameters of the model and the per-parameter learning rates that enhance continual learning performance. The advantage of this approach is that it allows for greater flexibility to adapt to non-stationary data distributions during continual learning. In the experiments, we demonstrate that this change leads to improved performance for the task of continual quality estimation. The proposed approach is illustrated in Algorithm 1.

We first initialize the parameters of the QE model, and the learning rate (line 1). Then for each mini-batch in a task t that arrives, we store its training instances in the buffer with a probability p (lines 2-6). In the inner loop, we perform K SVGD updates (using Equation 4) starting from the initial model parameters W_0 (lines 7-9). In the outer loop, instances in the current mini-batch are augmented with instances sampled from the buffer (line 10). Finally, the augmented mini-batch is used to perform a meta-update on the learning rate (line 11), and on the parameters of the QE model (line 12). Because this approach can also be considered the online counterpart to the Bayesian Model Agnostic Meta-Learning approach of Kim et al. (2018), we refer to it as Continual Quality Estimation with Online Bayesian Meta-Learning (*CQE-OBML*).

4 Experiments and Results

The QT21 Dataset We evaluate our approach with the publicly available **QT21** (Specia et al., 2017), a large-scale dataset containing translations

(b) QT21 en-cs (smt)

Table 1: Number of instances per post-editor (PE) for the QT21 dataset.

from both statistical (smt) and neural (nmt) machine translation systems in multiple language directions.[1] This is the largest dataset with annotator information available. We use data from the English-Latvian (en-lv) and English-Czech (en-cs) language pairs. These languages were chosen as they contain the largest number of annotators. Each instance in the dataset is a tuple of source sentence, its machine translation, the corresponding post-edited translation by a professional translator (post-editor), a reference translation and other information such as (anonymized) post-editor identifier. We construct a QE dataset from this corpus by computing the HTER (Snover et al., 2006) values between each source sentence and its post-edited translation. We thereafter split the data into train, dev and test splits for each post-editor. A breakdown of the number of train, dev and test instances per post-editor is available in Table 1.

Benchmark Approaches SEQUENTIAL is a baseline trained sequentially over the streaming data of each task. In each round, the model parameters are initialized from that of the previous round; A-GEM (Chaudhry et al., 2019) is a continual learning method which utilizes the gradients of samples of previous tasks saved in a buffer as an optimization constraint to prevent catastrophic forgetting; OML-ER (Holla et al., 2020) augments the Online-Aware Meta-Learning approach of Javed and White (2019) with experience replay from a buffer; LA-MAML (Gupta et al., 2020) learns per-parameter learning rates using meta-learning; MTL-IID is trained on the concatenated and shuffled data from all users for multiple epochs in multi-task fashion. It assumes i.i.d access to the data from all users, and thus serves as an upper-bound for the performance.

QE Model The quality estimation model used by all continual learning methods is based on multilingual DistilBERT (Sanh et al., 2019), a smaller version of multi-lingual BERT (Devlin et al., 2019) trained with knowledge distillation (Buciluǎ et al., 2006; Hinton et al., 2015). It accepts as input the source and machine translation outputs concatenated as a single text, separated by a '[SEP]' token and prepended with a '[CLS]' token. The representation of the '[CLS]' token is then passed to a linear layer to predict HTER (Snover et al., 2006) values as regression targets.

Evaluation We report Pearson's r correlation scores and Mean Absolute Error (MAE) between model output and gold labels, both standard evaluation metrics in QE.

Each experiment is repeated across five (5) different orders of the tasks and five (5) different random seeds, and we report the average.

4.1 Comparison with Benchmark Approaches

The results of our approach in comparison with other benchmark approaches are presented in Table 2. We can observe that naively training sequentially on the data of each task as it arrives (SEQUENTIAL) leads to poor results.

[1] http://www.qt21.eu/resources/data/

Method	en-lv		en-cs	
	Pearson ↑	MAE ↓	Pearson ↑	MAE ↓
MTL-IID	59.17	0.1450	54.79	0.1547
SEQUENTIAL	47.07	0.1773	50.08	0.1689
A-GEM	46.29	0.1794	46.49	0.1736
OML-ER	52.58	0.1621	50.40	0.1635
LA-MAML	52.86	0.1621	50.56	0.1631
CQE-OBML	**53.67**	**0.1596**	**51.19**	**0.1619**

Table 2: Comparison with benchmark approaches.

OML-ER outperforms both SEQUENTIAL and A-GEM, likely because of its combination of meta-learning and experience replay, which makes it better able to combat forgetting. LA-MAML slightly improves over the results of OML-ER, as a result of its meta-learned learning rate. We find that our approach, CQE-OBML, which combines a meta-learned adaptive learning rate together with Bayesian inference, outperforms previous approaches. This demonstrates the effectiveness of adequately modelling the various sources of uncertainty in continual meta-learning.

4.2 Analysis of Model Components

We investigate the effect of the various components of our approach through an ablation study. As shown in Table 3, our approach (CQE-OBML) without the adaptive learning rate (-LR (α)) has a drop in performance, especially for en-cs. Without inference with SVGD (-SVGD), we observe a larger reduction in performance on both datasets, demonstrating the usefulness of incorporating Bayesian inference into the continual meta-learning of quality estimation models.

Method	en-lv		en-cs	
	Pearson ↑	MAE ↓	Pearson ↑	MAE ↓
CQE-OBML	53.67	0.1596	51.19	0.1619
- LR (α)	53.48	0.1598	50.94	0.1623
- SVGD	52.86	0.1621	50.56	0.1631

Table 3: Ablation of model components.

5 Conclusions

We proposed a framework for the continual meta-learning of machine translation quality estimation models, which is able to learn continually from the streaming data of multiple quality estimation users. We further incorporate an adaptive learning rate together with online Bayesian inference for improved performance. In experiments on quality estimation data from two language directions, we demonstrate improved performance over recent state-of-the-art continual learning methods.

A Additional Results

We present additional results on the **WPTP12** dataset (Koponen et al., 2012),which is a small English-Spanish (en-es) translation dataset consisting of documents from the news domain. It features translations from eight different machine translation systems. Each instance in the dataset includes the corresponding post-edited translation along with post-editing time and HTER scores computed between the translation and the corresponding post-edit. Statistics about the number of instances per post-editor are in Table 4.

Table 5 contains the results obtained on this dataset. As a result of its size, all methods generally find it challenging, with reduced performance across-the-board. Despite reduced performance in terms of mean absolute error, our approach obtains better Pearson correlation than all previous methods.

Abstract

Sequential sentence classification aims to classify each sentence in the document based on the context in which sentences appear. Most existing work addresses this problem using a hierarchical sequence labeling network. However, they ignore considering the latent segment structure of the document, in which contiguous sentences often have coherent semantics. In this paper, we proposed a span-based dynamic local attention model that could explicitly capture the structural information by the proposed supervised dynamic local attention. We further introduce an auxiliary task called span-based classification to explore the span-level representations. Extensive experiments show that our model achieves better or competitive performance against state-of-the-art baselines on two benchmark datasets.

1 Introduction

The goal of Sequential Sentence Classification (SSC) is to classify each sentence in a document based on rhetorical structure profiling process (Jin and Szolovits, 2018), and the rhetorical label of each sentence is related to the surrounding sentences, which is different from the general sentence classification that does not involve context. An example is shown in Figure 1, the document is divided into rhetorical labels such as "background" and "outcome" for five sentences in NICTA dataset. The SSC task is crucial for downstream domains such as information retrieval (Edinger et al., 2017), question answering (Cohen et al., 2018) and so on.

Traditional statistical methods, such as HMM (Lin et al., 2006), CRF (Hirohata et al., 2008; Hassanzadeh et al., 2014), etc., heavily rely on numerous carefully hand-designed features. In contrast, recent methods based on end-to-end neural networks utilize hierarchical sequence encoders followed by the CRF layer to contextualize sentence representations, which achieved promising results. The first neural network approach (Lee and Dernoncourt, 2016) combined RNN with CNN that incorporates preceding sentences to encode the contextual content and further use a CRF layer to optimize the predicted label sequence. Recently, Jin and Szolovits (2018) propose a hierarchical sequential labeling network to make use of the contextual information within surrounding sentences to help classify. Conversely, Cohan et al. (2019) employ BERT (Devlin et al., 2018) to capture contextual dependencies without hierarchical encoding or CRF layer. Yamada et al. (2020) introduce Semi-Markov CRFs (Ye and Ling, 2018) to assign a rhetorical label at span-level rather than single sentence.

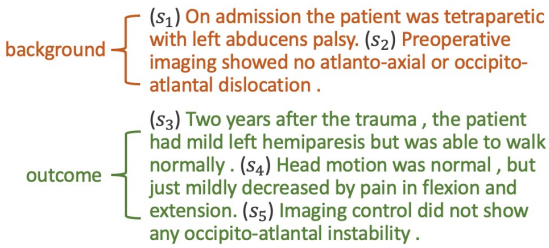

Figure 1: An example of NICTA dataset for SSC task. The text has five sentences and is divided into two segments $\{(s_1, s_2), (s_3, s_4, s_5)\}$ by labels.

Nevertheless, the above-mentioned methods ignore the latent structural information (e.g. segmentation) in the document, which is the grouping of content into topically coherent segments. Intuitively, a segment with several continuous sentences is expected to be more coherent semantics than the text spanning different segments, e.g., the text with two segments in Figure 1. In this paper, we propose a novel span-based dynamic local attention model to explore the latent segment structure in a document for SSC task. First, we introduce

dynamic local attention guided by segmentation supervision signal to focus on the surrounding sentences with coherent semantics, called Supervised Dynamic Local Attention (SDLA). Furthermore, we introduce an auxiliary task called span-based classification, which calculates semantic representations of spans and performs span classification on them to obtain predicted rhetorical labels. The dynamic local attention mechanism and the auxiliary task complement each other to enhance the model capacity to perceive segment structure and improve the performance of SSC task. The results on two benchmark datasets show that our method achieves better or competitive performance than state-of-the-art baselines.

2 Proposed Method

In this paper, we propose a Span-based Dynamic Local Attention Model for sequential sentence classification with two novel components: supervised dynamic local attention and auxiliary span-based classification task, respectively. The architecture of our model is shown in Figure 2.

2.1 Sentence Representations

For SSC task, given a sequence of sentences $X = \{x_1, x_2, \cdots, x_N\}$, the model needs to predict the label of each sentence $Y = \{y_1, y_2, \cdots, y_N\}$ based on the context which the sentence appears, where N is the number of sentences. Following the previous work (Yamada et al., 2020), we first feed each sentence into BERT pre-trained with PubMed (Peng et al., 2019) and then extract the encoding corresponding to [CLS] token as sentence encoding $S = \{s_1, s_2, \cdots, s_N\}$ (we implement it using Sentence-BERT (Reimers and Gurevych, 2019)). Then, we employ two bidirectional LSTM layers to produce context-informed sentence representation $h_i^c \in \mathbf{R}^d$ for whole document :

$$H^c = \{h_1^c, h_2^c, \cdots, h_N^c\} \tag{1}$$

2.2 Supervised Dynamic Local Attention

In this section, we introduce dynamic local attention guided by a supervised segmentation signal to learn latent segment structure in a document. Firstly, we generate the sentence-level attention spans for each sentence by training soft masking (Nguyen et al., 2020), using pointing mechanism (Vinyals et al., 2015) to approximate left and right boundary positions of the mask vector. Given the query Q and key K, where $Q = K = H^c$,

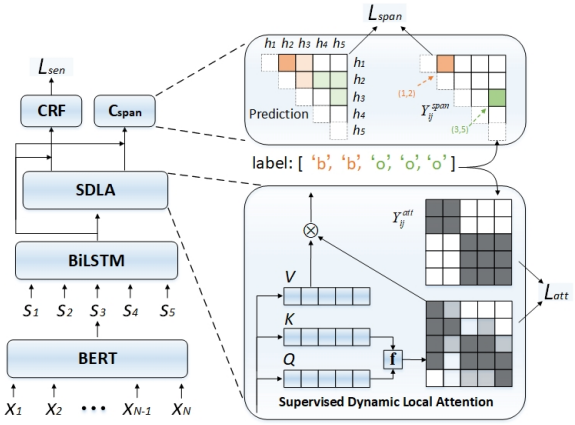

Figure 2: The overview of our model, exemplified by the sample in Figure 1. The labels 'b' and 'o' stand for "background" and "outcome", respectively. C_{span} denotes Auxiliary Span-based Classification Task.

we calculate the left and right boundary matrix $\hat{\phi}_l, \hat{\phi}_r \in R^{N \times N}$ for query Q as follows:

$$\hat{\phi}_l = \mathcal{S}(\frac{Q^T W_L^Q (K W_L^K)^T}{\sqrt{d}} \odot M) \tag{2}$$

$$\hat{\phi}_r = \mathcal{S}(\frac{Q^T W_R^Q (K W_R^K)^T}{\sqrt{d}} \odot M^T) \tag{3}$$

$$M_{ij} = \begin{cases} -\infty, & i < j \\ 1, & i \geq j \end{cases} \tag{4}$$

where $\mathcal{S}$ is the softmax function, $\odot$ is element-wise product, and $W_L^Q, W_L^K, W_R^Q, W_R^Q \in \mathbf{R}^{d \times d}$ are trainable parameters. Eq. (2)-(3) approximate the left and right boundary positions of the mask matrix for the query Q (Each row approximate the mask vector of the entire document corresponding to each sentence in sequence order). Note that we additionally introduce mask matrix M to ensure that the left boundary position l and the right boundary position r generated at position i satisfy this relationship such that $0 \leq l \leq i \leq r \leq N$.

Given the above definitions, the attention span masking matrix M_a can be achieved by compositing the left and right boundary matrix :

$$M_a = (\hat{\phi}_l L_N) \odot (\hat{\phi}_r L_N^T) \tag{5}$$

where $L_N \in \{0, 1\}^{N \times N}$ denotes a unit-value (1) upper-triangular matrix.

Then we combine self-attention with the attention span masking, enabling the model to focus on semantically related sentences around the target

position and eliminate noisy aggregations :

$$A = \frac{(QW^Q)(KW^K)^T}{\sqrt{d}} \odot M_a \quad (6)$$

$$H^{att} = \mathcal{S}(A)(H^c W^H) \quad (7)$$

where W^Q, W^K, W^H are the trainable parameters.

However, in the absence of a supervised process, the dynamic local attention may fail to focus on the corresponding informative sentences of the target, especially for limited data, so we further introduce the segmentation signal to guide the learning of dynamic local attention to capture coherent semantics more accurately. Specifically, we employ binary cross-entropy loss to describe the differences between attention matrix A and segment signal Y^{att}:

$$\mathcal{L}_{att} = BCE(\sigma(A), Y^{att}) \quad (8)$$

$$Y^{att}_{ij} = \begin{cases} 1, & E_{ij} = 1 \\ 0, & else \end{cases} \quad (9)$$

where σ is sigmoid function. $E_{ij} = 1$ denotes i-th sentence and j-th are in the same segment (e.g. (s_1, s_2) and (s_4, s_5) in Figure 1).

Finally, we concatenate H^c and H^{att} as the contextual representations H and add a CRF layer to classify each sentence.

2.3 Auxiliary Span-based Classification Task

Due to the obvious label consistency of sentences within spans, we introduce an additional auxiliary task called span-based classification to improve the performance at the span-level. To this effect, we consider all possible spans of various lengths and propose a tagging scheme for span-based classification. The scheme uses the same labels as sentence-level to represent the label of a span. Firstly, we represent a span from the i-th sentence to the j-th sentence as a vector h_{ij}, which is concatenated by four-vectors similar to Zhao et al. (2020):

$$h_{ij} = \{h_i; h_j; \hat{h}_{i:j}; \varphi(j - i + 1)\} \quad (10)$$

where $\hat{h}_{i:j}$ is the attention output over the final sentence representation H in the span, and $\varphi(j - i + 1)$ is the feature vector encoding the span size.

We employ a cross-entropy category loss for span-based classification:

$$\mathcal{L}_{span} = CE(\hat{Y}^{span}, Y^{span}) \quad (11)$$

$$Y^{span}_{ij} = \begin{cases} label, & F_{ij} = 1 \\ 0, & else \end{cases} \quad (12)$$

where $\hat{Y}^{span}$ is the output probability at span-level, F_{ij} denotes i-th sentence and j-th sentence (i, j satisfy the relationship $i < j$) are in the same segment and i, j is the beginning and end of the segment respectively (e.g. (s_1, s_2) and (s_3, s_5) in Figure 1).

2.4 Objective Function

The overall objective function includes cross-entropy loss $\mathcal{L}_{sen}$, $\mathcal{L}_{span}$ for sentence and span-based classification and supervised attention loss $\mathcal{L}_{att}$:

$$\mathcal{L} = \mathcal{L}_{sen} + \lambda_{att}\mathcal{L}_{att} + \lambda_{span}\mathcal{L}_{span} \quad (13)$$

where $\lambda_{att}, \lambda_{span}$ are the hyperparameters for balancing the strength of $\mathcal{L}_{att}$ and $\mathcal{L}_{span}$.

3 Experiments

3.1 Experimental Setup

Datasets and Baselines To evaluate the effectiveness of our model, we conduct extensive experiments on two standard benchmark datasets from medical scientific abstracts, i.e. NICTA-PIBOSO (Kim et al., 2011) and PubMed 20k RCT (Dernoncourt and Lee, 2017). The detailed description of both datasets can be found in the appendix. We compare our model with three recent strong neural models, i.e., those of Jin and Szolovits (2018), Cohan et al. (2019), Yamada et al. (2020).

Implementation Details We set the size of hidden state to 200 and apply dropout with the probability of 0.5 for BiLSTM. Both hyperparameters λ_{att} and λ_{span} are set to 0.3. The batch size is 30. We use Adam optimizer with learning rate 0.003 and weight decay 0.99 for training. For evaluation, we maximize the score from sentence-level CRF to get the predicted labels of the corresponding se-

quence. Following Yamada et al. (2020), we use Sentence-F1 and Span-F1 as evaluation metrics[1].

3.2 Experimental Results

Tabel 1 report the performance of our approaches against other methods on PubMed 20k RCT and NICTA-PIBOSO, respectively. The results of other methods are obtained from Yamada et al. (2020).

We can observe that our model, whether Sentence-F1 or Span-F1, is significantly better than other methods on NICTA-PIBOS, and we get a result comparable to Yamada et al. (2020) on PubMed 20k RCT. We believe that our model has remarkable performance on NICTA-PIBOS, which has fewer training samples but larger label space, because our model can capture latent segment structure by SDLA component and improve span representations by auxiliary span-based classification.

In addition, table 2 and 3 show the detail results of Span-F1 scores for each rhetorical label. Our model achieves better or similar performance than other baselines, except for "other" on NICAT-PIBOSO and "background" on PubMed 20k RCT. We speculate that the reason is that the sentence semantics corresponding to the "other" label are diverse and not significantly distinguishable from other labels, while the "background" usually appears before the "objective", and the sentence presentations of the two are easily confused.

3.3 Segmentation Performance Evaluation

Specially, if we ignore the rhetorical labels of sentences and only consider the segment boundaries (i.e. binary classification, whether it's a boundary), this can be regarded as text segmentation (Koshorek et al., 2018). We evaluate the segmentation performance of our model using the probabilistic P_k (Beeferman et al., 1999) error score (lower number, the better). The results[2] are shown in the last column of Table 1. Our model consistently outperforms other baselines, suggesting that it also contributes to the text segmentation task.

- w/o supervised signal	84.9	59.1
- w/o span-based classification	85.6	61.0
PubMed 20k RCT		
Ours	**92.8**	**84.5**
- w/o SDLA	92.3	82.4
- w/o supervised signal	92.6	82.9
- w/o span-based classification	92.6	83.4

Table 4: Ablation study on two datasets.

3.4 Ablation Study

To investigate the effectiveness of the designed components, we conduct an ablation study on the proposed model, and the results are listed in Table 4. With the help of the SDLA component, the performances are improved significantly, and the way we impose the supervised signal to guide the attention proves effective for yielding more true positives. And the auxiliary task of span classification effectively improves Span-F1.

3.5 Attention Visualization and Case Study

As shown in Figure 3, by incorporating supervised signal, the attention focus on a continuous local

[1]Please refer to Yamada et al. (2020) for the detailed calculation way of Sentence-F1 and Span-F1.

[2]Since Yamada et al. (2020) don't release their codes, we are unable to evaluate its P_k performance. The P_k results of other models are obtained by running their codes.

span around the gold span. The visualization results not only verifies the effectiveness of the supervised signal, but also reveals the interpretability of our proposed SDLA.

Table 5 shows the results of **Base** and **Ours** method for an abstract obtained from NICTA-PIBOSO. Our model correctly identified the boundary between the spans labeled by background (B) and other (O), which shows our model benefit from capturing latent segment structure identifying the more indistinguishable segmentation boundaries.

4 Conclusion

In this paper, we propose a novel model for SSC task, which includes a supervised dynamic local attention to explore the latent segment structure of the document, and an auxiliary task to improve the performance at span-level representations. We demonstrate the effectiveness of our model on two datasets and find that our model also performs well in the text segmentation scenario. In future work, we will consider joint learning sequential sentence classification and text segmentation.

How effective is BERT without word ordering? Implications for language understanding and data privacy

Jack Hessel

Abstract

Ordered word sequences contain the rich structures that define language. However, it's often not clear if or how modern pretrained language models utilize these structures. We show that the token representations and self-attention activations within BERT are surprisingly resilient to shuffling the order of input tokens, and that for several GLUE language understanding tasks, shuffling only minimally degrades performance, e.g., by 4% for QNLI. While bleak from the perspective of language understanding, our results have positive implications for cases where copyright or ethics *necessitates* the consideration of bag-of-words data (vs. full documents). We simulate such a scenario for three sensitive classification tasks, demonstrating minimal performance degradation vs. releasing full language sequences.

1 Introduction

Masked language models (MLMs) like BERT (Devlin et al., 2019) use an ordered sequence of tokens as input. And rightfully so! Any model capable of "language understanding" undoubtedly *should* need access to the hierarchical, syntactic structures implicitly encoded in language. But are MLMs really doing better *because* they have access to full word sequences?

To assess this question, we first compare the internal representations of BERT and RoBERTa (Liu et al., 2019) when the sequence of unigrams is not available.[1] We do this by using the bag-of-words counts of an input to generate a random ordering of the unigrams, i.e., "shuffling" the input. For example, in a sentiment classification corpus, if an intact input was "The movie was great!", a possible shuffled ordering might be "movie the great was" (tokenization details are in §4). We find that, though BERT appears to become more sensitive to ordering in later layers, shuffled token representations and self-attention activations still closely resemble their unshuffled counterparts.

Following cues from prior work (Sugawara et al., 2020; Si et al., 2019; K et al., 2020), we next report the performance of pre-trained MLMs fine-tuned on GLUE, a suite of English-language understanding benchmarks, when given access only to unigram count information by handing models randomly ordered sequences of words (an approach we call BoW-BERT, for short). For most GLUE tasks, performance degradation when shuffling is minimal, e.g., MNLI, QQP, and QNLI accuracy degrade by less than 5 accuracy points.

The bad news: Despite BERT being trained on intact word sequences, BoW-BERT demonstrates that MLMs can readily ignore syntax (while maintaining strong performance) when fine-tuned for even carefully designed downstream language understanding tasks.[2] We thus advocate for reporting BoW-BERT's performance as a strong baseline.

The good news: BoW-BERT offers a practical modeling choice for researchers who *must* operate with only bag-of-words representations for legal or ethical reasons.[3] Bag-of-words data releases are sometimes the *only legal format* in which copyright-sensitive corpora may be distributed, e.g., HathiTrust[4] (16M historical volumes) (Christenson, 2011), Google N-grams (Michel et al., 2011), etc. And while ethical considerations sometimes preclude the full release of privacy-sensitive docu-

[1] We use the "base" models supplied by the authors

[2] Bowman and Dahl (2021) provide perspective on "fixing" NLU tasks.

[3] This is a surprisingly common case: our initial motivation for BoW-BERT was our experience in exploring such a corpus.

[4] In Authors Guild, Inc. v. HathiTrust (2014), the 2nd Circuit U.S. Court of Appeals ruled that showing only "*the number of times [a search term] appears on each page*" constitutes legal fair use, but "[displaying] to the user any text from the underlying copyrighted work" might not.

ments (e.g., medical transcriptions), bag-of-words data release offers the potential for compromise. While releasing unigram counts is one way of anonymizing documents (Gallé and Tealdi, 2015), recent work in differential privacy (Dwork, 2008; Fernandes et al., 2019; Schofield et al., 2019; Schein et al., 2019) has resulted in randomized algorithms capable of privatizing BoW count data (under varying definitions of privacy).[5]

We explore classification tasks on three sensitive corpora, simulating different input fidelity availability: full sequences, BoW counts, and differentially private (DP) BoW counts. We find that BoW-BERT often significantly outperforms prior BoW models, especially for shorter documents. And, for longer documents, BoW-BERT can even outperform full-sequence BERT. Finally, for the (naive) DP configuration we consider, BoW-BERT is a viable option for classifying shorter privatized documents, though linear BoW models remain competitive for longer documents.

2 Related Work

Shuffling inputs to non-pretrained models. Word order shuffling has been tested as part of the full training process for non-pretrained models. Sankar et al. (2019) shuffle words in a dialog corpus, and find that LSTMs are more sensitive than Transformers to word order. Khandelwal et al. (2018) show that shuffling distant context words (e.g., beyond 50 tokens) has little effect in outcome for LM-LSTMs. Adi et al. (2017) show that LSTM autoencoders encode significant ordering information when fit to a corpus of Wikipedia sentences. Nie et al. (2019) report minimal performance decreases from word shuffling while training a number of model architectures, e.g., ESIM (Chen et al., 2017), for SNLI/MNLI tasks. In a multimodal setting, Cirik et al. (2018) show that shuffling doesn't affect performance for an LSTM in a referring expression task.

Shuffling inputs to pretrained MLMs. While at the time of submission of this work, shuffling results had not been fully reported on the popular GLUE taskset, prior results have used word-shuffling as a baseline with varying results.

Sugawara et al. (2020) operationalize ablations of reading comprehension skills from Kintsch (1988), and report that shuffling n-grams in 10 QA corpora results in 10-20% performance decreases for BERT. Si et al. (2019) report similar results when shuffling questions+answers in MCRC corpora, reporting absolute accuracy drops of between 5-20% when shuffling both passage/question words (e.g., BERT on DREAM drops from 63 → 41 accuracy relative to a 33% constant baseline). K et al. (2020) report that swapping tokens during pretraining of a multilingual BERT model results in moderate performance degradation for XNLI (e.g., 71 → 63 for en-es) but more significant performance degradation for NER (63 → 40 in the same setting). They find that a purely frequency-based corpus "is not enough for a reasonable cross-lingual performance."

Several works have examined shuffling inputs in multi-language scenarios (e.g., translation) when languages have variable syntax (Ahmad et al., 2019; Liu et al., 2020). Zhao et al. (2020) use a random token permutation to provide a baseline. Yang et al. (2019) find that self-attention networks are surprisingly bad at identifying two tokens that are swapped in the input. Ettinger (2020) show that shuffling BERT inputs decreases word cloze prediction performance on a corpus of 102 sentences without fine-tuning. Wang et al. (2020) incorporate a deshuffling objective into pre-training.

In some cases, shuffled inputs provide a stronger baseline than might be assumed, while in others, shuffling significantly degrades performance. At present, determining whether or not order is "needed" for a particular task is largely an experimental, empirical endeavor.

Syntax in MLMs. Prior works have investigated BERT's capacity to represent syntax: some researchers have designed prediction tasks that require syntactic knowledge (Linzen et al., 2016; Jawahar et al., 2019; Lin et al., 2019; Goldberg, 2019), while others have probed representations for linguistic information directly (Mareček and Rosa, 2018; Liu et al.; Hewitt and Manning, 2019; Reif et al., 2019). Tenney et al. (2019) find that contextual representations outperform lexical representations on many syntactic tasks, but not in a suite of semantic prediction tasks. Htut et al. (2019) and Clark et al. (2019) find that some attention heads encode information useful for dependency parsing. Glavaš and Vulić (2020) show that intermediate supervised training of a biaffine parser has little effect on downstream MLM performance.

[5] Releasing BoW counts is related to, but distinct from, the setting considered by Beigi et al. (2019), who produce private vector representations with uninterpretable dimensions.

A Bouquet of Contemporaneous Work. While this work was in submission, several related works were posted to arXiv. Gupta et al. (2021) examine NLI, paraphrase detection, and sentiment classification, and show that destructive interventions do not significantly affect either model predictions or model confidence. Sinha et al. (2020) find a similar result for NLI tasks, and, in follow-up work, Sinha et al. (2021) demonstrate pretraining is possible on unordered sequences. Pham et al. (2020) look specifically at GLUE classification for BERT-based models. Beyond contemporaneous confirmation of the GLUE results, our work contributes to this bouquet by: 1) examining internal activations/layers and 2) exploring classification settings where one might need to operate on (potentially differentially private) count-only data.

3 Representation analysis

We might expect that shuffling the order of tokens in an input sentence would significantly corrupt the internal representations of BERT, but is that actually the case? We investigate with two new metrics. Consider applying a pre-trained, fixed BERT model to $x =$"the movie was great" and the shuffled $x' =$"movie the great was".

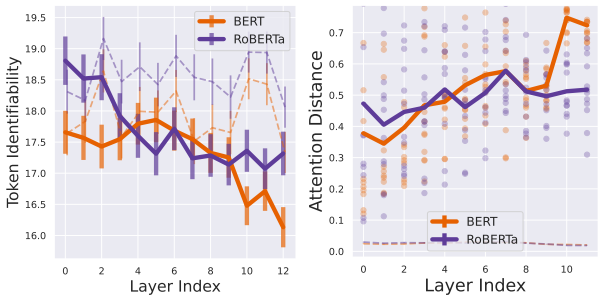
Token identifiability measures the similarity of BERT's vector representations of a word token (e.g., "movie") in x and x'. Identifiability is high if the model has similar representations for tokens after their order is shuffled.

Self-attention distance measures if BERT attends to similar tokens for each token in x and x' regardless of their order (e.g., is "the movie was great" $\approx$ "movie the great was" to BERT?). Self-attention distance is low if the model attends to the same tokens after input shuffling.

Token Identifiability. Let $\texttt{MLM}_l(x)$ be a $\mathbb{R}^{t\times d}$ matrix, where t is the number of tokens in sentence x, d is the MLM's dimension, and l is the layer index. In this setting, row i of $\texttt{MLM}_l(x)$ is the MLM's representation of the ith token in sentence x. We compare $\texttt{MLM}_l(x)$ to $\mathbb{E}[\texttt{MLM}_l(X')]$, where X' is drawn uniformly from the permutations of x: $perm(x)$. For a specific sample $x' \sim perm(x)$, we first take the row-wise cosine similarity of $\texttt{MLM}_l(x)$ and $\texttt{MLM}_l(x')$, and treat the resulting $t \times t$ matrix as an instance of a bipartite linear assignment problem. The *assignment accuracy* (AA) score for (x, x') is the proportion of assigned token pairs that have the same underlying word type. To avoid biasing towards shorter sentences, we take the ratio of the accuracy relative to chance, i.e.,

$$\text{ID-MLM}(x, l) = \frac{\mathbb{E}_{X'}[\text{AA}(\texttt{MLM}_l(x), \texttt{MLM}_l(X'))]}{\mathbb{E}_{\texttt{RAND}}[\text{AA}(\texttt{MLM}_l(x), \texttt{RAND})]}, \quad (1)$$

where RAND is a random matrix of reals $\mathbb{R}^{t\times d}$.[6]



(a) Identifiability (b) Self-Attention Distance

Figure 1: Token identifiability and attention distance by layer for BERT and RoBERTa; dashed lines represent baseline values of metrics with unshuffled sequences, error bars are 95% CI for mean, scatterplot=per-attention head result. Identifiability decreases towards 1 (pure random token features) when shuffled inputs produce very different embeddings from the intact inputs, while self-attention distance increases towards 1 (pure random attention) in this case. While later layers in both models are more order-sensitive, information is retained for shuffled inputs.

Self-Attention Distance. Let $\texttt{AMLM}_{l,h}(x)$ be the row-l_1-normalized $\mathbb{R}^{t\times t}$ matrix representing the self-attention matrix at layer l for attention head h. We can compute the same matrix for a shuffled input $\texttt{AMLM}_{l,h}(x')$, and then perform a transformation to re-order the rows and columns of this matrix to match the original order of tokens in x, yielding $\texttt{AMLM}^x_{l,h}(x')$. We then define the *row-wise Jensen-Shannon divergence* DS-JSD$(\texttt{AMLM}_{l,h}(x), \texttt{AMLM}^x_{l,h}(x'))$ as the mean row-wise JSD between $\texttt{AMLM}_{l,h}(x)$ and the DeShuffled reordered attention matrix $\texttt{AMLM}^x_{l,h}(x')$. As before, to reduce the effect of sentence length, we normalize using RND-JSD$(\texttt{AMLM}_{l,h}(x), \texttt{AMLM}^x_{l,h}(x'))$, which chooses a random row/column permutation. [7] The

[6] In practice, we simply compute the assignment step of AA using a $\mathbb{R}^{t\times t}$ matrix drawn from $U[0, 1)$.

[7] If there are multiple possible valid permutations of x' that match x (e.g., if there are repeated words), DS-JSD will choose the order that minimizes the JSD, and RND-JSD will search through a number of random orderings equal to the number of valid permutations. If the number of valid permutations is > 16, 16 random valid permutations are sampled.

	MNLI-(m/mm) Acc/Acc	QQP F1/Acc	QNLI Acc	SST-2 Acc	CoLA MCC	STS-B PCC-r/SCC-ρ	MRPC F1/Acc	RTE Acc

Table 1: GLUE test set prediction results.

final *attention distance* metric is defined as

$$\text{AD-MLM}(x, l, h) = \frac{\mathbb{E}_{X'}[\text{DS-JSD}(\texttt{AMLM}_{l,h}(x), \texttt{AMLM}^{x}_{l,h}(X'))]}{\mathbb{E}_{X'}[\text{RND-JSD}(\texttt{AMLM}_{l,h}(x), \texttt{AMLM}^{x}_{l,h}(X'))]} \quad (2)$$

Results. We randomly sample 100 sentences from each training set of 8 GLUE tasks, for a total of 800 sentences. To approximate expectations from Equations 1 and 2, we sample 32 random permutations per sentence. Figure 1 gives the per-layer token identifiability/attention similarity scores for both MLMs. For both metrics, later layers are more order sensitive to order, i.e., ID-MLM ↓ and AD-MLM ↑. Attention heads vary significantly in their order sensitivity: each attention head is a single point in the scatterplot of Figure 1b. But, even at late layers, both metrics suggest significantly more than random correspondence: internal representations of BoW-(Ro)BERT(a) clearly resemble their unshuffled counterparts.

4 BoW-BERT for Classification

We compare BERT and RoBERTa to their BoW counterparts on nine tasks from GLUE (Wang et al., 2019).[8] We run single-task training for six epochs, use early stopping, and optimize batch size ($\{16, 32\}$) and learning rate ($\{5, 2, 1, .5\} \times 10^{-5}$) via grid search on the validation set. To shuffle documents: we lowercase, tokenize, remove all tokens that consist only of punctuation, shuffle, then concatenate with whitespaces. We re-shuffle the training tokens each epoch, but fix validation and test tokens to one shuffled permutation.

[8]These tasks span NLI (MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016), and RTE (Dagan et al., 2006; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009)); semantic similarity estimation (QQP,[9] MRPC (Dolan and Brockett, 2005), STS-B (Cer et al., 2017)); sentiment analysis (SST-2 (Socher et al., 2013)), and grammaticality judgement (CoLA (Warstadt et al., 2019)). We omit WNLI (Levesque et al., 2011) as is common (all models achieve chance performance on that corpus).

Results. Table 1 gives the GLUE test set results of our algorithms vs. GloVe CBOW, the best BoW baseline on the GLUE leaderboard at the time of submission. In all cases BoW-BERT outperforms CBOW. The extent to which BoW-BERT underperforms relative to BERT varies for each dataset, but in terms of relative percent performance decrease, ranges from over ↓70% for CoLA to only ↓3% QQP. Outside of CoLA, performance degradation never exceeds 10 absolute points for any task's metric.

According to the GLUE diagnostic set (which tests 33 categories of linguistic phenomena) BoW-BERT has the most trouble with dealing with double negations (e.g., "I have never seen a hummingbird not flying.": MCC degrades 31.7 → -4.3 when switching BERT → BoW-BERT), quantifiers ("our sympathy to all [vs. some] of the victims": 61.8 → 46.1); and temporal logic ("Mary left before John entered": 8.0 → -8.6). Results for GLUE diagnostic meta-categories are: Knowledge (24.4 → 24.3); Pred-Arg Structure (39.2 → 39.1); Logic (24.7 → 22.1); Lexical Semantics (39.7 → 31.5).

Classification for Sensitive Texts

Privacy and legal concerns frequently necessitate BoW-only data releases. We ask: for potentially sensitive text classification tasks, *how does performance degrade if only bag of words counts are available (instead of full sequences)?* We consider three such tasks: Reddit controversy prediction on AskWomen/AskMen (CONT) (Hessel and Lee, 2019), offensiveness prediction in social media (SBF) (Sap et al., 2020), and sample medical transcript categorization (MTSAMP).[10] For each task, we compare models with access to sequences vs. models that can only access bag-of-words features. Our baselines are unigram/tfidf linear models, and CBOW models GloVe and fasttext (Mikolov et al., 2018). Table 2 contains corpus

[10]https://www.mtsamples.com/

statistics and prediction results. For CONT and SBF, BoW-BERT outperforms all BoW methods. For all tasks, performance drop-off from a full-sequence fine-tuned MLM to its BoW counterpart is less than 1%. CBOW/tfidf remain strong for MTSAMP, in which documents are longer.

Given that de-shuffling BoW representations is at least partially possible (Tao et al., 2021), we additionally consider a more robust *differentially private* (DP) unigram count data release (also known as the "local model" of DP) (Warner, 1965; Dwork et al., 2006; Schein et al., 2019). We follow a process similar to Schofield et al. (2019) by first compressing the original unigram count matrices via Gaussian random projection to 500D.[11] In the compressed space, we add noise per-entry with the Laplace mechanism (Dwork et al., 2006) with a per-feature privacy budget of ε. Then, we invert the random projection, normalize the vector to be a categorical word distribution, and sample (unordered) pseudodocuments from the resulting distribution with length $\sim Poisson(\ell)$.

We report results in an easier setting $\ell = 256, \varepsilon = 100$ and a harder setting $\ell = 128, \varepsilon = 50$ in the bottom half of Table 2. For these settings of DP, the linear baselines generally outperform BoW-(Ro)BERT(a). However, MLMs are again most competitive for the shortest document setting, SBF, where BoW-(Ro)BERT(a) exceeds the best linear model performance (60.4 vs. 62.0 F1).

Taken together, these results suggest 1) that releasing word counts instead of full document sequences is a viable data release strategy for some sensitive classification tasks; 2) BoW-BERT offers a means of accessing the representational power of modern MLMs in cases where only BoW information is available; and 3) for at least some local DP settings, linear models remain competitive particularly for long documents, while BoW-RoBERTa is viable when the underlying documents are shorter.

5 Conclusion and Future Work

We advocate for BoW-(Ro)BERT(a) as a surprisingly strong baseline for language understanding tasks, as well as a performant practical option for classifying (privatized) BoW texts when documents are short. Future work includes:

1. Evaluating BoW-BERT representations on BoW-only corpora in unsupervised text clustering scenarios (vs. classification) + designing self-supervised objectives for fine-tuning MLM weights from unlabelled domain-specific BoW corpora, e.g., HathiTrust.;
2. Extending (K et al., 2020) by further exploring BoW classification using non-English MLMs, where model dependence on syntactic information may differ;
3. Designing local private data release methods better adapted to MLM fine-tuning.

Acknowledgments. We thank David Mimno, Gregory Yauney, Chandra Bhagavatula, Keisuke Sakaguchi, and Max Chen for helpful discussions, comments, suggestions, and (in one case) physically rescuing files from an unplugged server. We also thank Gautam Kamath for feedback on an earlier version of the differential privacy section. Finally, we thank both our EACL and ACL reviewers for their thoughtful feedback.

Table 2: Top: text classification prediction results on sensitive texts; **best BoW** bolded, *best overall* italicized. Bottom: *DP* = results on differentially private data; "Best Linear" is the most performant linear model, tfidf for $DP^{\varepsilon=100}_{\ell=256}$ and unigram counts for $DP^{\varepsilon=50}_{\ell=128}$.

[11] Our original submission used DP PCA instead. But it was brought to our attention that the paper proposing that algorithm was retracted for being non-private (+ discontinued in the library we used after we submitted). We have adjusted our code and recompiled our experiments using a comparable mechanism. Our intent isn't to advocate for this particular DP method, but rather, to fairly compare NLP algorithms on the same DP corpora.

Abstract

Recent works have made significant advances on summarization tasks, facilitated by summarization datasets. Several existing datasets have the form of coherent-paragraph summaries. However, these datasets were curated from academic documents written for experts, making the essential step of assessing the summarization output through human-evaluation very demanding.

To overcome these limitations, we present a dataset[1] based on article summaries appearing on the WikiHow website, composed of how-to articles and coherent-paragraph summaries written in plain language. We compare our dataset attributes to existing ones, including readability and world-knowledge, showing our dataset makes human evaluation significantly more manageable and effective. A human evaluation conducted on PubMed and the proposed dataset reinforces our findings.

1 Introduction

Summarization is the task of preserving the key information in a text while reducing its length. Recently, many summarization datasets were published and helped push the boundaries of new summarization systems. These datasets differ on several properties, including the domain (e.g., academic or news) and the summary form. PubMed, arXiv, and BigPatent (Cohan et al., 2018; Sharma et al., 2019) provide a summary in the form of coherent paragraphs (i.e., each sentence flows smoothly into the next). In contrast, other summarization datasets (Hermann et al., 2015; Grusky et al., 2018; Koupaee and Wang, 2018; Ladhak et al., 2020) offer a summary in the form of a key points list (i.e., highlights). In this paper, we focus on coherent paragraph summarization datasets.

How to Bake Chicken Breast? To bake chicken breast, start by lining a baking dish with foil or parchment paper. Then, put the chicken in the baking dish and bake it for 30-40 minutes at 400 degrees Fahrenheit, or until it reaches an internal temperature of 160 degrees Fahrenheit.
How to Break Up with Your Friend? The best way to break up with a friend is to confront them. Choose a time and place to meet up and explain to them why you are ending the friendship. Allow your friend to speak their mind as well, and work together to set boundaries for moving forward.

Figure 1: Examples of how-to questions and their corresponding answer's summarization in WikiSum.

Automatic evaluation of summarization systems, e.g., by using the ROUGE metric, is challenging (Lloret et al., 2018) and is often inconsistent with human evaluation (Liu and Liu, 2008; Cohan and Goharian, 2016; Tay et al., 2019; Huang et al., 2020). To understand – and later improve – the quality of summarization systems, it is necessary to conduct a human evaluation. A human evaluation's quality depends on the ease of reading and understanding of the measured text: a simple text does not require annotators with unique expertise, can be evaluated faster, and is easier to annotate correctly. However, existing coherent-paragraph summarization datasets consist of academic papers and cannot be considered easy to read. Evaluating such summarization samples requires unique expertise, takes time, and comes at a high cost.

In this work, we present WikiSum, a new summarization dataset from the WikiHow knowledge base[2]. The WikiSum documents are written in simple English, and the summaries provide "non-obvious tips that mimic the advice a knowledgeable, empathetic friend might give."[3] Unlike previous WikiHow summarization (Koupaee and Wang, 2018; Ladhak et al., 2020) datasets and summaries

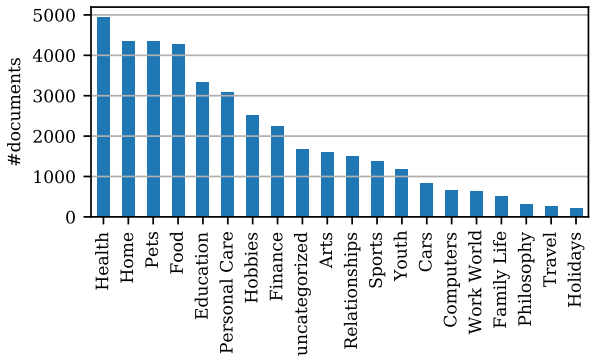

Figure 2: Category distribution in WikiSum.

from the news domain, the summaries of WikiSum are in the form of a coherent paragraph written by the document authors (examples in Figure 1). Moreover, in contrast to other coherent-paragraph summarization datasets from the academic domain, WikiSum is written using simple English. This critical property can help with the challenging task of evaluating summarization systems and provide insights that can go unnoticed using automatic evaluation methods.

The key attributes of WikiSum are: (1) Summaries written as a single, coherent passage. (2) Articles and summaries that are easy to read. (3) Articles and summaries require less world knowledge to understand. We evaluate the dataset readability and estimate the required world-knowledge in Section 3. Moreover, we reinforce our results by conducting a human-evaluation of a summarization dataset in Section 4. Finally, to establish a baseline on the proposed dataset, we benchmark WikiSum using recent summarization systems and report their performance on Section 5.

2 Related Work

The summarization landscape can be roughly divided into three primary summary-forms: (1) Single sentence (Napoles et al., 2012; Grusky et al., 2018; Narayan et al., 2018; Kim et al., 2019) - summarize the document in a single sentence; (2) Highlights (Hermann et al., 2015; Koupaee and Wang, 2018; Ladhak et al., 2020) - a summary in the form of bullets listing the key points in the text; (3) Coherent summary (Sharma et al., 2019; Cohan et al., 2018) - short coherent paragraphs describing the salient information. The summarization datasets from the news domain, which are commonly used for human evaluation, include summaries in the form of highlights or single-sentence summaries. However, summarization datasets written in a coherent format come from the academic domain, making them extremely difficult to annotate manually. Our proposed WikiSum is the only dataset written in a coherent format, yet easy for human evaluation. We do not claim that coherent paragraph summaries are *better*, but rather *different*; each format has its use cases, and human evaluation should be done on each of the different formats separately.

The existing WikiHow datasets (Koupaee and Wang, 2018; Ladhak et al., 2020) can be considered the closest to WikiSum, as they originate from the same knowledge base. However, while the existing WikiHow datasets split the article to generate the document and summary, WikiSum uses the entire article as the document and a summary specifically written by the article's author (called the Article Quick Summary). The former uses the concatenation of the first line of each step, called the step header, as the list of highlights and the remainder of step text's concatenation called "wrap-text," as the document[4]. In addition to the different summary-form of the highlight-based WikiHow and WikiSum, the content of the summaries is significantly different, which can be illustrated by the low BLEU-4 (0.06[5]) between the two.

BigPatent (Sharma et al., 2019), Arxiv and PubMed (Cohan et al., 2018) are recent summarization datasets with coherent paragraph summaries. These datasets focus on the academic domain and are written for experts. Like these datasets, WikiSum is composed of long documents and coherent paragraph summaries. Nonetheless, it uses common everyday language and ranges over many domains (see Figure 2). Finally, Table 1 compares WikiSum to common existing datasets. Additional details on WikiSum are available in the appendix.

3 Measuring Text Difficulty

This section focuses on two crucial attributes: ease of readability and external knowledge required, shown (in Section 4) to be important for easy and effective human evaluation. For brevity, we focus on summarization datasets with coherent-paragraph summaries.

[4]WikiHow author instructions (wikihow.com, 2020) specifically states that the authors can use the wrap-text to describe why the step header is important. This leads to many cases where the step headers are not a summary of the wrap-text.

[5]We used WikiSum as the reference, the results are very similar when WikiHow is used as a reference. ROUGE-1, 2 and L are 0.37, 0.13, and 0.23, respectively.

	Domain	# Docs	Comp. ratio	Summary # word	Summary # sent	Doc # word
WIKISUM	instructional	39,775	13.9	101.2	5.0	1,334.2
ARXIV	academic	215,913	39.8	292.8	9.6	6,913.8
PUBMED	academic	133,215	16.2	214.4	6.9	3,224.4
BIGPATENT	academic	1,341,362	36.4	116.5	3.5	3,572.8

XSUM	news	226,711	18.8	23.3	1.0	431.1

Table 1: Statistics comparison of summarization datasets. Datasets not in coherent-paragraph form are marked in gray.

3.1 Readability

Readability metrics attempt to indicate how difficult a passage in English is to read. We used classical readability measures, including FKGL (Farr et al., 1951), GFI (Robert, 1968), SMOG (Mc Laughlin, 1969), ARI (Senter and Smith, 1967), CLI (Coleman and Liau, 1975). All these metrics are based on lexical features of the text, e.g., number of words in a sentence or mean number of syllables per word. They produce a score that is interpreted as the number of years of formal education required (for a native English speaker) to understand a piece of text[6].

For each document, we measured readability scores[7] for the document and the ground truth summary. The document is longer than the summary, so its readability is of higher importance. We report the average readability score for all the samples in the dataset.

Readability scores for the documents are presented at the top of Table 2. The table shows that WikiSum is significantly easier to read than other documents from coherent-summary datasets (arXiv, PubMed, BigPatent). Similar results can be found for the readability scores for the summaries (bottom of Table 2). To conclude, WikiSum is measured as drastically simpler to read than other coherent-summary datasets.

3.2 External Knowledge

Existing datasets are composed of academic documents that are written for experts. Often, to fully understand academic texts requires domain knowledge, which makes the annotator pool smaller, and thus, in most cases, more expensive. Word frequency is a strong indicator of how familiar a word is (Paetzold and Specia, 2016), where rare words tend to be less familiar.

We used OpenSubtitles (Lison and Tiedemann, 2016), text corpora compiled from an extensive database of movie and TV subtitles to obtain word frequencies. We hypothesize that movie and TV subtitles can roughly represent common knowledge among many people. In Figure 3, we show the percentage of non-frequent words in a document (i.e., words that cannot be found in the top-k words in OpenSubtitles) as a function K, averaged over a random sample of $10,000$ documents from each dataset. This figure clearly shows that WikiSum is composed of significantly fewer words unpopular in TV shows and movies, requiring less specialized external knowledge.

[6]Other readability metrics such as FRE (Flesch, 1948), LIX and RIX (Björnsson, 1968), have a similar trend to the shown metrics, but require a translation to years of education, omitted from this paper for brevity.

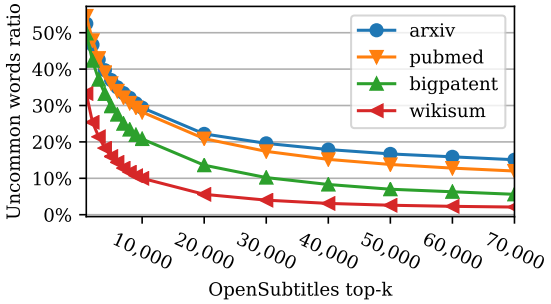

Figure 3: Ratio of uncommon words in the document, which cannot be found in the Top-K OpenSubtitles words, for different k values.

4 Human Evaluation

We conducted a standard human evaluation on a summarization task, in addition to the automatic readability and the external knowledge metrics. We gathered a pool of 6 annotators, without any prior knowledge of the project, all with a graduate degree (M.sc. or Ph.D.) and proficient English reading-level. We asked them to evaluate summaries generated by Pegasus (Zhang et al., 2020). The an-

dataset	time (minutes)	difficulty (rating)	exhausting (rating)	qualified (rating)	unknown (%)
WikiSum	6.8±1.2	1.9±0.3	2.2±0.5	4.2±0.3	0.2±0.1
PubMed	10.0±1.2	3.7±0.3	3.9±0.4	2.2±0.4	3.7±1.4

Table 3: Evaluation time per sample, evaluation difficulty/exhaustion rating, perceived qualification, and the ratio of unknown words in the document. ± denotes 95% confidence interval according to student's t distribution (df=20). Difficulty, qualification, and tiring were marked on a 1-5 scale.

notation task followed Huang et al. (2020) and consisted of relevance, consistency, fluency, and coherency.

Due to resource limitations (and the difficulty of annotating articles from the academic domain), we had to pick one coherent-paragraph dataset for comparison with WikiSum. To avoid annotators' domain bias, we selected articles from PubMed, which contains articles not in the area of expertise of any annotator, in addition to WikiSum. We sampled random articles with 950 - 1050 words to avoid length bias, ensuring that article length is similar in both datasets. All annotators allocated 1 hour, which amounted to 42 annotations, 21 for each dataset.

During the annotation task, we measured the evaluation time and asked the annotators to mark unfamiliar words. In addition, we asked the annotators to rate the following aspects on a 1-5 scale: (a) How difficult was the task? (b) How tiring was it? (c) How qualified are you for this task? After each pair of PubMed and WikiHow samples were completed, the annotators selected which dataset they prefer to evaluate.

In Table 3 we show the annotators' assessment of the tasks. Compared to PubMed, a WikiSum annotation takes significantly less time, is less difficult, and less tiring. Moreover, the annotators revealed that they were much more qualified to assess the WikiSum task summary. Finally, in 90% of the cases (19 out of 21), the annotators revealed that they preferred a WikiSum annotation task. This reinforces our findings that WikiSum is significantly easier to annotate than PubMed.

In the annotation task, we also asked the annotators to mark unfamiliar words in the article. We found a strong correlation between the count of unfamiliar words and the task difficulty, evaluation time, and perceived required qualification (Pearson correlation of $0.57, 0.36, -0.48$[8], respectively, $p < 0.05$). Strong correlation was also found between the ARI readability metric (Section 3.1) and the above-mentioned annotation metrics (Pearson correlation of $0.69, 0.49, -0.76$, $p < 0.05$). This demonstrates the effect of readability on the difficulty of an annotation task.

Finally, we found that unfamiliar words correspond to low-frequency OpenSubtitles words (Section 3.2). The *unfamiliar* words on WikiSum and PubMed appear in the top $91,550$ and $230,596$ words on average, respectively, while *familiar* words appear in the top $16,935$ and $59,244$ words on average, respectively. It also further validates Paetzold and Specia (2016) hypothesis about the strong correlation between word frequency and complexity.

Models	LEAD-3	TextRank	PEGASUS$_{\text{LARGE}}$
WIKISUM	25.3/6.84/16.2	32.7/8.8/18.9	43.35/15.48/26.91
ARXIV	25.53/5.98/15.22	33.1/9.7/18.1	43.07/19.70/34.79
PUBMED	26.38/8.73/16.6	35.3/13.1/20.4	44.70/17.27/25.80
BIGPATENT	28.9/7.96/18.17	33.0/9.8/19.6	45.49/19.90/27.69

Table 4: ROUGE-1/2/L F1 scores on coherent-summary datasets. Pegasus baseline results are from (Zhang et al., 2020), except for WikiSum.

5 Model Results and Discussion

To provide both abstractive and extractive baselines for WikiSum, we evaluate on PEGASUS$_{\text{LARGE}}$ (Zhang et al., 2020), TextRank (Mihalcea and Tarau, 2004), and the common LEAD-3 that selects the first three sentences of the document as the summary. We compare the results on WikiSum to the Arxiv, PubMed, and BigPatent Datasets results. Table 4 reports the F1 scores of ROUGE-1, 2 and L for all the models. The results show that the models' performance on WikiSum is not drastically different from the other datasets, making it an interesting dataset for benchmarking summarization systems. The detailed evaluation setup can be found in the supplementary materials.

To conclude, this paper presents the WikiSum dataset, which is drastically simpler for human evaluation than existing summarization datasets where the summary appears as a coherent paragraph. We showed WikiSum's simplicity via various readability metrics and demonstrated that the text requires less external knowledge to be understood. Finally, we validated our finding via a human evaluation task on WikiSum and PubMed.

[8]Many unfamiliar words implied annotators perceived themselves as less unqualified.

A Data Description

A.1 Gathering the data

We use Scrapy scraper[9] to download articles and summaries from the wikihow.com website. We removed HTML tags using BeautifulSoup[10]. Finally, we removed any sample in which the summary is a list of bullet points; around 7k samples were excluded in this manner.

A.2 Authors Instructions for Writing Quick Summaries

The wikihow.com website provides the following guidelines for authors writing a quick summary.[11]

> The goal of the "Quick Summary" section on wikiHow is to provide a short summary of non-obvious tips that mimic the advice a knowledgeable, empathetic friend might give you if you asked them for help on the given topic. Among other uses, Quick Summaries help smart devices like Google Homes and Amazon Echos deliver wikiHow advice to listeners in need of how-to guidance.

We remark that the quick summaries are indeed used by commercial voice assistants to answer how-to questions. As voice assistants gain popularity, so does the importance of such coherent-paragraph summaries.

A.3 Data Layout

Raw data is available in the supplementary material, in a json format. Each line consists of a single sample, with the following fields

1. Link to the original article
2. Article title
3. Article text
4. Quick summary
5. Split fold (train, dev, or test)

Finally, it also includes *step_headers*: the first line in each step. This is part of the article but might be considered more important, and therefore, it might find further uses by system designers.

A.4 Dataset Statistics

Most dataset statistics appear in Table 1 in the article's main body and are repeated here for completeness. The total number of samples in the WikiSum dataset is $39,775$. On average, each summary consists of 101.2 words, while each article consists of $1,334.2$ words. The average compression ratio is 13.9.

A.5 Evaluation details

We randomly split WikiSum into 35,775 (document, summary) training pairs, as well as 2,000 validation pairs and 2,000 test pairs. The rest of the datasets were downloaded from the HuggingFace dataset repository[12].

All the datasets were evaluated using TextRank[13] and Pegasus-large. The ROUGE scores throughout the paper were calculated using rouge-score[14]. We utilized TextRank to generate three summary sentences. The Pegasus results on Arxiv, Pubmed, and Arxiv were taken from the Pegasus paper. The results on WikiSum were computed by using the Github repository of the Pegasus paper[15]. Pegasus was trained on a single NVIDIA V100 Tensor Core

[15] https://github.com/google-research/pegasus

GPU, using max input and output sequence lengths of 1024 and 256, respectively.

B Example Summaries

In this appendix, we provide an example summary from WikiSum and arXiv, PubMed, and bigPatent. Note that the article can be quite long (for arXiv and PubMed, it is a full academic paper), so it is not presented in this appendix. Instead, we provide a link to the online version of the full article.

B.1 WikiSum

The WikiSum example summary is provided below:

"To ace a test, even if you're not prepared, start by glancing over the test before you get started to get an idea of how long it is so you can manage your time better. Then, read through each question twice and try to answer it. If you can't answer a question, skip it and come back to it later if you can, which will save you from wasting all of your time on one question. If your test is multiple choice and you don't know the answer, eliminate two answers, so you're left with just two options. Then, guess if necessary since you'll have a 50-percent chance of being right."

The article is available at https://www.wikihow.com/Ace-a-Test.

B.2 WikiHow

For the sake of comparison between WikiHow and WikiSum datasets, we provide the WikiHow summary originating from the same raw material (i.e., the same wikihow.com how-to article) as the WikiSum example at Appendix B.1. We remark that the article to be summarized is not exactly the same, as the WikiHow example does not contain the step headers from the article's text. The WikiHow summary is provided below.

"Study well before the test. Get a study friend. Take breaks. Relax. Pay attention in class. Do all available practice questions. Get some sleep the night before. Have proper meals before the test day. Have your test-taking materials assembled and ready. Listen to music you like. Go into the test in a positive manner. Take deep breaths to try to keep calm. Read the questions carefully. Do the easy questions first. Go with your first answer. Use logic if you're stuck on a multiple choice question. Review your answers thoroughly when you are done."

It can easily be seen that the WikiSum summary is a coherent, fluent paragraph, while the WikiHow summary is a set of bullet points. The content of the two summaries are also quite different between the two datasets.

Abstract

Despite the success of various text generation metrics such as BERTScore, it is still difficult to evaluate the image captions without enough reference captions due to the diversity of the descriptions. In this paper, we introduce a new metric UMIC, an **U**nreferenced **M**etric for **I**mage **C**aptioning which does not require reference captions to evaluate image captions. Based on Vision-and-Language BERT, we train UMIC to discriminate negative captions via contrastive learning. Also, we observe critical problems of the previous benchmark dataset (i.e., human annotations) on image captioning metric, and introduce a new collection of human annotations on the generated captions. We validate UMIC on four datasets, including our new dataset, and show that UMIC has a higher correlation than all previous metrics that require multiple references. We release the benchmark dataset and pre-trained models to compute the UMIC[1].

1 Introduction

Image captioning is a task that aims to generate a description that explains the given image in a natural language. While there have been many advances for caption generation algorithms (Vinyals et al., 2015; Anderson et al., 2018) and target datasets (Fang et al., 2015; Sharma et al., 2018), few studies (Vedantam et al., 2015; Anderson et al., 2016; Cui et al., 2018; Lee et al., 2020) have focused on assessing the quality of the generated captions. Especially, most of the evaluation metrics only use reference captions to evaluate the caption although the main context is an image. However, as shown in Figure 1, since there are many possible reference captions for a single image, a candidate caption can receive completely different scores depending on the type of reference (Yi et al., 2020). Because of this diverse nature of image captions, reference-based metrics usually use multiple references which are difficult to obtain. To overcome this limitation, we propose UMIC, an **U**nreference **M**etric for **I**mage **C**aptioning, which is not dependent on the reference captions and use an image-caption pair to evaluate a caption. We develop UMIC upon UNITER (Chen et al., 2020) which is a state-of-the-arts pre-trained representation for vision-and-language tasks. Since UNITER is pre-trained to predict the alignment for large amounts of image-text pairs, we consider that UNITER can be a strong baseline for developing an unreferenced metric. We fine-tune UNITER via contrastive learning, where the model is trained to compare and discriminate the ground-truth captions and diverse synthetic negative samples. We carefully prepare the negative samples that can represent most of the undesirable cases in captioning, such as *grammatically incorrect*, *irrelevant to the image*, or *relevant but have wrong keyword*.

Figure 1: An example where the metric score for a given candidate caption varies significantly depending on the reference type.

When evaluating the metric's performance, it is required to compare the correlations between human judgments and the metric's evaluation score for given datasets. We choose three standard benchmark datasets (i.e., Composite (Aditya et al., 2015), Flickr8k (Hodosh et al., 2013), PASCAL-50s (Vedantam et al., 2015)) and further analyze the quality of the dataset. Interestingly, we found that there exist critical issues in the benchmark datasets,

such as poor-label or polarized-label. To perform a rigorous evaluation as well as stimulate the research in this area, we collect new 1,000 human judgments for the model-generated caption. Finally, we evaluate our proposed metric on four benchmark datasets, including our new dataset. Experimental results show that our proposed unreferenced metric is highly correlated with human judgments than all of the previous metrics that use reference captions.

2 Related Work

Image Captioning Metrics Following other text generation tasks such as dialogue systems and machine translation, n-gram similarity metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and METEOR (Banerjee and Lavie, 2005) are widely used to evaluate an image caption. Especially, CIDEr (Vedantam et al., 2015), which weights each n-gram using TF-IDF, is widely used. SPICE (Anderson et al., 2016) is a captioning metric based on scene graph. BERTScore (Zhang et al., 2019), which computes the similarity of the contextualized embeddings, are also used. BERT-TBR (Yi et al., 2020) focuses on the variance in multiple hypothesis and ViLBERTScore (VBTScore) (Lee et al., 2020) utilizes ViLBERT (Lu et al., 2019) to improve BERTScore.

Different from these metrics, VIFIDEL (Madhyastha et al., 2019) computes the word mover distance (Kusner et al., 2015) between the object labels in the image and the candidate captions, and it does not require reference captions. Similar to VIFIDEL, our proposed UMIC does not utilize the reference captions. However, UMIC directly uses image features and evaluates a caption in various perspectives compared to VIFIDEL.

Quality Estimation Quality Estimation (QE) is a task that estimates the quality of the generated text without using the human references and this task is same as developing an unreferenced metric. QE is widely established in machine translation (MT) tasks (Specia et al., 2013; Martins et al., 2017; Specia et al., 2018). Recently, (Levinboim et al., 2021) introduces a large scale human ratings on image-caption pairs for training QE models in image captioning tasks. Our work also trains caption QE model, (i.e. unreferenced captioning metric) but we do not use human ratings to train the metric. Instead, we create diverse synthetic negative samples and train the metric with these samples via ranking loss.

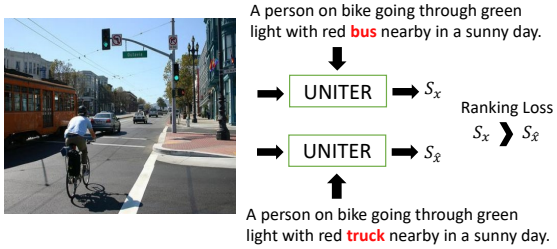

Figure 2: Overall training procedure of UMIC. Given an image I, a positive caption x and a negative caption $\hat{x}$, we compute the score of each image-caption pair S_x and $S_{\hat{x}}$ using UNITER respectively. Then, we fine-tune UNITER using raking loss that S_x is higher than $S_{\hat{x}}$.

3 UMIC

We propose UMIC, an unreferenced metric for image captioning using UNITER. We construct negative captions using the reference captions through the pre-defined rules. Then, we fine-tune UNITER to distinguish the reference captions and these synthetic negative captions to develop UMIC.

3.1 Modeling

Since UNITER is pre-trained to predict the alignment of large amounts of image-text pairs, we use the output of the layer that predicts this alignment as the baseline of UMIC to be fine-tuned. Specifically, we compute the score of a caption $\mathrm{S}(I, X)$ for given image $I = (i_1, ..., i_N)$ and $X = (x_1, ..., x_T)$ as follows.

We first compute the contextual embedding for I and X using UNITER to get the joint representation of image and text as follows.

$$i_{[CLS]}, i_1, ..., i_N, x_1, ..., x_T = \text{UNITER}(I, X), \quad (1)$$

where $i_{[CLS]}$ is a joint representation of the input image and input caption. Then we feed it into a single fully-connected layer to get a score as follows.

$$\mathrm{S}(I, X) = sigmoid(W i_{[CLS]} + b), \quad (2)$$

where W and b are trainable parameters.

3.2 Negative Samples

To model negative captions, we observe the captions' common error types in the model-generated captions. Specifically, we pick 100 bad captions in the order of whose human judgments are low in Composite and Flickr8k, respectively. Then, we categorize the main errors into three types:*relevant but have wrong keywords, totally irrelevant to the image, grammatically incorrect.* To model most

Target Image

Similar Image

Original: a woman hugging a girl who is holding a suitcase

Substitiution: a boy hugging a girl who is holding a suitcase

Random(Hard Negative): a very small cute child by a suitcase

Repetition & Removal: a woman hugging a girl is holding a suitcase suitcase

Figure 3: An example of the generated negative captions for the left image to train UMIC. Hard negative caption is one of the reference captions for the right image which is similar to the left image.

imperfect captions including these frequent type errors, we prepare negative captions as follows.

Substituting Keywords To mimic the captions that are relevant but have wrong keywords, as in the example of Figure 2, we randomly substitute 30% of the words in the reference captions and use them as negative samples like Figure 3. The motivation we choose 30% is that the average length of the generated caption is about 10 words and the number of keywords is usually around three. We only substitute *verb*, *adjective*, and *noun*, which are likely to be keywords since they are usually visual words. Also, we substitute them with the words with the same POS-Tags using the pre-defined dictionaries for the captions in the training set to conserve the sentence structure.

Random Captions We randomly sample captions from other images and use them as negative samples to generate totally irrelevant captions for the given image. Also, similar to the image-text retrieval task, we use hard-negative captions, which are difficult to be discerned, with a probability of 50%. Specifically, we utilize the captions of the images similar to the given images using the pre-trained image retrieval model. We get negative captions that are the captions of the similar image sets computed by image-text retrieval model VSE++ (Faghri et al., 2018) as in (Wang et al., 2020). Then, we sample the captions in the reference captions of the Top-3 similar image sets like the example in Figure 3.

Repetition & Removal We find that some of the captions have repeated words or have incomplete sentences. Hence, we randomly repeat or remove some words in the reference captions with a probability of 30% in the captions to generate these kinds of captions. Specifically, we choose to repeat or remove with a probability of 50% for the sampled word.

Word Order Permutation We further generate negative samples by randomly changing the word order of the reference captions, so that the model sees the overall structure of the sentence, not just the specific visual words.

3.3 Contrastive Learning

Using the negative captions generated by the above rules, we fine-tune UNITER via contrastive loss for positive caption X and negative caption $\hat{X}$ as follows.

$$Loss = max(0, M - (\mathrm{S}(I, X) - \mathrm{S}(I, \hat{X}))), \quad (3)$$

where M is the margin for the ranking loss, which is a hyperparameter. We make each batch composed of one positive caption and four negative captions that are made by each negative sample generation technique.

4 Dataset

We briefly explain the previous benchmark datasets for captioning metrics and analyze the problems for two of these datasets, Flickr8k and Composite. Also, we introduce a new benchmark dataset to alleviate the addressed problems.

4.1 Commonly Used Datasets

Composite consists of 11,985 human judgments for each candidate caption generated from three models and image pair. This dataset's human judgments range from 1 to 5, depending on the relevance between candidate caption and image.

Flickr8k provides three expert annotations for each image and candidate caption on 5,822 images. The score ranges from 1 to 4, depending on how well the caption and image match. All of the captions in this dataset are reference captions or captions from other images.

PASCAL50s contains 1,000 images from UIUC PASCAL Sentence Dataset with 50 reference captions for each image. Different from other datasets, this dataset provides 4,000 caption triplet <*A*, *B*, *C*> composed of 50 reference captions(*A*) and two candidate captions(*B*, *C*) for the given image. There

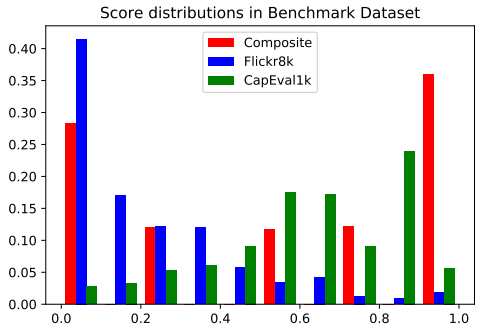

Figure 4: Score distributions of human judgments in Composite, Flickr8k and our proposed CapEval1k dataset. All scores were normalized from 0 to 1.

are human annotated answers to which is more similar to "*A*", "*B*" or "*C*".

4.2 Problems in Flickr8k and Composite

We investigate the human judgments in Flickr8k and Composite, and visualize the distributions of judgment scores for two datasets, Flickr8k and Composite in Figure 4, and find several problems.

For the Flickr8k, most of the scores are less than 0.2 since the candidate captions were sampled by an image retrieval system from a reference caption pool, not model-generated captions. Therefore, most captions are not related to images and differ significantly from the model-generated captions. We argue that this naive configuration is not enough to distinguish the performance of the metric precisely.

For the Composite, most of the scores are placed near 0 or 1. We explain this because only a single annotator annotates each sample's score resulting in biased output. We also manually investigated the captions and found that the captions are coarsely generated. Note that the captions for this dataset were generated by the old model (Karpathy and Fei-Fei, 2015; Aditya et al., 2015). For these reasons, we conclude that additional benchmark dataset is necessary to evaluate the captioning metrics.

4.3 CapEval1k Dataset

To alleviate the addressed issues in Flickr8k and Composite, we introduce a new dataset CapEval1k, which is composed of human judgments for the model-generated captions from four recently proposed models: Att2in (Rennie et al., 2017), Transformer (Vaswani et al., 2017), BUTD (Anderson et al., 2018) and AoANet (Huang et al., 2019). Different from Flickr8k and Composite, we ask each annotator to evaluate the captions by considering three dimensions: *fluency*, *relevance*, *descriptiveness*. We hire 5 workers who are fluent in English for each assignment from Amazon Mechanical Turk and use the average score. We also provide the full instructions and details in Appendix.

Since our CapEval1k dataset is composed of annotations via recently proposed models, the overall scores are relatively higher than other datasets as shown in Figure 4. Compared to other datasets, CapEval1k contains the annotators' comprehensive judgment across multiple dimensions in evaluating the quality of the generated captions, so we can see that the score distribution score is not concentrated in a particular area.

Metric	Flickr8k	Composite	CapEval1k	PASCAL50s
BLEU-1	0.274	0.406	0.233	74.3
BLEU-4	0.286	0.439	0.238	73.4
ROUGE-L	0.300	0.417	0.220	74.9

Table 1: Columns 1 to 3 represent Kendall Correlation between human judgments and various metrics on Flickr8k, Composite and CapEval1k. All p-values in the results are < 0.01. The last column shows the accuracy of matches between human judgments in PASCAL50s.

5 Experiments

5.1 Implementation Details

We use the pre-trained UNITER-base with 12 layers in the official code provided by the authors (Chen et al., 2020)[2]. We use the COCO dataset (Fang et al., 2015) to fine-tune UNITER through ranking loss. We use the train and validation split of COCO dataset in (Chen et al., 2020). The number of the training set is 414k, and the validation set is 25k. We set the batch size of 320, learning rate of 2e-6, and fine-tune UNITER for a maximum of 4k steps. We select the model that shows the minimum loss in the validation set. We set margin M as 0.2 in the ranking loss. We repeat training 5 times for each best-performing model.

5.2 Performance Comparison

We compute caption-level Kendall's correlation coefficient with human judgments for the Composite,

[2]https://github.com/ChenRocks/UNITER

Flickr8k, and our proposed CapEval1k. For the PASCAL50s, we compute the number of matches between human judgments for each candidate caption pair. For all of the reference based metrics, we use five reference captions and then get average score among the five references except for BERTScore where we use maximum.

We present the experimental results for all four datasets in Table 1. We show that although UMIC does not utilize any reference captions, UMIC outperforms the baseline metrics except for VBTScore in all of the datasets that depend on multiple references. We also report the strong unreferenced baseline UMIC$_{\text{-C}}$, which is directly using the pre-trained weights from UNITER without contrastive learning. Interestingly, UMIC$_{\text{-C}}$ shows a higher performance than most of the metrics. This high performance shows that pre-trained image-text matching layer of UNITER already has a good representation for evaluating image captions. Especially for Composite, both UMIC and UMIC$_{\text{-C}}$ significantly outperform baseline metrics. We explain this in the polarized distribution of human judgments as we explained in Section 4.2. In other words, the relevance of most image-caption pairs in this dataset is too obvious so that UNITER can easily distinguish them. However, while UMIC shows higher performance on all datasets, UMIC$_{\text{-C}}$ shows relatively low performance on Flickr8k and CapEval1k. And this demonstrates the effectiveness and generalization ability of our contrastive learning objective to develop UMIC.

Also, we can observe that the performance of each metric is relatively low and the rank of each metric changes in our proposed CapEval1k dataset. We explain that this is because the captions in CapEval1k are relatively difficult to be evaluated since the score distribution is not biased as explained in Section 4.3.

5.3 Case Study

We visualize one sample each showing the strengths and weaknesses of UMIC in Figure 5. In the above example, the candidate caption is partially relevant to the image, but the single word "three" in the caption is totally incorrect since there are only "two" giraffes in the image. And this leads to a low human judgment of 0.2. Nevertheless, unlike our UMIC, widely used metrics and UMIC$_{\text{-C}}$ give this caption a high score due to the many words overlaps or missing the keywords. The bottom example shows one of the error cases and the limitations of our proposed method. Since the detection model in UMIC could not recognize the important object like the "baseball bat", UMIC outputs very low score.

6 Conclusion

In this paper, we propose UMIC, an unreferened metric that does not require any reference captions for image captioning task through contrastive learning in UNITER. Also, we propose a new benchmark dataset for image captioning that relieve the issues in previous datasets. Experimental results on four benchmark datasets, including our new dataset, show that UMIC outperforms previous metrics.

Acknowledgements

We thank anonymous reviewers for their constructive and insightful comments. K. Jung is with ASRI, Seoul National University, Korea. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (No. 2021R1A2C2008855). This work was partially funded by gifts from Adobe Research.

Ethical Considerations

We compensate the annotators with competitive pay, which is above hourly USD $10 for collecting human annotated judgments for the model generated captions. Specifically, we pay $0.2 for each task that is composed of evaluating four candidate captions for a single image, where each task can be usually done in a minute. And we use public datasets to train the models.

Abstract

Good quality monolingual word embeddings (MWEs) can be built for languages which have large amounts of unlabeled text. MWEs can be aligned to bilingual spaces using only a few thousand word translation pairs. For low resource languages training MWEs monolingually results in MWEs of poor quality, and thus poor bilingual word embeddings (BWEs) as well. This paper proposes a new approach for building BWEs in which the vector space of the high resource source language is used as a starting point for training an embedding space for the low resource target language. By using the source vectors as anchors the vector spaces are automatically aligned during training. We experiment on English-German, English-Hiligaynon and English-Macedonian. We show that our approach results not only in improved BWEs and bilingual lexicon induction performance, but also in improved target language MWE quality as measured using monolingual word similarity.

1 Introduction

Bilingual Word Embeddings are useful for cross-lingual tasks such as cross-lingual transfer learning or machine translation. Mapping based BWE approaches rely only on a cheap bilingual signal, in the form of a seed lexicon, and monolingual data to train monolingual word embeddings (MWEs) for each language, which makes them easily applicable in low-resource scenarios (Mikolov et al., 2013b; Xing et al., 2015; Artetxe et al., 2016). It was shown that BWEs can be built using a small seed lexicon (Artetxe et al., 2017) or without any word pairs (Lample et al., 2018a; Artetxe et al., 2018) relying on the assumption of isomorphic MWE spaces. Recent approaches showed that BWEs can be built without the mapping step. Lample et al. (2018b) built FASTTEXT embeddings (Bojanowski et al., 2017) on the concatenated source and target language corpora exploiting the shared character n-grams in them. Similarly, the shared source and target language subword tokens are used as a cheap cross-lingual signal in Devlin et al. (2019); Conneau and Lample (2019). Furthermore, the advantages of mapping and jointly training the MWEs and BWEs were combined in Wang et al. (2020) for even better BWEs.

While these approaches already try to minimize the amount of bilingual signal needed for cross-lingual applications, they still require a larger amount of monolingual data to train semantically rich word embeddings (Adams et al., 2017). This becomes a problem when one of the two languages does not have sufficient monolingual data available (Artetxe et al., 2020). In this case, training a good embedding space can be infeasible which means mapping based approaches are not able to build useful BWEs (Michel et al., 2020).

In this paper we introduce a new approach to building BWEs when one of the languages only has limited available monolingual data. Instead of using mapping or joint approaches, this paper takes the middle ground by making use of the MWEs of a resource rich language and training the low resource language embeddings on top of it. For this, a bilingual seed lexicon is used to initialize the representation of target language words by taking the pre-trained vectors of their source pairs prior to target side training, which acts as an informed starting point to shape the vector space during the process. We randomly initialize the representations of all non-lexicon target words and run Continuous Bag-of-Words (CBOW) and skip-gram (SG) training procedures to generate target embeddings with both WORD2VEC (Mikolov et al., 2013a) and FASTTEXT (Bojanowski et al., 2017). Our approach ensures that the source language MWE space is intact, so that the data deficit on the target side does not result in lowered source

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 227–232

embedding quality. The improved monolingual word embeddings for the target language outperform embeddings trained solely on monolingual data for semantic tasks such as word-similarity prediction. We study low-resource settings for English-German and English-Hiligaynon, where previous approaches have failed (Michel et al., 2020), as well as English-Macedonian.

2 Method

Previous mapping approaches rely on the alignment of two pre-trained monolingual word embedding spaces. In case one of the two languages has significantly fewer resources available, this will strongly affect the resulting mapping negatively. This is also an issue for joint approaches because the shared token representations are biased towards the language with more training samples. Our approach instead leverages the high resource language to improve performance on the low-resource language.

We pre-train MWEs for the source language and use the source MWEs to initialize the space of the low resource target language. Using a set of initial seed pairs, the representation of a seed word in the target space is replaced with the representation of its translation (anchor points). Then, training is performed on the initialized space using only monolingual data from the low resource language by only updating the representation of non-seed words which are initialized randomly. Through this method a BWE representation is directly induced from the anchor points of the fixed vectors.

In some cases there are multiple valid translations for a single target language word. We experiment with either initializing with the average over these possible translations or randomly selecting only one of them. The averaging helps by finding a common anchor for the different semantic nuances the token might represent in different target language contexts. Additionally, we experiment with enabling or disabling the updates of anchor vectors during training. We implemented the anchor point based initialization in both WORD2VEC and FASTTEXT with only complete token representations serving as potential anchors. In the case of FASTTEXT these initializations have no influence on the subword (character n-gram) embeddings which are still initialized randomly, which makes intuitive sense in the common case of morphologically different language pairs. Training is performed using standard hyperparameters included in the GENSIM WORD2VEC and FASTTEXT packages (Řehůřek and Sojka, 2010). Unless stated otherwise, vectors are of dimensionality 300 with a context window of 5 words used during training. All models are trained for 5 epochs without further hyperparameter tuning utilizing a single desktop machine on a Intel Core i7-7700K CPU with 4.20Ghz, a NVIDIA GeForce GTX 1080 Ti graphics card and 32 GB of DDR4 SDRAM. The parameters of each trained model are equal to the standard implementation of the packages as listed above. Training time is largely dependent on input size, but corresponds to a few seconds up to roughly 5 minutes in the low resource setting.

2.1 Experimental Setup

First we conduct experiments on the German and English language pair, since large available corpora made it easier to test different sized dictionaries and corpora during training. The basic setup trains a MWE on the source language (English) up front. For this training the WMT 2019 News Crawl corpus in English, including approximately 532 million tokens, was chosen (Barrault et al., 2019). Similarly for the target language, we used the German WMT 2019 News Crawl from which we uniformly sample to obtain training sets of different sizes. All dataset are tokenized and lowercased before training.

To evaluate, we translate German words to English. We use the MUSE German-English dictionary (Lample et al., 2018a). There are 102K translation pairs with a total of roughly 68K unique German words. For each German word there might be multiple valid English translations, which are listed in the dictionary. For the initialization we select either randomly one translation option or the averaged word representations of all available translations, as discussed in section 2. However, many German words have only one valid translation. We used the MUSE test set containing roughly 3000 translation pairs in the frequency range 5000-6500, leaving 99K pairs as potential candidates for the initialization. In our experiments we mostly consider setups with much smaller training lexicon sizes, by taking the top-n most frequent source words and their translations from the lexicon.

In addition to the German experiments we test our system on two lower resource languages: Macedonian and Hiligaynon. For Macedonian we use data in the form of a Wikipedia dump, as well

as the MUSE dictionary for the language pair Macedonian-English for our test setup.[1] For Hiligaynon we use a corpus containing roughly 350K tokens as well as a corresponding dictionary containing 1100 translated terms between English and Hiligaynon and an additional test set of 200 terms released by Michel et al. (2020).

After training, bilingual lexicon induction (BLI) is done by taking the top n closest vectors measured by cross-domain similarity local scaling (CSLS) distance. For better comparability we use the evaluation method provided by MUSE (Lample et al., 2018a) for both the comparison baseline as well as our system. For Hiligaynon we use cosine to compare directly with (Michel et al., 2020).

3 Results

The following section evaluates different models quantitatively using $acc@5$ and $acc@1$ as a metric. The baseline runs MUSE tool in supervised mode using iterative procrustes refinement to obtain the mapping using default parameters as reported in Lample et al. (2018a). For the English embedding the full corpus size was used, while in the case of the (low-resource) languages the corpora sizes were varied to observe changes in performance.

3.1 Bilingual experiments

BLI was performed using the method from section 2. Since Word2Vec SG and FastText embeddings performed much worse with the anchored training, all following numbers report Word2Vec CBOW embeddings.

Table 1 shows the comparison between four different possible setups for the proposed method as explained in Section 2: Either fixing anchor-vectors or allowing them to train or initializing with single word vectors or averaged ones. The overall best performing model utilizes averaged and non-fixed anchor vectors. Table 1 also shows the baselines at varying corpora sizes. Overall the anchor method performs much better than the baseline at lower corpora sizes and stays competitive as corpus size increases. Results are similarly consistent when looking at either $acc@5$ or $acc@1$.

One important parameter for the proposed method is how it scales with the available amount of anchor-vectors used for training. In a range of experiments, different initialization sizes were compared. Figure 1 shows the result for varying the number of anchor vectors. The general trend is that the more anchor vectors, the better the performance, which slowly caps off at the higher end, as more vectors of lower frequency words start introducing noise. The same development is not true for the baseline, which does not benefit equally from increasing the potential seed lexicon vocabulary and even starts losing performance at larger dictionary sizes.

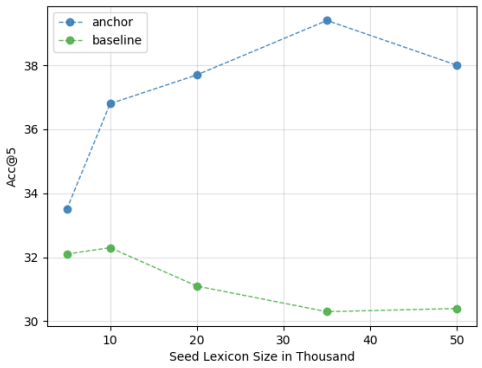

Figure 1: Anchor method for English-German with fixed vectors and baseline with varying training-dictionary sizes at corpus size 20 million

This difference is likely rooted in the inclusion of less frequent word pairs in the larger dictionaries. These words have worse quality representations which introduces noise in the mapping process, thus restricting the precision of their orthogonal alignment as described by (Søgaard et al., 2018). In contrast, our method initializes all target language word embeddings given their pairs, i.e., perfectly aligning all words in the training dictionary, which serve as high quality anchor points for the remaining words.

3.2 Macedonian and Hiligaynon

Another set of experiments was done on the language pair English-Macedonian, a language that already offers less resources than German and is also more dissimilar from English.

Results for experiments comparing between the MUSE baseline and the anchor method are shown in Table 2. The best performing model again combines averaged initialization with trainable anchors.

Compared to the previous experiments with German, results for Macedonian are similar, while the baseline model is overall weaker than before, suggesting the anchor method benefits more strongly

from a high-resource embedding, even when language pairs become more dissimilar.

For English-Hiligaynon previous approaches failed due to limitations of the available monolingual training data. Table 3 shows the performance for translating Hiligaynon words to English. The evaluation was done using cosine-distance for better comparability between the Michel et al. (2020) paper and our results. Since there were only single translations of words in the provided dictionary, the method of averaging vectors for initialization was not used. Similarly, during evaluation only one valid term per word was possible. While Michel et al. (2020) reported 0.5% for 50 dimensional vectors, in our baseline the 50 dimensional vectors achieved a constant 0 (not shown). The numbers are comparable to the low frequency experiments between German and English as seen in Table 1.

3.3 Monolingual experiments

In addition to better BWEs, our approach also improves the low-resource embedding for purely monolingual tasks. To confirm this, the anchor-vector trained embeddings for German were evaluated on monolingual word similarity and compared to the results achieved by regular training of the embedding space. We evaluate on multiple datasets: GUR350 and GUR65 (Gurevych, 2005), SEMEVAL17 (Cer et al., 2017), SIMLEX-999 (Leviant and Reichart, 2015), WS-353 (Agirre et al., 2009) and ZG22 (Zesch and Gurevych, 2006), and report the averaged Spearman's rho correlation between cosine similarity of vector pairs and human annotations. Similar monolingual datasets are not available for Macedonian and Hiligaynon. In Figure 2 the effect of employing the anchor method on monolingual word similarity performance is compared against Word2Vec CBOW trained without anchor initialization. The improvements across different training corpora sizes are in favor of the proposed method, suggesting that it can be employed to improve performance on monolingual tasks. Overall this serves to demonstrate the advantage of the anchor-method on small datasets and allows to learn better monolingual representation from the same amount of data by utilizing the information from a pretrained embedding for a completely different language with more readily available training data. The thus learned representation can not only serve as an already aligned space for translation tasks as shown above, but is also the better performing representation of the monolingual space.

4 Conclusion

We proposed a novel approach to build BWEs to improve performance on language pairs with limited monolingual data on the target side. By utilizing pre-trained MWEs of resource rich languages and a seed lexicon to fix anchor points before training, a structurally similar embedding space can be learned for the low resource language which is aligned with the source representations. We evaluated our approach on the BDI task using English-German to test varying training parameters and corpora sizes, on English-

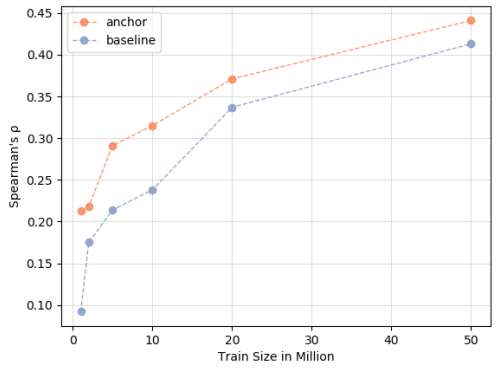

Figure 2: Spearman's rho correlation on monolingual word similarity across corpora sizes for German.

Macedonian and the extremely low resource language pair English-Hiligaynon on which previous approaches failed. We showed that the performance of existing mapping approaches degrades drastically with lower monolingual data sizes, even when there are large seed lexicons available. In contrast, our proposed system outperformed previous mapping based approaches on these setups including English-Hiligaynon. On top of improved BWEs, we showed improved MWE quality as well for the target language by outperforming standard MWEs on the monolingual word similarity task showing that it is beneficial for monolingual tasks as well. We implemented our approach for both Word2Vec and FastText which we publicly release to promote reproducibility and further research.[2]

Ethical Considerations

The proposed system acts as a tool to specifically help in the low resource setting that predominantly affects less researched languages. Even though part of the experiments were done on the higher resource language pair English-German, the results were further confirmed for other pairs of languages.

As a word embedding based system, the resulting mappings and embedding spaces are highly affected by the kind of monolingual content that goes into their training, which is why we made sure to train the embeddings on texts that should adhere to a higher standard, such as verified news media and online articles, instead of a general web crawl. Additionally the seed lexicons used come from verified sources, such as the popular MUSE lexicons in the case of English-German and English-Macedonian as well as from translations by a native speaker of Hiligaynon in the case of English-Hiligaynon.

We hope that in general the proposed methods can help alleviating some of the resource problems less researched languages are facing and thus to close the gap for language technology working with and on these languages.

As part of the ethical responsibility to ensure reproducibility and responsibility in terms of computational resources, we reported results with a set of standard hyperparameters instead of searching for the most optimal setting for our proposed method. Our models are as lightweight as regular training methods for word embeddings and are therefore not very demanding in terms of computation. This is especially true in the low-resource setting, where training time is reduced to just a fraction compared to the bigger corpora.

Abstract

Although multilingual neural machine translation (MNMT) enables multiple language translations, the training process is based on independent multilingual objectives. Most multilingual models can not explicitly exploit different language pairs to assist each other, ignoring the relationships among them. In this work, we propose a novel agreement-based method to encourage multilingual agreement among different translation directions, which minimizes the differences among them. We combine the multilingual training objectives with the agreement term by randomly substituting some fragments of the source language with their counterpart translations of auxiliary languages. To examine the effectiveness of our method, we conduct experiments on the multilingual translation task of 10 language pairs. Experimental results show that our method achieves significant improvements over the previous multilingual baselines.

1 Introduction

Multilingual neural machine translation (MNMT) has experienced rapid growth in recent years (Johnson et al., 2017; Zhang et al., 2020; Aharoni et al., 2019; Wang et al., 2019). It is not only capable of translating among multiple language pairs by encouraging the crosslingual knowledge transfer to improve low-resource translation performance (Firat et al., 2016b; Zoph et al., 2016; Sen et al., 2019; Qin et al., 2020; Hedderich et al., 2020; Raffel et al., 2020), but also can handle multiple language pairs in a single model, reducing model parameters and training costs (Firat et al., 2016a; Blackwood et al., 2018; Wang et al., 2020; Sun et al., 2020).

Previous works in MNMT simply optimize independent translation objectives and do not use arbitrary auxiliary languages to encourage the agreement across different translation directions. As shown in Figure 1, the multilingual baseline is separately trained on French-English and German-English directions and cannot explicitly promote each other. The German-English translation only implicitly helps the French-English translation since both translation directions share the same encoder. There still exists a gap between German-English and French-English translation directions. As a result, minimizing the difference across different translation directions by an explicit paradigm requires further exploration.

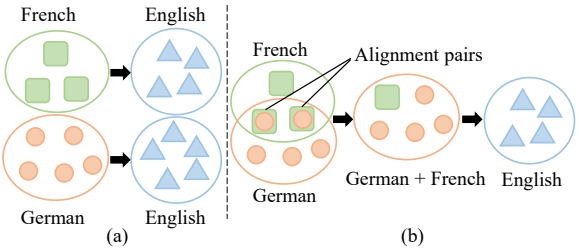

Figure 1: Comparison between (a) the multilingual translation and (b) our agreement-based method.

In this paper, we propose a novel agreement-based method, which explicitly models the shared semantic space for multiple languages and encourages the agreement across them. Our training procedure extends the multilingual translation with the agreement term, which encourages the model to produce the source sentence with multiple languages into the target sentence. As Figure 1 shows, we randomly substitute some source phrases with their counterparts of other languages to create code-switched sentences using word alignment. Our model is jointly trained with the multilingual translation and agreement objectives, where the code-switched sentences are translated into the target sentences. The key idea is to encourage the agreement among different translation directions simul-

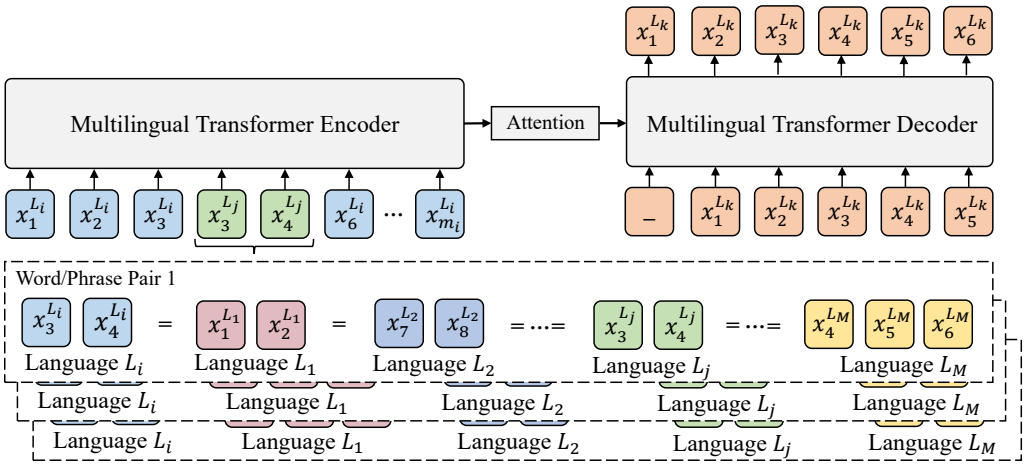

Figure 2: Overview of our method. $x_{m_i}^{L_i}$ denotes the m_i-th token in the sentence of language L_i. We randomly substitute source phrases of language $L_{src} = L_i$ with the translations of other languages $L_{aux} \in L_{all}$ to create code-switched sentences. Different words/phrases with the same meanings may contain different numbers of tokens. Then the code-switched source sentences are translated to the target language $L_{tgt} = L_k$ by the multilingual model. This process greatly encourages multilingual agreement across different translation directions.

taneously by leveraging alignment information of the bilingual source sentence pairs.

Experimental results on the multilingual translation task of WMT demonstrate that our method outperforms the multilingual baseline by a large margin. To better explain the BLEU improvements, we visualize the sentence-level crosslingual representations and the attention weights across different languages, which shows that our method effectively encourages the agreement between languages.

2 Our Approach

2.1 Multilingual Machine Translation

Our multilingual model is based on the single Transformer model (Vaswani et al., 2017) and shares all embedding matrices by a common vocabulary of all languages. Given M languages $L_{all} = \{L_1, \ldots, L_M\}$, the multilingual model appends special symbols to the source text to indicate the translation direction from the source language L_{src} to the target language L_{tgt}.

2.2 Agreement-based Training

Multilingual models can translate multiple source-side languages into target-side languages. Given N bilingual corpora $D_B = \{D_{B_1}, \ldots, D_{B_N}\}$, the multilingual model with parameters θ is jointly trained over N language directions to optimize the combined objective as below:

$$\mathcal{L}_{MT} = \sum_{n=1}^{N} \mathbb{E}_{x,y \in D_{B_n}} [-\log P_\theta(y|x)] \quad (1)$$

where x, y denote the sentence pair in the bilingual corpus D_{B_n}. $\mathcal{L}_{MT}$ is the combined translation objective of the multilingual model.

The agreement objective over the code-switched corpora D_C is calculated by:

$$\mathcal{L}_{AT} = \mathbb{E}_{x^{L_{src}/L_{aux}}, y \in D_C} [-\log P_\theta(y|x^{L_{src}/L_{aux}})] \quad (2)$$

where $x^{L_{src}/L_{aux}}$ is the code-switched sentence in which some phrases are substituted by their counterpart phrases in other languages and y is the target sentence. L_{aux} is the auxiliary language.

We combine the bilingual corpora D_B and code-switched corpora D_C to train our agreement-based model, which minimizes the gaps among different translation directions using word alignment:

$$\mathcal{L}_{ALL} = \mathcal{L}_{MT} + \mathcal{L}_{AT} \quad (3)$$

where $\mathcal{L}_{ALL}$ is the combined objective.

2.3 Constructing Training Samples

We use L_{src} as the source language, L_{tgt} as target language, and L_{aux} as auxiliary languages to construct training samples. As shown in Figure 2, $x^{L_{src}} = (x_1^{L_{src}}, \ldots, x_m^{L_{src}})$ is the source sentence with m tokens and $x^{L_{aux}} = (x_1^{L_{aux}}, \ldots, x_n^{L_{aux}})$ is the auxiliary sentence with n tokens. $x_{u:v}^{L_{src}}$ denotes the sentence fragment of $x^{L_{src}}$ from the u-th to v-th token and $x_{s:t}^{L_{aux}}$ denotes the fragment of $x^{L_{aux}}$ from the s-th to t-th token, where $x_{s:t}^{L_{aux}}$ of language L_{aux} is the translation of the $x_{u:v}^{L_{src}}$ of language L_{src}. Formally, the code-switched sequence

One-to-Many	34.2	20.9	40.0	15.0	18.1	20.9	26.0	14.5	17.3	13.2	22.0
One-to-Many + Pseudo	35.5	21.7	42.0	16.4	19.3	22.0	26.6	16.2	17.9	17.8	23.5
One-to-Many + AT (our method)	35.7	22.0	42.1	16.6	20.1	22.2	26.9	16.6	18.2	17.9	**23.9**

Table 1: En→X test results for bilingual and multilingual models of 10 language pairs on the WMT benchmark.

X → En	Fr	Cs	De	Fi	Lv	Et	Ro	Hi	Tr	Gu	Avg
Bilingual NMT	36.2	28.5	40.2	19.2	17.5	19.7	29.8	14.1	15.1	9.3	23.0
Many-to-One	34.8	29.0	40.1	21.2	20.4	26.2	34.8	22.8	23.8	19.2	27.2
Many-to-One + Pseudo	35.4	30.1	42.1	22.0	21.2	29.0	35.8	27.3	26.0	22.6	29.1
Many-to-One + AT (our method)	35.7	30.2	42.6	22.3	21.8	29.5	36.4	27.6	26.7	22.8	**29.6**

Table 2: X→En test results for bilingual and multilingual models of 10 language pairs on the WMT benchmark.

$x^{L_{src}/L_{aux}}$ is described as:

$$x^{L_{src}/L_{aux}} = (x_1^{L_{src}}, \ldots, x_{s:t}^{L_{aux}}, \ldots, x_m^{L_{src}}) \quad (4)$$

where most words in the code-switched sentence $x^{L_{src}/L_{aux}}$ are derived from $x^{L_{src}}$, while some source phrases $x_{u:v}^{L_{src}}$ are substituted by their counterpart phrases $x_{s:t}^{L_{aux}}$.

Given the parallel sentences among M different languages, we can construct code-switched source sentence $x^{L_{src}/L_{aux}}$ with different auxiliary languages. Therefore, the code-switched corpora D_C can be constructed in a similar way for other languages to encourage the agreement across different translation directions to help each other.

3 Experiment Setup

3.1 Multilingual Data

We use the same training, valid, and test sets as the previous work (Wang et al., 2020) to evaluate multilingual models by parallel data from multiple WMT datasets with various languages, including English (En), French (Fr), Czech (Cs), German (De), Finnish (Fi), Latvian (Lv), Estonian (Et), Romanian (Ro), Hindi (Hi), Turkish (Tr), and Gujarati (Gu). For each language, we concatenate the WMT data of the latest available year and get at most 10M sentences by randomly sampling. Detailed statistics of datasets are listed in Table 3. All sentences in our experiments are tokenized by SentencePiece[1] (Kudo and Richardson, 2018).

	Train Size	Valid	Test
En-Fr	10.00M	newstest13	newstest15
En-Cs	10.00M	newstest16	newstest18
En-De	4.60M	newstest16	newstest18

En-Gu	0.08M	newsdev19	newstest19

Table 3: The statistics of the training, valid, and test sets on WMT datasets of 10 language pairs.

3.2 Baselines and Evaluation

We compare our method against the following baselines. **Bilingual baseline** is trained on each language pair separately. **One-to-Many** and **Many-to-One** are trained on the En→X and X→En directions respectively. We collect all English sentences (33M) of the bilingual corpora described above and translate them into other languages sentences. We extract alignment pairs (Dyer et al., 2013) across different languages for our method. **One-to-Many + Pseudo** and **Many-to-One + Pseudo** are trained on multilingual data combined with the pseudo data. We average the last 5 checkpoints and employ the beam search strategy with a beam size of 5 for evaluation. The evaluation metric is case-sensitive detokenized sacreBLEU[2] (Post, 2018).

[2] BLEU+case.mixed+lang.{src}-{tgt}+numrefs.1+smooth.exp+tok.13a+version.1.4.14

3.3 Training Details

We adopt the `Transformer_big` architecture as the backbone model for all our experiments, which has 6 layers with an embedding size of 1024, a dropout of 0.1, the feed-forward network size of 4096, and 16 attention heads. We train multilingual models with Adam (Kingma and Ba, 2015) ($\beta_1 = 0.9$, $\beta_2 = 0.98$). The learning rate is set as 5e-4 with a warm-up step of 4,000. The models are trained with the label smoothing cross-entropy with a smoothing ratio of 0.1. The batch size is 5,120 tokens and the parameters are updated every 16 iterations to simulate a 128-GPU environment.

4 Results

The results of our model are separately listed in Table 1 and Table 2. Table 1 shows that **One-to-Many** outperforms **bilingual NMT** by +1.8 BLEU points on average. Our method further improves over both **One-to-Many** and **One-to-Many + Pseudo** consistently. Using pseudo and code-switched data brings more improvements to the low-resource languages (Et, Ro, Hi, Tr, and Gu) than high-resource languages (Fr, Cs, De, Fi, and Lv). These results suggest that our model encourages the agreement between different translation directions.

Table 2 reports the results on the X→En test sets. **Many-to-One** outperforms the **bilingual** NMT by +4.2 BLEU points on average. We combine the parallel data with the pseudo data, leading to an improvement of +1.9 BLEU points over **Many-to-One**. Our method further outperforms **Many-to-One + Pseudo** by a large gain of +0.5 BLEU points on average, showing the effectiveness of our agreement-based method and the significance of multilingual agreement.

5 Analysis

Attention Visualization The representations of attention in Figures 3 and 4 are averaged over all 16 heads of the last layer. Figure 3 shows the self-attention weights of a code-switched English sentence, where the source phrase "coordination between law enforcement" is substituted by the German phrase "Koordinierung zwischen Strafverfolgung sbehörden". Similar to the common attention pattern, our model can learn better crosslingual representations in this code-switching case. Figure 4 shows that the cross-attention weights between the input code-switched English sentence and the

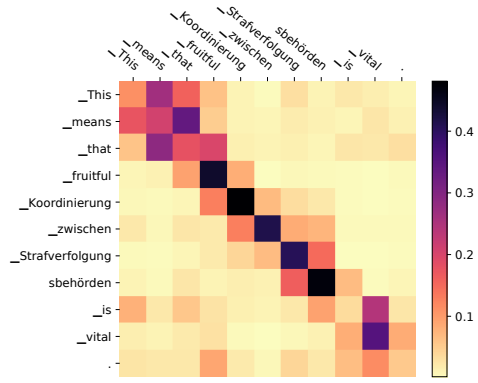

Figure 3: Visualization for the self-attention weights.

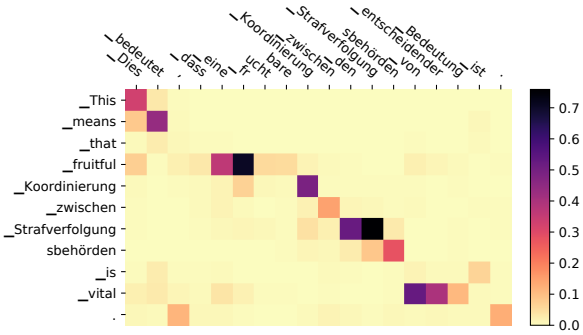

Figure 4: Visualization for the cross-attention weights between the code-switched input and target sentence.

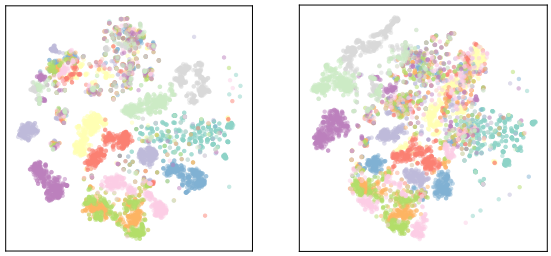
output German sentence. The words with similar meanings are aligned together between the code-switched input and target output.

Crosslingual Representation We select 500 parallel sentences across different languages and visualize their sentence vectors of multilingual baseline and our method in Figure 5. The vector of the special language symbol of the source sentence is used as the sentence representation for visualization. Compared to Figure 5(a), different languages become closer and overlap with each other in Figure 5(b), which shows our method aligns representations and minimizes the differences among different languages.

Substitution Strategy We employ both word-level and phrase-level substitution strategies for code-switching. The word-level and phrase-level methods replace some words or spans of the source sentence with other languages. In Table 4, phrase-level substitution works better. Furthermore, we investigate the effect of the substitution ratio of the source words. From Figure 6, the best substitution ratio is 10%. When increasing the ratio to 30%, the performance gets worse, which indicates substitut-



(a) (b)

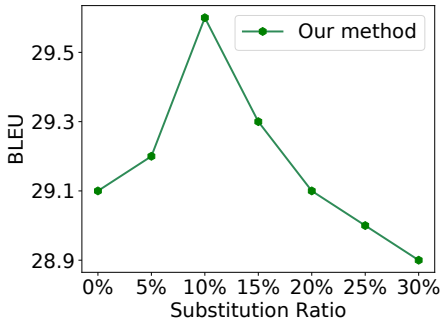

Figure 6: Average results of X→En directions on different substitution ratio settings. Large substitution ratio may degrade the model performance and is even worse than the multilingual baseline.

X → En	De	Lv	Ro	Tr	Avg
Word-level	42.5	21.5	35.9	26.2	31.5
Phrase-level	42.6	21.8	36.4	26.7	31.9

Table 4: Comparison of BLEU points between the word-level and the phrase-level substitution strategies on X→En directions.

ing too many words may degrade the performance.

As Equation 3 formulates, our method uses both the original corpora and code-switched corpora simultaneously to reduce the effect of the word alignment errors. Besides, `fast_align` (Dyer et al., 2013) is a simple, fast, and effective tool with a lower alignment error rate. Therefore, our method can avoid the disturbance introduced by the word alignment errors as much as possible.

Time Cost of Word Alignment In this work, we try a large pseudo parallel corpus (33M) to train the multilingual corpora. In most scenarios, the size of the parallel corpus is less than 33M and thus consumes less time to generate the alignment pairs. All the alignment pairs are offline generated only once before the training phase. Therefore, the time cost of the word alignment is much smaller than that of the model training.

6 Related Work

Multilingual Machine Translation Previous works (Zoph et al., 2016; Firat et al., 2016b; Johnson et al., 2017) have explored different settings of the multilingual neural machine translation (MNMT). Recent studies show that MNMT (Blackwood et al., 2018; Platanios et al., 2018; Gu et al., 2018) helps improve the performance of the low-resource or zero-shot translation. Some researchers use the sentence pairs to enhance the bilingual neural machine translation (Conneau and Lample, 2019; Song et al., 2019; Yang et al., 2020b).

Agreement-based Learning Many works try to use the agreement-based method (Liang et al., 2007, 2006; Al-Shedivat and Parikh, 2019) to encourage agreement among different translation orders and directions (Liang et al., 2006; Castilho, 2020; Yang et al., 2020a; Cheng et al., 2016; Zhang et al., 2019). Besides, the agreement-based method is also used to minimize the difference between the representation of source and target sentence (Yang et al., 2019). Our method further explores the approach of the multilingual agreement.

7 Conclusion

We propose a novel agreement-based framework to encourage multilingual agreement across different translation directions by the agreement term. Experimental results on the multilingual translation task demonstrate that our method effectively minimizes the gaps among different translation directions and significantly outperforms the multilingual baselines. The analytic experiment about the crosslingual representation shows the effectiveness of our multilingual agreement in minimizing the differences among different languages.

Higher-order Derivatives of Weighted Finite-state Machines

Ran Zmigrod [1] **Tim Vieira** [2] **Ryan Cotterell** [1,3]

Abstract

Weighted finite-state machines are a fundamental building block of NLP systems. They have withstood the test of time—from their early use in noisy channel models in the 1990s up to modern-day neurally parameterized conditional random fields. This work examines the computation of higher-order derivatives with respect to the normalization constant for weighted finite-state machines. We provide a general algorithm for evaluating derivatives of all orders, which has not been previously described in the literature. In the case of second-order derivatives, our scheme runs in the *optimal* $\mathcal{O}(A^2N^4)$ time where A is the alphabet size and N is the number of states. Our algorithm is significantly faster than prior algorithms. Additionally, our approach leads to a significantly faster algorithm for computing second-order expectations, such as covariance matrices and gradients of first-order expectations.

1 Introduction

Weighted finite-state machines (WFSMs) have a storied role in NLP. They are a useful formalism for speech recognition (Mohri et al., 2002), machine transliteration (Knight and Graehl, 1998), morphology (Geyken and Hanneforth, 2005; Lindén et al., 2009) and phonology (Cotterell et al., 2015) *inter alia*. Indeed, WFSMs have been "neuralized" (Rastogi et al., 2016; Hannun et al., 2020; Schwartz et al., 2018) and are still of practical use to the NLP modeler. Moreover, many popular sequence models, e.g., conditional random fields for part-of-speech tagging (Lafferty et al., 2001), are naturally viewed as special cases of WFSMs. For this reason, we consider the study of algorithms for the WFSMs of interest *in se* for the NLP community.

This paper considers inference algorithms for WSFMs. When WFSMs are acyclic, there exist simple linear-time dynamic programs, e.g., the forward algorithm (Rabiner, 1989), for inference. However, in general, WFSMs may contain cycles and such approaches are not applicable. Our work considers this general case and provides a method for efficient computation of m^{th}-order derivatives over a cyclic WFSM. To the best of our knowledge, no algorithm for higher-order derivatives has been presented in the literature beyond a general-purpose method from automatic differentiation. In contrast to many presentations of WFSMs (Mohri, 1997), our work provides a purely linear-algebraic take on them. And, indeed, it is this connection that allows us to develop our general algorithm.

We provide a thorough analysis of the soundness, runtime, and space complexity of our algorithm. In the special case of second-order derivatives, our algorithm runs *optimally* in $\mathcal{O}(A^2N^4)$ time and space where A is the size of the alphabet, and N is the number of states.[1] In contrast, the second-order expectation semiring of Li and Eisner (2009) provides an $\mathcal{O}(A^2N^7)$ solution and automatic differentiation (Griewank, 1989) yields a slightly faster $\mathcal{O}(AN^5{+}A^2N^4)$ solution. Additionally, we provide a speed-up for the general family of second-order expectations. Indeed, we believe our algorithm is the fastest known for computing common quantities, e.g., a covariance matrix.[2]

2 Weighted Finite-State Machines

In this section we briefly provide important notation for WFSMs and a classic result that efficiently finds the normalization constant for the probability distribution of a WFSM.

[1] Our implementation is available at https://github.com/rycolab/wfsm.

[2] Due to space constraints, we keep the discussion of our paper theoretical, though applications of expectations that we can compute are discussed in Li and Eisner (2009), Sánchez and Romero (2020), and Zmigrod et al. (2021).

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 240–248
August 1–6, 2021. ©2021 Association for Computational Linguistics

Definition 1. *A **weighted finite-state machine** $\mathcal{M}$ is a tuple $\langle \boldsymbol{\alpha}, \{\mathbf{W}^{(a)}\}_{a \in \overline{\mathcal{A}}}, \boldsymbol{\omega} \rangle$ where $\mathcal{A}$ is an alphabet of size A, $\overline{\mathcal{A}} \stackrel{\text{def}}{=} \mathcal{A} \cup \{\varepsilon\}$, each $a \in \overline{\mathcal{A}}$ has a symbol-specific transition matrix $\mathbf{W}^{(a)} \in {\mathbb{R}_{\geq 0}}^{N \times N}$ where N is the number of states, and $\boldsymbol{\alpha}, \boldsymbol{\omega} \in {\mathbb{R}_{\geq 0}}^{N}$ are column vectors of start and end weights, respectively. We define the matrix $\mathbf{W} \stackrel{\text{def}}{=} \sum_{a \in \overline{\mathcal{A}}} \mathbf{W}^{(a)}$.*

Definition 2. *A **trajectory** $\tau_{i \rightsquigarrow \ell}$ is an ordered sequence of transitions from state i to state ℓ. Visually, we can represent a trajectory by*

$$\tau_{i \rightsquigarrow \ell} \stackrel{\text{def}}{=} i \xrightarrow{a} j \cdots k \xrightarrow{a'} \ell$$

*The **weight** of a trajectory is*

$$w(\tau_{i \rightsquigarrow \ell}) \stackrel{\text{def}}{=} \alpha_i \left(\prod_{(j \xrightarrow{a} k) \in \tau_{i \rightsquigarrow \ell}} \mathrm{W}^{(a)}_{jk} \right) \omega_\ell \tag{1}$$

We denote the (possibly infinite) set of trajectories from i to ℓ by $\mathcal{T}_{i\ell}$ and the set of all trajectories by $\mathcal{T} \stackrel{\text{def}}{=} \bigcup_{i,\ell \in [N]} \mathcal{T}_{i\ell}$.[3] Consequently, when we say $\tau_{i \rightsquigarrow \ell} \in \mathcal{T}$, we make i and ℓ implicit arguments to which $\mathcal{T}_{i\ell}$ we are accessing.

We define the **probability** of a trajectory $\tau_{i \rightsquigarrow \ell} \in \mathcal{T}$,

$$p(\tau_{i \rightsquigarrow \ell}) \stackrel{\text{def}}{=} \frac{w(\tau_{i \rightsquigarrow \ell})}{\mathrm{Z}} \tag{2}$$

where

$$\mathrm{Z} \stackrel{\text{def}}{=} \boldsymbol{\alpha}^\top \sum_{k=0}^{\infty} \mathbf{W}^k \, \boldsymbol{\omega} \tag{3}$$

Of course, p is only well-defined when $0 < \mathrm{Z} < \infty$.[4] Intuitively, $\boldsymbol{\alpha}^\top \mathbf{W}^k \, \boldsymbol{\omega}$ is the total weight of all trajectories of length k. Thus, Z is the total weight of all possible trajectories as it sums over the total weight for each possible trajectory length.

Theorem 1 (Corollary 4.2, Lehmann (1977))**.**

$$\mathbf{W}^\star \stackrel{\text{def}}{=} \sum_{k=0}^{\infty} \mathbf{W}^k = (\mathbf{I} - \mathbf{W})^{-1} \tag{4}$$

Thus, we can solve the infinite summation that defines $\mathbf{W}^\star$ by matrix inversion in $\mathcal{O}(N^3)$ time.[5]

[3] $|\mathcal{T}|$ is infinite if and only if $\mathcal{M}$ is cyclic.

[3] Another formulation for Z is $\sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}} w(\tau_{i \rightsquigarrow \ell})$.

[4] This requirement is equivalent to $\mathbf{W}$ having a spectral radius < 1.

[5] This solution technique may be extended to closed semirings (Kleene, 1956; Lehmann, 1977).

Corollary 1.

$$\mathrm{Z} = \boldsymbol{\alpha}^\top \mathbf{W}^\star \, \boldsymbol{\omega} \tag{5}$$

Proof. Follows from (4) in Theorem 1. ■

By Corollary 1, we can find Z in $\mathcal{O}(N^3 + AN^2)$.[6]

Strings versus Trajectories. Importantly, WFSMs can be regarded as weighted finite-state acceptors (WFSAs) which accept strings as their input. Each trajectory $\tau_{i \rightsquigarrow \ell} \in \mathcal{T}$ has a **yield** $\gamma(\tau_{i \rightsquigarrow \ell})$ which is the concatenation of the alphabet symbols of the trajectory. The yield of a trajectory ignores any ε symbols, a discussion regarding the semantics of ε is given in Hopcroft et al. (2001). As we focus on distributions over trajectories, we do not need special considerations for ε transitions. We do not consider distributions over yields in this work as such a distribution requires constructing a latent-variable model

$$p(\sigma) = \frac{1}{\mathrm{Z}} \sum_{\substack{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}, \\ \gamma(\tau_{i \rightsquigarrow \ell}) = \sigma}} w(\tau_{i \rightsquigarrow \ell}) \tag{6}$$

where $\sigma \in \mathcal{A}^*$ and $\gamma(\tau_{i \rightsquigarrow \ell})$ is the yield of the trajectory. While marginal likelihood can be found efficiently,[7] many quantities, such as the entropy of the distribution over yields, are intractable to compute (Cortes et al., 2008).

3 Computing the Hessian (and Beyond)

In this section, we explore algorithms for efficiently computing the Hessian matrix $\nabla^2 \mathrm{Z}$. We briefly describe two inefficient algorithms, which are derived by forward-mode and reverse-mode automatic differentiation. Next, we propose an efficient algorithm which is based on a key differential identity.

3.1 An $\mathcal{O}(A^2 N^7)$ Algorithm with Forward-Mode Automatic Differentiation

One proposal for computing the Hessian comes from Li and Eisner (2009) who introduce a method based on semirings for computing a general family of quantities known as second-order expectations

[6] Throughout this paper, we assume a dense weight matrix and that matrix inversion is $\mathcal{O}(N^3)$ time. We note, however, that when the weight matrix is sparse and structured, faster matrix-inversion algorithms exist that exploit the strongly connected components decomposition of the graph (Mohri et al., 2000). We are agnostic to the specific inversion algorithm, but for simplicity we assume the aforementioned running time.

[7] This is done by intersecting the WFSA with another WFSA that only accepts σ.

(defined formally in §4). When applied to the computation of the Hessian their method reduces precisely to forward-mode automatic differentiation (AD; Griewank and Walther, 2008, Chap 3.1). This approach requires that we "lift" the computation of Z to operate over a richer numeric representation known as *dual numbers* (Clifford, 1871; Pearlmutter and Siskind, 2007). Unfortunately, the second-order dual numbers that we require to compute the Hessian introduce an overhead of $\mathcal{O}(A^2N^4)$ per numeric operation of the $\mathcal{O}(N^3)$ algorithm that computes Z, which results in $\mathcal{O}(A^2N^7)$ time.

3.2 An $\mathcal{O}(AN^5+A^2N^4)$ Algorithm with Reverse-Mode Automatic Differentiation

Another method for materializing the Hessian $\nabla^2\mathrm{Z}$ is through reverse-mode automatic differentiation (AD). Recall that we can compute Z in $\mathcal{O}(N^3+AN^2)$, and can consequently find $\nabla\mathrm{Z}$ in $\mathcal{O}(N^3+AN^2)$ using one pass of reverse-mode AD (Griewank and Walther, 2008, Chapter 3.3). We can repeat differentiation to materialize $\nabla^2\mathrm{Z}$. Specifically, we run reverse-mode AD once for each element i of $\nabla\mathrm{Z}$. Taking the gradient of $(\nabla\mathrm{Z})_i$ gives a row of the Hessian matrix, $\nabla[(\nabla\mathrm{Z})_i] = [\nabla^2\mathrm{Z}]_{(i,:)}$. Since each of these passes takes time $\mathcal{O}(N^3+AN^2)$ (i.e., the same as the cost of Z), and $\nabla\mathrm{Z}$ has size AN^2, the overall time is $\mathcal{O}(AN^5+A^2N^4)$.

3.3 Our Optimal $\mathcal{O}(A^2N^4)$ Algorithm

In this section, we will provide an $\mathcal{O}(A^2N^4)$-time and space algorithm for computing the Hessian. Since the Hessian has size $\mathcal{O}(A^2N^4)$, no algorithm can run faster than this bound; thus, our algorithm's time and space complexities are *optimal*. Our algorithm hinges on the following lemma, which shows that the each of partial derivatives of $\mathbf{W}^\star$ can be cheaply computed given $\mathbf{W}^\star$.

Lemma 1. *For $i,j,k,\ell \in [N]$ and $a \in \overline{\mathcal{A}}$*

$$\frac{\partial \mathrm{W}^\star_{i\ell}}{\partial \mathrm{W}^{(a)}_{jk}} = \mathrm{W}^\star_{ij}\dot{\mathrm{W}}^{(a)}_{jk}\mathrm{W}^\star_{k\ell} \tag{7}$$

where $\dot{\mathrm{W}}^{(a)}_{jk}$ is shorthand for $\partial \mathrm{W}^{(a)}_{jk}$.

Proof.

$$\begin{aligned}\frac{\partial \mathrm{W}^\star_{i\ell}}{\partial \mathrm{W}^{(a)}_{jk}} &= \frac{\partial}{\partial \mathrm{W}^{(a)}_{jk}}\left[(\mathbf{I}-\mathbf{W})^{-1}_{i\ell}\right] \\ &= -\mathrm{W}^\star_{ij}\frac{\partial}{\partial \mathrm{W}^{(a)}_{jk}}\left[(\mathbf{I}-\mathbf{W})\right]\mathrm{W}^\star_{k\ell} \\ &= \mathrm{W}^\star_{ij}\dot{\mathrm{W}}^{(a)}_{jk}\mathrm{W}^\star_{k\ell}\end{aligned}$$

The second step uses Equation 40 of the Matrix Cookbook (Petersen and Pedersen, 2008). ■

We now extend Lemma 1 to express higher-order derivatives in terms of $\mathbf{W}^\star$. Note that as in Lemma 1, we will use $\dot{\mathrm{W}}^{(a)}_{ij}$ as a shorthand for the partial derivative $\partial \mathrm{W}^{(a)}_{ij}$.

Theorem 2. *For $m \geq 1$ and m-tuple of transitions $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m\rangle$*

$$\frac{\partial^m \mathrm{Z}}{\partial \mathrm{W}^{(a_1)}_{i_1j_1}\cdots\partial \mathrm{W}^{(a_m)}_{i_mj_m}} = \sum_{\left\langle i'_1 \xrightarrow{a'_1} j'_1,\cdots,i'_m \xrightarrow{a'_m} j'_m\right\rangle \in \mathcal{S}_{\vec{\tau}}} \mathrm{s}_{i'_1}\dot{\mathrm{W}}^{(a'_1)}_{i'_1j'_1}\mathrm{W}^\star_{j'_1i'_2}\dot{\mathrm{W}}^{(a'_2)}_{i'_2j'_2}\cdots\mathrm{W}^\star_{j'_{m-1}i'_m}\dot{\mathrm{W}}^{(a'_m)}_{i'_mj'_m}\mathrm{e}_{j'_m} \tag{8}$$

where $\mathbf{s} = \boldsymbol{\alpha}^\top\mathbf{W}^\star$, $\mathbf{e} = \mathbf{W}^\star\boldsymbol{\omega}$ and $\mathcal{S}_{\vec{\tau}}$ is the multi-set of permutations of $\vec{\tau}$.[8]

Proof. See App. A.1 ■

Corollary 2. *For $i,j,k,l \in [N]$ and $a,b \in \overline{\mathcal{A}}$*

$$\frac{\partial^2 \mathrm{Z}}{\partial \mathrm{W}^{(a)}_{ij}\partial \mathrm{W}^{(b)}_{kl}} = \mathrm{s}_i\dot{\mathrm{W}}^{(a)}_{ij}\mathrm{W}^\star_{jk}\dot{\mathrm{W}}^{(b)}_{kl}\mathrm{e}_l + \mathrm{s}_k\dot{\mathrm{W}}^{(b)}_{kl}\mathrm{W}^\star_{li}\dot{\mathrm{W}}^{(a)}_{ij}\mathrm{e}_j \tag{9}$$

Proof. Application of Theorem 2 for the m=2 case. ■

Theorem 2 shows that, if we have already computed $\mathbf{W}^\star$, each element of the m^{th} derivative can be found in $\mathcal{O}(m\,m!)$ time: We must sum over $\mathcal{O}(m!)$ permutations, where each summand is the product of $\mathcal{O}(m)$ items. Importantly, for the Hessian ($m=2$), we can find each element in $\mathcal{O}(1)$ using Corollary 2. Algorithm $\mathtt{D}_m$ in Fig. 1 provides pseudocode for materializing the tensor containing the m^{th} derivatives of Z.

Theorem 3. *For $m \geq 1$, algorithm $\mathtt{D}_m$ computes $\nabla^m\mathrm{Z}$ in $\mathcal{O}(N^3 + m\,m!\,A^mN^{2m})$ time and $\mathcal{O}(A^mN^{2m})$ space.*

Proof. Correctness of algorithm $\mathtt{D}_m$ follows from Theorem 2. The runtime and space bounds follow by needing to compute and store each combination of transitions. Each line of the algorithm is annotated with its running time. ■

Corollary 3. *The Hessian $\nabla^2\mathrm{Z}$ can be materialized in $\mathcal{O}(A^2N^4)$ time and $\mathcal{O}(A^2N^4)$ space. Note that these bounds are optimal.*

[8] As $\vec{\tau}$ may have duplicates, $\mathcal{S}_{\vec{\tau}}$ can also have duplicates and so must be a multi-set.

def $\mathtt{D}_m(\mathbf{W}, \boldsymbol{\alpha}, \boldsymbol{\omega})$:

▷ *Compute the tensor of m^{th}-order derivative of a WFSM; requires $\mathcal{O}(N^3 + m\, m!\, A^m N^{2m})$ time, $\mathcal{O}(A^m N^{2m})$ space.*

$\mathbf{W}^\star \leftarrow (\mathbf{I} - \mathbf{W})^{-1}$ ▷ $\mathcal{O}(N^3)$

$\mathbf{s} \leftarrow \boldsymbol{\alpha}^\top \mathbf{W}^\star$; $\mathbf{e} \leftarrow \mathbf{W}^\star \boldsymbol{\omega}$ ▷ $\mathcal{O}(N^2)$

$\mathbf{D} \leftarrow \mathbf{0}$

for $\vec{\tau} \in ([N] \times [N] \times \overline{\mathcal{A}})^m$: ▷ $\mathcal{O}(mm!A^m N^{2m})$

  for $\langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m \rangle \in \mathcal{S}_{\vec{\tau}}$:

$$\mathrm{D}_{\vec{\tau}} \mathrel{+}= \mathrm{s}_{i_1} \dot{\mathrm{W}}^{(a_1)}_{i_1 j_1} \mathrm{W}^\star_{j_1 i_2} \dot{\mathrm{W}}^{(a_2)}_{i_2 j_2} \mathrm{W}^\star_{j_2 i_3} \cdots \mathrm{W}^\star_{j_{m-1} i_m} \dot{\mathrm{W}}^{(a_m)}_{i_m j_m} \mathrm{e}_{j_m}$$

return $\mathbf{D}$

def $\mathtt{E}_2(\mathbf{W}, \boldsymbol{\alpha}, \boldsymbol{\omega}, r, t)$:

▷ *Compute the second-order expectation of a WFSM; requires $\mathcal{O}(N^3 + N^2(\overline{R}\,\overline{T} + AR'T'))$ time, $\mathcal{O}(N^2 + RT + N(R+T))$ space where $\overline{R} \stackrel{\text{def}}{=} \min(NR', R)$ and $\overline{T} \stackrel{\text{def}}{=} \min(NT', T)$.*

Compute $\mathbf{W}^\star$, $\mathbf{s}$, and $\mathbf{e}$ as in $\mathtt{D}_m$ ▷ $\mathcal{O}(N^3)$

$\mathrm{Z} \leftarrow \boldsymbol{\alpha}^\top \mathbf{W}^\star \boldsymbol{\omega}$

$\widehat{r^s} \leftarrow \mathbf{0}$; $\widehat{r^e} \leftarrow \mathbf{0}$; $\widehat{t^s} \leftarrow \mathbf{0}$; $\widehat{t^e} \leftarrow \mathbf{0}$

for $i, j \in [N], a \in \overline{\mathcal{A}}$: ▷ $\mathcal{O}(AN^2)$

$\widehat{r^s_i}$ += $\mathrm{s}_j \dot{\mathrm{W}}^{(a)}_{ji} \mathrm{W}^{(a)}_{ji} r^{(a)}_{ji}$ ▷ $\mathcal{O}(R')$

$\widehat{r^e_i}$ += $\dot{\mathrm{W}}^{(a)}_{ij} \mathrm{e}_j \dot{\mathrm{W}}^{(a)}_{ji} \mathrm{W}^{(a)}_{ij} r^{(a)}_{ij}$ ▷ $\mathcal{O}(R')$

$\widehat{t^s_i}$ += $\mathrm{s}_j \dot{\mathrm{W}}^{(i)}_{aj} \mathrm{W}^{(a)}_{ji} t^{(a)}_{ji}$ ▷ $\mathcal{O}(T')$

$\widehat{t^e_i}$ += $\dot{\mathrm{W}}^{(a)}_{ij} \mathrm{e}_j \mathrm{W}^{(a)}_{ij} t^{(a)}_{ij}$ ▷ $\mathcal{O}(T')$

return $\frac{1}{\mathrm{Z}} \Big[\sum_{i,j=0}^{N} \widehat{r^s_i} \mathrm{W}^\star_{ij} \widehat{t^e_j}^\top + \Big[\widehat{t^s_i} \mathrm{W}^\star_{ij} \widehat{r^e_j}^\top \Big]^\top + \sum_{a \in \overline{\mathcal{A}}} \mathrm{s}_i \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{e}_j \mathrm{W}^{(a)}_{ij} r^{(a)}_{ij} t^{(a)\top}_{ij} \Big]$

▷ $\mathcal{O}(N^2(\overline{R}\,\overline{T} + AR'T'))$

Figure 1: Algorithms

Proof. Application of Theorem 3 for the m=2 case. ■

4 Second-Order Expectations

In this section, we leverage the algorithms of the previous section to efficiently compute a family expectations, known as a second-order expectations. To begin, we define an **additively decomposable** function $r\colon \mathcal{T} \mapsto \mathbb{R}^R$ as any function expressed as

$$r(\tau_{i \rightsquigarrow \ell}) = \sum_{(j \xrightarrow{a} k) \in \tau_{i \rightsquigarrow \ell}} r^{(a)}_{jk} \tag{10}$$

where each $r^{(a)}_{jk}$ is an R-dimensional vector. Since many r of interest are sparse, we analyze our algorithms in terms of R and its maximum density $R' \stackrel{\text{def}}{=} \max_{j \xrightarrow{a} k} \|r^{(a)}_{jk}\|_0$. Previous work has considered expectations of such functions (Eisner, 2001) and the *product* of two such functions (Li and Eisner, 2009), better known as second-order expectations. Formally, given two additively decomposable functions $r\colon \mathcal{T} \mapsto \mathbb{R}^R$ and $t\colon \mathcal{T} \mapsto \mathbb{R}^T$, a **second-order expectation** is

$$\mathbb{E}_{\tau_{i \rightsquigarrow \ell}} \Big[r(\tau_{i \rightsquigarrow \ell}) t(\tau_{i \rightsquigarrow \ell})^\top \Big] \stackrel{\text{def}}{=} \sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}} p(\tau_{i \rightsquigarrow \ell}) r(\tau_{i \rightsquigarrow \ell}) t(\tau_{i \rightsquigarrow \ell})^\top \tag{11}$$

Examples of second-order expectations include the Fisher information matrix and the gradients of first-order expectations (e.g., expected cost, entropy, and the Kullback–Leibler divergence).

Our algorithm is based on two fundamental concepts. Firstly, expectations for probability distributions as described in (1), can be decomposed as expectations over transitions (Zmigrod et al., 2021). Secondly, the marginal probabilities of transitions are connected to derivatives of Z.[9]

Lemma 2. *For $m \geq 1$ and m-tuple of transitions $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m \rangle$*

$$p(\vec{\tau}) = \frac{1}{\mathrm{Z}} \sum_{n=1}^{m} \frac{\partial^n \mathrm{Z}}{\partial \mathrm{W}^{(a_1)}_{i_1 j_1} \ldots \partial \mathrm{W}^{(a_n)}_{i_n j_n}} \prod_{k=1}^{n} \mathrm{W}^{(a_k)}_{i_k j_k} \tag{12}$$

Proof. See App. A.2. ■

We formalize our algorithm as $\mathtt{E}_2$ in Fig. 1. Note that we achieve an additional speed-up by exploiting associativity (see App. A.3).

Theorem 4. *Algorithm $\mathtt{E}_2$ computes the second-order expectation of additively decomposable functions $r\colon \mathcal{T} \mapsto \mathbb{R}^R$ and $t\colon \mathcal{T} \mapsto \mathbb{R}^T$ in:*

$$\mathcal{O}(N^3 + N^2(\overline{R}\,\overline{T} + AR'T')) \text{ time}$$
$$\mathcal{O}(N^2 + RT + N(R+T)) \text{ space}$$

where $\overline{R} = \min(NR', R)$ and $\overline{T} = \min(NT', T)$.

Proof. Correctness of algorithm $\mathtt{E}_2$ is given in App. A.3. The runtime bounds are annotated on each line of the algorithm. We note that each $\widehat{r}$ and $\widehat{t}$ is $\overline{R}$ and $\overline{T}$ sparse. $\mathcal{O}(N^2)$ space is required to store $\mathbf{W}^\star$, $\mathcal{O}(RT)$ is required to store the expectation, and $\mathcal{O}(N(R+T))$ space is required to store the various $\widehat{r}$ and $\widehat{t}$ quantities. ■

Previous approaches for computing second-order expectations are significantly slower than $\mathtt{E}_2$. Specifically, using Li and Eisner (2009)'s second-order expectation semiring requires augmenting the

[9] This is commonly used in the case of single transition marginals, which can be found by $\nabla \log \mathrm{Z}$

arc weights to be $R \times T$ matrices and so runs in $\mathcal{O}(N^3RT + AN^2RT)$. Alternatively, we can use AD, as in §3.2, to materialize the Hessian and compute the pairwise transition marginals. This would result in a total runtime of $\mathcal{O}(AN^5 + A^2N^4R'T')$.

5 Conclusion

We have presented efficient methods that exploit properties of the derivative of a matrix inverse to find m-order derivatives for WFSMs. Additionally, we provided an explicit, novel, algorithm for materializing the Hessian in its *optimal* complexity, $\mathcal{O}(A^2N^4)$. We also showed how this could be utilized to efficiently compute second-order expectations of distributions under WFSMs, such as covariance matrices and the gradient of entropy. We hope that our paper encourages future research to use the Hessian and second-order expectations of WFSM systems, which have previously been disadvantaged by inefficient algorithms.

A Proofs

A.1

Theorem 2. *For $m \geq 1$ and m-tuple of transitions $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m \rangle$*

$$\frac{\partial^m \mathrm{Z}}{\partial \mathrm{W}^{(a_1)}_{i_1 j_1} \ldots \partial \mathrm{W}^{(a_m)}_{i_m j_m}} = \sum_{\left\langle i'_1 \xrightarrow{a'_1} j'_1, \ldots, i'_m \xrightarrow{a'_m} j'_m \right\rangle \in \mathcal{S}_{\vec{\tau}}} \mathrm{s}_{i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \dot{\mathrm{W}}^{(a'_2)}_{i'_2 j'_2} \cdots \mathrm{W}^{\star}_{j'_{m-1} i'_m} \dot{\mathrm{W}}^{(a'_m)}_{i'_m j'_m} \mathrm{e}_{j'_m}$$

where $\mathbf{s} = \boldsymbol{\alpha}^\top \mathbf{W}^\star$, $\mathbf{e} = \mathbf{W}^\star \boldsymbol{\omega}$ and $\mathcal{S}_{\vec{\tau}}$ is the multi-set of permutations of $\vec{\tau}$.

Proof. We prove this by induction on m.
Base Case: $m = 1$ and $\vec{\tau} = \langle i \xrightarrow{a} j \rangle$:

$$\frac{\partial \mathrm{Z}}{\partial \mathrm{W}^{(a)}_{ij}} = \frac{\partial}{\partial \mathrm{W}^{(a)}_{ij}} \left[\sum_{k,l=0}^{N} \alpha_k \mathrm{W}^{\star}_{kl} \omega_l \right] = \sum_{k,l=0}^{N} \alpha_k \mathrm{W}^{\star}_{ki} \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{W}^{\star}_{jl} \omega_l = \mathrm{s}_i \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{e}_j$$

Inductive Step: Assume that the expression holds for m. Let $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m \rangle$ and consider the tuple $\vec{\tau}\,'$, the concatenation of $(i \xrightarrow{a} j)$ and $\vec{\tau}$.

$$\frac{\partial^{m+1} \mathrm{Z}}{\mathrm{W}^{(a)}_{ij} \partial \mathrm{W}^{(a_1)}_{i_1 j_1} \ldots \partial \mathrm{W}^{(a_m)}_{i_m j_m}} = \frac{\partial}{\partial \mathrm{W}^{(a)}_{ij}} \sum_{\left\langle i'_1 \xrightarrow{a'_1} j'_1, \ldots, i'_m \xrightarrow{a'_m} j'_m \right\rangle \in \mathcal{S}_{\vec{\tau}}} \mathrm{s}_{i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \cdots \dot{\mathrm{W}}^{(a'_m)}_{i'_m j'_m} \mathrm{e}_{j'_m}$$

Consider the derivative of each summand with respect to $\mathrm{W}^{(a)}_{ij}$. By the product rule, we have

$$\begin{aligned}
&\frac{\partial}{\partial \mathrm{W}^{(a)}_{ij}} \left[\mathrm{s}_{i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \cdots \dot{\mathrm{W}}^{(a'_m)}_{i'_m j'_m} \mathrm{e}_{j'_m} \right] \\
&= \mathrm{s}_i \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{W}^{\star}_{j i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \cdots \dot{\mathrm{W}}^{(a'_m)}_{i'_m j'_m} \mathrm{e}_{j'_m} + \\
&\quad \cdots + \mathrm{s}_{i'_1} \cdots \mathrm{W}^{\star}_{j_k i} \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{W}^{\star}_{j i_{k+1}} \cdots \mathrm{e}_{j'_m} + \\
&\quad \cdots + \mathrm{s}_{i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \cdots \dot{\mathrm{W}}^{(a'_m)}_{i'_m j'_m} \mathrm{W}^{\star}_{j'_m i} \dot{\mathrm{W}}^{(a)}_{ij} \mathrm{e}_j
\end{aligned}$$

The above expression is equal to inserting $i \xrightarrow{a} j$ in every spot of the induction hypothesis's permutation, thereby creating a permutation over $\vec{\tau}\,'$. Reassembling with the expression for the derivative,

$$\frac{\partial^{m+1} \mathrm{Z}}{\partial \mathrm{W}^{(a)}_{ij} \partial \mathrm{W}^{(a_1)}_{i_1 j_1} \ldots \partial \mathrm{W}^{(a_m)}_{i_m j_m}} = \sum_{\left\langle i'_1 \xrightarrow{a'_1} j'_1, \ldots, i'_{m+1} \xrightarrow{a'_{m+1}} j'_{m+1} \right\rangle) \in \mathcal{S}_{\vec{\tau}\,'}} \mathrm{s}_{i'_1} \dot{\mathrm{W}}^{(a'_1)}_{i'_1 j'_1} \mathrm{W}^{\star}_{j'_1 i'_2} \dot{\mathrm{W}}^{(a'_2)}_{i'_2 j'_2} \cdots \dot{\mathrm{W}}^{(a'_{m+1})}_{i'_{m+1} j'_{m+1}} \mathrm{e}_{j'_{m+1}}$$

■

A.2

Lemma 2. *For $m \geq 1$ and m-tuple of transitions $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_m \xrightarrow{a_m} j_m \rangle$*

$$p(\vec{\tau}) = \frac{1}{\mathrm{Z}} \sum_{n=1}^{m} \frac{\partial^n \mathrm{Z}}{\partial \mathrm{W}^{(a_1)}_{i_1 j_1} \ldots \partial \mathrm{W}^{(a_n)}_{i_n j_n}} \prod_{k=1}^{n} \mathrm{W}^{(a_k)}_{i_k j_k} \tag{10}$$

Proof. Let $\mathcal{T}_{\vec{\tau}}$ be the set of trajectories such that $\tau_{i \rightsquigarrow \ell} \in \mathcal{T}_{\vec{\tau}} \iff \vec{\tau} \subseteq \tau_{i \rightsquigarrow \ell}$. Then,

$$p(\vec{\tau}) = \frac{1}{\mathrm{Z}} \sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}_{\vec{\tau}}} w(\tau_{i \rightsquigarrow \ell})$$

We prove the lemma by induction on m.
Base Case: Then, $m = 1$ and $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1 \rangle$. We have that

$$\frac{1}{\mathrm{Z}} \frac{\partial \mathrm{Z}}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)}} \mathrm{W}_{i_1 j_1}^{(a_1)} = \frac{1}{\mathrm{Z}} \frac{\partial}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)}} \left[\sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}} w(\tau_{i \rightsquigarrow \ell}) \right] \mathrm{W}_{i_1 j_1}^{(a_1)} \overset{\text{(a)}}{=} \frac{1}{\mathrm{Z}} \left(\sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}_{\vec{\tau}}} w(\tau_{i \rightsquigarrow \ell}) \right) = p(i_1 \xrightarrow{a_1} j_1)$$

Step (a) holds because taking the derivative of Z with respect to $\mathrm{W}_{i_1 j_1}^{(a_1)}$ yields the sum of the weights all trajectories which include $i_1 \xrightarrow{a_1} j_1$ where we exclude $\mathrm{W}_{i_1 j_1}^{(a_1)}$ from the computation of the weight. Then, we can push the outer $\mathrm{W}_{i_1 j_1}^{(a_1)}$ into the equation to obtain the sum of the weights of all trajectories containing $i_1 \xrightarrow{a_1} j_1$.
Inductive Step: Suppose that (10) holds for any m-tuple. Let $\vec{\tau} = \langle i_1 \xrightarrow{a_1} j_1, \ldots, i_{m+1} \xrightarrow{a_{m+1}} j_{m+1} \rangle$. Without loss of generality, fix $i_1 \xrightarrow{a_1} j_1$ and let $\vec{\tau}'$ be $\vec{\tau}$ without $i_1 \xrightarrow{a_1} j_1$.

$$\begin{aligned}
&\frac{1}{\mathrm{Z}} \sum_{n=1}^{m+1} \frac{\partial^n \mathrm{Z}}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)} \ldots \partial \mathrm{W}_{i_n j_n}^{(a_n)}} \prod_{k=1}^{n} \mathrm{W}_{i_k j_k}^{(a_k)} \\
&\overset{\text{(b)}}{=} \mathrm{W}_{i_1 j_1}^{(a_1)} \frac{\partial}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)}} \underbrace{\left[\frac{1}{\mathrm{Z}} \sum_{n=2}^{m+1} \frac{\partial^{(n-1)} \mathrm{Z}}{\partial \mathrm{W}_{i_2 j_2}^{(a_2)} \ldots \partial \mathrm{W}_{i_n j_n}^{(a_n)}} \prod_{k=2}^{n} \mathrm{W}_{i_k j_k}^{(a_k)} \right]}_{\text{Inductive hypothesis}} \\
&\overset{\text{(c)}}{=} \mathrm{W}_{i_1 j_1}^{(a_1)} \frac{\partial}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)}} \overbrace{\left[\frac{1}{\mathrm{Z}} \sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}_{\vec{\tau}'}} w(\tau_{i \rightsquigarrow \ell}) \right]} \\
&\overset{\text{(d)}}{=} \frac{1}{\mathrm{Z}} \frac{\partial}{\partial \mathrm{W}_{i_1 j_1}^{(a_1)}} \left[\sum_{\tau_{i \rightsquigarrow \ell} \in \mathcal{T}_{\vec{\tau}'}} w(\tau_{i \rightsquigarrow \ell}) \right] \mathrm{W}_{i_1 j_1}^{(a_1)} \\
&\overset{\text{(e)}}{=} p(\vec{\tau})
\end{aligned}$$

Step (b) pushes $\frac{1}{\mathrm{Z}}$ and $\prod_{k=2}^{n} \mathrm{W}_{i_k j_k}^{(a_k)}$ as constants into the derivative and step (c) uses our induction hypothesis on $\vec{\tau}'$. Then, step (d) takes $\frac{1}{\mathrm{Z}}$ out of the derivative as we pushed it in as a constant. Finally, step (e) follows by the same reasoning as step (a) in the base case above. ■

A.3

Theorem 4. *Algorithm E_2 computes the second-order expectation of additively decomposable functions $r\colon \mathcal{T} \mapsto \mathbb{R}^R$ and $t\colon \mathcal{T} \mapsto \mathbb{R}^T$ in:*

$$\mathcal{O}(N^3 + N^2(\overline{R}\,\overline{T} + AR'T')) \text{ time}$$
$$\mathcal{O}(N^2 + RT + N(R+T)) \text{ space}$$

where $\overline{R} = \min(NR', R)$ and $\overline{T} = \min(NT', T)$.
Proof. We provide a proof of correctness (the time and space bounds are discussed in the main paper). Zmigrod et al. (2021) show that we can find second-order expectations over by finding the expectations over pairs of transitions. That is,

$$\mathbb{E}_{\tau_{i \rightsquigarrow \ell}} \left[r(\tau_{i \rightsquigarrow \ell}) t(\tau_{i \rightsquigarrow \ell})^\top \right] = \sum_{i,j,k,l=0}^{N} \sum_{a,b \in \overline{\mathcal{A}}} p\Big(i \xrightarrow{a} j, k \xrightarrow{b} l \Big) r_{ij}^{(a)} t_{kl}^{(b)^\top}$$

We can use Lemma 2 for the $m = 2$ case, to find that the expectation is given by

$$\begin{aligned}
&\mathbb{E}_{\tau_{i\rightsquigarrow\ell}}\Big[r(\tau_{i\rightsquigarrow\ell})t(\tau_{i\rightsquigarrow\ell})^\top\Big] \\
&= \frac{1}{\mathrm{Z}}\Big[\sum_{i,j=0}^{N}\sum_{a\in\overline{\mathcal{A}}}\frac{\partial \mathrm{Z}}{\partial \mathrm{W}_{ij}^{(a)}}\mathrm{W}_{ij}^{(a)}r_{ij}^{(a)}t_{ij}^{(a)\top} + \sum_{i,j,k,l=0}^{N}\sum_{a,b\in\overline{\mathcal{A}}}\frac{\partial^2 \mathrm{Z}}{\partial \mathrm{W}_{ij}^{(a)}\partial \mathrm{W}_{kl}^{(b)}}\mathrm{W}_{ij}^{(a)}\mathrm{W}_{kl}^{(b)}r_{ij}^{(a)}t_{kl}^{(b)\top}\Big]
\end{aligned}$$

The first summand can be rewritten as

$$\sum_{i,j=0}^{N}\sum_{a\in\overline{\mathcal{A}}}\frac{\partial \mathrm{Z}}{\partial \mathrm{W}_{ij}^{(a)}}\mathrm{W}_{ij}^{(a)}r_{ij}^{(a)}t_{ij}^{(a)\top} = \sum_{i,j=0}^{N}\sum_{a\in\overline{\mathcal{A}}}\mathrm{s}_i\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{e}_j\mathrm{W}_{ij}^{(a)}r_{ij}^{(a)}t_{ij}^{(a)\top}$$

The second summand can be rewritten as

$$\begin{aligned}
&\sum_{i,j,k,l=0}^{N}\sum_{a,b\in\overline{\mathcal{A}}}\frac{\partial^2 \mathrm{Z}}{\partial \mathrm{W}_{ij}^{(a)}\partial \mathrm{W}_{kl}^{(b)}}\mathrm{W}_{ij}^{(a)}\mathrm{W}_{kl}^{(b)}r_{ij}^{(a)}t_{kl}^{(b)\top} \\
&\quad= \sum_{i,j,k,l=0}^{N}\sum_{a,b\in\overline{\mathcal{A}}}\mathrm{s}_i\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{W}_{jk}^{\star}\dot{\mathrm{W}}_{kl}^{(b)}\mathrm{e}_l\mathrm{W}_{ij}^{(a)}\mathrm{W}_{kl}^{(b)}r_{ij}^{(a)}t_{kl}^{(b)\top} + \mathrm{s}_k\dot{\mathrm{W}}_{kl}^{(b)}\mathrm{W}_{li}^{\star}\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{e}_j\mathrm{W}_{ij}^{(a)}\mathrm{W}_{kl}^{(b)}r_{ij}^{(a)}t_{kl}^{(b)\top}
\end{aligned}$$

Consider the first summand of the above expression

$$\begin{aligned}
&\sum_{i,j,k,l=0}^{N}\sum_{a,b\in\overline{\mathcal{A}}}\mathrm{s}_i\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{W}_{jk}^{\star}\dot{\mathrm{W}}_{kl}^{(b)}\mathrm{e}_l\mathrm{W}_{ij}^{(a)}\mathrm{W}_{kl}^{(b)}r_{ij}^{(a)}t_{kl}^{(b)\top} \\
&=\sum_{j,k=0}^{N}\underbrace{\Big[\sum_{i=0}^{N}\sum_{a\in\overline{\mathcal{A}}}\mathrm{s}_i\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{W}_{ij}^{(a)}r_{ij}^{(a)}\Big]}_{\stackrel{\text{def}}{=}\widehat{r_j^s}}\mathrm{W}_{jk}^{\star}\underbrace{\Big[\sum_{l=0}^{N}\sum_{b\in\overline{\mathcal{A}}}\dot{\mathrm{W}}_{kl}^{(b)}\mathrm{e}_l\mathrm{W}_{kl}^{(b)}t_{kl}^{(b)}\Big]^\top}_{\stackrel{\text{def}}{=}\widehat{t_k^e}^\top} \\
&=\sum_{j,k=0}^{N}\widehat{r_j^s}\mathrm{W}_{jk}^{\star}\widehat{t_k^e}^\top
\end{aligned}$$

Similarly, the second summand can be written as

$$\sum_{j,k=0}^{N}\widehat{r_k^e}\mathrm{W}_{jk}^{\star}\widehat{t_j^s}^\top$$

Finally, recomposing all the pieces together,

$$\mathbb{E}_{\tau_{i\rightsquigarrow\ell}}\Big[r(\tau_{i\rightsquigarrow\ell})t(\tau_{i\rightsquigarrow\ell})^\top\Big] = \frac{1}{\mathrm{Z}}\Big[\sum_{i,j=0}^{N}\widehat{r_i^s}\mathrm{W}_{ij}^{\star}\widehat{t_j^e}^\top + \widehat{r_j^e}\mathrm{W}_{ij}^{\star}\widehat{t_i^s}^\top + \sum_{a\in\overline{\mathcal{A}}}\mathrm{s}_i\dot{\mathrm{W}}_{ij}^{(a)}\mathrm{e}_j\mathrm{W}_{ij}^{(a)}r_{ij}^{(a)}t_{ij}^{(a)\top}\Big]$$

Abstract

The growth of online consumer health questions has led to the necessity for reliable and accurate question answering systems. A recent study showed that manual summarization of consumer health questions brings significant improvement in retrieving relevant answers. However, the automatic summarization of long questions is a challenging task due to the lack of training data and the complexity of the related subtasks, such as the question focus and type recognition. In this paper, we introduce a reinforcement learning-based framework for abstractive question summarization. We propose two novel rewards obtained from the downstream tasks of (i) question-type identification and (ii) question-focus recognition to regularize the question generation model. These rewards ensure the generation of semantically valid questions and encourage the inclusion of key medical entities/foci in the question summary. We evaluated our proposed method on two benchmark datasets and achieved higher performance over state-of-the-art models. The manual evaluation of the summaries reveals that the generated questions are more diverse and have fewer factual inconsistencies than the baseline summaries. The source code is available here: https://github.com/shwetanlp/CHQ-Summ.

1 Introduction

The growing trend in online web forums is to attract more and more consumers to use the Internet for their health information needs. An instinctive way for consumers to query for their health-related content is in the form of natural language questions. These questions are often excessively descriptive and contain more than required peripheral information. However, most of the textual content is not particularly relevant in answering the question (Kilicoglu et al., 2013). A recent study showed that manual summarization of consumer health questions (CHQ) has significant improvement (58%) in retrieving relevant answers (Ben Abacha and Demner-Fushman, 2019). However, three major limitations impede higher success in obtaining semantically and factually correct summaries: **(1)** the complexity of identifying the correct question type/intent, **(2)** the difficulty of identifying salient medical entities and focus/topic of the question, and **(3)** the lack of large-scale CHQ summarization datasets. To address these limitations, this work presents a new reinforcement learning based framework for abstractive question summarization. We also propose two novel question-aware semantic reward functions: Question-type Identification Reward (QTR) and Question-focus Recognition Reward (QFR). The QTR measures correctly identified question-type(s) of the summarized question. Similarly, QFR measures correctly recognized key medical concept(s) or focus/foci of the summary.

We use the reinforce-based policy gradient approach, which maximizes the non-differentiable QTR and QFR rewards by learning the optimal policy defined by the Transformer model parameters. Our experiments show that these two rewards can significantly improve the question summarization quality, separately or jointly, achieving the new state-of-the-art performance on the MEQSUM and MATINF benchmark datasets. The main contributions of this paper are as follows:

- We propose a novel approach towards question summarization by introducing two question-aware semantic rewards **(i)** *Question-type Identification Reward* and **(ii)** *Question-focus Recognition Reward*, to enforce the generation of semantically valid and factually correct question summaries.
- The proposed models achieve the state-of-the-art performance on two question summa-

rization datasets over competitive pre-trained Transformer models.

- A manual evaluation of the summarized questions reveals that they achieve higher abstraction levels and are more semantically and factually similar to human-generated summaries.

2 Related Work

In recent years, reinforcement learning (RL) based models have been explored for the abstractive summarization task. Paulus et al. (2017) introduced RL in neural summarization models by optimizing the ROUGE score as a reward that led to more readable and concise summaries. Subsequently, several studies (Chen and Bansal, 2018; Pasunuru and Bansal, 2018; Zhang and Bansal, 2019; Gupta et al., 2020; Zhang et al., 2019b) have proposed methods to optimize the model losses via RL that enables the model to generate the sentences with the higher ROUGE score. While these methods are primarily supervised, Laban et al. (2020) proposed an unsupervised method that accounts for fluency, brevity, and coverage in generated summaries using multiple RL-based rewards. The majority of these works are focused on document summarization with conventional non-semantics rewards (ROUGE, BLEU). In contrast, we focus on formulating the semantic rewards that bring a high-level semantic regularization. In particular, we investigate the question's main characteristics, i.e., question focus and type, to define the rewards.

Recently, Ben Abacha and Demner-Fushman (2019) defined the CHQ summarization task and introduced a new benchmark (MEQSUM) and a pointer-generator model. Ben Abacha et al. (2021) organized the MEDIQA-21 shared task challenge on CHQ, multi-document answers, and radiology report summarization. Most of the participating team (Yadav et al., 2021b; He et al., 2021; Sänger et al., 2021) utilized transfer learning, knowledge-based, and ensemble methods to solve the question summarization task. Yadav et al. (2021a) proposed question-aware transformer models for question summarization. Xu et al. (2020) automatically created a Chinese dataset (MATINF) for medical question answering, summarization, and classification tasks focusing on maternity and infant categories. Some of the other prominent works in the abstractive summarization of long and short documents include Cohan et al. (2018); Zhang et al. (2019a); MacAvaney et al. (2019); Sotudeh et al. (2020).

3 Proposed Method

Given a question, the goal of the task is to generate a summarized question that contains the salient information of the original question. We propose a RL-based question summarizer model over the Transformer (Vaswani et al., 2017) encoder-decoder architecture. We describe below the proposed reward functions.

3.1 Question-aware Semantic Rewards

(a) Question-type Identification Reward: Independent of the pre-training task, most language models use maximum likelihood estimation (MLE)-based training for fine-tuning the downstream tasks. MLE has two drawbacks: (1) "*exposure bias*" (Ranzato et al., 2016) when the model expects gold-standard data at each step during training but does not have such supervision when testing, and (2) "*representational collapse*" (Aghajanyan et al., 2021), is the degradation of generalizable representations of pre-trained models during the fine-tuning stage. To deal with the *exposure bias*, previous works used the ROUGE and BLEU rewards to train the generation models (Paulus et al., 2017; Ranzato et al., 2016). These evaluation metrics are based on n-grams matching and might fail to capture the semantics of the generated questions. We, therefore, propose a new question-type identification reward to capture the underlying question semantics.

We fine-tuned a $\text{BERT}_{\text{BASE}}$ network as a question-type identification model to provide question-type labels. Specifically, we use the `[CLS]` token representation ($\boldsymbol{h}_{[CLS]}$) from the final transformer layer of $\text{BERT}_{\text{BASE}}$ and add the feed-forward layers on top of the $\boldsymbol{h}_{[CLS]}$ to compute the final logits

$$l = \boldsymbol{W}(tanh(\boldsymbol{U}h_{[CLS]} + \boldsymbol{a})) + \boldsymbol{b}$$

Finally, the question types are predicted using the *sigmoid* activation function on each output neuron of logits l. The fine-tuned network is used to compute the reward $r_{QTR}(Q^p, Q^*)$ as F-Score of question-types between the generated question summary Q^p and the gold question summary Q^*.

(b) Question-focus Recognition Reward: A good question summary should contain the key information of the original question to avoid factual inconsistency. In the literature, ROUGE-based rewards have been explored to maximize the coverage of the generated summary, but it does not guarantee to preserve the key information in the

question summary. We introduce a novel reward function called question-focus recognition reward, which captures the degree to which the key information from the original question is present in the generated summary question. Similar to QTR, we fine-tuned the $\text{BERT}_{\text{BASE}}$ network for question-focus recognition to predict the focus/foci of the question. Specifically, given the representation matrix ($\boldsymbol{H} \in \mathcal{R}^{n \times d}$) of n tokens and d dimensional hidden state representation obtained from the final transformer layer of $\text{BERT}_{\text{BASE}}$, we performed the token level prediction using a linear layer of the feed-forward network. For each token representation (h_i), we compute the logits $l_i \in \mathcal{R}^{|C|}$, where ($|C|$) is the number of classes and predict the question focus as follows: $f_i = softmax(\boldsymbol{W}h_i + \boldsymbol{b})$. The fine-tuned network is used to compute the reward $r_{QFR}(Q^p, Q^*)$ as F-Score of question-focus between the generated question summary Q^p and the gold question summary Q^*.

3.2 Policy Gradient REINFORCE

We cast question summarization as an RL problem, where the "*agent*" (ProphetNet decoder) interacts with the "*environment*" (Question-type or focus prediction networks) to take "*actions*" (next word prediction) based on the learned "policy" p_θ defined by ProphetNet parameters (θ) and observe "*reward*" (QTR and QFR). We utilized ProphetNet (Qi et al., 2020) as the base model because it is specifically designed for sequence-to-sequence training and it has shown near state-of-the-art results on natural language generation task. We use the REINFORCE algorithm (Williams, 1992) to learn the optimal policy which maximizes the expected reward. Toward this, we minimize the loss function $\mathcal{L}_{RL} = -E_{Q^s \sim p_\theta}[r(Q^s, Q^*)]$, where Q^s is the question formed by sampling the words q_t^s from the model's output distribution, i.e. $p(q_t^s | q_1^s, q_2^s, \ldots, q_{t-1}^s, \mathcal{S})$. The derivative of $\mathcal{L}_{RL}$ is approximated using a single sample along with baseline estimator b:

$$\bigtriangledown_\theta \mathcal{L}_{RL} = -(r(Q^s, Q^*) - b) \bigtriangledown_\theta logp_\theta(Q^s) \quad (1)$$

The Self-critical Sequence Training (SCST) strategy (Rennie et al., 2017) is used to estimate the baseline reward by computing the reward with the question generated by the current model using the greedy decoding technique, i.e., $b = r(Q^g, Q^*)$. We compute the final reward as a weighted sum of QTR and QFR as follows:

$$r(Q^p, Q^*) = \gamma_{QTR} \times r_{QTR}(Q^p, Q^*) + \gamma_{QFR} \times r_{QFR}(Q^p, Q^*) \quad (2)$$

We train the network with the mixed loss as discussed in Paulus et al. (2017). The overall network loss is as follows:

$$\mathcal{L} = \alpha \mathcal{L}_{RL} + (1 - \alpha)\mathcal{L}_{ML} \quad (3)$$

where, α is the scaling factor and $\mathcal{L}_{ML}$ is the negative log-likelihood loss and equivalent to $-\sum_{t=1}^{t=m} logp(q_t^* | q_1^*, q_2^*, \ldots, q_{t-1}^*, \mathcal{S})$, where $\mathcal{S}$ is the source question.

4 Experimental Results & Analysis

4.1 Datasets

We utilized two CHQ abstractive summarization datasets: MEQSUM and MATINF[1] to evaluate the proposed framework. The MEQSUM[2] training set consists of $5,155$ CHQ-summary pairs and the test set includes 500 pairs. We chose 100 samples from the training set as the validation dataset.

For fine-tuning the question-type identification and question-focus recognition models, we manually labeled the MEQSUM dataset with the question type: (*'Dosage', 'Drugs', 'Diagnosis', 'Treatments', 'Duration', 'Testing', 'Symptom', 'Usage', 'Information', 'Causes'*) and foci. We use the labeled data to train the question-type identification and question-focus recognition networks. For question-focus recognition, we follow the BIO notation and classify each token for the beginning of focus token (**B**), intermediate of focus token (**I**), and other token (**O**) classes. Since, the gold annotations for question-types and question-focus were not available for the MATINF dataset, we used the pre-trained network trained on the MEQSUM dataset to obtain the silver-standard question-types and question-focus information for MATINF[3]. The MATINF dataset has $5,000$ CHQ-summary pairs in the training set and 500 in the test set.

4.2 Experimental Setups

We use the pre-trained uncased version[4] of ProphetNet as the base encoder-decoder model. We use a beam search algorithm with beam size 4 to decode the summary sentence. We train all summarization models on the respective training dataset for 20 epochs. We set the maximum question and summary sentence length to 120 and 20, respectively.

[1] Since the dataset was in Chinese, we translated it to English using Google Translate.

Table 2: Results of the manual evaluation of the summaries generated by ProphetNet (M1), M1+QTR (M2), M1+QFR (M3), and M1+QTR+QFR (M4). For *Semantic Preserved* and *Factual Consistent*, we report the partially correct (PC) and fully correct (FC) numbers.

We first fine-train the proposed network by minimizing only the maximum likelihood (ML) loss. Next, we initialize our proposed model with the fine-trained ML weights and train the network with the mixed-objective learning function (Eq. 3). We performed experiments on the validation dataset by varying the α, γ_{QTR} and γ_{QFR} in the range of $(0, 1)$. The scaling factor (α) value 0.95, was found to be optimal (in terms of Rouge-L) for both the datasets. The values of $\gamma_{QTR} = 0.4$ and $\gamma_{QFR} = 0.6$ were found to be optimal on the validation sets of both datasets. To update the model parameters, we used Adam (Kingma and Ba, 2015) optimization algorithm with the learning rate of $7e-5$ for ML training and $3e-7$ for RL training. We obtained the optimal hyper-parameters values based on the performance of the model on the validation sets of MEQSUM and MATINF in the respective experiments. We used a cosine annealing learning rate (Loshchilov and Hutter, 2017) decay schedule, where the learning rate decreases linearly from the initial learning set in the optimizer to 0. To avoid the gradient explosion issue, the gradient norm was clipped within 1. For all the baseline experiments, we followed the official source code of the approach and trained the model on our datasets. We implemented the approach of Ben Abacha and Demner-Fushman (2019) to evaluate the performance on both datasets. All experiments were performed on a single NVIDIA Tesla V100 GPU having GPU memory of 32GB. The average runtimes (each epoch) for the proposed approaches M_2, M_3 and M_4 were $2.7, 2.8$ and 4.5 hours, respectively. All the proposed models have 391.32 million parameters.

4.3 Results

We present the results of the proposed question-aware semantic rewards on the MEQSUM and MATINF datasets in Table-1. We evaluated the generated summaries using the ROUGE (Lin, 2004) metric[5]. The proposed model achieves new state-of-the-art performance on both datasets by

[5] https://pypi.org/project/py-rouge/

Original Question-I: who makes bromocriptine i am wondering what company makes the drug bromocriptine... i have on my pituitary gland ... i have to buy them...
Reference: who manufactures bromocriptine?
Generated Summary
ProphetNet: what is bromocriptine? **Proposed Approach**: what company makes bromocriptine and how much does it cost?
Original Question-II: Have been on methadone for four years. I am interested in the rapid withdrawal under anesthesia, but do not have a clue where I can find a doctor or hospital who does this. I also would like to know the approximate cost and if or what insurance companies pay for this.
Reference: how can I find a physician (s) or hospital (s) who specialize in rapid methadone withdrawal under anesthesia, and the cost and insurance benefits for the procedure?
Generated Summary
ProphetNet: what is the treatment for rapid withdrawal of methadone under anesthesia? **Proposed Approach**: where can i find physician (s) who specialize in rapid withdrawal of methadone?

Table 3: Correct/Incorrect summaries generated on MEQSUM. Example-I shows a perfect summary over ProphetNet. The second example shows an incorrect summary with a partially extracted focus ('*under anesthesia*') and two missing types ('*cost*', '*procedures*').

outperforming competitive baseline Transformer models. We also compare the proposed model with the joint learning baselines, where we regularize the question summarizer with the additional loss obtained from the question-type (Q-type) identification and question-focus (Q-focus) recognition model. To make a fair comparison with the proposed approach, we train these joint learning-based models with the same weighted strategy shown in Eq. 3. The results reported in Table 1 show the improvement over the ProphetNet on both datasets.

In comparison to the benchmark model on MEQ-SUM, our proposed model obtained an improvement of 9.63%. A similar improvement is also observed on the MATINF dataset. Furthermore, the results show that individual QTR and QFR rewards also improve over ProphetNet and ROUGE-based rewards. These results support two major claims: **(1)** question-type reward assists the model to capture the underlying question semantics, and **(2)** awareness of salient entities learned from the question-focus reward enables the generation of fewer incorrect summaries that are unrelated to the question topic. The proposed rewards are model-independent and can be plugged into any pre-trained Seq2Seq model. On the downstream tasks of question-type identification and question-focus recognition, the pre-trained BERT model achieves the F-Score of 97.10% and 77.24%, respectively, on 10% of the manually labeled MEQ-SUM pairs.

Manual Evaluation: Two annotators, experts in medical informatics, performed an analysis of 50 summaries randomly selected from each test set. In MATINF, nine out of the 50 samples contained translation errors. We thus randomly replaced them. In both datasets, we annotated each summary with two labels '*Semantics Preserved*' and '*Factual Consistent*' to measure **(1)** whether the semantics (i.e., question intent) of the source question was preserved in the generated summary and **(2)** whether the key entities/foci were present in the generated summary. In the manual evaluation of the quality of the generated summaries, we categorize each summary into one of the following categories: '*Incorrect*', '*Acceptable*', and '*Perfect*'. We report the human evaluation results (average of two annotators) on both datasets in Table-2. The results show that our proposed rewards enhance the model by capturing the underlying semantics and facts, which led to higher proportions of perfect and acceptable summaries. The error analysis identified two major causes of errors: **(1)** Wrong question types (e.g. the original question contained multiple question types or has insufficient type-related training instances) and **(2)** Wrong/partial focus (e.g. the model fails to capture the key medical entities).

5 Conclusion

In this work, we present an RL-based framework by introducing novel question-aware semantic rewards to enhance the semantics and factual consistency of the summarized questions. The automatic and human evaluations demonstrated the efficiency of these rewards when integrated with a strong encoder-decoder based ProphetNet transformer model. The proposed methods achieve state-of-the-art results on two-question summarization benchmarks. In the future, we will explore other types of semantic rewards and efficient multi-rewards optimization algorithms for RL.

Abstract

Relation linking is a crucial component of Knowledge Base Question Answering systems. Existing systems use a wide variety of heuristics, or ensembles of multiple systems, heavily relying on the surface question text. However, the explicit semantic parse of the question is a rich source of relation information that is not taken advantage of. We propose a simple transformer-based neural model for relation linking that leverages the AMR semantic parse of a sentence. Our system significantly outperforms the state-of-the-art on 4 popular benchmark datasets. These are based on either DBpedia or Wikidata, demonstrating that our approach is effective across KGs.

1 Introduction

Knowledge base question answering (KBQA) has received significant interest due to its real-world applications. KBQA is a task where a natural language question is transformed into a precise structured query, using Entity Linking and Relation Linking as necessary sub-tasks to retrieve an answer. For example, the question *"Who founded the city where Pat Vincent died?"* requires mapping (a) *founded* and *died* to relations *dbo:founder* and *dbo:deathPlace*, and (b) entity *Pat Vincent* to *dbr:Pat_Vincent*, given DBpedia as the knowledge base.

Semantic parses such as Abstract Meaning Representation (AMR) have recently shown to be useful for the KBQA task (Lim et al., 2020). However, critical tasks for KBQA such as Relation Linking continue to be addressed primarily using the question text (Mulang' et al., 2020; Sakor et al., 2019b; Lin et al., 2020), ignoring the AMR parses of the question which can introduce additional semantics. In the literature, some systems such as SLING (Mihindukulasooriya et al., 2020) have used AMR for relation linking. However, similar to other rule-based approaches (Sakor et al., 2019b), SLING depends heavily on the specific target KG (DBpedia) and it is based on a complex ensemble of different approaches, making portability to new knowledge bases a non-trivial task.

In this work, we propose SemReL; a single Semantics-aware neural model for Relation linking. SemReL takes as input the question text annotated with its AMR parse and entity information and outputs a ranked list of relations. The key contributions of this work are as follows: (a) a simple, knowledge graph agnostic neural model for relation linking over knowledge bases, (b) leveraging AMR parses for better question representation, and (c) an experimental evaluation using four datasets based on DBpedia and Wikidata where we show that SemReL consistently outperforms existing systems on all datasets.

2 Semantics-aware Relation Linking

We propose a relation linking system that exploits the semantic structure of a sentence to retrieve relevant relations from the underlying knowledge base. We hypothesise that semantic representations abstract away from lexical forms, providing structural clues that are more consistent across training examples than surface text. To this end, we use the AMR graph of the sentence as its semantic structure. AMRs are directed acyclic graphs that capture *who is doing what to whom* in a sentence. The nodes in the graph are concepts and the edges are labelled with relations between those concepts. Figure 1 shows example AMR graphs for the question *"Who founded the city where Pat Vincent died?"*. Note that the AMR graph for the question represents the target of the query as a special node labelled 'amr-unknown'.

The inputs to our system are: the question text,

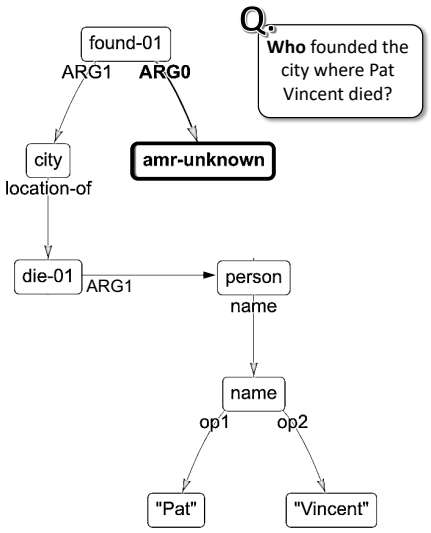

Figure 1: A question AMR: The *amr-unknown* represents the query target and the *name* node marks entities.

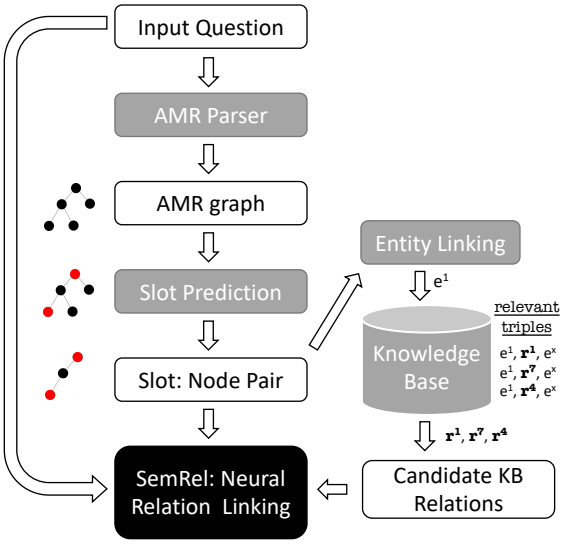

Figure 2: Overall system flow: grey blocks are various systems and white blocks show the inputs and outputs.

its AMR graph and the entities in the question marked and linked[1]. Relation linking is performed in two steps. First, our system identifies the number of expected relations and their location both in the sentence and in the AMR graph. Next, for each identified slot, the most likely relation is predicted using a transformer based neural model, that ranks them using their English labels from the KG. The AMR structure of the sentence is crucial in both steps. Figure 2 shows a schematic diagram of overall system. In the following, we first explain the process of finding potential relation slots using AMR graph. Next we describe in detail our relation linking module.

2.1 Relation Slot Prediction

AMR explicitly marks named entity nodes (see Figure 1). These nodes are linked to knowledge base entities using BLINK entity linker. The entity nodes in graph are also used to predict the number and locations of relation slots. A *slot* is defined as a pair of nodes in the AMR graph, where the corresponding entities have a relation in knowledge base in the context of the question. For instance, in Figure 3, nodes *city* and *person* are involved in a KB relation *death place* relevant for this question. Slot prediction is done using a deterministic rule-based transformation described in (Kapanipathi et al., 2021). In particular, we use their path-based approach where all the paths between the *amr-unknown* node and the linked entity nodes are retrieved. Then all node pairs along the path that are joined by a predicate node are considered a relation slot. We refer the reader to the original publication for more details of the method.

2.2 Neural Relation Linking Model

SemReL employs a Siamese network, where the input question and target relations are embedded in the same vector space. The most likely relation is the one whose representation is closest to that of the input question. Figure 3 shows the overall architecture of our model. We use a Transformer model (Vaswani et al., 2017) as a shared encoder for both the input questions and candidate relations. In particular, we use the pre-trained BERT model (Devlin et al., 2018) to initialize the encoder parameters. The output vector corresponding to the starting [CLS] token is used as the vector representation of the input. This vector is passed through a feed-forward linear layer that projects it to the shared embedding space. Unlike the transformer parameters, the weights of the linear projection layer on top are *not* shared between the questions and the relations.

Semantic information is given as part of the question input to the encoder. As mentioned above, during the preprocessing step, the pairs of nodes in AMR graph are identified for relation linking. For instance, in figure 3, the nodes 'person' and 'city' are marked in the input graph as the participants

[1]We use the stack transformer parser of Astudillo et al. (2020); Lee et al. (2020) for generating AMR graphs and the BLINK system of Wu et al. (2019) for entity linking.

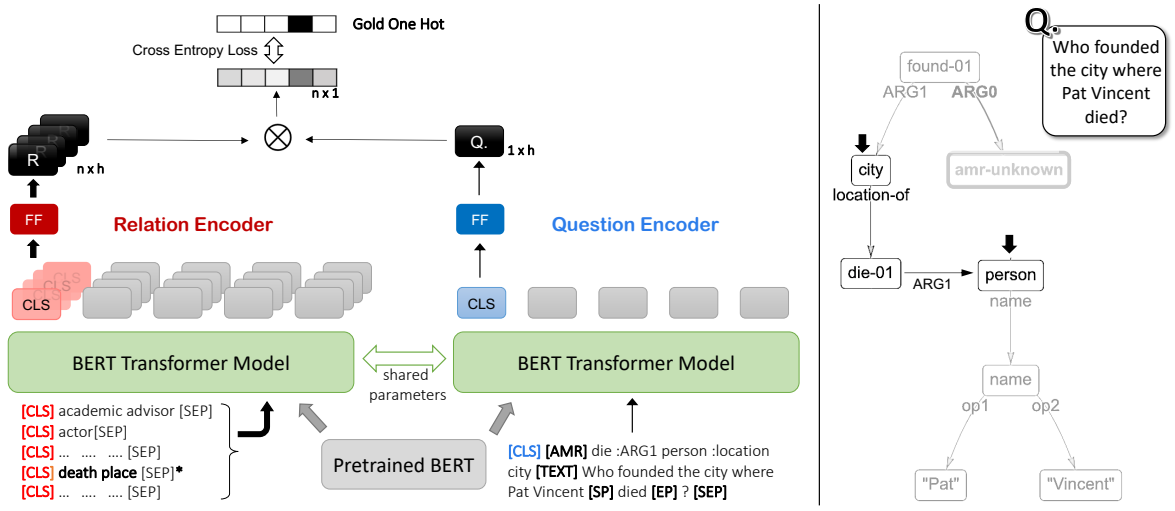

Figure 3: SemReL model architecture (left) and inputs to the model (right).

of a potential relation. The subgraph connecting these nodes is traversed in a top-down manner to form a linearized representation; in this case, it will yield the linearized string '*die :ARG1 person :location city*'. Note that the sense label of the node 'die-01' is dropped. Moreover, all reversed AMR relations with *-of* suffix are normalized to their original relation name and direction. In this example *:location-of* is mapped to *:location* with direction reversed. We prepend this linearized AMR path string to the input question text along with a special leading token [AMR]. The question text also starts with a special leading token [TEXT]. The word aligned to the root of the AMR subgraph is marked as the predicate[2], using special start and end predicate tokens [SP] and [EP].

Figure 3 shows the complete input for the example question that goes into the Question Encoder. The same transformer model also serves as relation encoder. Relation names are tokenized using BERT tokenizer without any additional pre-processing. We add special tokens [AMR], [TEXT], [SP] and [EP] as well as the AMR relation labels into the BERT vocabulary.

Training Objective: During training, for each example, scores are computed for the gold relation as well as a set of negative examples based on the inner product of their vectors with that of the question. For a relation r_i with vector representation $\mathbf{r_i}$ and a question q_n with vector representation $\mathbf{q_n}$, the score would be $s(r_i, q_n) = \mathbf{r_i}.\mathbf{q_n}$. The training objective is to minimize cross-entropy loss between the one-hot gold truth and the vector of predicted scores:

$$L(r_n, q_n) = -\log\left(\frac{\exp(s(r_n, q_n))}{\sum_i \exp(s(r_i, q_n))}\right)$$

We take the top one thousand relations from training data and use them as negative examples, excluding the gold. We compute the vector representation of all relations only once for each batch during training. Since relation representations are independent of the question representations, they can be reused for all examples in the batch. However, due to parameter update, they need to be computed anew for each batch.

Inference: During inference, we use $s(r, q)$ for scoring and ranking relations. Since the model parameters stay fixed, we compute the relation representations for all relations only once. If candidate KB relations are available from Entity analysis, we pick the highest-ranked relation from that set.

3 Evaluation

In this section, we detail our experimental setup and evaluate our approach against the state-of-the-art KBQA relation linking approaches. For fair comparisons, we replicate the same settings adopted by the systems we compare with both in terms of datasets and metrics.

3.1 Experimental Setup

Benchmarks: We perform experiments on four datasets targeting two popular KBs, DBpedia and

[2]The AMR parser of Astudillo et al. (2020) provides node to word alignments.

Wikidata. Each question in these datasets comes with its corresponding SPARQL query, annotated with gold relations. In particular, we used the following datasets:

- **QALD-9** (Usbeck et al., 2017): a dataset based on DBpedia with 150 test questions in natural language.
- **LC-QuAD 1.0** (Trivedi et al., 2017): another dataset based on DBpedia with a total of 5,000 questions (4,000 train and 1,000 test) based on templates.
- **LC-QuAD 2.0** (Dubey et al., 2019): A large dataset based on Wikidata with 6,046 test questions and around 24k training questions. Questions in this dataset have good variety and complexity levels such as multi-fact questions, temporal questions and questions that utilise qualifier information.
- **SimpleQuestions** (Diefenbach et al., 2017): A version of the popular SimpleQuestions dataset mapped to Wikidata. It comprises of 5,622 test questions, and around 19K training questions. As the name implies, all questions in this dataset are simple with queries encompassing a single triple in the KB.

Training: We train SemReL for DBpedia on the train data of LC-QuAD 1.0 and QALD-9. In addition, we use a subset of 80k examples from the distance supervisions data prepared by Mihindukulasooriya et al. (2020). This dataset is generated by retrieving Wikipedia sentences that contained pairs of entities from Knowledge Base triples. For our experiments, we filter our the sentences where the AMR path between the entities is more than two hops. For Wikidata experiments we train out system on the LC-QuAD 2.0 train dataset. Encoder parameters are initialized with the pretrained BERT base model (Wolf et al., 2020).

Baselines: For the DBpedia-based benchmarks, we compare SemReL with Falcon (Sakor et al., 2019a) and SLING (Mihindukulasooriya et al., 2020). As for Wikidata-based benchmarks, we compare against Falcon 2.0 (Sakor et al., 2020) and KB-Pearl (Lin et al., 2020).

[3]The KBPearl paper reports F1 of 0.41 due to a typo but its authors confirmed the correct F1 to be 0.52.

Dataset	Method	P	R	F1
QALD-9	Falcon	0.23	0.23	0.23
	SLING	0.39	0.50	0.44
	SemReL	0.46	0.44	**0.45**
LC-QuAD 1.0	Falcon	0.42	0.44	0.43
	SLING	0.41	0.55	0.47
	SemReL	0.51	0.51	**0.51**
LC-QuAD 2.0	Falcon 2.0	0.44	0.37	0.40
	SemReL	0.59	0.38	**0.46**
LC-QuAD 2.0 (1942 set)	KB-Pearl*	0.57	0.48	0.52[3]
	SemReL	0.70	0.45	**0.55**
Simple Questions	Falcon 2.0	0.35	0.44	0.39
	SemReL	0.69	0.70	**0.69**

Table 1: SemReL compared to SoTA systems on the DBpedia (above) and Wikidata (below) benchmarks.

Setup	all	one-hop	multi-hop
SemReL	0.51	0.54	0.50
w/o AMR	0.49	0.53	0.47
w/o TEXT	0.38	0.37	0.39
w/o KB rels	0.46	0.48	0.45

Table 2: SemReL F1 for *all*, *one-hop* and *multi-hop* questions with inputs ablated on LC-QuAD 1.0 testset. 'KB rels' refers to Knowledge Base relation candidates.

3.2 Results and Discussion

Table 1 compares SemReL with existing approaches. KB-Pearl used a subset of 1,942 test questions in their LC-QuAD 2.0 evaluation. For fair comparison, we also evaluate SemReL on the same subset.

SemReL outperforms all baselines across all benchmarks with respect to F1 score. Note that the baseline systems, specially SLING, achieve higher recall than precision. In contrast, SemReL has either balanced precision and recall, or much higher precision. This is in part due to missing entity or slot predictions, indicating that improving the preprocessing can further boost the system's performance. The results on SimpleQuestions are also worth noting, since the corresponding training set was not used in Wikidata model training. We also performed a zero-shot cross-KB experiment where we test our Wikidata model on a DBpedia dataset, LC-QuAD 1.0. The model is tested as is, and despite the relation names and granularity differences, it achieves an F1 of 0.33.

Ablation on Model Inputs: Table 2 shows the results of ablation experiments on LC-QuAD 1.0 testset where each of the system inputs are removed one at a time. As expected, the question text is the most crucial input: when combined with either KB candidates or AMR, it shows good performance. When AMR is removed, overall score drops by 2 points; it mostly comes from multi-hop questions. This indicates that focusing on different subgraphs of the input AMR improves retrieval of multi-hop relations. A similar effect was observed on QALD-9 and LC-QuAD 2.0 test sets when AMR was removed, degrading performance by 4.0 and 2.9 points respectively.

Impact on KBQA Performance: We integrated SemReL into the Neuro-Symbolic Question Answering (NSQA) system of Kapanipathi et al. (2021). NSQA is a modular system for KBQA where each sub-task is handled by a different module, allowing easy integration of new components. We found that the impact of using AMR in relation linking translates into nice performance gains in overall KBQA results. When AMR is incorporated in the relation linking module, the system performance on LC-QuAD 1.0 test dataset improves by 2.4 achieving a new state-of-the-art F1 of 44.5. We refer the reader to the NSQA paper (Kapanipathi et al., 2021) for more details on the system and experiments.

4 Related Work

Several relation linking systems have been proposed recently (Mulang et al., 2017; Singh et al., 2017; Dubey et al., 2018; Sakor et al., 2019a; Pan et al., 2019; Lin et al., 2020). Most of these methods are rule-based and rely solely on the question text and/or its dependency parse. Therefore, they try to improve their question understanding by using standard NLP tools such as POS tagging, tokenization n-gram tiling and even lexical database such as WordNet. FALCON 2.0 (Sakor et al., 2020) is a joint entity and relation linking tool over Wikidata. it uses a search engine indexed with Wikidata, a pipeline of text processing including POS tagging, tokenization, N-gram tiling/splitting and a catalog of rules for entity and relation linking. KBPearl (Lin et al., 2020) is another system that performs joint entity and relation linking to Wikidata. It first create a semantic graph of text using OpenIE and maps both entities and relations to a given KB.

However, none of the above mentioned methods for KBQA perform relation linking on two different KBs using the same system whilst our work is the first to perform relation linking over both DBpedia and Wikidata using the same system. In addition, some of these systems are KG-specific; e.g. Falcon (Sakor et al., 2019a) vs. Falcon 2.0 (Sakor et al., 2020), where adapting it from one KG to another requires non-trivial changes. Unlike these systems, SemReL leverages well-established semantic parsers such as AMR to achieve out-of-the-box better question representation.

Similar to our approach, SLING (Mihindukulasooriya et al., 2020) is a relation linking framework based on DBpedia which leverages semantic parsing using AMR and distant supervision. It consists of four distinct modules that capture different signals such as linguistic cues, semantic representation, and information from the knowledge base. Unlike SLING, SemReL is a KG-agnostic, single end-to-end neural model that does not require various ensemble components and yet achieves state-of-the-art performance on DBPedia and Wikidata datasets.

5 Conclusions and Future Work

In this paper, we present a simple transformer-based neural model for relation linking that leverages the semantic structure of a sentence. In contrast to existing systems such as SLING and Falcon, which are either rule-based or ensembles of several components, our neural architecture enables us to adapt the system to multiple KGs (e.g. DBpedia and Wikidata). It outperforms state-of-the-art systems on a variety of benchmarks.

Our ablation study shows that including the AMR graph improves performance, even with the relatively simple encoding scheme (plain text). In future, we will explore modeling the graph structure explicitly. This model also relies on a deterministic slot-finding algorithm based on AMR. While this identifies the correct relation slots most of the time, it is rule-based, and not always correct. In future work, we will explore learning algorithms to identify the slots from the AMR graph.

Finally, AMR parsers can be trained jointly with the relation linking objective. Currently, these parsers are sensitive to small changes in the input. Joint training can make them robust against text variations and more sensitive to the errors affecting slot identification and relation prediction.

Abstract

Early fusion models with cross-attention have shown better-than-human performance on some question answer benchmarks, while it is a poor fit for retrieval since it prevents pre-computation of the answer representations. We present a supervised data mining method using an accurate early fusion model to improve the training of an efficient late fusion retrieval model. We first train an accurate classification model with cross-attention between questions and answers. The cross-attention model is then used to annotate additional passages in order to generate weighted training examples for a neural retrieval model. The resulting retrieval model with additional data significantly outperforms retrieval models directly trained with gold annotations on Precision at N (P@N) and Mean Reciprocal Rank (MRR).

1 Introduction

Open domain question answering (QA) involves finding answers to questions from an open corpus (Surdeanu et al., 2008; Yang et al., 2015; Chen et al., 2017; Ahmad et al., 2019). The task has led to a growing interest in scalable end-to-end retrieval systems for question answering.

When QA is formulated as a reading comprehension task, cross-attention models like BERT (Devlin et al., 2019) have achieved *better-than-human* performance on benchmarks such as the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016). Cross-attention models are especially well suited for problems involving comparisons between paired textual inputs, as they provide *early* fusion of fine-grained information within the pair. This encourages careful comparison and integration of details across and within the two texts.

However, early fusion across questions and answers is a poor fit for retrieval, since it prevents pre-computation of the answer representations. Rather, neural retrieval models independently compute embeddings for questions and answers, typically using dual encoders for fast scalable search (Henderson et al., 2017; Gillick et al., 2018; Yang et al., 2019b; Karpukhin et al., 2020). Using dual encoders results in *late* fusion within a shared embedding space.

For machine reading, early fusion using cross-attention introduces an inductive bias to compare fine grained text spans within questions and answers. This inductive bias is missing from the single dot-product scoring operation of dual encoder retrieval models. Thus, late fusion is expected to require more training data to learn the necessary representations for fine grained comparisons.

To support learning improved representations for retrieval, we explore a supervised data augmentation approach leveraging a complex classification model with cross-attention between question-answer pairs. Given gold question passage pairs, we first train a cross-attention classification model as the supervisor. Then any collection of questions can be used to mine potential question passage pairs under the supervision of the cross-attention model. The retrieval model training benefits from additional training pairs annotated with the graded predictions from the cross-attention model augmenting the existing gold data. Experiments on MultiReQA-SQuAD and MultiReQA-NQ establish significant improvements on Precision at N (P@N) and Mean Reciprocal Rank (MRR).

The supervised mining approach is closely connected to the recently studied hard negative mining for neural retrieval models (Xiong et al., 2020; Lu et al., 2020). The key differences is that the proposed approach finds the positive training examples, while the negative mining approaches find the negative examples for training. The two approaches are complementary and can be combined.

2 Neural Passage Retrieval for Open Domain Question Answering

Open domain question answering systems usually follow a two-step approach: first retrieve question relevant passages, and then scan the returned text to identify the answer span using a reading comprehension model (Jurafsky and Martin, 2018; Kratzwald and Feuerriegel, 2018; Yang et al., 2019a). Prior work has focused on the answer span annotation task and has even achieved super human performance on some datasets. However, the evaluations implicitly assume the trivial availability of passages for each question that are likely to contain the correct answer. While the retrieval task can be approached using traditional keyword based retrieval methods such as BM25, there is a growing interest in developing more sophisticated neural retrieval methods (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020).

3 Retrieval Question-Answering (ReQA)

Ahmad et al. (2019) introduced Retrieval Question-Answering (ReQA), a task that has been rapidly adopted by the community (Guo et al., 2020; Chang et al., 2020; Ma et al., 2020; Zhao and Lee, 2020; Roy et al., 2020). Given a question, the task is to retrieve the answer sentence from a corpus of candidates. ReQA provides direct evaluation of retrieval, independent of span annotation. Compare to Open Domain QA, ReQA focuses on evaluating the retrieval component and, by construction, avoids the need for span annotation.

We explore the proposed approach on MultiReQA-NQ and MultiReQA-SQuAD (Guo et al., 2020).[1] MultiReQA (Guo et al., 2020) established standardized training / dev / test splits. Statistics for each tasks are listed in Table 1.

Dataset	Training Pairs	Test	
		Questions	Candidates
NQ	106,521	4,131	22,118
SQuAD	87,133	10,485	10,642

Table 1: Statistics of MutiReQA NQ and SQuAD tasks: # of training pairs, # of questions, # of candidates.

4 Methodology

In this section we describe the proposed approach using a neural retrieval model augmented with supervised data mining. Figure 2 illustrates our approach using a cross-attention classifier to supervise the data augmentation process for training a retrieval model. After training the cross-attention model, we retrieve additional potential answers to questions using an off-the-shelf retrieval system[2]. The predicted scores from our classifier with cross-attention are then used to weight and filter the retrieved candidates with positive examples serving as additional training data for the dual encoder based retrieval model.

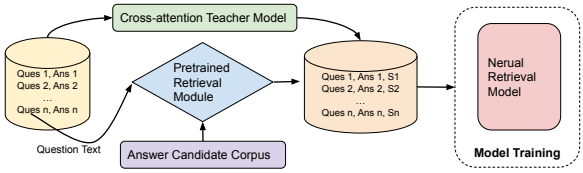

Figure 1: Use of a cross-attention model for the supervised mining of additional QA pairs. Our accurate cross-attention model supervises the mining process by identifying new previously unannotated positive pairs. Mined QA pairs augment the original training data for the dual encoder based neural passage retrieval model.

4.1 BERT Classification Model

Cross-attention models like BERT are often used for re-ranking after retrieval and can significantly improve performance as they allow for fine-grained interactions between paired inputs (Nogueira et al., 2019; Han et al., 2020). Here we formalize a binary classification task for predicting question answer relatedness. We use the question-answer pairs from the training set as our positive examples. Negatives are sampled for each question using the following strategies with a 1:1:1 ratio: *(1) A sentence from the top 10 nearest neighbors returned by a term based BM25 (Robertson and Zaragoza, 2009) over a sentence pool containing all supporting documents in a corpus. (2) A sentence from the top 10 nearest neighbors using the Universal Sentence Encoder - QA (USE-QA) (Yang et al., 2019b). (3) A sentence randomly sampled from its supporting documents, excluding the question's gold answer.* The sampled non-answer sentences are paired with their questions as negative examples. A BERT model is fine-tuned following the default setup from the Devlin et al. (2019).

[1] https://github.com/google-research-datasets/MultiReQA

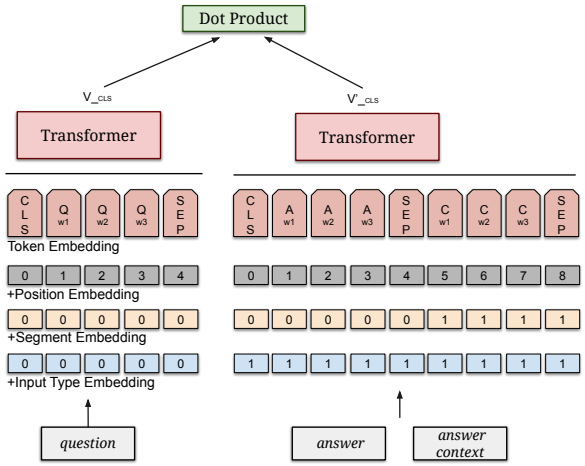

Figure 2: The BERT dual encoder architecture. The answer and context are concatenated and fed into the answer encoder. Figure from (Guo et al., 2020).

4.2 Dual-Encoder Retrieval Model

We follow Guo et al. (2020) and employ a BERT based dual-encoder model for retrieval. The model architecture is illustrated in figure **??**. The dual-encoder model critically differs from the cross-attention model in that there is no early interactions (cross-attention) between the question and answer. The resulting independent encodings are only combined in the final dot-product scoring a pair. The same BERT encoder is used for questions and answers with the output of the CLS token taken as the output encoding. For answers, the answer and context are concatenated and segmented using the segment IDs from the original BERT model. A learned *input type embedding* is added to each input token representation to distinguish questions and answers within the encoding model.

The BERT dual-encoder model can be fine-tuned using the in batch sampled softmax loss (Gillick et al., 2018):

$$\mathcal{J} = \sum_{(x,y)\in Batch} \frac{e^{\phi(x,y)}}{\sum_{\bar{y}\in\mathcal{Y}} e^{\phi(x,\bar{y})}} \quad (1)$$

Where x is the question, y is the correct answer, $\mathcal{Y}$ is all answers in the same batch that are used as sampled negatives, and $\phi(x, y)$ is the dot product of question and answer representations. Note that the dot product is scaled by X100 during training, which is a critical component when applying l_2 normalization to the embeddings.

[2]Note the approach can also be applied to any collection of questions, even for those without ground truth answers.

4.3 Mining Augmented Training Pairs

We create an augmented training set for the retrieval model using our cross-attention based QA model. For each question in the training set, we employ USE-QA to mine the top 10 nearest neighbors from the entire training set, and then remove those retrieved pairs which are true positives. Next the cross-attention based QA model is used to score the retrieved pairs. The dual-encoder based neural retrieval model is then trained on the combination the additional scored positive pairs and the original QA pairs from the training set. The original pairs are assigned a score 1.

4.4 Weighted In-batch Softmax for Dual-Encoder Retrieval Model

The neural retrieval model is trained using the batch negative sampling loss (Gillick et al., 2018) in equation 2. We modify the standard formulation to include a weight, $w(x, y)$, for each pair.

$$\mathcal{J}' = \sum_{(x,y)\in Batch} w(x,y) \frac{e^{\phi(x,y)}}{\sum_{\bar{y}\in\mathcal{Y}} e^{\phi(x,\bar{y})}} \quad (2)$$

We set $w(x, y)$ to 1 if (x, y) is a ground truth positive pair and $p(x, y)^2$, otherwise, whereby $p(x, y)$ is the probability from the cross-attention model.

5 Evaluation

In this section we evaluate the proposed approach using the MultiReQA evaluation splits for NQ and SQuAD. Models are assessed using Precision at N (P@N) and Mean Reciprocal Rank (MRR). Following the ReQA setup (Ahmad et al., 2019), we report P@N for N=$[1, 5, 10]$. P@N evaluates whether the true answer sentence appears in the top-N ranked candidates. MRR is calculated as MRR $= \frac{1}{N}\sum_{i=1}^{N}\frac{1}{rank_i}$, where N is the total number of questions, and $rank_i$ is the rank of the first correct answer for the ith question.

5.1 Configurations

Our cross-attention QA models are fine-tuned from the public English BERT for 10 epochs, using a batch size of 256 and a weighted Adam optimizer with learning rate 3e-5. We experiment with both $\text{BERT}_{\text{Base}}$ and $\text{BERT}_{\text{Large}}$. All hyper-parameters are set using a dev set split out from the training data (10%). When mining for silver data, we only keep candidate pairs with positive cross-attention QA model scores (≥ 0.5).

Models	NQ		SQuAD	
	ACC	AUC-PR	ACC	AUC-PR
Majority	73.7	–	74.8	–
$\text{BERT}_{\text{dual\_encoder}}$	75.8	49.3	80.3	62.0
(x-attn) $\text{BERT}_{\text{Base}}$	84.3	92.8	92.6	96.5
(x-attn) $\text{BERT}_{\text{Large}}$	84.9	93.5	93.6	97.1

Table 2: Accuracy (ACC) and area under the precision-recall curve (AUC-PR) for the classification task. **Majority** is a simple baseline that always predicts false. **(x-attn)** indicates cross-attention QA models.

The $\text{BERT}_{\text{Base}}$ model is used to initialize the dual encoder retrieval model. During training we use a batch size of 64, and a weighted Adam optimizer with learning rate 1e-4. The maximum input length is set to 96 for questions and 384 for answers. Models are trained for 200 epochs. The embeddings are l_2 normalized. Hyper-parameters are manually tuned on a held out development set.

5.2 Performance for the Classification Task

The classification data created using the method from section 4.1 contains a total of 531k and 469k training examples for NQ and SQuAD, respectively. Test sets extracted from the SQuAD and NQ test splits contain 15k and 41k examples.[3]

Table 2 provides the performance of the cross-attention models, compared to a majority baseline which always predict false and a $\text{BERT}_{\text{dual\_encoder}}$ retrieval model without any mined examples that uses cosine similarity for prediction. Cross-attention based models outperform the baselines by a wide margin,[4] with $\text{BERT}_{\text{Large}}$ achieving the highest performance on all metrics. This is consistent with our hypothesis that early fusion models outperform late fusion based retrieval models. Both models achieve better performance on SQuAD than NQ. The SQuAD task has higher token overlap, as described in section 3, making the task somewhat easier. We use the $\textbf{BERT}_{\textbf{Large}}$ model to supervise the data augmentation in the next section.

5.3 Mined Examples

We mined the SQuAD and NQ training data to construct additional QA pairs. After collecting and scoring addition pairs using the method described in section 4.3, we obtained 53% (56,148) and 12% (10,198) more examples for NQ and SQuAD, respectively. Table 4 illustrated the examples retrieved by USE-QA and predicted as positive examples by our cross-attention QA classification model. Both examples are clear positive QA pairs.

Much less data is mined for SQuAD then NQ. We believe it is because of the way SQuAD was created, whereby workers write the questions based on the content of a particular article. The resulting questions are much more specific and biased toward a particular question types, e.g. *what* questions Ahmad et al. (2019). Additionally, the candidate pool for SQuAD is only half that of NQ, resulting in questions having fewer opportunities to be matched to good additional answers.

5.4 Results on the Retrieval QA

Table 3 gives P@N and MRR@100 for retrieval models on MultiReQA-SQuAD and MultiReQA-NQ. The first two rows show the result from two simple baselines: BM25 (Robertson and Zaragoza, 2009), USE-QA, and $\text{USE-QA}_{\text{finetune}}$ reported by Guo et al. (2020). BM25 remains a strong baseline, especially with 62.8% P@1 and 70.5% MRR for SQuAD. BM25's performance on NQ is much lower, as there is much less token overlap between NQ questions and answers. USE-QA matches the performance of BM25 on NQ but performs worse on SQuAD.[5] $\text{BERT}_{\text{dual\_encoder}}$ performs well compared to other baselines, especially on NQ with a +6.6 point improvement compared to the $\text{USE-QA}_{\text{finetune}}$ model.[6] Its P@1 on SQuAD performs better than USE-QA and BM25, but -3.1 points MRR worse than $\text{USQ-QA}_{\text{finetune}}$. On average, $\text{BERT}_{\text{dual\_encoder}}$ is the best among those baselines.

Performance improves by a large margin using augmented training data from our cross-attention QA model, obtaining a +8.6 and +7.0 improvement on NQ P@1 and MRR. Compare to NQ, the improvement on SQuAD is rather marginal. The augmented $\text{BERT}_{\text{dual\_encoder}}$ retrieval model only achieves slightly improved performance on SQuAD, with +1 points for both P@1 and MRR. As discussed in section 5.3, we mine much less data from SQuAD compare to NQ, with only 10% more data than the original training set. As demonstrated by the strong BM25 performance and shown in (Guo et al., 2020), the SQuAD QA pairs have high token overlap between question and answers,

[3] The positive / negative ratio is roughly 1:3.

[4] The poor performance of $\text{BERT}_{\text{dual\_encoder}}$ is also aligned with the hypothesis that cosine similarity score is not a globally consistent measurement of how good a pair (Guo et al., 2018).

[5] USE-QA can be fine-tuned, which usually significantly outperforms the default USE-QA model (Guo et al., 2020).

[6] Our $\text{Bert}_{\text{dual\_encoder}}$ performs better than the one reported in Guo et al. (2020), likely due to additional training epochs.

Models	NQ				SQuAD			
	P@1	P@5	P@10	MRR	P@1	P@5	P@10	MRR
BM25	24.7	–	–	36.6	62.8	–	–	70.5
USE-QA	24.7	–	–	34.7	51.0	–	–	62.1
USE-QA$_{\text{finetune}}$	38.0	–	–	52.3	**66.8**	–	–	**75.9**
BERT$_{\text{dual_encoder}}$	44.7	77.1	85.1	58.9	62.8	85.4	91.0	72.8
BERT$_{\text{dual_encoder}}$ Augmented	**53.3**	**82.3**	**88.5**	**65.9**	63.8	86.1	91.6	73.7

Table 3: Precision at N(P@N) (%) N=$[1, 5, 10]$ and Mean Reciprocal Rank (MRR) (%) on the MultiReQA tasks.

Score	Silver QA Pair
0.92	**Q:** what are the names of the two old muppets in the balcony that heckle everyone ? **A:** Statler and Waldorf are a pair of Muppet characters known for their cantankerous opinions and shared penchant for heckling.
0.90	**Q:** where the phrase dressed to the nines come from **A:** It appears in book six of Jean - Jacques Rousseau 's Confessions , his autobiography ...

Table 4: Mined positive examples identified using our cross-attention QA classification model.

minimizing the advantage of the neural methods in capturing more complex semantic relationships.

Effectiveness of Weighted Softmax. We further experimented the Retrieval QA tasks using the model with the non-modified softmax using the augmented data. All other configurations are keep the same. The MRR of the model using non-modified softmax is 60.1 on MultiReQA-NQ and 71.9 on MultiReQA-SQuAD, which are much worse than the model using weighted softmax. This result indicates the weighted softmax is important for the proposed approach.

6 Conclusion

In this paper, we propose a novel approach for making use of an early fusion classification model to improve late fusion retrieval models. The early fusion model is used for data mining to augment the training set for the late fusion model. The proposed approach mines 53% (56,148) and 12% (10,198) more examples for MultiRQA-NQ and MultiRQA-SQuAD, respectively. Compared to the models directly trained with gold annotations, the resulting retrieval models improve +8.6% and +1.0% P@1 on NQ and SQuAD respectively. The current pipeline assumes there exists annotated in-domain question answer pairs to train the cross-attention model. With a strong general purpose cross-attention model, our method could be modified to train in-domain retrieval models without gold data. We leave this to the future work.

Abstract

Generating *descriptive* sentences that convey non-trivial, detailed, and salient information about images is an important goal of image captioning. In this paper we propose a novel approach to encourage captioning models to produce more detailed captions using natural language inference, based on the motivation that, among different captions of an image, descriptive captions are more likely to entail less descriptive captions. Specifically, we construct directed inference graphs for reference captions based on natural language inference. A PageRank algorithm is then employed to estimate the descriptiveness score of each node. Built on that, we use reference sampling and weighted designated rewards to guide captioning to generate descriptive captions. The results on MSCOCO show that the proposed method outperforms the baselines significantly on a wide range of conventional and descriptiveness-related evaluation metrics[1].

1 Introduction

Automatically generating visually grounded descriptions for given images, a problem known as image captioning (Chen et al., 2015), has drawn extensive attention recently. In spite of the significant improvement of image captioning performance (Lu et al., 2017; Anderson et al., 2018; Xu et al., 2015; Lu et al., 2018), existing models tend to *play safe* and generate generic captions. However, generating *descriptive* captions that carry detailed and salient information is an important goal of image captioning. For example, recent work (Luo et al., 2018; Liu et al., 2018b, 2019a) leveraged cross-modal retrieval (Faghri et al., 2017; Feng et al., 2014) to solve this problem, based on the observation that more *descriptive* captions often result in better discriminativity in retrieval.

In the paper, we explore to develop better descriptive image captioning models from a novel perspective— considering that among different captions of an image, descriptive captions are more likely to entail less descriptive ones, we develop descriptive image captioning models that leverage natural language inference (NLI, or also known as recognizing textual entailment) (Dagan et al., 2005; MacCartney and Manning, 2009; Bowman et al., 2015), which can utilize multiple references of captions (Young et al., 2014; Lin et al., 2014) to guide the models to produce more descriptive captions.

Specifically, the proposed model first predicts NLI relations for all pairs of references, i.e., *entailment* or *neutral*[2]. Built on that, we construct inference graphs and employ a PageRank algorithm to estimate descriptiveness scores for individual captions. We use reference sampling and weighted designated rewards to incorporate the descriptiveness signal into the Maximum Likelihood Estimation and Reinforcement Learning phase, respectively, to guide captioning models to produce *descriptive* captions. Extensive experiments were conducted on the MSCOCO dataset using different benchmark baseline methods (Huang et al., 2019; Luo et al., 2018; Rennie et al., 2017).

We demonstrate that the proposed method outperforms the baselines, achieving better performances on various evaluation metrics. In summary, the major contributions of the paper are three-fold: (1) To the best of our knowledge, this is the first attempt to connect natural language inference to image captioning, which helps generate more descriptive captions; (2) we propose a reference sampling distribution and weighted designated rewards to guide captioning model to produce more descriptive captions; (3) the proposed method attains better performance on various evaluation metrics over the

[1] https://github.com/Gitsamshi/Nli-image-caption

[2] As reference captions are unlikely to contradict to each other, we ignore the *contradiction* relation in our study.

state-of-the-art baselines.

2 Related Work

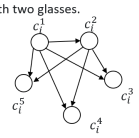
Image captioning Image captioning aims at generating visually grounded descriptions for images. It often leverages a CNN or variants as the image encoder and an RNN as the decoder to generate sentences (Vinyals et al., 2015; Karpathy and Fei-Fei, 2015; Donahue et al., 2015; Yang et al., 2016). To improve the performance on reference-based automatic evaluation metrics, previous work has used visual attention mechanism (Anderson et al., 2018; Lu et al., 2017; Pedersoli et al., 2017; Xu et al., 2015; Pan et al., 2020), explicit high-level attributes detection (Yao et al., 2017; Wu et al., 2016; You et al., 2016), reinforcement learning methods (Rennie et al., 2017; Ranzato et al., 2015; Liu et al., 2018a), contrastive or adversarial learning (Dai and Lin, 2017; Dai et al., 2017), multi-step decoding (Liu et al., 2019a; Gu et al., 2018), weighted training by word-image correlation (Ding et al., 2019) and scene graph detection (Yao et al., 2018; Yang et al., 2019; Shi et al., 2020).

The work of (Luo et al., 2018; Liu et al., 2018b) is most related to ours, which uses retrieval loss as a rewarding signal to encourage descriptive captioning. Different from the above approaches, our method explicitly explore the different *descriptiveness* in references using NLI models and incorporate the information into the training objectives to guide the model to generate more informative sentences. We build our method on top of the existing methods to verify the effectiveness.

Applications of NLI There are basically three major application types for NLI, (1) Direct application of trained NLI models. Trained NLI models are directly used in Fact Extraction and Verification (Thorne et al., 2018) to decide whether a piece of evidence supports a claim (Nie et al., 2019) and generation of longer sentences as a discriminator (Holtzman et al., 2018) to prevent a text decoder from contradicting itself; (2) NLI as a research and evaluation task for new methods. It is widely used as a major evaluation when developing novel language model pretraining (Devlin et al., 2018; Peters et al., 2018; Liu et al., 2019c); (3) NLI as a pre-training task in transfer learning. Training neural network models on NLI corpora and then fine-tuning them on target tasks often yields substantial improvements in performance (Liu et al., 2019b; Phang et al., 2018).

c_i^1: A glass for wine sitting next to a bottle.
c_i^2 : A wine bottle and some wine glasses in the hay.
c_i^3 : Two wine glasses lie beside a bottle of wine in straw.
c_i^4 : Two wine glasses lie beside a wine bottle on straw.
c_i^5 : A bottle of wine on it's side with two glasses.

$$\begin{array}{c} \\ c_i^1 \\ c_i^2 \\ c_i^3 \\ c_i^4 \\ c_i^5 \end{array} \begin{array}{c} \begin{array}{ccccc} c_i^1 & c_i^2 & c_i^3 & c_i^4 & c_i^5 \end{array} \\ \begin{pmatrix} e & n & n & n & n \\ e & e & n & n & n \\ e & e & e & e & e \\ e & e & e & e & e \\ e & e & e & e & e \end{pmatrix} \end{array}$$



Label	Description	Example
Paraphrase	Two way entailment, X entails Y and vice versa	X: Two wine glasses lie beside a bottle of wine in straw Y: Two wine glasses lie beside a wine bottle on straw
Forward Entailment	One way entailment, X entails Y and Y is neutral to X	X: Two wine glasses lie beside a bottle of wine in straw Y: A wine bottle and some wine glasses in the hay
Reverse Entailment	One way entailment, Y entails X and X is neutral to Y	X: A wine bottle and some wine glasses in the hay Y: Two wine glasses lie beside a bottle of wine in straw
Mutual Neutral	Two way neutral, X is neutral to Y and vice versa	X: a tall house with a large clock mounted on its face Y: a building and outdoor seating for a café

Figure 1: A NLI matrix and inference graph.

3 Our Method

The goal of image captioning is to train conditional generation model $p_\theta(c \mid x)$ based on training instances $(x_i, C_i)_{i=1}^m$ in a training dataset and $C_i = \{c_i^1, \cdots, c_i^n\}$, where m is the number of training instances and n is the number of reference captions for an image.

The typical models leverage a two-phase learning process to estimate $p_\theta(c \mid x)$: the first uses MLE objective, which minimizes a cross-entropy loss with regard to the ground truth captions:

$$\mathcal{L}_{\text{ML}}(\theta) = -\sum_{i=1}^{m}\sum_{j=1}^{n} \log p_\theta(c_i^j \mid x_i) \qquad (1)$$

RL is then used to optimize models by maximizing the expected reward for generating captions.

$$\mathcal{L}_{\text{RL}}(\theta) = -\sum_{i=1}^{m} E_{\hat{c}\sim p_\theta(c|x_i)}[r(\hat{c}, x_i)] \qquad (2)$$

where $r(\hat{c}, x_i)$ could be CIDEr reward (r_{cd}) (Rennie et al., 2017) or a combination of CIDEr (r_{cd}) and discriminative loss (l_{dis}) (Luo et al., 2018).

In this work, we enhance these two basic learning objectives by considering the descriptiveness of references $\{c_i^1, \cdots, c_i^n\}$.

3.1 Constructing Inference Graphs

NLI Matrix The SNLI corpus (Bowman et al., 2015) is widely used for training natural language inference models. To leverage the data for our task, we extract a subset of SNLI to fit our needs, e.g., removing *contradiction* sentence pairs (see Appendix B for details). Our NLI model is built upon BERT (Devlin et al., 2018), which achieves near state-of-the-art performance and is sufficient for our purpose. Given reference captions $C_i =$

$\{c_i^1, \cdots, c_i^n\}$ of an image, we obtain a NLI label for each ordered pair $\langle c_i^j, c_i^k \rangle$, forming a NLI relation matrix, as shown in Figure 1. Note that a NLI relation matrix is not necessary to be a symmetric matrix. For example, it is possible that $\langle c_i^j, c_i^k \rangle$ has an entailment relation (i.e., c_i^j entails c_i^k) and $\langle c_i^k, c_i^j \rangle$ is neutral, by the definition in NLI (Bowman et al., 2015).

Inference Graphs Built on the NLI matrix, we construct the inference graphs. For c_i^j and c_i^k, if the ordered pair $\langle c_i^j, c_i^k \rangle$ and $\langle c_i^k, c_i^j \rangle$ are both *entailment* in the NLI matrix, c_i^j and c_i^k are *paraphrases*. If $\langle c_i^j, c_i^k \rangle$ is entailment and $\langle c_i^k, c_i^j \rangle$ is neutral, then $\langle c_i^j, c_i^k \rangle$ is said to be a *forward entailment* (FwdEntail). On the contrary, if $\langle c_i^j, c_i^k \rangle$ is neural and $\langle c_i^k, c_i^j \rangle$ is entailment, then $\langle c_i^j, c_i^k \rangle$ is said to be a *reverse entailment* (RevEntail). If both directions are neutral, we call it mutual neutral (muNeutral).

To construct a directed inference graph, captions in a given image are added as vertexes. We add a directed edge from c_i^j to c_i^k if $\langle c_i^j, c_i^k \rangle$ is revEntail; i.e., the edge's head c_i^k is expected to be more descriptive than the tail c_i^j, and the edge points towards c_i^k. If $\langle c_i^j, c_i^k \rangle$ is fwdEntail, we add an edge from c_i^k to c_i^j. We do not add edges for paraphrase and muNeural pairs.

Descriptiveness Scorer PageRank (Page et al., 1999) is a link analysis model applied to collections of nodes with quotations or references. We perform PageRank on a inference graph to compute the *descriptiveness* score for each node/caption, which measures at which node a random walk is more likely to stop. Nodes with a higher score assigned by PageRank can be viewed as more *descriptive*. We then normalize the score to obtain distribution $q(c \mid x_i), c \in C_i$.

3.2 Descriptiveness Regularized Learning

Reference sampling (Rs) for MLE We can verify that $\mathcal{L}_{\text{ML}}$ in Equation (1) is equivalent to the KL divergence between a uniform target reference distribution $U(c \mid x_i)$ and model distribution $p_\theta(c \mid x_i)$:

$$\mathcal{L}_{\text{ML}}(\theta) = \sum_{i=1}^{m} \text{KL}(U(c \mid x_i) || p_\theta(c \mid x_i)) \quad (3)$$

Note that Equation (3) indicates that any c that belongs to reference set of C_i will be equally learned without considering their *descriptiveness*. To resolve the issue, for an image x_i, we use the probability distribution q obtained from graph nodes. We obtain an enhanced MLE loss $\mathcal{L}'_{\text{ML}}$, which is equivalent to minimizing the KL divergence between the target reference sampling distribution q and p_θ:

$$\mathcal{L}'_{\text{ML}}(\theta) = \sum_{i=1}^{m} \text{KL}(q(c \mid x_i) || p_\theta(c \mid x_i)) \quad (4)$$

Weighted reward (Wr) for RL We modify the reward function in RL to integrate the *descriptiveness* score to encourage more contribution from descriptive references in designated reward. Specifically, we change the CIDEr reward item r_{cd} in $r(\hat{c}, x_i)$ as shown in equation (2) by replacing $U(c \mid x_i)$ with $q(c \mid x_i)$:

$$r'_{cd}(\hat{c}, x_i) = \sum_{j=1}^{n} q(c_i^j \mid x_i) \cdot \text{CD}(\hat{c}, c_i^j) \quad (5)$$

where CD denotes the CIDEr similarity score.

4 Experiment

4.1 Setup

Dataset and Evaluation Metrics We perform experiments on the Karpathy split of the MSCOCO dataset (Lin et al., 2014; Karpathy and Fei-Fei, 2015). We employ a wide range of conventional image caption evaluation metrics, i.e., SPICE(SP) (Anderson et al., 2016), CIDEr(CD) (Vedantam et al., 2015), METEOR(ME) (Denkowski and Lavie, 2014), ROUGE-L(RG) (Lin, 2004), and BLEU (Papineni et al., 2002) to evaluate the generated captions. Following (Liu et al., 2019a), we also use the caption generated $\hat{c}$ to retrieve image x using a separately trained image-matching model (Lee et al., 2018). The retrieval evaluation is based on 1K images (Lee et al., 2018) from the Karpathy test set. Retrieval performances are measured by R@K ($K = 1, 5$), i.e., whether x is retrieved within the top K retrieved images. We also perform human evaluation on *descriptiveness, fluency*, and *fidelity*.

Implementation Details To make a fair comparison, we use the same experiment setup that the compared baselines used. See more implementation details for NLI model, retrieval model in evaluation, and descriptiveness score normalization in appendix B.

Compared Models We use AoANet, ATTN, and DISC(λ set to 1) as the baselines. ATTN (Rennie et al., 2017) is a LSTM based decoder with

visual attention mechanism. AoANet (Huang et al., 2019) adopts the attention on attention module. We also leverage the discriminativity enhanced model DISC (Luo et al., 2018) which is built upon ATTN.

4.2 Results and Analyses

Overall Performance Table 1 shows the overall performance of different models.

Results on conventional metrics. Our method consistently outperforms the baseline models on most conventional metrics, especially SPICE and CIDEr; e.g., the proposed model improves the AoANet baseline from 118.4 to 119.1 on CIDEr, 21.5 to 21.7 on SPICE in the MLE phase, and improves the ATTN baseline on CIDEr from 117.4 to 120.1, SPICE from 20.5 to 21.0 in the RL phase. As CIDEr is based on tf-idf weighting, it helps to differentiate methods that generate more image-specific details that are less commonly occur across the dataset. As our method is designed to encourage models to generate sentences with more objects, attributes, or relations, the effect was also suggested by the improvement on SPICE.

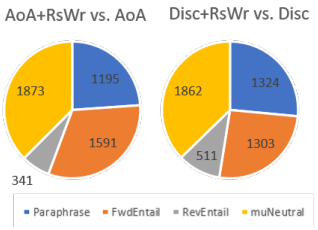


Figure 2: Inference labels in different models

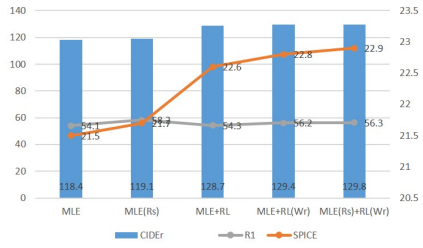

Figure 3: Ablation Analysis based on AoANet

Performance on descriptiveness related metrics. Our methods achieve consistently better results on R@1 and R@5 in both the MLE and RL optimization phases. Note that the proposed model can further boost the retrieval performance on the discriminativity enhanced baseline (DISC), improving R@1 from 46.5 to 48.1 and R@5 from 83.6 to 87.9. Our weighted CIDEr reward is complementary to the discriminative loss item in DISC and further boost the retrieval performance.

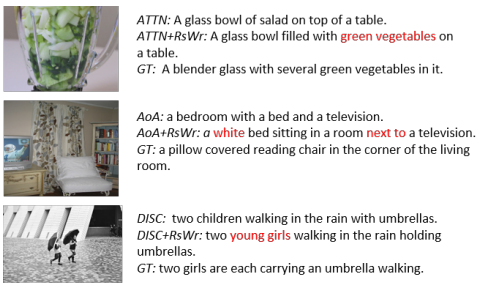

Figure 4: Examples generated by different models.

Labels between generated sentences. We use the externally trained NLI model (Section 3.1) to further investigate the NLI relationships between the captions generated by our method and by the baselines (AoA and DISC) on the testset. Figure 2 shows that our model generates more descriptive sentences. For example, comparing the generation results of AoA+RsWr and AoA on 5,000 testing images, captions generated by AoA+RsWr *forward-entails* those generated by AoA on 1,591 images, and *reverse-entails* on 341 images.

Ablation analysis. As shown in Figure 3, both reference sampling (Rs) and weighted reward (Wr) can improve performance in their respective optimization period, i.e., MLE to MLE(Rs), MLE+RL to MLE+RL(Wr). There is also a marginal improvement when using MLE(Rs) instead of MLE before the RL(Wr) optimization period, i.e., MLE+RL(Wr) to MLE(Rs)+RL(Wr), showing that MLE(Rs) has a positive impact even after RL(Wr) optimization.

Human Evaluation We further perform human evaluation on our method and two baselines (here, ATTN and DISC) using 100 images randomly sampled from the test set. Three human subjects rate captions with 1-5 Likert scales (higher is better) with respect to three criteria: *fluency*, *descriptiveness*, and *fidelity*. See more details in appendix A for rating details. Table 2 shows that ATTN+RsWr performs better than ATTN on descriptiveness. Moreover, DISC+RsWr can further improve the *descriptiveness* performance over the baseline discriminativity enhanced captioning model.

Case Study. Figure 4 includes three examples, in which our model produces captions with more attributes, objects, or relations.

5 Discussion

5.1 Descriptiveness and Entailment

We perform human analysis between descriptiveness and entailment. Specifically we randomly

DISC+RsWr	3.49	**3.30**	**3.31**

Table 2: Human evaluation on different models.

sample 50 images from the MSCOCO training set. For one image, there are five references, constituting ten reference pairs. So we have 500 reference pairs. For each reference pair, we ask three subjects to annotate whether one sentence conveys more non-trivial, important and detailed information than the other in terms of the described image. If the majority of the three subjects annotate yes, they further annotate the NLI relation—entailment or neutral, with the more informative caption as premise and the other as the hypothesis. As a result, out of the 500 reference pairs, we obtained 208 pairs that have differences in descriptiveness. The annotated NLI relations show that 164 of the 208 collected pairs have the entailment relation; i.e., for around 80% of the 208 pairs, "descriptive captions entail less descriptive captions" holds in the randomly sampled MSCOCO subset, where MSCOCO is a widely used multi-reference image caption benchmark.

5.2 Pairwise similarity and Re-ranking

We apply a pairwise similarity approach to AoA, in which we use Jaccard similarity between a pair of sentences to build the graph and run PageRank to get scores. Table 3 shows that pairwise similarity baseline approach (AoA+Sim) did not further improve performance over the corresponding baselines, showing pairwise similarity does not suggest descriptiveness, unlike entailment.

We perform re-ranking on the ATTN baseline; we use beam search with a beam size of 3, and then rank the captions in the beam by descriptiveness scores, which is calculated by BERT based NLI model. As shown in Table 3, the re-ranked sentences in the beam do not have much improvement in terms of baseline. Sentences generated by beam search (c.f. appendix C) do not vary significantly in terms of descriptiveness; these sentences are usually neutral to each other and sentences ranked low in the beam may have the fidelity/fluency issues.

	Pairwise Similarity Comparison						
	B@4	ME	RG	CD	SP	R@1	R@5
AoA	39.0	29.0	**58.9**	128.7	22.6	54.3	88.6

Table 3: Comparison with pairwise similarity and re-ranking.

6 Conclusions

We explore a novel approach to encourage image captioning models to produce more descriptive sentences using natural language inference. We construct inference graphs and descriptiveness scores are assigned to nodes using the PageRank algorithm. Built on that, we use reference sampling and weighted designated rewards to guide captioning to generate descriptive captions. We demonstrate the effectiveness of the model on various evaluation metrics and perform detailed analyses.

A Human Evaluation Details

The human evaluation is performed with three non-author human subjects. We ask the subjects to rate on three 1-5 Likert scales, corresponding to *fidelity* (the sentences' fidelity to the corresponding images), *fluency* (the quality of captions in terms of grammatical correctness and fluency), and *descriptiveness* (how much the sentences convey more detailed and faithful information about the images).

B More Implementation Details

NLI We exclude the training instances labeled with *contradiction*, since our task does not need to consider contradiction—reference captions for the same image are unlikely to contradict each other. We also sample training instances in the SNLI dataset to make the subset's length distribution similar to the caption references. We obtained a filtered dataset with around 250K sentence pairs as our training set, 4K and 4K as validation and test set, respectively. We leverage BERT (Devlin et al., 2018) as the framework for training which is a basis for many state-of-the-art models and achieve near state-of-the-art performance, which is sufficient for our purpose. The training gets stabled after 3 epochs, reaching an accuracy around 88% on the test set.

Retrieval Model in Evaluation The model is trained with the published package of SCAN (Lee et al., 2018). For the specific parameters, we followed the "SCAN t-i LSE" setting in their published report.

Descriptiveness Score We use the entailment probability as the weights on the edges and then we perform PageRank using the toolkit from (Hagberg et al., 2008). We set the damping parameter of 0.95 for descriptiveness score at MLE training stage and 0.1 for descriptiveness score at RL training stage, as we find that a smooth score distribution on reward (c.f. Equation 5) and a peaked score distribution on MLE(c.f. Equation 4) lead to improved performance in the RL and MLE training stage respectively.

C Beam Search Generation

Example 1. {*"image˙id": 247625, "caption": a man holding a snowboard in the snow, a man standing on a snowboard in the snow, a man is standing on a snowboard in the snow*}

{*"image˙id": 131019, "caption": a group of zebras are standing in a field, a group of zebras are standing in a field with a zebra, a group of zebras are walking in a field*}

These are sentences generated by beam search by ATTN model after RL stage (before re-ranking).

MOLEMAN: Mention-Only Linking of Entities with a Mention Annotation Network

Abstract

We present an instance-based nearest neighbor approach to entity linking. In contrast to most prior entity retrieval systems which represent each entity with a single vector, we build a contextualized mention-encoder that learns to place similar *mentions* of the same entity closer in vector space than mentions of different entities. This approach allows all mentions of an entity to serve as "class prototypes" as inference involves retrieving from the full set of labeled entity mentions in the training set and applying the nearest mention neighbor's entity label. Our model is trained on a large multilingual corpus of mention pairs derived from Wikipedia hyperlinks, and performs nearest neighbor inference on an index of 700 million mentions. It is simpler to train, gives more interpretable predictions, and outperforms all other systems on two multilingual entity linking benchmarks.

1 Introduction

A contemporary approach to entity linking represents each entity with a textual description d_e, encodes these descriptions and contextualized mentions of entities, m, into a shared vector space using dual-encoders $f(m)$ and $g(d_e)$, and scores each mention-entity pair as the inner-product between their encodings (Botha et al., 2020; Wu et al., 2019). By restricting the interaction between e and m to an inner-product, this approach permits the pre-computation of all $g(d_e)$ and fast retrieval of top scoring entities using maximum inner-product search (MIPS).

Here we begin with the observation that many entities appear in diverse contexts, which may not be easily captured in a single high-level description. For example, Actor Tommy Lee Jones played football in college, but this fact is not captured in the entity description derived from his Wikipedia page (see Figure 1). Furthermore, when new entities need to be added to the index in a zero-shot setting, it may be difficult to obtain a high quality description. We propose that both problems can be solved by allowing the entity mentions themselves to serve as exemplars. In addition, retrieving from the set of mentions can result in more interpretable predictions – since we are directly comparing two mentions – and allows us to leverage massively multilingual training data more easily, without forcing choices about which language(s) to use for the entity descriptions.

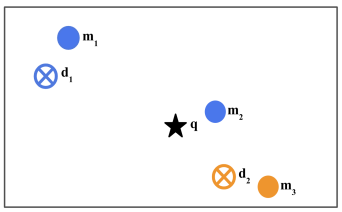
We present a new approach (MOLEMAN[1]) that maintains the dual-encoder architecture, but with the same mention-encoder on both sides. Entity linking is modeled entirely as a mapping between mentions, where inference involves a nearest neighbor search against all known mentions of all entities in the training set. We build MOLEMAN using exactly the same mention-encoder architecture and training data as Model F (Botha et al., 2020). We show that MOLEMAN significantly outperforms Model F on both the Mewsli-9 and Tsai and Roth (2016) datasets, particularly for low-coverage languages, and rarer entities.

We also observe that MOLEMAN achieves high accuracy with just a few mentions for each entity, suggesting that new entities can be added or existing entities can be modified simply by labeling a small number of new mentions. We expect this update mechanism to be significantly more flexible than writing or editing entity descriptions. Finally, we compare the massively multilingual MOLEMAN model to a much more expensive English-only dual-encoder architecture (Wu et al., 2019) on the well-studied TACKBP-2010 dataset (Ji et al., 2010) and show that MOLEMAN is competitive even in this setting.

[1]Mention Only Linking of Entities with a Mention Annotation Network

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 278–285
August 1–6, 2021. ©2021 Association for Computational Linguistics

Query Mention (q): "Harvard, with only five players of the 13, placed captain Vic Gatto and guard {Tom Jones} on the offensive team."



[Q170587]	$\mathbf{d}_1$	"Tommy Lee Jones is an American actor and film director."
	$\mathbf{m}_1$	"{Jones} moved to New York to become an actor in 1969 …"
	$\mathbf{m}_2$	"En Harvard {Jones} jugó como guard ofensivo en el equipo de fútbol americano universitario de 1968."
[Q18152778]	$\mathbf{d}_2$	"Thomas Lee Jones was an American and Canadian football player …"
	$\mathbf{m}_3$	"The Cleveland Browns selected {Tom Jones} …"

Figure 1: Illustration of hypothetical contextualized mention (m) and multilingual description (d) embeddings for the entities 'Tommy Lee Jones (Q170587)' and 'Tom Jones (Q18152778). The query mention [★] pertains to the former's college football career, which is unlikely to be captured by the high-level entity description. A retrieval against descriptions would get this query incorrect, but with indexed mentions gets it correct. Note that prior dual-encoder models that use a single vector to represent each entity are forced to contort the embedding space to solve this problem.

2 Overview

Task definition We train a model that performs entity linking by ranking a set of entity-linked *indexed mentions-in-context*. Formally, let a mention-in-context $\mathbf{x} = [x_1, ..., x_n]$ be a sequence of n tokens from vocabulary $\mathcal{V}$, which includes designated entity span tokens. An *entity-linked* mention-in-context $m^i = (\mathbf{x}^i, e^i)$ pairs a mention with an entity from a predetermined set of entities $\mathcal{E}$. Let $\mathcal{M}_\mathcal{I} = [m^1, ..., m^k]$ be a set of entity-linked mentions-in-context, and let $\texttt{entity}(\cdot) : \mathcal{M}_\mathcal{I} \rightarrow \mathcal{E}$ be a function that returns the entity $e^i \in \mathcal{E}$ associated with m^i, and $\mathbf{x}(\cdot)$ returns the token sequence $\mathbf{x}^i$.

Our goal is to learn a function $\phi(m)$ that maps an arbitrary mention-in-context token sequence m to a fixed vector $\mathbf{h}_m \in \mathcal{R}^d$ with the property that

$$y^* = \texttt{entity}\left(\underset{m' \in \mathcal{M}_I}{\text{argmax}}[\phi(\mathbf{x}(m'))^T \phi(\mathbf{x}_q)]\right)$$

gives a good prediction y^* of the true entity label of a query mention-in-context $\mathbf{x}_q$.

3 Method

3.1 Model

Recent state-of-the-art entity linking systems employ a dual encoder architecture, embedding mentions-in-context and entity representations in the same space. We also employ a dual encoder architecture but we score mentions-in-context (hereafter, mentions) against other mentions, with no consolidated entity representations. The dual encoder maps a pair of mentions (m, m') to a score:

$$s(m, m') = \frac{\phi(m)^T \phi(m')}{\|\phi(m)\| \|\phi(m')\|}$$

where ϕ is a learned neural network that encodes the input mention as a d-dimensional vector.

As in (Févry et al., 2020) and (Botha et al., 2020), our mention encoder is a 4-layer BERT-based Transformer network (Vaswani et al., 2017; Devlin et al., 2019) with output dimension $d = 300$.

3.2 Training Process

3.2.1 Mention Pairs Dataset

We build a dataset of mention pairs using the 104-language collection of Wikipedia mentions as constructed by Botha et al. (2020). This dataset maps Wikipedia hyperlinks to WikiData (Vrandečić and Krötzsch, 2014), a language-agnostic knowledge base. We create mention pairs from the set of all mentions that link to a given entity.

We use the same division of Wikipedia pages into train and test splits used by Botha et al. (2020) for compatibility to the TR2016 test set (Tsai and Roth, 2016). We take up to the first 100k mention pairs from a randomly ordered list of all pairs regardless of language, yielding 557M and 31M training and evaluation pairs, respectively. Of these, 69.7% of pairs involve two mentions from different languages. Our index set contains 651M mentions, covering 11.6M entities.

3.2.2 Hard Negative Mining and Positive Resampling

Previous work using a dual encoder trained with in-batch sampled softmax has improved performance with subsequent training rounds using an auxiliary cross-entropy loss against hard negatives sampled from the current model (Gillick et al., 2019; Wu et al., 2019; Botha et al., 2020). We investigate the effect of such negative mining for MOLEMAN, controlling the ratio of positives to negatives on a per-entity basis. This is achieved by limiting each entity to appear as a negative example at most 10

times as often as it does in positive examples, as done by Botha et al. (2020).

In addition, since MOLEMAN is intended to retrieve the *most similar* indexed mention of the correct entity, we experiment with using this retrieval step to resample the positive pairs used to construct our mention-pair dataset for the in-batch sampled softmax, pairing each mention m with the highest-scoring other mention m' of the same entity in the index set. This is similar to the index refreshing that is employed in other retrieval-based methods trained with in-batch softmax (Guu et al., 2020; Lewis et al., 2020a).

3.2.3 Input Representations

Following prior work (Wu et al., 2019; Botha et al., 2020), our mention representation consists of the page title and a window around the mention, with special mention boundary tokens marking the mention span. We use a total context size of 64 tokens.

Though our focus is on entity mentions, the entity descriptions can still be a useful additional source of data, and allow for zero-shot entity linking (when no mentions of an entity exist in our training set). We therefore experiment with adding the available entity descriptions as additional "pseudo-mentions". These are constructed in a similar way to the mention representations, except without mention boundaries. Organic and psuedo-mentions are fed into BERT using distinct sets of token type identifiers. We supplement our training set with additional mention pairs formed from each entity's description and a random mention, adding 38M training pairs, and add these descriptions to the index, expanding the entity set to 20M.

3.3 Inference

For inference, we perform a distributed brute-force maximum inner product search over the index of training mentions. During this search, we can either return only the top-scoring mention for each entity, which improves entity-based recall, or else all mentions, which allows us to experiment with k-Nearest Neighbors inference (see Section 4.1).

4 Experiments

4.1 Mewsli-9

Table 1 shows our results on the Mewsli-9 dataset compared to the models described by Botha et al. (2020). Model F is a dual encoder which scores entity mentions against entity descriptions, while Model F$^+$ adds two additional rounds of training with hard negative mining and an auxiliary cross-lingual objective. Despite using an identically-sized transformer, and trained on the same data, MOLEMAN outperforms Model F$^+$ when training only on mention pairs, and sees minimal improvement from a further round of training with hard negative and resampled positives (as described in Section 3.2.2). This suggests that training MOLEMAN is a simpler learning problem compared to previous models which must capture all an entity's diverse contexts with a single description embedding. Additionally, we examine a further benefit of indexing multiple mentions per entity: the ability to do top-K inference, and find that top-1 accuracy improves by half a point with k=5.

	I	HN	R@1	R@10	R@100
Model F	D	N	63.0	91.7	97.4
Model F$^+$	D	Y	89.4	96.4	98.2
MGENRE	–	–	90.6	–	–
MOLEMAN	M	N	89.5	97.4	98.3
	B	N	89.6	98.0	99.2
	B	Y	89.9	98.1	99.2
+ k=5	B	Y	90.4	–	–

Table 1: Results on Mewsli-9 compared to the models described by (Botha et al., 2020) and (De Cao et al., 2021). Column I indicates what is being indexed (Descriptions, Mentions, Both), and the HN indicates if additional rounds of Hard Negative training are applied.

We also compare to the recent MGENRE system of De Cao et al. (2021), which performs entity linking using constrained generation of entity names. It should be noted that this work uses an expanded training set that results in fewer zero- and few-shot entities (see De Cao et al. (2021) Table 3).

4.1.1 Per-Language Results

Table 2 shows per-language results for Mewsli-9. A key motivation of Botha et al. (2020) was to learn a massively multilingual entity linking system, with a shared context encoder and entity representations between 104 languages in the Wikipedia corpus. MOLEMAN takes a step further: the indexed mentions from all languages are included in the retrieval index, and can contribute to the prediction in any language. In fact, we find that for 21.4% of mentions in the Mewsli-9 corpus, MOLEMAN's top prediction came from a different language.

Language	R@1	R@10	R@100
ar	+1.1	+0.9	+0.3
de	-0.1	+1.5	+0.5
en	+0.3	+2.8	+2.3
es	-0.2	+1.1	+0.4
fa	+1.1	+0.9	+0.9
ja	+0.8	+1.2	+0.5
sr	-0.1	+0.8	+0.5
ta	+3.7	+1.3	+0.6
micro-avg	+0.2	+1.6	+1.0
macro-avg	+0.8	+1.3	+0.7

Table 2: MOLEMAN results on the Mewsli-9 dataset by language, listed as a delta against Model F^+ (Botha et al., 2020).

4.1.2 Frequency Breakdown

Table 3 shows a breakdown in performance by entity frequency bucket, defined as the number of times an entity was mentioned in the Wikipedia training set. When indexing only mentions, MOLEMAN can never predict the entities in the 0 bucket, but it shows significant improvement in the other frequency bands, particularly in the "few shot" bucket of [1,10). This suggests when introducing new entities to the index, labelling a small number of mentions may be more beneficial than producing a single description. To further confirm this intuition, we retrained MOLEMAN with a modified training set which had all entities in the [1, 10) band of Mewsli-9 removed, and only added to the index at inference time. This model achieved +0.2 R@1 and +5.6 R@10 relative to Model F^+ (which was trained with these entities in the train set). When entity descriptions are added to the index, MOLEMAN outperforms Model F^+ across frequency bands.

4.1.3 Inference Efficiency

Due to the large size of the mention index, nearest neighbor inference is performed using distributed maximum inner-product search. We also experiment with approximate search using ScaNN (Guo et al., 2020). Table 4 shows throughput and recall statistics for brute force search as well as two approximate search approaches that run on a single multi-threaded CPU, showing that inference over such a large index can be made extremely efficient with minimal loss in recall.

4.2 Tsai Roth 2016 Hard

In order to compare against previous multilingual entity linking models, we report results on the "hard" subset of Tsai and Roth (2016)'s cross-lingual dataset which links 12 languages to English Wikipedia. Table 5 shows our results on the same 4 languages reported by Botha et al. (2020). MOLEMAN outperforms all previous systems.

4.3 TACKBP 2010

Recent work on entity linking have employed dual-encoders primarily as a retrieval step before reranking with a more expensive cross-encoder (Wu et al., 2019; Agarwal and Bikel, 2020). Table 6 shows results on the extensively studied TACKBP 2010 dataset (Ji et al., 2010). Wu et al. (2019) used a 24-layer BERT-based dual-encoder which scores the 5.9 million entity descriptions from English Wikipedia, followed by a 24-layer cross-encoder reranker. MOLEMAN does not achieve the same level of top-1 accuracy as their full model, as it lacks the expensive cross-encoder reranking step, but despite using a single, much smaller Transformer and indexing the larger set of entities from multilingual Wikipedia, it outperforms this prior work in retrieval recall at 100.

We also report the accuracy of a MOLEMAN model trained only with English training data, and using an Enlish-only index for inference. This experiment shows that although the multilingual index contributes to MOLEMAN's overall performance, the pairwise training data is sufficient for high performance in a monolingual setting.

5 Discussion and Future Work

We have recast the entity linking problem as an application of a more generic mention encoding task. This approach is related to methods which perform clustering on test mentions in order to improve inference (Le and Titov, 2018; Angell et al., 2020), and can also be viewed as a form of cross-document coreference resolution (Rao et al., 2010; Shrimpton et al., 2015; Barhom et al., 2019). We also take inspiration from recent instance-based language modelling approaches (Khandelwal et al., 2020; Lewis et al., 2020b).

Our experiments demonstrate that taking an instance-based approach to entity-linking leads to better retrieval performance, particularly on rare entities, for which adding a small number of mentions leads to superior performance than a single description. For future work, we would like to explore the application of this instance-based approach to entity knowledge related tasks (Seo et al., 2018; Petroni et al., 2020), and to entity discovery (Ji et al., 2017).

	MOLEMAN (mentions only)		MOLEMAN (+ descriptions)		mGENRE
Freq. bin	R@1	R@10	R@1	R@10	R@1
[0, 1)	-8.3†	-33.9†	-0.2	+18.3	+13.8

A Appendices

A.1 Training setup and hyperparameters

To isolate the impact of representing entities with multiple mention embeddings, we follow the training methodology and hyperparameter choices presented in Botha et al. (2020) (Appendix A).

We train MOLEMAN using in-batch sampled softmax (Gillick et al., 2018) using a batch size of 8192 for 500k steps, which takes about a day. Our model is implemented in Tensorflow (Abadi et al., 2016), using the Adam optimizer (Kingma and Ba, 2014; Loshchilov and Hutter, 2017) with the mention encoder preinitialized from a multilingual BERT checkpoint[2]. All model training was carried out on a Google TPU v3 architecture[3].

A.3 Profiling Details

The brute-force numbers we've reported are the theoretical maximum throughput for computing 300D dot-products on an AVX-512 processor running at 2.2Ghz, and are thus an overly optimistic baseline. Practical implementations, such as the one in ScaNN, must also compute the top-k and rarely exceed 70% to 80% of this theoretical limit. The brute-force latency figure is the minimum time to stream the database from RAM using 144 GiB/s of memory-bandwidth. In practice, we ran distributed brute-force inference on a large cluster of CPUs, which took about 5 hours.

The numbers for ScaNN are empirical single-machine benchmarks of an internal solution that uses the open-source ScaNN library [4] on a single 24-core CPU. We use ScaNN to search a multi-level tree that has the following shape: $78,000 => 83:1 => 105:1$ (687.3 million datapoints). We used a combination of several different anisotropic vector quantizations that combine 3, 6, 12, or 24 dimensions per 4-bit code, as well as re-scoring with an `int8`-quantization.

A.4 Expanded experimental results

Abstract

Bidirectional Encoder Representations from Transformers (BERT) have been shown to be extremely effective on a wide variety of natural language processing tasks, including sentiment analysis and emotion detection. However, the proposed pre-training objectives of BERT do not induce any sentiment or emotion-specific biases into the model. In this paper, we present Emotion Masked Language Modeling, a variation of Masked Language Modeling, aimed at improving the BERT language representation model for emotion detection and sentiment analysis tasks. Using the same pre-training corpora as the original BERT model, Wikipedia and BookCorpus, our BERT variation manages to improve the downstream performance on 4 tasks for emotion detection and sentiment analysis by an average of 1.2% F1. Moreover, our approach shows an increased performance in our task-specific robustness tests. We make our code and pre-trained model available at https://github.com/tsosea2/eMLM.

1 Introduction

Language models have been studied extensively in the NLP community (Dai and Le, 2015; Howard and Ruder, 2018; Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019), with approaches attaining state-of-the-art results on multiple token-level or sentence-level tasks. BERT (Devlin et al., 2019) is a pre-trained language model, which proposed a new pre-training objective inspired by the Cloze task (Taylor, 1953), which enables the training of a deep bi-directional transformer network. This objective, called Masked Language Modeling (MLM) is used on large amounts of unlabeled data from Wikipedia and BookCorpus to produce powerful universal language representations. However, the pre-training does not take into account the downstream task on which the model will be applied.

In this paper, we posit that we can leverage the characteristics of a downstream task to design better task-tailored pre-training objectives. Concretely, we induce information from emotion or sentiment lexicons into our BERT pre-training objective to improve the performance on tasks from sentiment analysis and emotion detection.

There are numerous studies that focus on emotion detection (Demszky et al., 2020; Desai et al., 2020; del Arco et al., 2020; Sosea and Caragea, 2020; Majumder et al., 2019; Mohammad and Kiritchenko, 2018; Abdul-Mageed and Ungar, 2017; Mohammad and Kiritchenko, 2015; Mohammad, 2012; Strapparava and Mihalcea, 2008) and sentiment analysis (Yin et al., 2020; Tian et al., 2020; Phan and Ogunbona, 2020; Zhai and Zhang, 2016; Chen et al., 2016; Liu, 2012; Glorot et al., 2011; Pang and Lee, 2005). Various lexicons have been used to improve model performance on these tasks. For instance, Katz et al. (2007) used occurrences of emotion words to identify various emotion types in news headlines. Moreover, emotion lexicons have been used to produce important features which can be used inside a machine learning algorithm to improve the performance on emotion detection tasks (Mohammad, 2012; Sykora et al., 2013; Khanpour and Caragea, 2018; Biyani et al., 2014). In this paper, however, instead of leveraging these lexicons to design features, in contrast, we use them to obtain language representations that are more suitable for emotion and sentiment tasks.

To this end, we introduce Emotion Masked Language Modeling (eMLM), a new pre-training BERT (Devlin et al., 2019) objective aimed at improving the BERT performance on tasks related to sentiment analysis and emotion detection. Inspired by the well-known Masked Language Modeling objective, eMLM adds only a few simple, yet powerful changes. Instead of uniformly masking the tokens in the input sequence, eMLM leverages

lexicon information, and assigns higher masking probabilities to words that are more likely to be important in the sentiment or emotion contexts. To enable a fair comparison with the vanilla BERT model, we train the eMLM BERT model in the same fashion as the vanilla BERT, pre-training on Wikipedia and BookCorpus (Zhu et al., 2015). To our knowledge, we are the first to study different masking probabilities for the BERT pre-training procedure guided by sentiment and emotion lexicons. Similar to our work, some studies also focused on incorporating sentiment information into pre-trained language models. For example, Yin et al. (2020) built an attention network on top of BERT to predict sentiment labels of phrase nodes obtained through a constituency parse tree. On the other hand, Tian et al. (2020) designed various pre-training objectives, such as masking and predicting all words from a pre-defined small set of seeds, and predicting an aspect-sentiment pair or the polarity of words. In contrast, we leverage information from available sentiment and emotion lexicons.

We show the feasibility of our approach by testing eMLM on two sentiment analysis benchmark datasets and two emotion detection datasets. These datasets span diverse domains, such as movie reviews, online health communities, and Reddit discussions, enabling a comprehensive analysis of eMLM.

Our contributions are as follows: **1)** We introduce a new pre-training objective for BERT (leveraging available lexicons), aimed at producing better task-guided universal representations for downstream tasks from sentiment analysis and emotion detection. We offer the pre-trained model as an easy way to leverage our approach on downstream applications. **2)** We show the efficacy of our approach by testing our method on four benchmark datasets for emotion and sentiment and obtain an average improvement in F1 score of 1.2%. **3)** We verify the robustness of our model in the face of input perturbations, which occur frequently in informal contexts (e.g., due to mispellings).

2 Proposed Approach

Background Bidirectional Encoder from Transformers for Language Understanding (BERT) (Devlin et al., 2019) is a pre-trained language model trained on large amounts of unlabeled data using two objectives: **1)** Masked Language Modeling (MLM) randomly masks 15% of tokens in a sequence, followed by a supervised prediction of the masked tokens; **2)** Next Sentence Prediction (NSP) predicts in a binary fashion if two sentences follow each other. By using these two tasks on large-scale data repositories such as BookCorpus (800M words) (Zhu et al., 2015) and Wikipedia ($2,500$M words), BERT produces powerful universal language representations, applicable on a wide range of tasks, such as sentiment analysis, question answering, and commonsense reasoning.

However, to be used in various downstream tasks, BERT has to undergo a task-specific fine-tuning step (Devlin et al., 2019), where the contextualized embedding is adapted to the needed task. We posit that we can improve the downstream performance by focusing on the target task in the pre-training phase as well. Specifically, we focus on sentiment analysis and emotion detection, and show that task-guided unsupervised pre-training helps the performance considerably.

Masking Emotion Words Now we introduce Emotion Masked Language Modeling (eMLM), a variation of MLM targeted at inducing emotion or sentiment-specific biases in the BERT pre-training phase. Specifically, unlike BERT, which uses a uniform probability (15%) to mask the tokens in an input sentence, we assign higher probabilities to tokens which are emotionally rich words from an available lexicon $\mathcal{L}$. We denote this probability by k, which is a hyperparameter in our eMLM method. Our masking process can be summarized as follows: Given an input sentence S: **1)** We extract the words that belong to the lexicon $\mathcal{L}$, and we denote them by E; **2)** We set the masking probability of these words as $P(w_e) = k \; \forall \; w_e \in E$; **3)** To ensure

we mask 15% of the words in total, we lower the masking probability of the non-emotionally-rich words using the following formula:

$$P(w_n) = \frac{max(|S| \cdot 0.15 - |E| \cdot k,\ 0)}{|S| - |E|},\ \forall\ w_n \notin E$$

where $|\cdot|$ represents the size of a set. We show examples of how our masked probabilities change from MLM to eMLM in Table 1. For instance, in the first example, there are two emotion words, *perfect* and *hope*, and we use a masking probability of $k = 0.50$. While the probabilities of these two words are set to 50%, the non emotionally-rich word probability is lowered from 15% to 9% to keep the sum of probabilities constant. The rest of the training process is the same as the original BERT pre-training. That is, we train our BERT model from scratch using eMLM and NSP on the same datasets: Wikipedia and BookCorpus. We mention that we use whole word masking, both for eMLM and the MLM (i.e., we mask all the subtokens corresponding to a word).

3 Experiments and Results

In this section, we first describe our experimental setup (§3.1), then present our datasets and lexicons (§3.2), and then discuss the results that contrast **eMLM** with the original BERT **MLM** (§3.3).

3.1 Experimental Setup

We use various benchmark datasets from sentiment analysis and emotion detection to test our eMLM approach. For every dataset considered, we use the provided training, validation, and test splits. To assert statistical significance, we fine-tune each model 10 times with different random seeds and report the average F1 score. We investigate various masking probabilities k, ranging from 0.2 to 1.0, and find that 0.5 works best in our setting. For low values around 0.2 we notice that the performance is similar to that of the original BERT, while for high values (closer to 1.0), the performance is negatively affected.

3.2 Datasets and Lexicons

We test our models on various benchmark datasets described below.

Stanford Sentiment Treebank (**SST**) (Socher et al., 2013) SST contains 11,855 sentences from movie reviews, annotated with five sentiment labels: *negative*, *somewhat negative*, *neutral*, *somewhat positive*, and *positive*. First, we consider the binarized dataset, called SST-2, where the examples with the *negative* and *somewhat negative* labels are merged into a *negative* class, and the examples with the *somewhat positive* and *positive* labels are merged into a *positive* class (with neutral class being removed). Second, we consider the SST fine-grained version (SST-5), which uses all five labels.

	SST-2		SST-5	
	ACC	F-1	ACC	F-1
BERT	0.912	0.922	0.532	0.541
eMLM (S)	0.919	0.928	0.541	0.552
eMLM (E)	**0.920**	**0.931**†	**0.547**	**0.558**†

Table 2: Performance on the sentiment analysis task. We assert significance† if $p < 0.05$ under a t-test with the vanilla BERT model.

GoEmotions (Demszky et al., 2020) is a sentence-level multilabel dataset of 58,000 comments curated from Reddit and annotated with 27 emotion categories and the neutral class.

CancerEmo (Sosea and Caragea, 2020) is a sentence-level multilabel dataset of 8,500 sentences labeled with the eight Plutchik (Plutchik, 1980) basic emotions from an Online Health Community for people suffering from diseases such as cancer.

We analyze the behaviour of eMLM in diverse environments: sentiment analysis or emotion detection, various data platforms (e.g., Reddit, OHCs), and variate emotion or sentiment granularity (from 2 classes to as many as 28 classes).

Lexicons As mentioned above, our eMLM focuses on emotionally rich words from a lexicon. In this paper, we use EmoLex (Mohammad and Turney, 2013), a lexicon of 6,000 words associated with eight Plutchik basic emotions (Plutchik, 1980) (sadness, anger, joy, surprise, anticipation, trust, fear, disgust) and 5,555 words associated with the positive and negative sentiments. We consider the sentiment and emotion words separately to analyze the impact of each on the performance of eMLM. We denote the approach which masks the emotion-revealing words by eMLM (E), and the sentiment-revealing words by eMLM (S).

Table 3: F-1 scores on the Goemotion dataset. We assert significance† if $p < 0.05$ under a t-test with the vanilla BERT model.

3.3 Results

Results on Sentiment Analysis We show the results of our approaches on SST in Table 2. First, we observe that eMLM (E) and eMLM (S) improve upon the vanilla BERT model on both tasks, with eMLM (E) obtaining as much as 1.7% improvement in F1. Interestingly, eMLM (E) outperforms eMLM (S) suggesting that masking finer-granularity emotion words in eMLM produces better representations for the task. At the same time, eMLM (E) achieves better performance on the fine-grained SST-5 task, where the improvements over the vanilla BERT are considerable.

Results on Emotion Detection We show the results of eMLM on the GoEmotions dataset in Table 3 and observe that, similar to sentiment analysis, eMLM (E) is the best performing approach, improving upon vanilla BERT by 1.4% in F1. We show the results on CancerEmo in Table 4 and observe the same pattern: **eMLM (E) consistently outperforms the other approaches**. We see improvements as high as 4% on Joy and 2% on Sadness. Overall, eMLM (E) obtains an 1.7% F1 improvement over the vanilla BERT model.

Table 5: Average F-1 on the considered datasets using various values of the emotion masking probability k.

Discussion The presented results reveal the feasibility of our proposed approach. Our BERT model trained using the eMLM objective produces high quality contextualized embeddings for downstream tasks that span the sentiment analysis and emotion detection tasks. Moreover, our methods incur no additional computational cost over the original BERT (Devlin et al., 2019), and undergo the same amount of pre-training. We also tried combining and masking both sentiment and emotion words; however, we did not see any performance improvements. As a step forward, we are interested in gaining more insights into the differences between eMLM (E) and the vanilla BERT model. We study this in the robustness context in the next section, and analyze how our models behave in the face of various input perturbations (i.e., noise).

Varying the Emotion Masking Probability k To offer additional insights into our eMLM approach and show the impact of the sentiment or emotion-rich word masking probability on downstream tasks, we show the results obtained using various values of k in Table 5. First, we note that using a slightly lower probability of 0.30 still adds improvements to our model on three of the considered datasets. In contrast, too high of a proba-

bility hurts the F1 performance. Concretely, using $k = 0.90$, our eMLM approach decreases the F1 compared to the vanilla BERT by 1% on **CancerEmo**, 5% on GoEmotions, and 1% on **SST-2**.

4 Robustness Test

It has been shown that neural models are often sensitive to various input perturbations (Niu et al., 2020; Belinkov and Bisk, 2018). In this section, we aim to investigate the robustness of our proposed approach in the face of input noise. We focus on the following two questions: **1)** Does eMLM improve the robustness of the model? **2)** What type of input noise is successful in misleading our model? We study these questions on the SST-5 sentiment analysis task using the framework introduced by Hsieh et al. (2019). We explore three ways to generate input perturbations and verify their "success." We say a perturbation is "successful" on a model M for an example e if **1)** The model M classifies e correctly and **2)** The model M misclassifies the example e when noise is applied to it. Naturally, the lower the perturbation success rate, the more robust a model is. The perturbations that we considered are as follows:

1. **Random** (Alzantot et al., 2018) replaces one word from the input sentence with a random word from the vocabulary. For a word, we repeat this process 100 times. If at least one of the replacements leads to an incorrect prediction, the perturbation is deemed to be successful.

2. **LIST** (Alzantot et al., 2018) replaces each word (one at a time) in the input text with a synonym. The input perturbation is successful if at least one replacement leads to an incorrect prediction.

3. **EmoWord** If there is an emotion word in the input sentence, then we zero out that word, otherwise, we zero out a random word from the input sequence.

Results We show the results of the robustness tests for the vanilla BERT and the eMLM approach in Table 6. First, EmoWord is the most successful perturbation, being twice as effective compared to the other methods. Second, we observe that Random and LIST obtain the same success rates among both the BERT and eMLM approach. However, on EmoWord, our eMLM approach is considerably more robust, outperforming the simple BERT model by 4.4%. We argue that this is the byproduct of the eMLM training procedure, which focuses on predicting emotion words in the pre-training step.

EMOTION	RANDOM	LIST	EMOWORD
BERT	1.5%	2.4%	9.8%
eMLM	1.5%	2.4%	**5.4%**

Table 6: Robustness of our models in terms of perturbation success rates. Lower success rates indicate more robust models.

5 Conclusion

In this paper, we introduced a new BERT pre-training objective suited for sentiment analysis and emotion detection tasks. We showed that the approach is feasible; it needs no additional pre-training compared to the vanilla BERT, and improves the performance by 1.2% F1 on average on various tasks. Our analysis also suggests that eMLM is more robust in the face of input perturbations. As future work, we note that our approach is general enough, so we plan to leverage different lexicons outside the sentiment analysis and emotion detection domains to investigate if the model generalizes well on other domains (e.g., financial). We also plan to study if our method is effective for non-English languages. Finally, we note that there exist lexicons that assign to words not only their emotion, but also their emotion intensity (Mohammad, 2018). Therefore, we plan to investigate if associating the masking probability with the emotion intensity (i.e., assign a higher probability to a more intensive word) would further help improve the performance.

On Positivity Bias in Negative Reviews

Madhusudhan Aithal
University of Colorado Boulder

chenhao@uchicago.edu

Abstract

Prior work has revealed that positive words occur more frequently than negative words in human expressions, which is typically attributed to positivity bias, a tendency for people to report positive views of reality. But what about the language used in negative reviews? Consistent with prior work, we show that English negative reviews tend to contain more positive words than negative words, using a variety of datasets. We reconcile this observation with prior findings on the pragmatics of negation, and show that negations are commonly associated with positive words in negative reviews. Furthermore, in negative reviews, the majority of sentences with positive words express negative opinions based on sentiment classifiers, indicating some form of negation.

1 Introduction

A battery of studies have validated the Pollyanna hypothesis that positive words occur more frequently than negative words in human expressions, using corpora ranging from Google Books to Twitter (Dodds et al., 2015; Garcia et al., 2012; Boucher and Osgood, 1969; Kloumann et al., 2012). The typical interpretation is connected with the positivity bias, which broadly denotes 1) a tendency for people to report positive views of reality, 2) a tendency to hold positive expectations, views, and memories, and 3) a tendency to favor positive information in reasoning (Carr, 2011; Augustine et al., 2011; Hoorens, 2014). However, it remains an open question whether the Pollyanna hypothesis holds in negative reviews, where the communicative goal is to express negative opinions.

In this work, we use a wide variety of review datasets to examine the use of positive and negative words in negative reviews. Table 1 shows a negative review from Yelp. Although the overall opinion is clearly negative, the author expressed the excitement to try the place and deemed the food OK. Zooming into individual words, they used the same number of positive and negative words in this negative review. Interestingly, this short review has as many as three negations, one directly applied to "great" (hence "not great").

Food was ok...*not* the money they charge. I was unimpressed and will *not* return. I was excited to try this place and was so disappointed as my expectations were high. Service *not* great and The parking is awful.

Table 1: Example negative review on Yelp. Positive words are in blue and negative words are in red, based on Vader (Hutto and Gilbert, 2014). Negations are in italics. This short review contains three negations.

More generally, we find that negative reviews contain *more* positive words than negative words, which is consistent with the Pollyanna hypothesis. Two possible reasons may explain this observation: 1) negative reviews tend to still include positive opinions due to a naïve interpretation of the positivity bias, where positive words express positive sentiments without accounting for negation or other contextual meaning of these words; 2) negative reviews tend to use *indirect expressions* (i.e., applying negations to positive words) to indicate negative opinions (e.g., "not clean"). Note that a broad interpretation of positivity bias may encompass the second reason,[1] but indirect expressions could also be related to other factors, e.g., verbal politeness (Brown et al., 1987)).

We aim to delineate these two reasons by examining the use of negations. Our results provide support for the latter reason: negative reviews tend to use more negations than positive reviews. The

[1] Boucher and Osgood (1969) used a morphological analysis to show negative affixes are more commonly applied to positive words than negative words (unhappy vs. non-violent).

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 294–304
August 1–6, 2021. ©2021 Association for Computational Linguistics

differences become even more salient when we compare negations applied to positive words vs. negative words. Finally, among sentences with positive words in negative reviews, the majority are classified as negative than as positive by sentiment classifiers, indicating some form of negation.

2 Related Work

In addition to positivity bias, our work is closely related to experimental studies on understanding the effect of direct (e.g., "bad") and indirect (e.g., "not good") wordings. Colston (1999) and Kamoen et al. (2015) observe no difference in people's interpretation of direct and indirect wordings in negative opinions; but direct wordings receive higher evaluations than indirect ones in positive opinions. In this work, we examine whether and how individuals use indirect wordings *in practice* (in negative reviews).

Our work is also related to Potts (2010), which finds that negation is used more frequently in negative reviews and is thus pragmatically negative. We extend Potts (2010) in two ways: 1) we demonstrate a high frequency of negation followed by positive words in negative reviews compared to other combinations, a new observation motivated through the lens of positivity bias; 2) we conduct a systematic study using a wide variety of datasets with multiple dictionaries.

Finally, our work builds on sentiment classification (Pang et al., 2002, 2008; Liu, 2012). The NLP community has made significant progress in recognizing the sentiment in texts of various languages, obtaining accuracies of over 95% (English) in binary classification (Devlin et al., 2019; Liu et al., 2019). Researchers have also developed novel approaches to identify fine-grained sentiments (e.g., aspect-level sentiment analysis (Schouten and Frasincar, 2015; Wang et al., 2016; Yang and Cardie, 2013)) as well as semi-supervised and unsupervised approaches (Hu et al., 2013; Zhou et al., 2010; Tan et al., 2011).

3 Datasets

We use a wide range of English review datasets to ensure that our results are robust across domains.

- Yelp.[2] We only consider restaurant reviews.
- IMDB movie reviews (Maas et al., 2011). This dataset provides train and test splits, so we follow their split when appropriate.

[2] https://www.yelp.com/dataset.

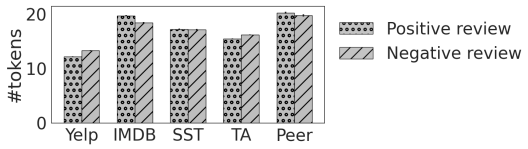

Figure 1: Sentence-length comparison. Although negative reviews can be much longer than positive reviews, sentences in positive reviews and negative reviews have similar lengths. Results on Amazon reviews are shown in the appendix. Tiny error bars show standard errors.

- Stanford sentiment treebank (SST) (Socher et al., 2013). SST contains processed snippets of reviews from the Rotten Tomatoes website (movie reviews). It has ground truth sentiment scores of reviews at the sentence level and the word level.
- Tripadvisor (Wang et al., 2010). This dataset consists of hotel reviews.
- PeerRead (Kang et al., 2018). We use reviews for papers in ACL, CoNLL, and ICLR.
- Amazon (Ni et al., 2019). This dataset contains Amazon reviews grouped by categories. We choose five categories that are substantially different from movies, hotels, and restaurants to ensure that our results are robust, namely, "Automotive", "Cellphones and accessories", "Luxury beauty", "Pet supplies", and "Sports and outdoors".

For datasets with ratings in 1-5 scale, we label reviews with ratings greater than 3 as positive and reviews with ratings less than 3 as negative following prior work (Pang et al., 2002), and ignore reviews with rating 3. Similarly, for datasets with ratings scale of 1-10 (IMDB, ICLR reviews in PeerRead), we label reviews with ratings greater than 6 as positive and review with ratings less than 5 as negative, and ignore reviews with ratings 5 and 6.

We use spaCy to tokenize the reviews in all datasets (Honnibal and Montani, 2017), except that Stanford Core NLP is used to tokenize SST reviews (Manning et al., 2014). We present results for Amazon reviews in the appendix, and our main results are robust on Amazon reviews. Our code is available at https://github.com/madhu-aithal/Positivity-Bias-in-Negative-Reviews.

Length of positive vs. negative opinions. In general, negative opinions tend to be longer than positive opinions ($p < 0.05$ after Bonferroni correction in 6 out 10 datasets; see the appendix for details). In comparison, the difference in length is smaller at the sentence level (Figure 1). Therefore, we use sentences as the basic unit in this work. To further

rule out sentence length as a confounding factor, we also present word-level results in the appendix.

4 Results

We first investigate the occurrences of positive words, negative words, and negations in reviews. We find that negative reviews contain more positive words than negative words in all datasets. We show that this observation relates to the prevalence of negation in negative reviews compared to positive reviews in all datasets. Furthermore, these negations are commonly associated with positive words in all datasets, and sentences with positive words tend to be negative based on sentence-level prediction, supporting the prevalence of indirect wordings in negative reviews.

4.1 Negative Reviews Have More Positive Words than Negative Words

We use lexicon-based methods to examine the frequency of positive and negative words in reviews. For most of the datasets, we randomly sample 5,000 positive reviews and 5,000 negative reviews to compute the lexicon distribution using LIWC (Pennebaker et al., 2007) and Vader (Hutto and Gilbert, 2014). In the case of SST, PeerRead, and negative reviews of Amazon Luxury Beauty, we use the entire dataset for our analysis as it has a relatively small number of reviews.

Figure 2 shows that as expected, negative reviews have more negative words and fewer positive words than positive reviews, based on Vader. Intriguingly, despite the negative nature of negative reviews, they tend to have more *positive* words than *negative* words ($p < 0.001$ on all datasets except SST after Bonferroni correction). Our results are robust at the word level and also hold based on LIWC and validate the Pollyanna hypothesis even in negative reviews.

4.2 Negative Reviews Have More Negations and Indirect Expressions

We hypothesize that in addition to the tendency to report positive views of reality, an important factor that can explain this observation in negative reviews is the use of indirect expressions (i.e., negation of positive words). To measure the amount of negation, we use two approaches: 1) a lexicon-driven approach based on Vader including *aint*, *cannot*, *not*, and *never* (Hutto and Gilbert, 2014)[3]; 2)

[3]See the appendix for the full list of negation lexicons.

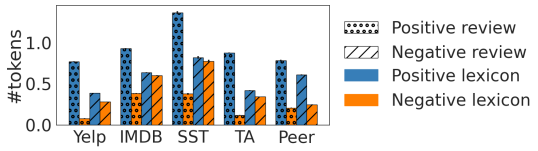

Figure 2: Number of positive and negative words based on Vader. Negative reviews have more positive words than negative words.

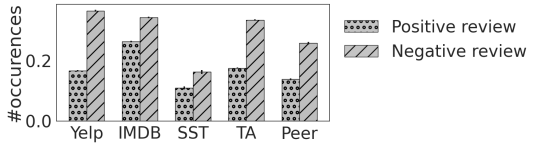
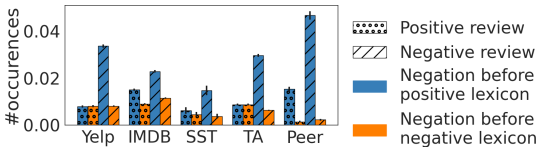


(a) Overall negation.



(b) Negation before positive and negative lexicons.

Figure 3: Negative reviews generally have more negations at the sentence level (Figure 3a). Among those negations, Figure 3b shows that there are substantially more negations before positive lexicons in negative reviews than any other combinations.

the negation relation in dependency parsing.[4] We present the results based on Vader negation in the main paper as it may have higher precision, and all results hold using dependency parsing.

Negative reviews have more negations than positive reviews in all datasets. Figure 3a presents the number of negations at the sentence level. In all datasets, negative reviews have more negations than positive reviews ($p < 0.001$ in all datasets). In fact, the number of negations in negative reviews almost doubles that in positive reviews in Yelp, TripAdvisor, and PeerRead (see samples in the appendix). This observation is robust at the word level, which accounts for the fact that negative reviews tend to be longer.

Negations are commonly associated with positive words in negative reviews. To further examine the relation between negations and sentimental lexicons, we investigate the occurrences of negations immediately followed by positive words and negative words. Figure 3b shows that there are more negations before positive words in negative reviews than any other combination ($p < 0.001$ in all datasets). The difference is especially salient in

[4]We used spaCy for dependency parsing (Honnibal and Montani, 2017).

Dataset	Positive words associated with negations
Yelp	recommend, sure, like, good, care, great, special, impressed, fresh, help, ready, enjoy, friendly, honor, helpful, clean, happy, accept, greeted, amazing
IMDB	like, care, funny, help, sure, recommend, good, save, fit, great, special, interesting, enjoy, well, play, better, giving, original, convincing, true
PeerRead	clear, sure, convincing, convinced, ready, well, true, clearly, surprising, novel, convincingly, recommend, guarantee, improve, interesting, support, satisfactory, help, acceptable, convince

Table 2: Most frequent positive words that immediately follow negations in negative reviews, based on Vader.

Yelp, TripAdvisor, and PeerRead. In particular, in negative reviews in PeerRead, negation before positive lexicon are approximately 20 times as frequent as negation before negative lexicon. These results demonstrate the prevalence of indirect wordings when people express negative opinions. Moreover, using indirect expressions to express negative opinions (negation before positive words) is also common in positive reviews for IMDB and PeerRead.

Table 2 shows the 20 most common words that immediately follow negations in Yelp, IMDB, and PeerRead, highlighting the prevalence of "not clear", "not convincing", and "not surprising" in negative reviews of NLP/ML submissions.

A natural question is how much of the usage of positive words in Figure 2 can be explained by negations before positive words. We find that it is sufficient to explain 11.3% on average. For instance, negative reviews in Yelp have 0.389 positive words per sentence, out of which 0.033 words follow a negation. This accounts for 8.7% of the usage of positive words. This suggests that negations before positive words only account for a small fraction of positive words, despite that they dominate other combinations of negations and sentiment lexicon. We hypothesize for positive words in negative reviews, they may be negated in ways beyond immediate preceding negations (e.g., "nor is the food great" and "fail to support").

Similarly, the number of negations followed by positive/negative words is a fraction of all the negations (14.2% in negative reviews and 9.7% in positive reviews). For example, "I will not return" counts as negation but there is no sentimental lexicon. We hypothesize that these negations also tend to express negative sentiments.

4.3 Sentence-level Sentiment Classification

To capture the sentiment of sentences with positive words or negations beyond negations immediately followed by positive words, we rely on sentiment classifiers. Specifically, we use sentence-level classification to quantify the extent of negative sentences in those contexts compared to the overall average in negative reviews.

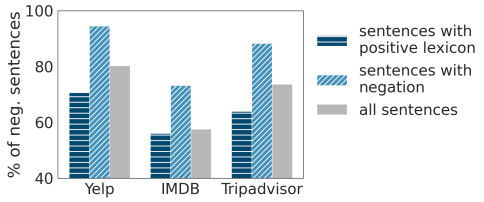
We fine-tune BERT (Devlin et al., 2019) to perform review-level classification for each dataset except SST and PeerRead. This is because all reviews in SST are very short and sentences in negative reviews are mostly negative whether negation occurs or not. In the case of PeerRead, the number of samples is too small to fine-tune the BERT model. For all other datasets except IMDB and Amazon Luxury Beauty, we randomly sample 25K positive reviews and 25K negative reviews as the training set, and 5K positive reviews and 5K negative reviews as the test set. For IMDB, we use 12.5K positive and 12.5K negative training samples provided for fine-tuning, and for Luxury Beauty, we use a balanced set of 2.3K positive and 2.3K negative samples for fine-tuning. We use 90% of the training samples to fine-tune the BERT model and 10% as the development set to select hyperparameters. We achieved accuracies varying from 94% to 98% for the test set reviews in all datasets. See the appendix for details of the data split and accuracies.

We use the BERT model fine-tuned on reviews to predict sentiment of sentences. Note that this prediction entails a distribution shift as sentences are shorter than full reviews used to fine-tune BERT models. However, this is a common strategy for evaluating rationales in the interpretable machine learning literature and there exists evidence that transformer-based models provide strong performance despite the distribution shift in the form of reduced inputs (DeYoung et al., 2020; Hsu et al., 2020; Carton et al., 2020).[5]

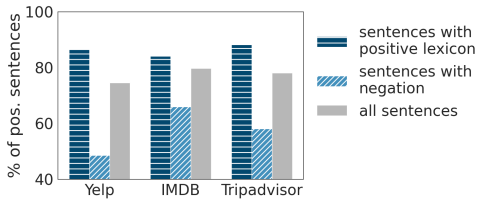
Figure 4a shows that sentences with positive words in negative reviews are more likely to be negative than to be positive (65.1% on average across all datasets; notably, IMDB is lower but still at 56.13%, above 50%).[6] It suggests that the majority of positive words are negated in some way. While the remaining minority of sentences with positive

[5] Bastan et al. (2020) investigates the reverse direction, i.e., from paragraph-level predictions to document-level predictions.

[6] Similar trends hold if we adjust the estimates using TPR, TNR, FPR, and FNR. See the appendix.



(a) Fractions of negative sentences in negative reviews.



(b) Fractions of positive sentences in positive reviews.

Figure 4: Sentence-level prediction results based on fine-tuned BERT classifiers. In negative reviews, sentences with positive words tend to be negative, and sentences with negations are overwhelmingly negative. In comparison, sentences with negations are more balanced (44.7% negative) in positive reviews.

words are indeed positive and align with the tendency to report positive views, our results highlight the important role of indirect expressions in explaining the positive words in negative reviews.

Furthermore, sentences with negation tend to be negative (88.6%) based on our classifiers, confirming our hypothesis that most negations are used to express negative sentiments in negative reviews. This is even higher than the average fraction of negative sentences (73.1%) among all sentences in negative reviews. In comparison, Figure 4b shows that positive words in positive reviews tend to reflect positive sentiments, indicating no common use of negation associated with positive words. Meanwhile, negations are not usually associated with negative sentiments in positive reviews (44.7%), substantially lower than negations associated with negative sentiments in negative reviews (88.6%).

5 Conclusion

In this paper, we investigate positivity bias in negative reviews and highlight the role of indirect expressions in understanding this phenomenon. We show that negations followed by positive words are more prevalent than any other combination in negative reviews. Given that these indirect wordings account for only 11.3% of the occurrences of positive words in negative reviews, we further show that such sentences with positive words tend to be negative, based on sentiment classifiers.

While our findings support the prevalence of indirect expressions, we do not take sentiment intensity into account. In practice, "not good" provides a different meaning from "not amazing". We believe exploring the relationship between negation and semantic intensity is a promising direction. Our lexical-driven approaches are limited by the lexicons included in the dictionaries, which are typically evaluated independent of the context, so their sentiment may be different in the specific context.[7] Similarly, our sentence-level prediction results are limited by the distribution shift when applying BERT trained on documents to sentences. It is reassuring that our high-level results hold across multiple datasets based on both lexical-driven approaches and sentence-level prediction.

As our study focuses on negative reviews in English, it is important to examine the generalizability of our results. For instance, it is important to understand to what extent the observed positivity bias in general expressions is driven by such indirect expressions. Another natural extension is to investigate other languages. Although our findings are limited to English reviews, we believe that they may be applicable to negative opinions in other languages, as Pollyanna hypothesis (Boucher and Osgood, 1969) has been validated across languages and cultures. Finally, our work has implications for sentiment-related applications in NLP. The prevalence of indirect expressions in negative reviews underscores the importance of modeling and understanding negation in sentiment analysis and sentiment transfer (Ettinger, 2020).

In general, we believe that online reviews not only provide valuable data for teaching machines to recognize sentiments but also allow us to understand how humans express sentiments. We hope that our work encourages future work to further investigate the framing choices when we express emotions and opinions, and their implications on NLP applications.

Acknowledgments

We thank anonymous reviewers and the members of the Chicago Human+AI lab for their helpful comments. This work was supported in part by an Amazon research award, a Salesforce research award, and NSF IIS-1941973.

[7] One reviewer pointed out an interesting hypothesis: judges assume the nicest interpretation of a word out of context in the annotation process, as a result, the Pollyanna hypothesis may be an instrumentation bias.

A Vader Lexicons

Table 3 shows the list of negation lexicons in Vader.

aint, arent, cannot, cant, couldnt, darent, didnt, doesnt, ain't, aren't, can't, couldn't, daren't, didn't, doesn't, dont, hadnt, hasnt, havent, isnt, mightnt, mustnt, neither, don't, hadn't, hasn't, haven't, isn't, mightn't, mustn't, neednt, needn't, never, none, nope, nor, not, nothing, nowhere, oughtnt, shant, shouldnt, uhuh, wasnt, werent, oughtn't, shan't, shouldn't, uh-uh, wasn't, weren't, without, wont, wouldnt, won't, wouldn't, rarely, seldom, despite

Table 3: Negation lexicons in Vader used for our negation analysis.

B Samples from PeerRead

Table 4 shows a list of 6 sentences with negation selected from random negative PeerRead reviews. Negations are mostly associated with positive words, both directly and indirectly.

Please do *not* make incredibly unscientific statements like this one :"
I'm *not* convinced about the value of having this artificial dataset.
For example, at the end of sec 4.4, " This result is *not* surprising, given that FOV-R contains additional information ....
It is *not* clear whether the improvements (if there is) of the ensemble disappear after data-augmentation.
Empirical analysis is *not* satisfactory.
But I'm *not* sure from reading the paper.

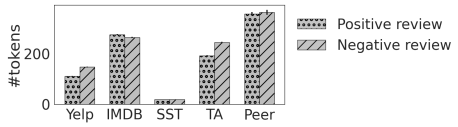
Table 4: Sentences with negation sampled from negative reviews of PeerRead. Positive words are in blue and negative words are in red. Negations are in italics.

C Additional Plots

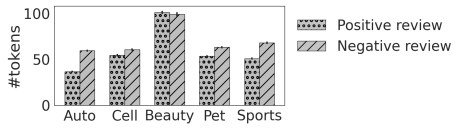
Length distribution. See Figure 5 for review-level length and Figure 6 for sentence-level length distribution for Amazon reviews.

Lexicon distribution. Figure 7 shows the sentiment lexicon distribution of all reviews using LIWC. Figure 8 shows the lexicon distribution of Amazon reviews using Vader.

Negation distribution. See Figure 9 and Figure 11 for the negation distribution of Amazon reviews using Vader and dependency parsing respectively. Figure 10 shows the negation distribution found using dependency parsing for non-Amazon reviews.



(a) SST, Yelp, IMDB, and Tripadvisor (non-Amazon datasets).



(b) Amazon datasets.

Figure 5: Review-level length distribution. This shows the length comparisons of positive and negative reviews of different datasets. The values represent the average number of tokens present in each review. Negative reviews are longer than positive reviews in all datasets except IMDB and Amazon Luxury Beauty.

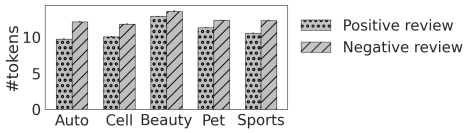


Figure 6: Sentence-level length distribution of Amazon datasets.

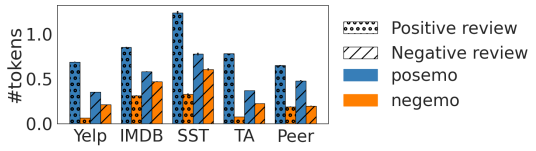
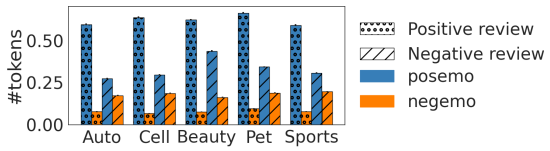


(a) Non-Amazon datasets.



(b) Amazon datasets.

Figure 7: Lexicon distributions based on LIWC. Figure 7a and Figure 7b shows the lexicon distribution of reviews using *posemo* and *negemo* LIWC categories. In all datasets, negative reviews have fewer positive emotions than positive reviews. They also have more positive words than negative words. This trend is similar to that obtained using Vader lexicons in case of non-Amazon reviews.

In case of negation distributions found using dependency parsing, we used Vader to identify positive and negative words.

Sentiment predictions. See Figure 4a and Figure 12 for the fractions of negative sentences in negative non-Amazon reviews measured by the BERT model. See Figure 13 for fractions of negative sentences in negative reviews of Amazon. Figure 14

Dataset	Training set	Validation set	Test set	Test accuracy (%)
Yelp	45000	5000	10000	97.51
IMDB	22500	2500	10000	94.38
Tripadvisor	45000	5000	10000	96.66
Automotive	45000	5000	10000	95.65
Cellphones and accessories	45000	5000	10000	95.39
Luxury beauty	4195	467	3040	96.10
Pet supplies	45000	5000	10000	95.60
Sports and outdoors	45000	5000	10000	95.12

Table 5: Dataset split and test accuracies of BERT fine-tuning. For all datasets except IMDB, Luxury Beauty, we use 45K samples as training set, 5K as validation set, and 10K as test set, randomly sampled from the entire dataset. In the case of IMDB, we use 22.5K samples for training and 2.5K samples for validation, randomly sampled from the provided training set of size 25K. We then use 10K samples randomly sampled from the provided test set of size 25K for testing purposes. In the case of Amazon Luxury Beauty, we use a balanced set of 4195 samples for training and 467 samples for validation. We then use 3K samples (imbalanced) randomly sampled from the dataset for testing. All these random samplings were done without replacement.

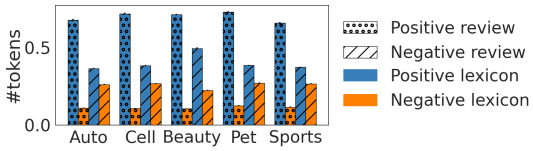


Figure 8: Lexicon distribution of Amazon datasets using Vader. Negative reviews have more positive words than negative words, similar to the trend in SST, Yelp, IMDB, Tripadvisor, and PeerRead.

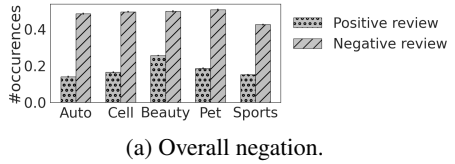
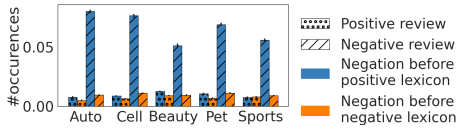
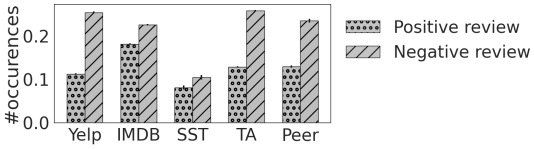


(a) Overall negation.

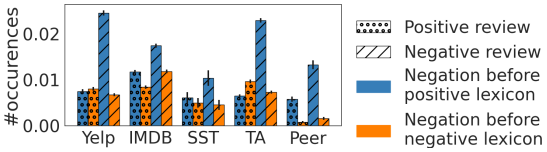


(b) Negation before positive and negative lexicons.

Figure 9: Negation distribution of Amazon datasets using Vader lexicons. Negative reviews use more negation words compared to positive reviews. Negative reviews have substantially more negation words associated with positive words than negative words.



(a) Overall negation.



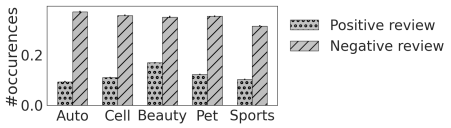
(b) Negation before positive and negative lexicons.

Figure 10: Negation distribution using dependency parsing - non-Amazon datasets. In all non-Amazon datasets, negative reviews use more negation words than positive reviews. This observation is inline with the negation results obtained using Vader lexicons. Dependency parsing is used to extract negations from reviews, and to identify words associated with a negation word.

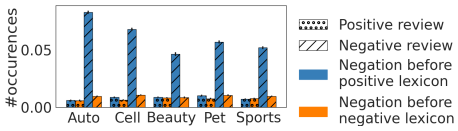
shows the fractions of positive sentences in positive reviews. Some of the fractions in our results are computed based on the TPR, TNR, FPR, and FNR of the BERT model. We used test set reviews of the datasets to compute these metrics as they give more accurate estimate of percentage of positive and negative sentences in reviews. All BERT classifiers that we used for predicting the sentiment of sentences are fine-tuned using the reviews of corresponding datasets. Table 5 shows the dataset split and test accuracies of BERT fine-tuning.

Hyperparameter tuning. We did hyperparameter tuning by varying number of epochs, batch size, and learning rate. We fine-tuned BERT for 4 epochs with batch sizes of 2, 4 and 8, with a learning rates of 1e-5 and 2e-5. Based on validation accuracies, the model trained for 2 epochs, with a batch size of 8 and learning rate of 2e-5 turned out to be the best performing model for most of the datasets.

Word-level results. Figure 15 shows the lexicon distribution using LIWC and Vader. See Figure 16 and Figure 17 for word-level results of negation distribution using Vader and dependency parsing respectively.



(a) Overall negation.



(b) Negation before positive and negative lexicons.

Figure 11: Negation distribution using dependency parsing - Amazon datasets. Figure 11a shows that negative reviews have substantially more negation words than positive words. Figure 11b shows the negation distribution associated with positive and negative words. This corresponds to about 16.68% of all negation words used in the positive and negative reviews based on our dictionary. Negative reviews also have substantially more negations before positive words, compared to other combinations.

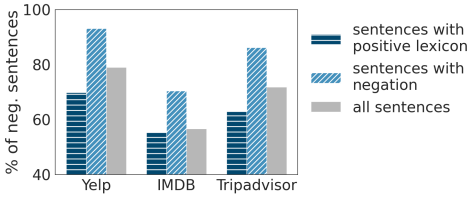


Figure 12: Fractions of negative sentences in negative reviews of Yelp, IMDB, and Tripadvisor. These fractions are corrected using TPR, TNR, FPR, and FNR. It can be seen that higher proportion of negative reviews with negation are classified as negative by our BERT model. This shows that negations in negative reviews are mostly used to express negative opinions. This observation holds for other datasets also.

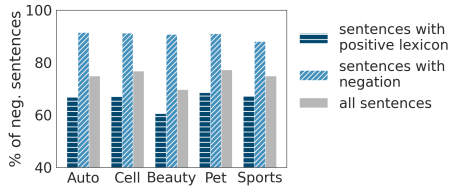
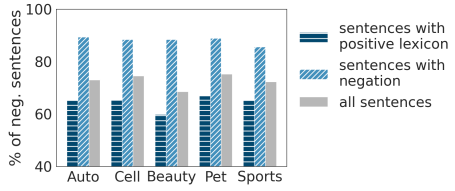
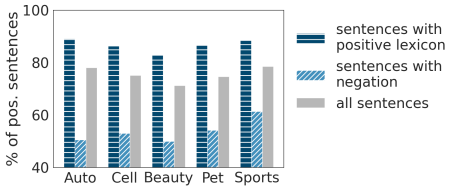


(a) Fractions based on accuracy.

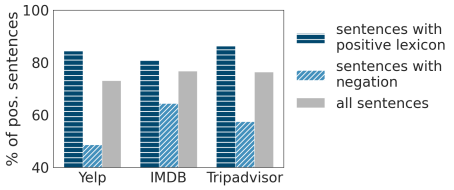


(b) Fractions based on TPR, TNR, FPR, and FNR.

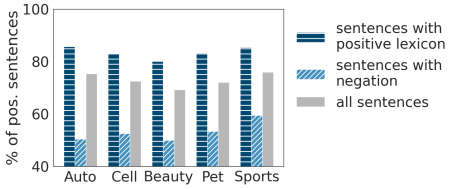
Figure 13: Fractions of negative sentences in negative Amazon reviews based on fine-tuned BERT classifiers. The distribution confirms our hypothesis that most negations are used to express negative sentiments.



(a) Fractions based on accuracy.

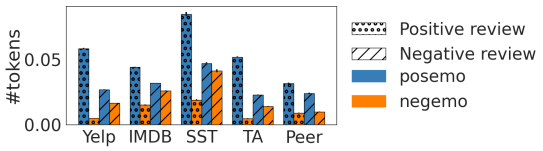


(b) Fractions based on TPR, TNR, FPR, and FNR.

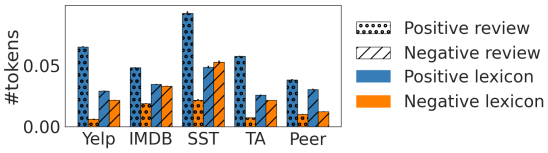


(c) Fractions based on TPR, TNR, FPR, and FNR.

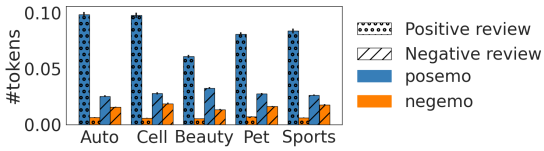
Figure 14: Fractions of positive sentences in positive reviews. We can see that negations in positive reviews are more balanced with positive and negative sentences when compared to negative reviews. Also, sentences with positive lexicons are mostly positive (86.5%). There are very few negative sentences with positive lexicons. This holds for all datasets.



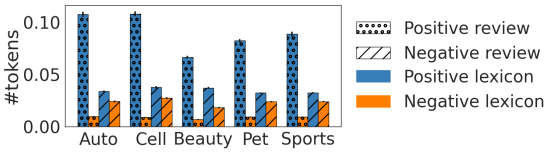
(a) LIWC distribution of non-Amazon datasets.



(b) Vader distribution of non-Amazon datasets.

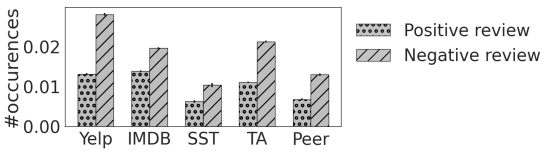


(c) LIWC distribution of Amazon datasets.

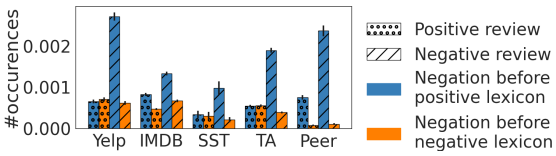


(d) Vader distribution of Amazon datasets.

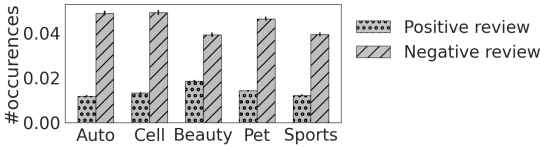
Figure 15: Word-level lexicon distribution. At the word-level, positive reviews have more positive words than negative reviews. However, negative reviews contain more positive words than negative words (except SST with Vader). The trend that we observe in the sentence-level results can be seen here as well.



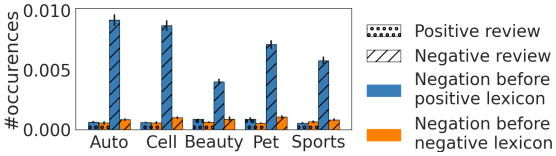
(a) Non-Amazon datasets.



(b) Non-Amazon datasets.

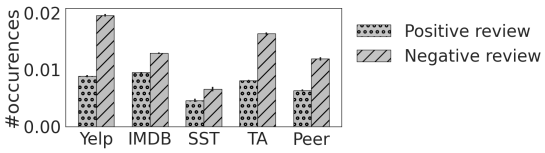


(c) Amazon datasets.

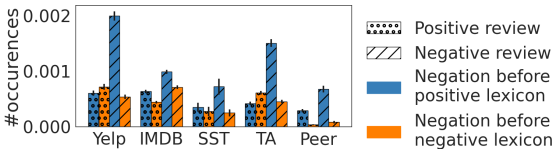


(d) Amazon datasets.

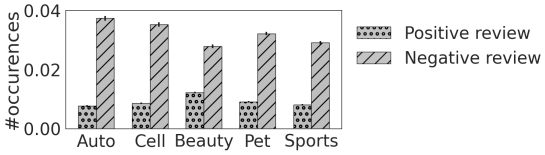
Figure 16: Word-level negation distribution using Vader. Figure 16a and Figure 16c indicate the more frequent use of negation in negative reviews than in positive reviews at the word-level. Negative reviews have more negations before positive words in all datasets. This difference is substantially large in case of Yelp, Tripadvisor, PeerRead and Amazon reviews. This shows that although negative reviews have more positive words than negative words, these positive words are associated with negations.



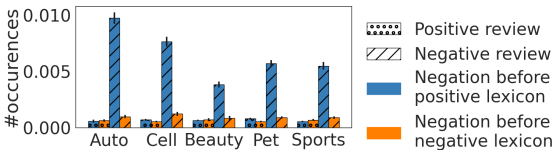
(a) Overall negation in non-Amazon datasets.



(b) Negation before positive and negative lexicons in non-Amazon datasets.



(c) Overall negation in Amazon datasets.



(d) Negation before positive and negative lexicons in Amazon datasets.

Figure 17: Word-level negation distribution of all reviews using dependency parsing. With dependency parsing, we observe the same pattern as in Figure 16. Negative reviews in Yelp, Tripadvisor, PeerRead and Amazon datasets have substantially more negations in general and also before positive words. This high number of negation associated with positive words partially explains the higher proportion of positive words in negative reviews.

PRAL: A Tailored Pre-Training Model for Task-Oriented Dialog Generation

Jing Gu* UC Davis jkgu@ucdavis.edu
Qingyang Wu* Columbia University qingyang.wu@columbia.edu
Chongruo Wu UC Davis crwu@ucdavis.edu
Weiyan Shi Columbia University shi.weiyan@columbia.edu
Zhou Yu Columbia University zy2461@columbia.edu

Abstract

Large pre-trained language generation models such as GPT-2 have demonstrated their effectiveness as language priors by reaching state-of-the-art results in various language generation tasks. However, the performance of pre-trained models on task-oriented dialog tasks is still under-explored. We propose a Pre-trained Role Alternating Language model (PRAL), explicitly designed for task-oriented conversational systems. We design several techniques: start position randomization, knowledge distillation, and history discount to improve pre-training performance. In addition, we introduce a high quality large-scale task-oriented dialog pre-training dataset. We effectively adapt PRAL on three downstream tasks. With much less training data, PRAL outperforms or is on par with state-of-the-art models.

1 Introduction and Related Work

Current approaches to building task-oriented dialog systems still require a substantial amount of annotations and therefore are labor-intensive. On the other hand, large-scale pre-trained language models such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2019) have achieved great success on various NLP tasks. There have been several attempts to apply these language models to dialog systems directly. For example, Transfer-Transfo (Wolf et al., 2019) fine-tuned GPT on the Persona-Chat dataset (Zhang et al., 2018b) and achieved the state-of-the-art performance on chitchat dialog generation. DialoGPT (Zhang et al., 2020) utilizes a large Reddit corpus to further pre-train GPT-2 (Zhang et al., 2020). All of these studies pointed to a promising direction towards building dialog systems with large-scale language models and less annotation.

However, these language models applied to dialog systems still have some limitations. First, further pre-training language models for dialog systems requires a considerable amount of training data. Small pre-training dialog datasets would not provide a large amount of commonsense knowledge needed for dialog generation. However, a diverse collection of high-quality dialog datasets is difficult to obtain. Besides, these language models usually do not consider dialog feature in their structures.

To tackle these issues, we propose Pre-trained Role Alternating Language model (PRAL), a language model designed explicitly for dialog generation. To begin with, we collect and process 13 dialog datasets, ranging from TV transcripts to pizza ordering dialogs, to enrich the pre-training data with high-quality dialog corpora. Second, we adopt ARDM proposed in Wu et al. (2019) and use two separate GPT-2 to model the two speakers in the dialog. Next, we apply Start Position Randomization (SPR) to cope with the variable lengths in dialogs, which prevents the language model from binding the position index with the text information. Additionally, we utilize a Teacher model to perform knowledge distillation and incorporate common sense knowledge into the dialog generation. Finally, we re-weigh each utterance with discount factors and emphasize on the later part in a dialog to better incorporate contextual information.

In summary, we propose PRAL and design several effective techniques to improve the dialog model pre-training. Our pre-trained model improves the success rate on CamRest676 and MultiWOZ dataset, and the coherence and diversity scores on PersuasionForGood. Our model is data-efficient and use 10x less than SOLOIST and 1000x less than DialoGPT in terms of training data size. We also process and present a collection of high-

Avg. tokens per dialogue	149.25
Total unique tokens	108,106

Table 1: Statistics of our dataset

quality dialog datasets suitable for pre-training large-scale language models for dialog systems.

2 *PretrainDial* Dataset for Pre-training

Large clean dialog datasets are difficult to find. Therefore, we constructed *PretrainDial*, a large-scale multi-domain dialog corpus for dialog pre-training. *PretrainDial* is a large-scale pre-training dataset and can only be collected from existing dialogs. We carefully selected 13 existing dialog corpora, ranging from chitchat such TV transcripts to task-oriented dialogs, and design a sophisticated text processing pipeline. Table. 1 shows the statistics of the *PretrainDial* dataset. Please check appendix A for more details about the dataset statistic and the text processing pipeline.

3 Methods

In this section, we will first briefly introduce ARDM, our base dialog model, and then describe a set of techniques proposed in PRAL. Figure 1 shows the main structure of PRAL.

3.1 Alternating Roles Dialog Model

The basic idea behind ARDM (Wu et al., 2019) is to simultaneously model the user and system with two separate GPT-2 to capture the different language styles among different speakers. A dialog can be considered as a sequence of utterances $d = \{u_1, s_1, u_2, s_2, \ldots, u_T, s_T\}$, where T is the total number of turns. We use p_u and p_s to represent the probability of the user utterance and system utterance. The dialog distribution is defined as:

$$p(d) = \prod_{t=1}^{T} p_u(u_t|u_{<t}, s_{<t})\, p_s(s_t|u_{\leq t}, s_{<t}) \quad (1)$$

However, ARDM does not contain prior knowledge about dialog. In contrast, PRAL is designed for dialog system and absorbs abundant dialog knowledge during the pre-training process. To further improve ARDM or other dialog generation models, we propose three effective techniques to improve pre-training efficiency.

3.2 Start Position Randomization

We propose to randomize the start position to improve pre-training model's quality. Transformer-based language models use position embedding to encode the location information for each token. It supports a fixed maximum position, and the position index always starts from 0. However, since most dialogs contain less than 1024 tokens, most vectors in the positional embedding would remain

zero and not update during pre-training. Besides, position embedding should only provide location information. However, the fixed start position will bond specific text with a particular position index. For example, "hi" is bonded with index 0 as "hi" usually appears at the beginning of the dialog. Therefore, the model is likely to overfit on the first several positional embeddings.

To address this issue, we propose to perform Start Position Randomization (SPR). L stands for the total number of tokens in a dialog, and the maximum start position index is $1024 - L$. We randomize the start position to be any number between 0 to $1024 - L$. It would disentangle the positional information from the textual meaning and force the model to update all the positional embeddings.

3.3 Teacher GPT

Neural networks models suffer from catastrophic forgetting (Kirkpatrick et al., 2016). Since we have finetuned GPT-2 with a new dialog corpus, the updated model is at risk in forgetting the prior knowledge from the original GPT-2. Teacher Model is used to calculate the distillation loss (Hinton et al., 2015) between the fixed GPT and our two language models. It constrains the language model from generating a token distribution that is too different from the original token distribution. The Teacher Model has two functions. First it avoids language model from catastrophic forgetting the knowledge in the original GPT-2 weights (Kirkpatrick et al., 2016). Secondly, when GPT-2 Large is used as Teacher Model, it imparts knowledge into our language models. The ablation study in table 2a validates the the functions.

3.4 History Discount

In dialog generation, historical utterances closer to current utterance should have a more significant impact on the generation than the ones that are further. Because in human conversations, we tend to prioritize local coherence over distant history coherence as well .Therefore, we introduce discount factor γ to re-weigh the importance of each utterance based on the turn number. For a dialog with a total number of T utterances and its current utterance index to be t, we weigh the language model loss with γ^{T-t}. By incorporating the discount factor γ, the model focus more on recent history in the generation process.

3.5 Optimization

We use a language modeling loss to optimize our model, shown in Equation 2.

$$Loss_{LM} = \sum_{t=1}^{T} \gamma^{T-t} \sum_{l=1}^{L_t - 1} CE(P_{tl},\, G_{t(l+1)}) \tag{2}$$

CE denotes the cross-entropy loss. T is the total number of utterances in a dialog, and L_t is the total number of tokens in the t^{th} utterance. For the loss of each utterance t in the dialog, it is weighed by the discount factor described in section 3.4. We combine loss from all words as the cross-entropy between the output probability distribution $P_{t(l+1)}$ and the ground truth $G_{t(l+1)}$.

The final loss combines the language model loss and KL divergence loss:

$$Loss = Loss_{LM} + \alpha\, \mathrm{KL}(p,\, p^{constriant}) \tag{3}$$

The factor α is used to expedite model convergence and it decreases exponentially as the number of iterations increases, i.e. $\alpha = \alpha_0\, \lambda^{iter}$.

4 Experiments

We pre-train PRAL on *PretrainDial*. We use GPT-2 large as the Teacher model. We use AdamW optimizer with warm-up steps as 10 percent of the training step. The learning rate is set to be 1×10^{-4}. For the calculation of loss, we set α_0 to be 0.1 and set λ to be 0.9999. The discount factor γ is set to be 0.95. To show the generalizability, we finetune PRAL on three downstream dialog generation tasks, CamRest676, MultiWOZ and PersuasionForGood, as is shown in Table. 2. Refer to Appendix B for more experiment setting.

CamRest676 (Rojas-Barahona et al., 2016) is a dialog dataset for restaurant recommendation containing 680 dialogs. We use BLEU-4 metrics to measure the quality of generated sentences, and Success F1 to evaluate the responses on specific slots, such as address, phone, postcode. Sequicity is the state-of-the-art method in task-oriented dialog tasks that requires annotations. PRAL beat all other models, including a concurrent work SOLOIST (Peng et al., 2020) on both BLEU-4 and Success F1. It is worth noting that PRAL does not need any annotation. SOLOIST and DialoGPT have a close performance with our model. However, SOLOIST uses around 1 Million dialogues, DialoGPT uses around 147 million dialogues, meanwhile we only use around 142K dialogues, which

Model	BLEU-4	Success F1
Sequicity	21.4	0.852
Sequicity (w/o RL)	22.9	0.821
GPT-2-finetune	21.8	0.851
DialoGPT	25.2	0.861

(c) PersuasionForGood. Automatic Evaluation and Human Evaluation Results

Table 2: Evaluation on three datasets

is a thousand times less. This further shows PRAL is data-efficient.

Ablation studies on CamRest676 shows that the Teacher GPT plays the most important role. The fact that PRAL with Teacher GPT (Small) in table 2a outperforms PRAL without Teacher GPT (Small) shows the importance of the knowledge in the original model weights. When using GPT-2 Large as Teacher Model, the performance is better than that of using GPT-2 small, which validates the effect of knowledge distillation.

MultiWOZ (Budzianowski et al., 2018) contains around 10k dialogues covering various domains. We evaluate the models with on BLEU-4, Inform Rate, and Success Rate which measures if the system provides the requested information. PRAL outperforms the attention seq2seq model which is used as the baseline in Multiwoz (Budzianowski et al., 2018) in all metrics. Without using any annotation, PRAL also outperforms or achieve comparable results with HDSA (Budzianowski et al., 2018), LaRL (Zhao and Kawahara, 2019) and SOLOIST. Except for HDSA which requires both dialog state and dialog act, PRAL achieves a better BLEU score than all other models. PRAL outperforms ARDM in all metrics, which further validates the effectiveness of the pre-training process.

PersuasionForGood We also evaluate our method on PersuasionForood (Wang et al., 2019), where a persuader tries to persuade users to donate money to children. There are a total of 1,017 dialogues. Although not a traditional task-oriented dialog benchmark, it is a good benchmark for human evaluation. Automatic metrics evaluation is efficient but could fail to capture the text quality on a deeper and complicated level. We choose this task also because it benefits children. Unlike CamRest676 and Multiwoz, the language in PersuasionForGood dataset is so diverse that BLEU-4 scores of all of the models are too low to be scientific metrics. Therefore, we use BLEU-1 and BLEU-2 instead. Our model achieves a significantly higher score on BLUE metrics, especially on BLEU-2 (63% up). In human evaluation, we ask evaluators that how much they are willing to donate after the conversation and acquire their ratings in terms of fluency, logic, coherence, and diversity. The result suggests that PRAL outperforms ARDM on all the metrics. For human evaluation details, please refer to Appendices C.

Case studies show some linguistic problems in ARDM, such as repetition and unnaturalness. Meanwhile, with pre-training, PRAL is more natural and persuasive. Please refer to Appendices D for an example of PRAL and ARDM.

5 Conclusion

We propose PRAL, a large pre-trained dialog system for task-oriented generation. We incorporated methods that are designed for large dialog system into PRAL with good performances on three downstream tasks. The model generates more fluent, coherent, diverse, and logical dialogs according to human evaluation results. We also release a high-quality dialog dataset for the pre-training process.

A Dataset sources

Our dataset contains high-quality dialogues which are selected from other 13 datasets listed in Table 3. PretrainDial is a large-scale pre-training dataset and can only be collected from existing dialogs. Due to the page limit as a short paper, we didn't elaborate on the process in the paper. First, we collected dialog datasets that are commonly used in recent years. Then we filtered out the datasets with various standards such as content appropriateness. For example, we filtered "Conversations Gone Awry" Dataset because the conversation involves necessary background knowledge. Then, we process the text in the selected datasets. This step is essential since these datasets contain unnecessary noise, especially for datasets that contain raw text such as Friends dataset. The processing includes: (1) We replaced less informative appeared entity. For example, replace a long URL link with the word "URL". (2) Delete meaningless repetition. (3) Delete responses that are not written in English. (4) Delete offensive language. (5).In some datasets such as Reddit, the conversation involves more than two people, so we extract a complete conversation flow involving only two people. Note there are more detailed process steps. We cannot describe all of them. We will release the text processing script, which we believe is helpful for the community when collecting dialog datasets.

B Experiment Setting Detail

B.1 Training Details

We initialize PRAL with a large pre-trained language model GPT-2 small with 117M parameters (Radford et al., 2019). We follow a special format in GPT-2 as the "trigger" so that the model can zero-shot dialog response generation, by prefixing the user role token "A:" or "B:", and suffixing the end of utterance token "\n\n\n". We first pre-train PRAL on *PretrainDial* and then further fine-tune PRAL on the specific task dataset. We apply AdamW optimizer (Loshchilov and Hutter, 2019), and the number of warm-up ratio is set to 0.1. Learning rate is 1×10^{-4} in the pre-training process and 3×10^{-5} in fine-tune process.The dropout rate is set to 0.1 for all tasks. For the calculation of loss in the pre-training process, we set α_0 to be 0.1 and set λ to be 0.9999. The discount factor γ is set to be 0.95.

B.2 Decoding Details

In the downstream task, we decode utterances by nucleus sampling (Holtzman et al., 2020) with different hyper-parameters (top-p, top-k). We also vary the temperature of $T < 1$ to find the best setting for the specific down-stream dialog task. We use nucleus sampling for all methods. In CamRest676 task, we set top-p 0.2 and temperature 0.7 for our model. For MultiWOZ task, we set the top-p to 0.2 and the temperature to 0.7. In PersuasionForGood task, to generate diverse responses, we use a top-p of 0.9 and a temperature of 0.7.

C Human Evaluation Detail

Twenty people participated in the human evaluation. ARDM is the state-of-the-art model for PersuasionForGood task. Each person will have ten conversations with PRAL and ARDM in random orders, five conversations for each model. 1) For the donation task, the participants will be asked, "How much will you donate after talking to the bot? Please choose from 0-2$". 2) For fluency, logic, and coherence, the participants will be asked, "Which one do you think is more fluent/logic/coherent?" and choose the model with better performance on the corresponding metric. 3) For diversity, participants compare performances across dialogs, so they will be asked, "Which bot do you think generates more diverse responses?" after talking with each model for five times.

D Persuasion Example

Table 4 and Table 5 show an PRALexample and an ARDM example.

E Ethical Statement

As knowledge in language model comes from training corpus, we used a strict pipeline to avoid offensive and other inappropriate text. We believe such a selective training source could contribute a more unbiased dialog system. However, the Teacher Model could be a potential source of biased knowledge, although we notice that is not the case in our experiments. In the future, we will also explore how to select the knowledge to import from Teacher Model.

Abstract

Natural reading orders of words are crucial for information extraction from form-like documents. Despite recent advances in Graph Convolutional Networks (GCNs) on modeling spatial layout patterns of documents, they have limited ability to capture reading orders of given word-level node representations in a graph. We propose Reading Order Equivariant Positional Encoding (ROPE), a new positional encoding technique designed to apprehend the sequential presentation of words in documents. ROPE generates unique reading order codes for neighboring words relative to the target word given a word-level graph connectivity. We study two fundamental document entity extraction tasks including word labeling and word grouping on the public FUNSD dataset and a large-scale payment dataset. We show that ROPE consistently improves existing GCNs with a margin up to 8.4% F1-score.

1 Introduction

Key information extraction from form-like documents is one of the fundamental tasks of document understanding that has many real-world applications. However, the major challenge of solving the task lies in modeling various template layouts and formats of documents. For example, a single document may contain multiple columns, tables, and non-aligned blocks of texts (e.g. Figure 1).

The task has been studied from rule-based models (Lebourgeois et al., 1992) to learning-based approaches (Palm et al., 2017; Tata et al., 2021). Inspired by the success of sequence tagging in NLP (Sutskever et al., 2014; Vaswani et al., 2017; Devlin et al., 2019), a natural extension is applying these methods on linearly serialized 2D documents (Palm et al., 2017; Aggarwal et al., 2020).

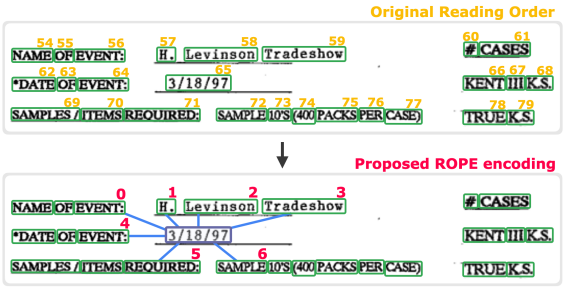

Figure 1: Illustration of the proposed Reading Order Equivariant Positional Encoding (ROPE). **Top:** a portion of a form document with the original word reading order. **Bottom:** given a graph connectivity, ROPE generates equivariant reading order codes with respect to the target word (in this case the date "3/18/97").

Nevertheless, scattered columns, tables, and text blocks in documents make the serialization extremely difficult, largely limiting the performance of sequence models. Katti et al. (2018); Zhao et al. (2019) explore to directly work on 2D document space using grid-like convolutional models to better preserve spatial context during learning, but the performance is restrictive to the resolution of the grids. Recently, Qian et al. (2019); Davis et al. (2019); Liu et al. (2019) propose to represent documents using graphs, where nodes define word tokens and edges describe the spatial patterns of words. Yu et al. (2020) show state-of-the-art performance of Graph Convolutional Networks (GCNs) (Duvenaud et al., 2015) on document understanding.

Although GCNs capture the relative spatial relationships between words through edges, the specific word ordering information is lost during the graph aggregation operation, in the similar way to the average pooling in Convolutional Neural Networks (CNNs). However, we believe reading orders are strong prior to comprehending languages. In this work, we propose a simple yet effective Reading Order Equivariant Positional Encoding (ROPE) that embeds the relative reading order context into

[*] Work done while an intern at Google Research.

August 1–6, 2021. ©2021 Association for Computational Linguistics

graphs, bridging the gap between sequence and graph models for robust document understanding. Specifically, for every word in a constructed graph, ROPE generates unique reading order codes for its neighboring words based on the graph connectivity. The codes are then fed into GCNs with self-attention aggregation functions for effective relative reading order encoding. We study two fundamental entity extraction tasks including word labeling and word grouping on the public FUNSD dataset and a large-scale payment dataset. We observe that by explicitly encoding relative reading orders, ROPE brings the same or higher performance improvement compared to spatial relationship features in existing GCNs in parallel.

2 Other Related Work

Attention models show state-of-the-art results in graph learning (Veličković et al., 2018) and NLP benchmarks (Vaswani et al., 2017). As attention models with positional encodings are proven to be universal approximators of sequence-to-sequence functions (Yun et al., 2020), encoding positions or ordering is an important research topic. For sequence, learned positional embeddings (Gehring et al., 2017; Devlin et al., 2019; Shaw et al., 2018), sinusoidal functions and its extensions (Liu et al., 2020) have been studied. Beyond that, positional encodings are explored in graphs (You et al., 2019), 2D images (Parmar et al., 2018) and 3D structures (Fuchs et al., 2020). Lastly, graph modeling is also applied to other document understanding tasks, including document classification (Yao et al., 2019) and summerization (Yasunaga et al., 2017).

3 Method

We follow recent advances in using GCNs for document information extraction that relax any serialization assumptions by sequence modeling. GCNs take inputs (word tokens in this case) of arbitrary numbers, sizes, shapes and locations, and encode the underlying spatial layout patterns of documents through direct message passing and gradient updates between input embedding in the 2D space.

Node definition. Given a document D with N tokens denoted by $T = \{t_1, t_2, ..t_N\}$, we refer t_i to the i-th token in a linearly serialized text sequence returned by the Optical Character Recognition (OCR) engine. The OCR engine generates the bounding box sizes and locations for all tokens, as

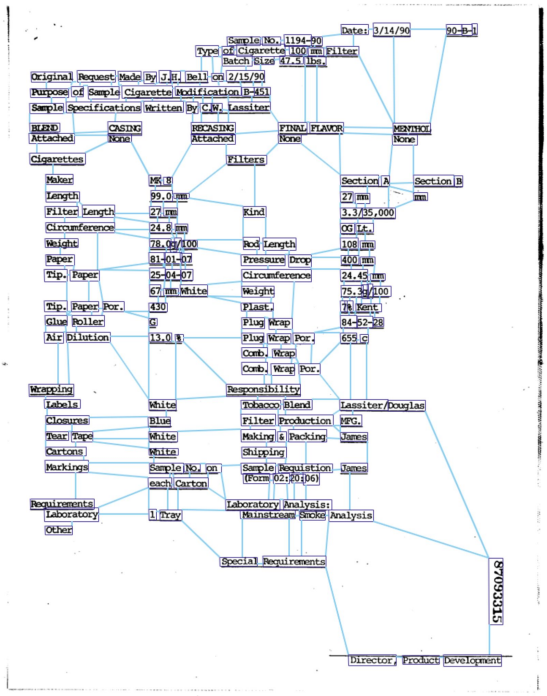

Figure 2: Sample of a β-skeleton graph of a document of FUNSD.

well as the text within each box. We define node input representation for all tokens T as vertices $V = \{v_1, v_2, ..v_N\}$, where v_i concatenates quantifiable attributes available for t_i. In our design, we use two common input modalities: (a) word embeddings from an off-the-shelf pre-trained BERT model (Devlin et al., 2019), and (b) spatial embeddings from normalized bounding box heights, widths, and Cartesian coordinate values of four corners.

Edge definition. While the vertices V represent tokens in a document, the edges characterize the relationship between the vertices. Precisely, we define directional edges for a set of edges E, where each edge e_{ij} connects two vertices v_i and v_j, concatenating quantifiable edge attributes. In our design, we use two input modalities given an edge e_{ij} connecting two vertices: (a) spatial embeddings from horizontal and vertical normalized relative distances between centers, top left corners and bottom right corners of the bounding boxes. It also contains height and width aspect ratios of v_i, v_j, and relative height and width aspect ratios between v_i and v_j. (b) Visual embeddings that utilizes ImageNet pre-trained MobileNetV3 (Howard et al., 2019) to extract visual representations of union bounding boxes containing v_i and v_j. The visual embedding in edge formation picks up visual cues

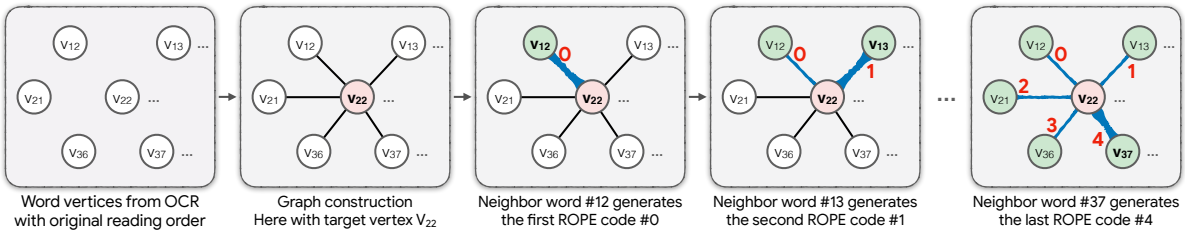

Figure 3: Implementation of the proposed Reading Order Equivariant Positional Encoding (ROPE). Given a graph connectivity, ROPE iterates through the neighboring word vertices in the original reading order and assigns new ROPE codes (red numbers) to the neighbors, starting from zero. Note that the proposed ROPE codes remain unchanged if the neighbors and the target shift equally in the document with the same relative reading order, therefore being equivariant.

such as colors, fonts, separating symbols or lines between two token bounding boxes (through their union bounding box). We refer to the spatial embedding in (a) as the edge geometric (EdgeGeo) feature used in the experimental section.

Graph construction. Our implementation is based on the β-skeleton graph (Kirkpatrick and Radke, 1985) with $\beta = 1$ for graph construction. By using the "ball-of-sight" strategy, β-skeleton graph offers high connectivity between word vertices for necessary message passing while being much sparser than fully-connected graphs for efficient forward and backward computations (Wang et al., 2021). A β-skeleton graph example can be found in Figure 2, and more can be found in Figure 5 in the Appendix.

Aggregation function. Inspired by the Graph Attention Networks (Veličković et al., 2018) and the Transformers (Vaswani et al., 2017), we use multi-head self-attention module as our GCN aggregation (pooling) function. It calculates the importance of individual message coming from its neighbors to generate the new aggregated output.

3.1 Reading Order Equivariant Positional Encoding (ROPE)

Positional encoding (Gehring et al., 2017) in sequence models is with an assumption that the input is perfectly serialized. However, as illustrated in Figure 1, form-like documents often contain multiple columns or sections. A simple left-to-right and top-to-bottom serialization commonly provided by OCR engines does not provide accurate sequential presentation of words – two consecutive words in the same sentence might have drastically different reading order indexes by naive serialization.

Instead of assigning absolute reading order indexes for the entire document at the beginning, we propose to encode the relative reading order context of neighboring words w.r.t. the target word based on the given graph connectivity. Figure 3 demonstrates the process of the proposed method: ROPE iterates through the neighboring word vertices in the original reading order and assigns new ROPE codes $p \in \mathbb{N}$ (red numbers) to the neighbors, starting from zero. The generated codes are then appended to the corresponding incoming messages during graph message passing. Hence, ROPE provides a relative reading order context of the neighborhood for order-aware self-attention pooling.

Note that the generated ROPE codes remain unchanged if the neighbors and the target shift equally in the document with the same relative order, therefore being equivariant. Additionally, ROPE provides robust sequential output that is consistent even when the neighborhood crosses multiple columns or sections in a document.

Finally, we also explore sinusoidal encoding matrix (Vaswani et al., 2017) besides the index-based encoding. Our ablation study in Section 4 shows that using both results in the best performance.

4 Experiments

We evaluate how reading order impacts overall performance of graph-based information extraction from form-like documents. We adopt two form understanding tasks as Jaume et al. (2019), including word labeling and word grouping. Word labeling is the task of assigning each word a label from a set of predefined entity categories, realized by node classification. Word grouping is the task of aggregating words that belong to the same entity, realized by edge classification. These two fundamental entity extraction tasks do not rely on perfect entity word groupings provided by the dataset and therefore help decouple the modeling capability provided by the proposed ROPE in practice. These two tasks

also effectively demonstrate the quality of the node embedding and edge embedding of the proposed graph architecture and decouple any performance gain from sophisticated Conditional Random Field (CRF) decoders often used on top of the model.

4.1 Datasets

Payment. We follow Majumder et al. (2020) to prepare a large-scale payment document collection that consists of around 18K single-page payments. The data come from different vendors with different layout templates. For both word labeling and word grouping experiments, we use a 80-20 split of the corpus as the training and test sets.

We use a public OCR service[1] to extract words from the payment documents. The service generates the text of each word with their corresponding 2D bounding box. The word boxes are roughly arranged in an order from left to right and from top to bottom. We then ask human annotators to label the words with 13 semantic entities. Each entity ground truth is described by an entity type and a list of words generated by the OCR engine, resulting in over 3M word-level annotations. Labelers are instructed to label all instances of a field in a document, therefore our GCNs are trained to predict all instances of a field as well.

FUNSD. FUNSD (Jaume et al., 2019) is a public dataset for form understanding in noisy scanned documents, containing a collection of research, marketing, and advertising documents that vary widely in their structure and appearance. The dataset consists of 199 annotated forms with 9,707 entities and 31,485 word-level annotations for 4 entity types: header, question, answer, and other. For both word labeling and word grouping experiments, we use the official 75-25 split for the training and test sets.

4.2 Experimental Setup

All GCN variants used in the experiment have the same architecture: The node update function is a 2-layer Multi-Layer Perceptron (MLP) with 128 hidden nodes. The aggregation function uses a 3-layer multi-head self-attention pooling with 4 heads and 32 as the head size. The number of hops in the GCN is set to 7 for payment dataset and 2 for FUNSD dataset due to the complexity and scale of the former. We use cross-entropy loss for both multi-class word labeling and binary word grouping tasks. We train the models from scratch using Adam optimizer with the batch size of 1. The learning rate is set to 0.0001 with warm-up proportion of 0.01. The training is conducted on 8 Tesla P100 GPUs for approximately 1 day on the largest corpus.

Table 2: Ablation of positional encoding function used in the proposed ROPE. We observe that either index or sine encoding works better than no positional encoding. Combined works the best.

4.3 Results

We train the GCNs from scratch on all datasets. For word labeling we use multi-class node classification F1-scores as the metric and for word grouping we use binary edge classification F1-scores as the metric with the corresponding precision and recall values.

Importance of reading order. Positional encoding mechanisms are the key components to exploiting layout patterns of words – `Answer` entities are usually next to or below the `Question` entities. Existing GCN approaches rely on edge geometric (EdgeGeo) features to capture such spatial relationships between words in 2D space. Here we evaluate the importance of the proposed reading order encoding ROPE with various combinations of EdgeGeo over the baseline GCN (Qian et al.,

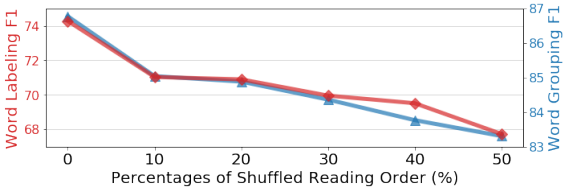

Figure 4: Sensitivity of ROPE to OCR reading order on Payment. The proposed ROPE codes remain the same if the connected neighboring words and target word shift equally in the document.

2019) as summarized in Table 1. Without any positional encoding, word labeling F1 drops by 13.75 points and word grouping F1 drops by 2.84 points on payment dataset. Then, we pass ROPE to incoming messages and find that this reduces the drop to 6.38 points on word labeling and 0.76 points on word grouping. Similar trend can be observed on FUNSD as well. Surprisingly, ROPE reduces performance drop more effectively than EdgeGeo on the larger payment dataset. Given these ablations, we conclude that reading order information is at least the same or more important than geometric features, and they bring orthogonal improvements to the overall performance.

Reading order encoding function. In practice, each target word usually has less than 8 neighboring words given a constructed β-skeleton graph. Therefore, a natural approach to assigning relative reading orders is to simply use the ROPE encoded indexes. In Table 2 we observe that simple index encoding immediately improves GCN without ROPE by 6.32 points on word labeling and 1.59 points on word grouping using payment corpus. Next we explore the popular sinusoidal function (with 3 base frequencies) for reading order encoding. It improves GCN without ROPE by 4.85 points on word labeling and 0.72 points on word grouping. Interestingly, sine function provides on par performance but does not outperform index encoding. The reason might be because the β-skeleton graph does not generate an extremely large number of neighbors, so simple index encoding is sufficient.

Sensitivity to OCR reading order. We investigate the robustness of ROPE to the quality of the input reading order. We shuffle the reading order provided by the OCR engine with a varying percentage of words before feeding into ROPE. Figure 4 exhibits the performance. For both word labeling and word grouping tasks, ROPE provides performance improvement up to less than 30% word order shuffling on the large payment corpus. With 30% or more word order shuffled, we observe less performance degradation on the word labeling, suggesting that the word grouping task is more sensitive to the original OCR reading order.

5 Conclusion

We present a simple and intuitive reading order encoding method ROPE that is equivariant to relative reading order shifting. It embeds the effective positional encoding from sequence models while leveraging the existing spatial layout modeling capability of graphs. We foresee the proposed ROPE can be immediately applicable to other document understanding tasks.

Abstract

Event extraction has long been a challenging task, addressed mostly with supervised methods that require expensive annotation and are not extensible to new event ontologies. In this work, we explore the possibility of zero-shot event extraction by formulating it as a set of Textual Entailment (TE) and/or Question Answering (QA) queries (e.g. "*A city was attacked*" entails "*There is an attack*"), exploiting pretrained TE/QA models for direct transfer. On ACE-2005 and ERE, our system achieves acceptable results, yet there is still a large gap from supervised approaches, showing that current QA and TE technologies fail in transferring to a different domain. To investigate the reasons behind the gap, we analyze the remaining key challenges, their respective impact, and possible improvement directions[1].

1 Introduction

Event extraction (EE) has long been an important and challenging NLP task. Figure 1 exemplifies a TRANSFER-OWNERSHIP event from the ACE-2005 dataset (Walker et al., 2006), where the *trigger* is "*purchased*" and the *arguments* include "*China*" (Buyer), "*Russia*" (Seller), etc. The subtasks of EE involve identifying and classifying event triggers and their corresponding arguments.

The predominant approaches normally require supervision (e.g. Lin et al., 2020), which is both expensive and inflexible when moving to new event ontologies. Recent works (Chen et al., 2020; Du and Cardie, 2020) have pointed out the connection between Question Answering (QA) and EE in developing supervised systems. Meanwhile, several efforts have explored unsupervised methods. Peng et al. (2016) first attempted to extract event *triggers* with minimal supervision using similarity-based heuristics. Huang et al. (2018) and Lai et al. (2020) explored both trigger and argument extraction under a slightly different setting: training on some event types and testing on unseen ones. Recently, Liu et al. (2020) proposed a QA-based zero-shot argument extraction method, which did not handle triggers. So far, no method has been proposed to extract *both* event triggers and arguments without any EE training data[2]. Moreover, the performance of existing zero-shot attempts, especially on arguments, is still far from satisfactory, yet little is known about possible underlying reasons.

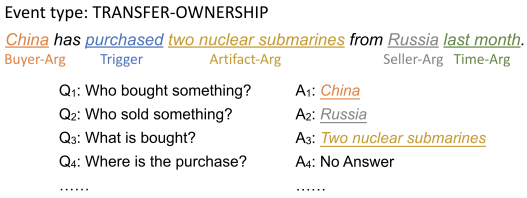

Figure 1: An example of an event from ACE-2005, and how arguments are extracted via QA.

In this work, we investigate the possibility of zero-shot EE via transfer learning from Textual Entailment (TE) and QA. Observe that given pretrained TE/QA models, extracting events can be viewed as answering questions/verifying hypotheses about a text. For example, the sentence in Figure 1, taken as the premise, would entail the hypothesis "*There is a transfer of ownership*", therefore providing the event type. Then, by asking Q_1 "*Who bought something?*", we obtain "*China*" as the Buyer. Similarly, Q_2, Q_3 will yield the Seller and Artifact, and so on.

Based on the observation above, we propose an intuitive zero-shot EE approach. It does not require any event training data, but we still make several design choices based on the development set. To demonstrate the level of generalization, we choose the optimal model with the ACE development set, and evaluate it on both ACE and ERE (LDC2015E29) test sets. The performance

surpasses previous zero-shot approaches on every subtask when the gold trigger span is given, yet is still unsatisfying compared to supervised methods, revealing a large gap in using off-the-shelf TE/QA models for direct transfer. To shed light on why it is the case, we identify the key challenges behind the gap, and attribute each of them to the intrinsic weakness of pretrained models, our usage of them, or the task itself. We then anatomize their individual impact with an ablation study.

Our contributions are: (1) We propose the first TE/QA-based event extraction system that tackles *both* triggers and arguments without any event training data; (2) We show that existing TE/QA models do not support direct domain transfer well; and (3) We provide insights into the remaining challenges, their individual influence, and possible directions for future research.

2 Approach

Our pipeline consists of two modules, trigger extraction and argument extraction, both relying on pretrained TE/QA models for direct transfer.

The pretrained models we use are all BERT-based (Devlin et al., 2019; Liu et al., 2019; Lewis et al., 2020), including a TE model trained on MNLI (Williams et al., 2018), a Yes/No QA model trained on BoolQ (Clark et al., 2019), and an extractive QA model trained on QAMR (Michael et al., 2018) and/or SQuAD2.0[3] (Rajpurkar et al., 2018)[4]. The TE model, when given a *premise* and a *hypothesis*, predicts the relation between them ("entailment", "contradiction", or "neutral"). The Yes/No QA model takes as input a *context* and a *Yes/No question*, and returns either Yes or No. Finally, the extractive QA model is also given a *context* but with a *Wh-question*, and the answer is a span in the context. With these models, we design the two modules for event extraction.

2.1 Trigger Extraction (T-Ext)

We formulate Trigger Extraction (T-Ext) as a TE or a Yes/No QA task. Only the TE case is illustrated, since the other only differs in the query format.

To obtain potential event triggers from a sentence, we first run Semantic Role Labeling (SRL) as a preprocessing step. We use a BERT-based Verb+Nominal SRL model[5]. The sentence is then chunked into "text pieces", each containing an SRL predicate and its core arguments (e.g. A_0, A_1, A_2).

Then, for each text piece, we pass it to the TE model as the premise, coupled with a *hypothesis* in the format of "*This text is about ...*" for each event type, inspired by Yin et al. (2019). For example, the hypothesis for BE-BORN is "*This text is about someone's birth.*". Then, for each hypothesis, the model returns the probability that it is entailed by the premise. If the highest entailment probability across all event types surpasses a threshold, we output the corresponding SRL predicate as an event trigger of this type.[6]

Argument	Question
Artifact	"What is bought?"
Buyer	"Who buys something?"
Seller	"Who sells something?"
Price	"How much does something cost?"
Beneficiary	"Who is something bought for?"
Time	"When is the purchase?"
Place	"Where is the purchase?"

Table 1: The predefined question for each argument type in an TRANSFER-OWNERSHIP event.

2.2 Argument Extraction (A-Ext)

We formalize the task of Argument Extraction (A-Ext) as a sequence of QA interactions with the pretrained extractive QA model.

Given an input sentence and the extracted trigger, we ask a set of questions based on the event type definition, and retrieve the QA model's answers as argument predictions.

Consider the example in Figure 1. Assume that T-Ext has identified a TRANSFER-OWNERSHIP event with the trigger "*purchased*". With this information, we consult a predefined set of questions for each argument type in the current event type. For instance, Table 1 provides a full collection of questions for all arguments in TRANSFER-OWNERSHIP. Finally, to obtain the head of the argument (e.g. "submarines" in "two nuclear submarines"), we implement a simple heuristics-based head identifier based on the AllenNLP Dependency Parser[7] as a post-processing step.

An important caveat in the above process concerns missing arguments. Specifically, many argument types in the event template do not occur in every sentence, e.g. in Figure 1, there is no Place argument. For simplicity, we call questions with a non-empty gold answer "has-answer" (HA) ques-

scratch (zero-shot)	Huang et al. 18[8]	55.6	49.1	**27.8**	15.8
	Zhang et al. 20	**58.3**	**53.5**	16.3	6.3
	Ours	45.5	41.7	27.0	**16.8**
gold TI (zero-shot)	Huang et al. 18	-	33.5	-	14.7
	Zhang et al. 20	-	82.9	-	-
	Ours	-	**83.7**	**38.9**	**24.2**
gold TI+TC (zero-shot)	Liu et al. 20	-	-	-	25.8
	Ours	-	-	**44.3**	**27.4**

Table 2: The F1 score on ACE-2005. Subtasks include Trigger Identification (TI), Trigger Classification (TC), Argument Identification (AI), and Argument Classification (AC). See Section 3 for setting definitions. SOTA results among zero-shot methods are in boldface.

tions and the rest "no-answer" (NA) questions. The QA model is considered to output NA when it predicts an empty span or the highest non-empty span confidence is lower than a threshold.

3 Experimental Setup

We evaluate our system on the ACE-2005 dataset. Its event ontology has 7 types and 33 subtypes, and we evaluate T-Ext directly on the subtypes. The same train/development/test split from Lin et al. (2020) is used. We make several design choices[9] on the development and report results on the test, ignoring the training set.

To demonstrate how our model generalizes, we also directly evaluate the optimal model on the ERE dataset (LDC2015E29). To adapt to ERE, we define a query for each new event type.

There are four subtasks of event extraction: Trigger Identification (**TI**), Trigger Classification (**TC**), Argument Identification (**AI**), and Argument Classification (**AC**). We experiment under three settings: **scratch**, where the system performs all subtasks without any gold annotation; **gold TI**, where gold trigger spans are given; **gold TC**, where gold trigger spans and types are given[10].

Following Ji and Grishman (2008), Precision, Recall, and F1 are used for evaluation[11]. We evaluate argument spans on the head level, consistent with most prior work (Huang et al., 2018; Wadden et al., 2019; Lin et al., 2020; Zhang et al., 2021).

4 Results

We report results in comparison with several existing zero-shot methods (Huang et al., 2018; Liu et al., 2020; Zhang et al., 2021), as well as a supervised SOTA system (Lin et al., 2020).

Setting	System	TI	TI+TC	AI	AI+AC
scratch (supervised)	Lin et al. 20	68.4	57.0	50.1	46.5
scratch	Ours	39.8	31.8	23.0	15.0
gold TI		-	58.4	30.8	18.8
gold TI+TC (zero-shot)		-	-	47.9	27.5

Table 3: The F1 score on the ERE. The optimal model is chosen on ACE dev and directly evaluated on ERE.

As shown in Table 2, on the ACE test set, our system outperforms prior zero-shot methods in every subtask under both the "gold TI" and "gold TI+TC" settings. However, it fails in "scratch", indicating that the main bottleneck lies in identifying exact trigger spans. Compared with the supervised SOTA, our system is still notably worse on TI, AI, and AC in particular, like other zero-shot systems.

Table 3 shows the results on ERE. Compared to ACE, our argument detection module generalizes well, whereas the trigger module does not. Under the gold TI setting, the TC F1 on overlapping event types is 70.4, whereas on new event types it is only 19.0, likely because the newly added event types in ERE have a finer definition. For example, a model needs to understand "whether a contact is in-person or not" to distinguish between MEET (in-person), CORRESPONDENCE (not in-person), and CONTACT (unsure). Further research should focus on how to effectively generalize to new event types with subtle definitions.

5 Analysis

Using the results on ACE, we now present an analysis of the remaining core challenges of the task, along with an ablation study on their individual impact. To further understand the challenges, we attribute each to the fragility of the pretrained *models* (**M-Error**), our *usage* of the models (**U-Error**), or the *task* itself (**T-Error**).

5.1 Trigger Extraction

5.1.1 Error Analysis

We first analyze the distribution of error types. Specifically, we manually check 100 wrong predictions and show the counts in Figure 2(a). Only the most frequent types are discussed here, and the remaining can be found in Appendix E.1.1.

Subtle trigger (M-Error): This is the main intrinsic error from the TE model (17%). Event types like DIE & EXECUTE, ATTACK & INJURE, and MEET & PHONE-WRITE are especially confus-

[8] Trained on 10 event types; tested on unseen ones.

[9] See Appendix C.2 and C.3.

[10] We don't have a **gold AI** setting, since the proposed QA-based A-Ext module cannot do AC alone.

[11] Evaluation scripts are adapted from `http://blender.cs.illinois.edu/software/oneie`.

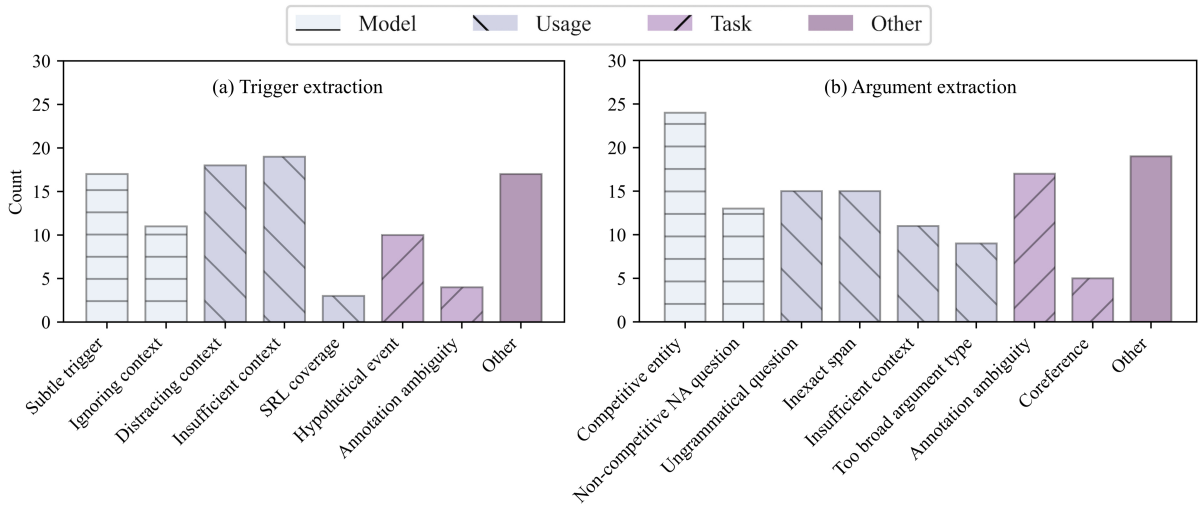

Figure 2: Error types in trigger and argument extraction in 100 wrong predictions. The count sum exceeds 100 since a prediction can contain multiple types of error. Colors/patterns indicate the origin of the error type.

ing. Though their definitions slightly differ, the model fails to capture this level of subtlety.

Distracting & Insufficient context (U-Error): Two other error types from our usage of the TE model concern distracting (18%) or insufficient (19%) contexts. An example of distracting context is "*The woman's parents ... found the decomposing body*". Given the word "decomposing", the model predicts it as a DIE event trigger, due to "*body*" in the premise. In contrast, insufficient contexts provide too little information. For example, in the sentence "*Turkey sent 1,000 troops ... and said it would send more*", the TE model is asked to predict the event type of "*send*" but only sees "*it send more*" as the premise, since "troops" is not part of the SRL arguments of "*send*". As a result, the model predicts a TRANSFER-MONEY instead of TRANSPORT event.

Hypothetical event & Annotation ambiguity (T-Error): Finally, two error types stem from the task itself: "hypothetical events" (10%) and "annotation ambiguity" (4%) . Hypothetical events refer to sentences like "*They will not buy it if it is too expensive*", where the TE model predicts "*buy*" as a TRANSFER-OWNERSHIP event trigger. Though such events should be annotated as per the ACE Annotation Guideline (3.4), this is not always strictly followed. Other cases of inconsistent annotation also cause errors, e.g. among all occurrences of "*give birth to*", the trigger is "*give*" in some cases, while "*birth*" in others.

5.1.2 Ablation Study

We further explore the two U-Error types, by measuring their influence on the performance while controlling for other factors. Only one type is included in this section, and the remaining can be found in Appendix E.1.2.

Premise design: To see the impact of **insufficient & distracting context**, we select all instances of these two types, and change the premise design. The re-prediction is done under gold-TI. For insufficient contexts, the premise is now the entire sentence. For distracting contexts, we adopt a "minimal-pair premise" strategy: Premise A is the original (e.g. "*...decomposing body...*"); Premise B is formed by deleting the candidate trigger from A (e.g. "*...body...*"). Then, we take the event type with the highest entailment probability *difference* between A and B as the prediction. Intuitively, this difference signifies the semantic *contribution* of the candidate trigger toward an event type.

After re-prediction, 59% errors are corrected on insufficient contexts. Among the remaining 41%, it is either the case that the model still ignores the context, or that the longer context now brings distraction.

On distracting contexts, only 18% errors are corrected. The model still cannot overcome the distraction in most remaining errors, which suggests that a more complicated strategy is needed in addition to manipulating the premise.

5.2 Argument Extraction

5.2.1 Error Analysis

Likewise, we analyze 100 wrong argument predictions and discuss several major error types. Figure 2(b) shows their respective counts. For a full explanation, see Appendix E.2.1.

Competitive entity & Non-competitive NA ques-

tions (M-Error): The QA model is intrinsically weak on "competitive entities" (24%) and "non-competitive NA questions" (13%).

When identifying an argument for the target event, another entity of the same type, i.e. a "competitive entity", can co-occur in the context. For example, the sentence "*A unit ... meets in confidential sessions to review terrorist activities in Europe*" has a MEET event. When asked "*Where is the meeting*", our model answers "*Europe*" whereas the gold answer is empty, since "*in Europe*" is attached to "*activities*". We find that models trained on extractive QA data are easily fooled by such entities, if they are of the desired type asked by the question. Note that competitive entities can occur for both HA and NA questions.

The other type involves NA questions without any competitive entity. For example, given the sentence "*Iraqi forces responded with artillery fire*", the question "*When is the fire*" has no answer, and there is no Time-type entity to distract the model. However, the model can still give arbitrary answers (e.g. "*artillery*") with very high confidence, due to its inherent incapacity for NA questions.

Ungrammatical question (U-Error): This relatively frequent error type (15%) is attributable to our usage of the QA model. To facilitate the model to better locate the target event, we embed the trigger in the questions whenever possible, which sometimes unavoidably makes them ungrammatical. For example, our question for the Place argument in a TRANSFER-OWNERSHIP event is "*Where is the* {*trigger*}". This is only grammatical when the trigger is a noun. Thus, the QA model may be confused by such questions.

5.2.2 Ablation Study

To isolate A-Ext, we perform the ablation study under the gold TI+TC setting. We explore four error types involving both M-Error and U-Error, two of which are included in this section, the rest in Appendix E.2.2.

Pretraining data: To examine the influence of **NA questions**, we compare QA models trained on QAMR (He et al., 2020) and SQuAD2.0, only the latter of which has NA questions. Results show that the one trained on QAMR greatly outperforms the one on SQuAD (+16.9 on AI; +13.6 on AC). To unveil why it is the case, we propose three hypotheses: (1) QAMR and ACE both have one-sentence contexts, while SQuAD has paragraphs. (2) The NA questions in SQuAD "confuses" the model, i.e. SQuAD and ACE have similar types of HA questions, while different types of NA questions. (3) The *density* of answers per sentence is high in both QAMR and ACE, while low in SQuAD. We test each hypothesis using controlled experiments, but none of them turns out to provide a full explanation of the performance difference[12].

Moreover, we train a binary classifier for HA and NA questions on a balanced sample of SQuAD, resulting in over 86 in-domain accuracy. On ACE, this number drops to 57. This shows that the QA model cannot even distinguish well between HA and NA questions when it comes to a new dataset, let alone answer them.

Question grammaticality: To see the impact of **ungrammatical questions**, we manually correct the grammatical error and re-predict with the model. Among all relevant wrong predictions, 40% are now correct. The rest 60% are mostly also NA questions that prove to require more than just fixing the grammar to solve.

6 Conclusions

We propose the first complete zero-shot event extraction system via transfer learning from TE and QA. While QA/TE models perform exceptionally well on standard benchmarks (SQuAD, QAMR, MNLI), they do not generalize as expected when being used on EE datasets. We analyze the limited success and several main challenges of the current approach, and provide insights for future improvements.

A Dataset Statistics

The pretraining datasets we use include MNLI (Williams et al., 2018), BoolQ (Clark et al., 2019), QAMR (Michael et al., 2018), and SQuAD2.0 (Rajpurkar et al., 2018). Our evaluation dataset is ACE-2005 (LDC2006T06) and ERE (LDC2015E29). Table 4 shows the number of examples in each dataset.

Dataset	Train	Dev	Test
MNLI	392,702	20,000	20,000
BoolQ	9,427	3,270	3,245
QAMR	73,561	27,535	26,994
SQuAD2.0	130,319	11,873	8,862
ACE-2005	17,172	923	832
ERE	-	-	2,069

Table 4: Number of examples in all datasets used.

B Details on Pretrained Models

We use three different pretrained representations, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and BART (Lewis et al., 2020). All models are implemented with HuggingFace Transformers[13].

The pretrained model checkpoints we use include: `bert-base-uncased` (110M parameters), `bert-large-uncased` (336M parameters), `roberta-base` (125M parameters), `roberta-large` (335M parameters), `facebook/bart-base` (373M parameters), `facebook/bart-large` (406M parameters)[14].

For TE and Yes/No QA, we finetune the pretrained models using the standard `SequenceClassification` pipeline. For extractive QA, we finetune the models using the `QuestionAnswering` pipeline[15]. The finetuning scripts are adapted from the `text-classification` and `question-answering` examples in the HuggingFace Transformers repository[16]. The hyperparameter values and pretrained models will be made available via the HuggingFace model sharing service.

We run our experiments on an NVIDIA GeForce RTX 2080 Ti GPU, with half-precision floating point format (FP16) with O1 optimization. The finetuning take 3 hours to 20 hours depending on the task.

C Details on Event Extraction System

We include here a full list of hyperparameter configurations explored in building our event extraction system. To select the optimal configuration, we perform grid-search on the development set based on the F1 score.

C.1 Preprocessing

We adapt the preprocessing script from Lin et al. (2020)[17]. In addition, we use several general-purpose NLP tools to further process the text, including a Part-of-Speech Tagger, a Dependency Parser, a Constituency Parser[18].

C.2 Trigger Extraction Module

Pretrained representation As said in Appendix B, we experiment with three representations (BERT, RoBERTa, and BART) with their base and large versions.

[13] https://github.com/huggingface/transformers

[14] All models above are available at https://huggingface.co/transformers/pretrained_models.html

[15] Both pipelines are available from https://huggingface.co/transformers/model_doc/

[16] https://github.com/huggingface/transformers/tree/master/examples/legacy

[17] http://blender.cs.illinois.edu/software/oneie

[18] The POS tagger is from http://www.nltk.org/; the rest are from https://demo.allennlp.org/.

Pretraining task We have two pretraining task choices, TE (using MNLI as training data) and Yes/No QA (using BoolQ as training data).
SRL constituents in the premise For each predicate, we only include itself and a few core arguments to form the premise. The combinations we try include: Predicate only; Predicate, Arg0, Arg1, Arg2; Predicate and all arguments.
Confidence threshold For an SRL predicate to be identified as an event trigger, we require that the confidence score of the TE model on the "Entailment" label (resp. the Yes/No QA model on the "Yes" label) exceeds a threshold. We search the threshold value within the range of $[0.80, 0.85, 0.90, 0.95, 0.99]$.
Hypothesis format We experiment with two strategies to phrase the hypothesis:

- *Topical*: The hypothesis is in the format of "*This text is about* {*topic*}", where the "{*topic*}" is predefined for each event type. For example, for ATTACK, the hypothesis is "This text is about an attack".

- *Natural*: The hypothesis is in a natural language format. For example, for ATTACK, it is "*Someone is attacked*"[19].

The optimal configuration for trigger extraction is:
- Pretrained representation: RoBERTa-large;
- Pretraining task: TE;
- SRL arguments in the premise: Predicate, Arg0, Arg1, Arg2;
- Confidence threshold: 0.99;
- Hypothesis format: Topical.

C.3 Argument Extraction Module

Pretrained representation As said in Appendix B, we experiment with three representations (BERT, RoBERTa, and BART) with their base and large versions.
Pretraining data We have two extractive QA datasets for pretraining, SQuAD2.0 and QAMR (and also their combination).
Question format We experiment with two question formats:

- *Static*: The questions are fixed for each event type. For example, the question for the Place argument in an ATTACK event is always "*Where is the attack?*".

- *Contextualized*: The questions are instantiated with the trigger of event instances when possible. For example, the question for the Place argument in an ATTACK event is "*Where is the* {*trigger*}*?*", where "{*trigger*}" is the specific trigger token(s) of the current event instance[20].

Confidence threshold For the extractive QA model to predict a non-empty answer, we require that its confidence score should be higher than a threshold. We search within the range of $[0.0, 0.1, 0.3, 0.5, 0.7, 0.9, 0.99]$.

The optimal configuration for argument extraction is:
- Pretrained representation: RoBERTa-large;
- Pretraining data: QAMR;
- Question format: Contextualized;
- Confidence threshold: 0.0 (the threshold value makes almost no difference, since most model prediction confidence scores are over 0.99).

D Full Results

Complementary to Section 4, Table 5 and Table 6 shows the full results including Precision, Recall, and F1 score on ACE and ERE respectively.

E Analysis (Continued)

This section elaborates on the remaining error types and ablation study experiments not covered by Section 5.

E.1 Trigger Extraction

E.1.1 Error Analysis

Ignoring context (M-Error): This is another prevalent error type (11%), which can also be attributed to the TE model. The model focuses too much on the candidate trigger itself while disregarding the context. Consider the sentence "*He was instrumental in creating such shows as 'married with children'...*". The word "*married*" is wrongly predicted as a MARRY event trigger. The TE model identifies it as an actual event rather than the name of a show.
SRL coverage (U-Error): Among all errors, 3% originate from the fact that the target trigger is not covered by SRL in the first place. This is a matter

[19] See the Supplemental Material for a list of all hypotheses.

[20] See the Supplemental Material for a list of all questions.

Table 6: The full performance on ERE.

of our usage of the TE model. Specifically, current SRL systems cannot handle nominal triggers perfectly, and cannot detect multi-word triggers like "*step aside*" or adjectival triggers like "*dead*" at all.

Others: Other less-frequent error types besides those mentioned in the main text are related to coreference (e.g. when pronouns like "*this*" are triggers,), proper names (e.g. historical events like "*intifada*"), confidence scores being too low (thus not identifying a gold trigger), ambiguity of the hypothesis (e.g. a "*nuclear test*" is predicted as a TRIAL-HEARING event because of the word "*test*" and the hypothesis "*There is a trial or hearing*".)

E.1.2 Ablation Study

SRL models: To examine the influence of **SRL coverage**, we experiment with two more SRL models: Illinois SRL (Punyakanok et al., 2008)[22], and one that identifies almost every verb and nominal[23]. None of the three can identify adjectival/multi-word predicates. In comparison, every model can cover over 90% verb triggers, while the nominal trigger coverage varies from 60% to 95%. On T-Ext, the highest-coverage model performs the best (+4.0 F1 on TI, +6.8 on TC over the lowest-coverage model), proving that the gain from greedy identification does compensate for the cost in precision.

Pretraining task: Our results show that the TE-based TC far outperforms its Yes/No QA counterpart (by 52.6%). One hypothesis is that the pretraining data for the TE model (MNLI; about 400K examples) is much larger than that for the QA model (BoolQ; about 9K). To verify that, we retrain a TE model on a portion of MNLI of the same size as BoolQ. As a result, the gap shrinks to 31.4%, though still quite large. This proves the importance of the training data size. It also implies that in order to further improve the current TE-based method, using larger-scale training data might be promising.

Hypothesis design: It is observed that the hypothesis format also plays a nontrivial role. As said in Appendix C.2, we experiment with two hypothesis designs, *topical* and *natural*. Experiments show that "topical" is better than "natural" by 1.9% on TC, suggesting the sensitivity of current TE systems to the phrasing of texts.

E.2 Argument Extraction

E.2.1 Error Analysis

Too broad argument type (M-Error/U-Error): For this error type (9%), both the model and our usage are to blame. Though ACE has a strict definition of arguments, the QA model sometimes interprets them too broadly. For instance, with the context "*A blindfolded woman was shot in the head by a hooded militant*", given the question "*Where is the shot*", the model answers "*in the head*". This is not technically wrong, but certainly not the desired Place argument either. We cannot hold the QA model entirely accountable, since the questions

[22] https://cogcomp.seas.upenn.edu/page/software_view/SRL

[23] Also from https://github.com/CogComp/SRL-English.

are indeed too generic as well.

Inexact span (U-Error): 15% errors are because of the inexact match of gold and predicted argument spans. For instance, the gold is "*Saturday morning*" while the predicted is "*morning*". Though in our evaluation, we compare only heads of the phrases whenever possible, not all ACE arguments (i.e. those of the "value" type instead of the "entity" type) have head annotations. Under this circumstance, the current evaluation framework does not give credit to a partial match, which can be an imperfection for potential improvement.

Insufficient context (U-Error): Like in trigger extraction, the model is sometimes given insufficient context when predicting arguments (11%). The target argument can be entirely outside the SRL constituents of the predicate, thus making it impossible to extract.

Coreference & Annotation ambiguity (T-Error): Error types ascribed to the task include "coreference" (5%) and "annotation ambiguity" (17%). The former refers to the case when the model predicts a coreferent of the gold argument. However, the current evaluation framework still takes it as an error. The latter happens when the model makes a sensible prediction, yet it is inconsistent with the annotation. For example, in the sentence "*Iraqi forces responded with artillery fire*", the model recognizes "*artillery*" as the Instrument for the ATTACK event triggered by "fire". However, no Instrument is annotated. Future evaluation framework should consider allowing multiple correct answers in such cases of human disagreement.

Others: Other errors are related to multiple arguments (i.e. the model only predicts one of them), lacking document-level knowledge (i.e. the sentence itself is not informative enough), and also arbitrary predictions with no obvious reason.

E.2.2 Ablation Study

Pretraining data: Continuing from the "Pretraining data" paragraph in Section 5.2.2, we test three hypotheses for the gap between training on QAMR and SQuAD.

Hypothesis(1): QAMR and ACE both have one-sentence contexts, while SQuAD has paragraphs.

We try to verify it by retraining a QA model on a new version of QAMR with longer contexts, subject to the same length distribution of SQuAD. This is done by either a) adding random sentences, or b) repeating the original sentence. It is observed that a) almost doesn't hurt AI at all but AC a little (3%), and b) lowers AI by 4% and AC by 3%. Therefore, though longer contexts do weaken the performance slightly, it is not the main reason behind the gap between QAMR and SQUAD.

Hypothesis(2): The NA questions in SQuAD "confuses" the model, i.e. SQuAD and ACE have similar types of HA questions, while different types of NA questions.

To test this hypothesis, we retain all HA questions in SQuAD to make a new dataset. We also construct a control set of the same size, but with both NA and HA questions randomly sampled from the original SQuAD. We retrain a QA model on each dataset, and find that the HA-only set brings about an increment by 7% on AI but a drop by 2% on AC, compared to the control set. This suggests that the addition of NA questions in SQuAD does have mixed effects on event extraction. Future research should focus on how to better transfer a model's ability to identify NA questions to a different domain.

Hypothesis (3): The *density* of answers per sentence is high in both QAMR and ACE, while low in SQuAD.

To see if this is the cause, we construct a new version of QAMR by retaining only one QA pair for each sentence. A control set of the same size, but with multiple QA pairs per sentence, is also constructed by randomly deleting sentences (along with all their QA pairs) from the original QAMR. Results show that the low-density set is only worse than the control set on AI by 0.5% and on AC by 0.2%, indicating that the density of answers is not a critical aspect.

Type constraints in question: Since generic questions may have been a cause for **too broad argument types**, we experiment with a new set of question templates that contain specific entity-type requirements whenever possible. For example, instead of "*Where is the shot*", we ask "*What is the location of the shot*", which may prevent the model from answering "*in the head*". However, only 11% errors are fixed after re-prediction, indicating that encoding type constraints is non-superficial.

Question design: Like the hypothesis format in trigger extraction, the design of questions also makes a difference for arguments. As mentioned in Appendix C.3, we explore two formats, *static* and *Contextualized*. Experiments show that switching from "static" to "contextualized" boosts AI by 7%

while impairs AC by 3%, suggesting that contextualized questions overall helps the model better locate the event.

Context design: To measure the influence of *insufficient context*, we now use the entire sentence as the context on these instances, similar to trigger extraction. Results show that 27% of them are now correct, and another 27% are partially correct (inexact span).

Using Adversarial Attacks to Reveal the Statistical Bias in Machine Reading Comprehension Models

Abstract

Pre-trained language models have achieved human-level performance on many Machine Reading Comprehension (MRC) tasks, but it remains unclear whether these models truly understand language or answer questions by exploiting statistical biases in datasets. Here, we demonstrate a simple yet effective method to attack MRC models and reveal the statistical biases in these models. We apply the method to the RACE dataset, for which the answer to each MRC question is selected from 4 options. It is found that several pre-trained language models, including BERT, ALBERT, and RoBERTa, show consistent preference to some options, even when these options are irrelevant to the question. When interfered by these irrelevant options, the performance of MRC models can be reduced from human-level performance to the chance-level performance. Human readers, however, are not clearly affected by these irrelevant options. Finally, we propose an augmented training method that can greatly reduce models' statistical biases.

1 Introduction

Reading comprehension tasks are useful to quantify language ability of both humans and machines (Richardson et al., 2013; Xie et al., 2018; Berzak et al., 2020). Deep neural network (DNN) models have achieved high performance on many MRC tasks, but these models are not easily explainable (Devlin et al., 2019; Brown et al., 2020). It is also shown that DNN models are often sensitive to adversarial attacks (Jia and Liang, 2017; Ribeiro et al., 2018; Si et al., 2019, 2020). Furthermore, it has been shown DNN models can solve MRC tasks with relatively high accuracy when crucial information is removed so that the tasks are no longer solvable by humans (Gururangan et al., 2018; Si et al., 2019; Berzak et al., 2020). All such evidence suggests that the high accuracy DNN models achieve on MRC tasks does not solely rely on these models' language comprehension ability. At least to some extent, the high accuracy reflects exploitation of statistical biases in the datasets (Gururangan et al., 2018; Si et al., 2019; Berzak et al., 2020).

Here, we propose a new model-independent method to evaluate to what extent models solve MRC tasks by exploiting statistical biases in the dataset. As a case study, we only focus on the classic RACE dataset (Lai et al., 2017), which requires MRC models to answer multiple-choice reading comprehension questions based on a passage. The advantage of multiple-choice questions is that its performance can be objectively evaluated. At the same time, it does not require the answer to be within the passage, allowing to test, e.g., the summarization or inference ability of models. Nevertheless, since models are trained to select the right option from 4 options, which are designed by humans and may contain statistical biases, models may learn statistical properties of the right option. Consequently, models may tend to select options with these statistical properties similar to the properties of the right option without referring to the passage and question. Our method is designed to reveal this kind of statistical bias.

The logic of our method is straightforward: For each multiple-choice question, we gather a large number of options that are irrelevant to the question and passage. We ask the model to score how likely each irrelevant option is the right option. If a model is biased, it may always assign higher scores to some irrelevant options than others, even if all the options are irrelevant. If a model is so severely biased, which turns out to be true for all models tested here, it may assign higher scores to some irrelevant options than the true answer and select the irrelevant option as the answer. Here, the irrelevant

options that are often selected as the answer are referred to as magnet options.

2 Dataset and Pre-trained Models

We used RACE dataset in our experiment (Lai et al., 2017), which is a large-scale reading comprehension data set covering more than 28,000 passages and nearly 100,000 questions. The task was to answer multi-choice questions based on a passage. Specifically, each question contained a triplet (p_i, q_i, o_i), where p_i denoted a passage, q_i denoted a question, and o_i denoted a candidate set of 4 options, i.e., $o_i = \{o_{i,1}, o_{i,2}, o_{i,3}, o_{i,4}\}$. Only one option was the correct answer, and the accuracy was evaluated by the percent of questions being correctly answered.

We tested 3 pre-trained language models, i.e., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2019). For each model, we separately tested the base version and large version. We built our models based on pre-trained transformer models in the Huggingface (Wolf et al., 2020). We fine-tuned pre-trained models based on the RACE dataset and the parameters we used for fine-tuning were shown in Appendix A.1.

The passage, question, and an option were concatenated as the input to models, i.e., [CLS, p_i, SEP, q_i, $o_{i,j}$, SEP]. The 4 options were separately encoded. The concatenated sequence was encoded through the models and the output embedding of CLS was denoted as $C_{i,j}$. We used a linear transformation to convert vector $C_{i,j}$ into a scalar $S(o_{i,j})$, i.e., $S(o_{i,j}) = WC_{i,j}$. The scalar $S(o_{i,j})$ was referred to as the score of the option $o_{i,j}$. A score was calculated for each option, and the answer to a question was determined as the option with the highest score, i.e., $\text{argmax}_j S(o_{i,j})$.

3 Adversarial Method

3.1 Screen Potential Magnet Options

We evaluated potential statistical biases in a model by giving it a large number of irrelevant options. For each question, we augmented the options using a set of irrelevant options, i.e., $O_A = \{o_{a1}, o_{a2}, ..., o_{aN}\}$. O_A was randomly selected from the RACE dataset with 2 constraints. First, the options belonged to questions that were not targeted at passage p_i. Second, none of the options in O_A was identical to any of the original options in o_i. The augmented question was denoted as $(p_i, q_i, \{o_{i,1}, o_{i,2}, o_{i,3}, o_{i,4}, o_{a1}, ..., o_{aj}, ..., o_{aN}\})$. A score was independently computed for each option using the procedure mentioned above. Since the options in O_A were irrelevant, an ideal model should never select them as answers. If $\text{max}_j S(o_{i,j}) < S(o_{ak})$ for any k, however, the model would select the k^{th} irrelevant option as the answer. We define an interference score T_k using the following equation.

$$T_k = \frac{1}{N}\sum_{i=1}^{N} T_{i,k}, \qquad where$$

$$T_{i,k} = \begin{cases} 1, & if \quad \text{max}_j S(o_{i,j}) < S(o_{ak}) \\ 0, & otherwise \end{cases}$$

For an ideal model, $T_{i,k}$ should always be 0. For a model that makes mistakes but shows no consistent bias, the interference score should be comparable for all o_{ak}. If the model is biased, the interference score may be always high for some options so that the model always selects them as the answer whether they are relevant to the question or not.

3.2 Adversarial Attack

We constructed an adversary attack to the MRC models using one magnet option. For each question, we replaced a wrong option with a magnet option, i.e., o_{ak}. The replaced option set was $\{o_{i,1}, o_{i,2}, o_{i,3}, o_{ak}\}$. The passage and the question were not modified, and the answer did not change. An example was shown in Figure 1. If the model chooses the original answer even when a magnet option is introduced, it is stable, not sensitive to the attack. In contrast, if it chooses the magnet option, i.e., o_{ak}, as the answer, it is successfully attacked.

4 Results and Analyses

4.1 Experiments Setup

To screen potential magnet options, we constructed a large set of irrelevant options, i.e., O_A, by randomly selecting 300 passages from the RACE test set, which were associated with 1064 questions. Furthermore, to test whether options in the training set can cause stronger interference, we also randomly selected 300 passages from the RACE training set, which had 1029 questions. The options from the test and training set were pooled to create O_A, which had 8372 options in total.

Passage: "...Quantum computers could be able to do what modern supercomputers are unable to do by using transistors that are able to take on many states at the same time..."

Question: According to the text, quantum computing _ .

Original Options:	**Adversarial Options:**
A. can reduce the cost of computers	*A*. can reduce the cost of computers
B. can make computers run by themselves	*B*. misfortune may be an actual blessing
C. **will work by using transistors**	*C*. **will work by using transistors**
D. has been put in use so far	*D*. has been put in use so far
Model Choice: *C* – correct	**Model Choice:** *B* – incorrect, **successfully attacked**
A, B, or D – incorrect	*C* – correct, not attacked
	A or D – incorrect, not attacked

Figure 1: An example of the task and adversarial attack. The option in bold is the true answer, and the option in red indicates the irrelevant option that was used for attack.

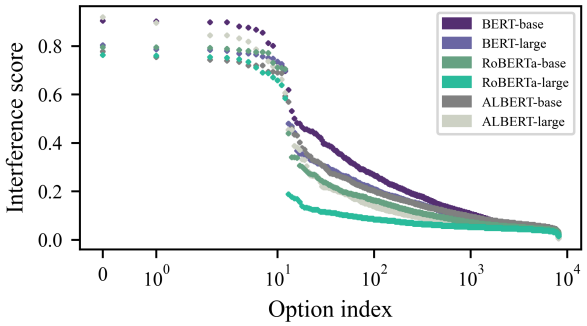

Figure 2: Interference score evaluated based on a subset of questions.

For such a large number of irrelevant options, it was computationally challenging to evaluate the interference score of each option based on each question in the RACE test set. Therefore, as a screening procedure, we first randomly selected 100 passages from the RACE test set, which have a total of 346 questions. The interference score for each of the 8372 irrelevant options was evaluated based on the 346 questions.

After potential magnet options were determined by the screening procedure, the interference score of magnet options were further evaluated using all questions in RACE test set. For RACE test set, the accuracy of the models ranged between about 0.6 and 0.85, with RoBERTa-large achieving the highest performance (Table 1).

4.2 Screening for Magnet Options

The interference score for 8372 options was independently calculated for each model. Results were shown in Figure 2, where the interference score was sorted for each model. It is found that most of the irrelevant options had a non-zero interference score, and some irrelevant options yielded high interference scores around 0.8, which meant the models would choose those irrelevant options as the answer for about 80% of the questions. Irrelevant options from the training and test sets had similar interference scores (Appendix B.1).

It was found that the options with exceptionally high interference scores around 0.8 were options that combined other options, such as "all the above", which were called the option-combination series. However, not all the magnet options were from the option-combination series. Normal statements, e.g., "The passage doesn't tell us the end of the story of the movie", could also reach an average interference score around 0.34.

The correlation between the interference score between models were shown in Appendix B.2. We separately showed the results for options from the option-combination series and the others. The correlation coefficient between models had an average value around 0.76, which proved that the interference score was correlated across models. From another perspective, it also implied that our method could work as a model-insensitive adversarial attack method.

4.3 Validate Magnet Options and Adversarial Attack

We further evaluated the interference score of potential magnet options based on all the questions in the RACE test set. To construct a set of magnet options for this analysis, we averaged the interference score across 3 models, i.e., BERT-large, RoBERTa-large, and ALBERT-large. All options in O_A were sorted based on the average score, and we selected 20 options with the highest interference scores to construct the magnet option set, with the

	BERT		ALBERT		RoBERTa	
Version	base	large	base	large	base	large
Original accuracy	0.614	0.681	0.683	0.752	0.738	0.846
Adversarial accuracy[1]	0.094	0.167	0.217	0.064	0.166	0.297
Adversarial accuracy[2]	0.381	0.524	0.334	0.506	0.656	0.798

Table 1: Model performance on the RACE test set and model performance after being attacked. The superscript 1 meant use "A, B and C" to attack, and the superscript 2 meant use "The passage doesn't tell us the end of the story of the movie" to attack.

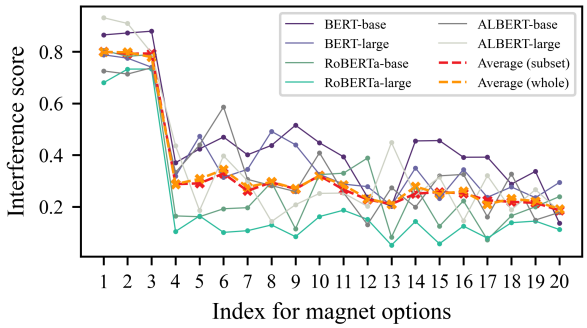

Figure 3: Interference score evaluated based on the whole RACE test set.

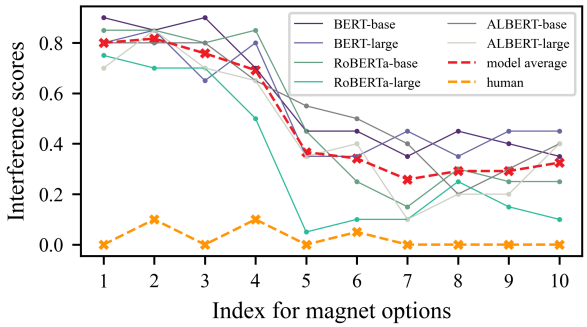

Figure 4: Interference score for the human experiment and the corresponding interference scores for the models.

following constraint: Since options with the highest interference scores were often from the option-combination series, to increase diversity, we only included 3 options from the option-combination series. We listed all the 20 magnet options in Appendix A.2. The interference score calculated based on the whole RACE test set was shown in Figure 3, which was very similar to the results based on the subset of 346 questions in Figure 2 (comparing average-whole and average-subset in Figure 3).

Table 1 showed the accuracy of models when attacked by 2 example magnet options. When attacked, the model performance could drop by as much as 0.68.

4.4 Human Evaluation

Next, we verified whether humans were also confused by the magnet options. We randomly selected 20 questions and 10 magnet options. The 10 magnet options selected were listed in Appendix A.3. Ten questions were not modified while the other 10 questions were attacked using the procedure shown in Figure 1. Twenty human evaluators answered these 20 questions online. The accuracy of humans did not reduce under attack (0.90 in the original samples and 0.94 in the adversarial samples). The interference score for humans, also the corresponding interference score for the models, was shown in Figure 4. Humans were not confused by the magnet options.

4.5 Training with Adversarial Examples

To reduce sensitivity to magnet options and to potentially reduce the statistical biases of MRC models, we proposed an augmented training method and tested the method using the base version of all models. In the augmented training method, 400 options with the highest interference scores were selected as the irrelevant option set. For each question in the RACE training set, the option set was augmented by adding an option randomly chosen from the irrelevant option set. In other words, although each original question has 4 options, during the augmented training each question has 5 options, including the 4 original options and a randomly chosen irrelevant option. We fine-tuned pre-trained models based on the training set with augmented options.

The accuracy of models fine-tuned using augmented options were shown in Table 2, comparable to the original accuracy in Table 1. When attacked, however, the accuracy of models fine-tuned using augmented options were much higher than the adversarial accuracy in Table 1.

The 1000 options with the highest interference

base version	BERT	ALBERT	RoBERTa
Original accuracy	0.601	0.689	0.723
Adversarial accuracy[1]	0.576	0.681	0.725
Adversarial accuracy[2]	0.670	0.740	0.778

Table 2: Model performance on the RACE test set based on augmented training.

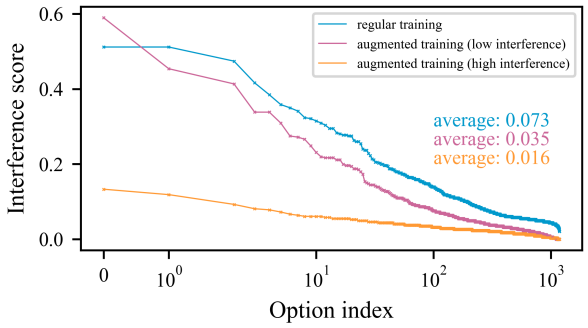

Figure 5: Interference score of 1186 randomly chosen options that are not used in augmented training.

scores were selected to evaluate the effect of augmented training, as shown in Appendix C. Result showed that the interference score dropped for both the 400 options used for augmented training and the other 600 options that were not used for training. Therefore, the effect of augmented training could generalize to samples not used for augmented training.

Another experiment was implemented to explore the impact of irrelevant option set selection. We separately used options with high and low interference scores for training and found that options with higher interference score were more effective at reducing statistical biases (Figure 5).

4.6 Interference Score Analysis

Did the statistical biases revealed in previous analyses originate from the pre-training process or the fine-tuning process? Without fine-tuning, the pre-trained models performed poorly on RACE. However, results showed that such an imprecise model could show strong biases (Appendix B.3). Interestingly, the interference score was not correlated between the pre-trained model and the fine-tuned model, suggesting that fine-tuning overrode the biases caused by pre-training and introduced new forms of biases.

5 Related Work

Our attack strategy distinguishes from previous work in two ways. First, unlike, e.g., gradient-based methods (Ebrahimi et al., 2018; Cheng et al., 2020), our method does not require any knowledge about the structure of DNN models. Second, some methods manipulate the passage in a passage-dependent way (Jia and Liang, 2017; Si et al., 2020; Zhao et al., 2018), while our method manipulate the options in a passage-independent way. Furthermore, we proposed a strategy to train more robust models that are insensitive to our attack.

Here, we restricted our discussion to RACE, but our method is applicable to other tasks in which the answer is selected from a limited set of options. For example, for span extraction tasks, such as SQuAD, the method will insert a large number of irrelevant phrases into the passage and analyze which phrases are often selected as the answer. In this way, our method is similar to the trigger-based attack methods (Wallace et al., 2019), but the difference is that our method test whether the inserted irrelevant phrase is selected as the answer while the trigger-based methods test whether the content following the trigger phrase is selected.

6 Conclusion

In summary, we propose a new method to evaluate the statistical biases in MRC models. It is found that current MRC models have strong statistical biases, and are therefore sensitive to adversarial attack. When attacked using the method proposed here, model performance can drop from human-level performance to chance-level performance. To alleviate sensitivity to such attacks, we provided an augmented training procedure that effectively enhances the robustness of models.

10. Not all of it is man-made Ming dynasty structure.

B Study of Interference Score

B.1 Comparison of Irrelevant Options from RACE Training and Test Set

Different models in Figure 2 were separately shown in Figure 6. It denoted that irrelevant options from the training and test sets had similar interference score. Only in BERT-large and ALBERT-large models, the interference scores of the irrelevant options from the training set were higher than those

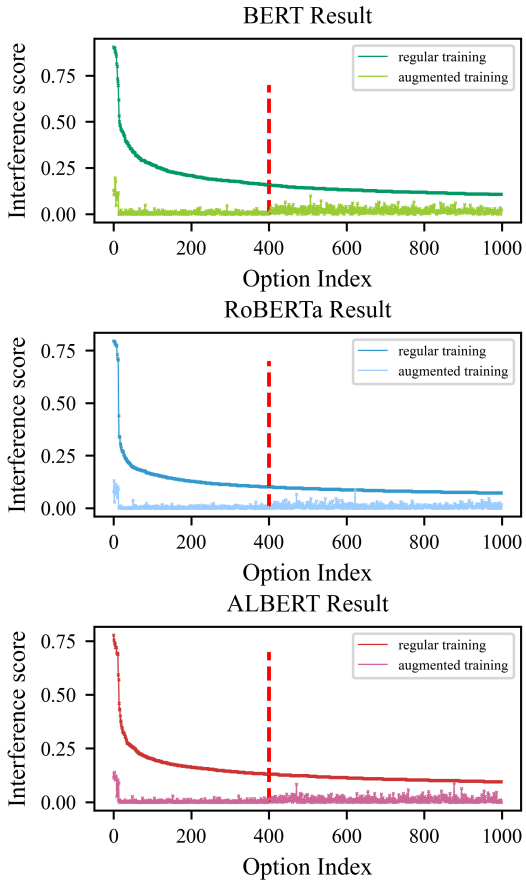

Figure 8: Interference score comparison of models evaluated based on a subset of questions.

from the test set in a certain range.

B.2 Comparison of Interference Scores Based on Different Models

The scatter matrix diagram of the interference scores of the irrelevant options among different models was shown in Figure 7. The detailed experimental process was described in Section 4.2. Here, text in black showed the correlation coefficient of all options; text in green showed the options of the option-combination series; text in blue showed the options except the option-combination series.

In general, the interference scores between models had high correlation coefficients. Models from the same architecture were more likely to have similar interference scores.

B.3 Comparison of Interference Scores During Fine-tuning

For each model architecture, the pre-trained model, partly fine-tuned model (fine-tuned the linear transformation mentioned in Section 2), and fully fine-tuned model were collected, and were used to evaluate the interference score of 1,000 randomly selected irrelevant options. The results were shown in Table 4. The subset of questions mentioned in Section 4.1 were used to evaluate the interference score.

C Augmented Training Result

The augmented training results were shown in Figure 8. In the figures, the left side of the red line contains the irrelevant options that were used in augmented training, and the right is the irrelevant options that were not involved in augmented training.

Quantifying and Avoiding Unfair Qualification Labour in Crowdsourcing

Jonathan K. Kummerfeld
Computer Science & Engineering
University of Michigan, Ann Arbor
jkummerf@umich.edu

Abstract

Extensive work has argued in favour of paying crowd workers a wage that is at least equivalent to the U.S. federal minimum wage. Meanwhile, research on collecting high quality annotations suggests using a qualification that requires workers to have previously completed a certain number of tasks. If most requesters who pay fairly require workers to have completed a large number of tasks already then workers need to complete a substantial amount of poorly paid work before they can earn a fair wage. Through analysis of worker discussions and guidance for researchers, we estimate that workers spend approximately 2.25 months of full time effort on poorly paid tasks in order to get the qualifications needed for better paid tasks. We discuss alternatives to this qualification and conduct a study of the correlation between qualifications and work quality on two NLP tasks. We find that it is possible to reduce the burden on workers while still collecting high quality data.

1 Introduction

Workers using Amazon Mechanical Turk earn a median wage of $2.54 an hour (Hara et al., 2018), far below the U.S.-federal minimum wage of $7.25. Many researchers pay workers a higher wage, estimating the time spent on a task and giving bonuses when the time required is higher than expected. At the same time, researchers try to maintain the quality of work completed using a variety of methods (Mitra et al., 2015). One common approach, used by 19% of tasks (HITs) on the platform (Hara et al., 2018), is to restrict tasks to workers who have had a certain number of HITs approved. Tasks with this restriction have a median wage of $4.14 an hour, far above the overall average. If most high paying requesters use this restriction it means workers need to do a substantial amount of low paid "Qualification Labour": work to achieve the qualifications necessary for fairly paid tasks. These tasks may also be particularly unpleasant work that more experienced workers are unwilling to do, e.g., they might involve unsavoury content.

This paper is the first to identify the qualification labour issue and explore it. We study norms around the setting of the qualification and the effort workers put in to achieve common milestones. 5,000 accepted tasks, a common requirement, takes over 2 months of effort. We consider several ways to address the issue, and study the work quality of groups with different qualifications.[1] Using two tasks, coreference resolution and sentiment analysis, we find that high quality annotations can be collected with a lower threshold, though there are task dependent patterns.

2 Background and Related Work

Crowd work involves large groups of workers doing small paid tasks, known as Human Intelligence Tasks (HITs). Services such as Amazon Mechanical Turk provide a marketplace to connect workers with requesters. Requesters create tasks, workers choose which tasks to do, then either complete them or return them. Requesters approve or reject the completed work. Tasks can be restricted to workers with certain qualifications, e.g. location. Amazon tracks some statistics that can be used as qualifications. This work focuses on (1) the total number of approved HITs a worker has, and (2) the percentage of their HITs that were accepted.

Since the earliest uses of crowd work in NLP, there has been work discussing issues such as poor wages and the lack of worker rights (Fort et al., 2011). These have also been discussed in the Human-Computer Interaction research community (Bederson and Quinn, 2011; Hara et al., 2018). There has been work on proposing guidelines for requesters (Sabou et al., 2014), incorporating workers into the IRB process (Libuše Hannah Vepřek,

2020), and developing tools to help workers address the power imbalance in the online workplace (Irani and Silberman, 2013, 2016). Concurrent with this work, another study showed that crowdsourcing is being used more each year in NLP research, and there is limited awareness of the ethical issues in this type of work (Shmueli et al., 2021).

Prior work has considered hidden labour in the day-to-day work of the crowd (Hara et al., 2018). By observing a large set of workers, they measured time involved in searching for tasks, returned tasks, and breaks. Some of these issues have received additional attention, such as the wasted effort on tasks that are returned rather than completed (Han et al., 2019). While informative, those studies do not account for the hidden labour identified in this paper, which spans a long period and relates to worker qualifications.

Part of this work uses online discussion between workers to understand their work. Prior work has used a similar approach to understand the overall experience of crowd workers (Martin et al., 2014).

3 Norms for the Approved HITs Value

The value used as the Approved HITs threshold is rarely reported in prior work. Three recent papers specify a 1,000 HIT threshold (Vandenhof, 2019; Oppenlaender et al., 2020; Whiting et al., 2019). Outside of Computer Science, advice in articles (Young and Young, 2019) and tutorials (Dozo, 2020) is to set the value to 100 because that is when another qualification (approval percentage) becomes active. This difference may be because other fields primarily use crowdsourcing for surveys rather than data annotation or human computation systems. It is unclear how representative these samples are. However, there are other sources that can provide information about conventions.

One source is Amazon itself. The Mechanical Turk web-interface provides six options: 50, 100, 500, 1,000, 5,000, 10,000. The MTurk blog has mentioned this qualification in four posts over the past eight years (Amazon Mechanical Turk, 2012, 2019, 2017, 2013). In three cases, the value was 5,000 and in the fourth it was 10,000.

Another source is forums and blogs. One pinned thread on the MTurk Crowd forum advises that "For your first 1000 HITs you may want to concentrate on approval milestones rather than $$$ ... most of the better-paying requesters require 1000/5000/10000+ approved HITs" ([jklmnop], 2016). This advice is repeated elsewhere on the forum and on Reddit ([WhereIsTheWork], 2019; [CaptainSlop], 2019; [Crazybritzombie], 2018). This is consistent with observations that 80% of tasks available to new users pay less than 10 cents (El Maarry et al., 2018). In one discussion between a worker and a requester, the worker recommended a threshold of 5,000 ([clickhappier], 2016). In the blog "Tips For Requesters On Mechanical Turk", one post recommends at least 5,000 if not 10,000 (Miele, 2012) while another recommends at least 1,000 (Miele, 2018). A web article by a Computer Vision researcher recommended 1,000 (Kumar, 2014). The CloudResearch blog mentions the threshold once, noting that a value of 10,000 maintains quality without significantly increasing the time to finish a set of HITs (Robinson, 2015).

Qualifications are also discussed by courses and tutorials. In the Crowdsourcing & Human Computation course at the University of Pennsylvania, a guest lecture on "The Best Practices of the Best Requesters" mentioned the approved HITs qualification and used 10,000 as an example (Milland, 2016). One guide recommends a cutoff of 5,000 (Carlson , née Feenstra).

Overall, we conclude that while practises vary, 5,000 or higher are commonly used as a qualification for tasks.

3.1 Impact on Workers

It is difficult to estimate how much time workers have to spend to achieve this qualification. Academic studies of time spent on HITs may be skewed by experienced workers, who have strategies for finding and completing tasks rapidly. Posts on Reddit mention taking anywhere from a month to a year to reach 5,000 approved HITs. The median of values reported across several Reddit threads was 2.25 months ([alisonlovepowell], 2015; [GnomeWaiter], 2013; [FrobozzYogurt], 2020; [Wat3rloo], 2016). Assuming 20 hours of work a week that is almost 200 hours of effort (140 seconds per task).

3.2 Potential Solutions

If this type of qualification undercuts our commitment to paying a fair wage, what are alternative ways to maintain quality? Options include:

1. Introduce screening questions that workers must complete correctly to proceed to the rest of the task, e.g., requiring 70%+ on three questions (Shvartzshnaid et al., 2019). This approach is prob-

lematic because it the workers who fail the screening are doing unpaid labour.

2. Address quality after collection by either dropping the lowest performing workers (e.g., the bottom 25% in Bansal et al., 2019), aggregating a larger number of responses per example, or including attention check questions and discarding workers who get them wrong. All of these incur a substantial cost to researchers.

3. Controlled crowdsourcing (Roit et al., 2020) uses an initial task that a broad set of workers can complete and then limits participation to the workers who did well on that task.[2] The cost of this solution depends on the percentage of workers who do well on the initial task.

4. Lower the threshold, reducing the required volume of earlier work. This reduces, but does not eliminate the qualification labour issue.

These methods can also be combined. Controlled crowdsourcing (method 3) with a very low Accepted HITs threshold (method 4) for the initial task would address the ethical concern we raise here while limiting the additional cost to the recruitment phase. Attention checks and aggregation (method 2) would then address natural variation in skill and attention during large-scale annotation.

4 Studying the Approved HITs Value

All of the options above have tradeoffs that will be task dependent and in practise some combination is most likely to be the best approach. The first three have been studied in prior work, but the impact of lowering the threshold has not. In this section, we consider the quality of work completed by workers grouped by how many tasks they have previously completed and what percentage were accepted.[3]

4.1 Tasks

Coreference Resolution This is an unusual task for crowdsourcing, with a novel user interface, shown in Figure 1. Workers were shown a 244 word document from the Ontonotes dataset (Hovy et al., 2006). We identified noun phrases using the Allen NLP parser (Gardner et al., 2018) and asked workers to identify when one of two specific entities was mentioned. This is not the complete coreference resolution task, but a useful subset. We refined the task over several rounds of trial annotation to ensure the instructions were clear and the interface was efficient. Workers were asked to check their answers if they tried to submit in less than 75 seconds. If they labeled 8 items in the first 19 words, they were reminded to only label the two entities specified. We estimated that the task would take 3 minutes and paid workers 60 cents ($12 / hour). Reviews on TurkerView (https://turkerview.com/) indicated that workers effective hourly rates were $7.88, $11.25, $12.93, and $14.59.

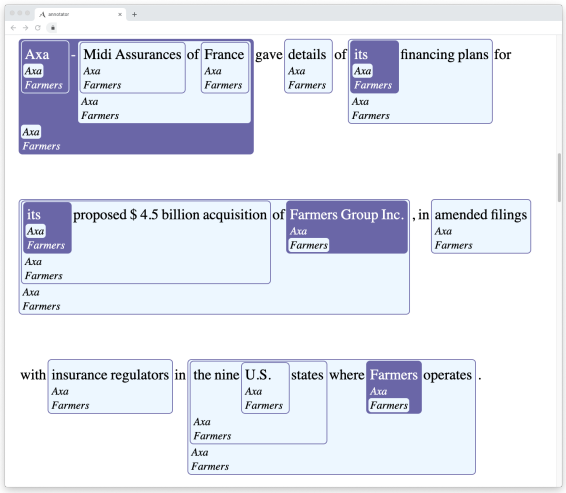

Figure 1: The user interface for coreference resolution (zoomed in). Spans are noun phrases automatically assigned by the Allen NLP syntactic parser (Gardner et al., 2018). The two entities being identified are the two most frequently mentioned entities in the text. Workers select a label by clicking on it.

We measure performance by comparing with the Ontonotes annotations. An F-score of 80% or above was considered acceptable, to allow for minor errors and points of confusion.

Sentiment Analysis This task is very intuitive and has been crowdsourced extensively in the past. We closely followed the set up used to annotate the Stanford Sentiment Treebank (Socher et al., 2013), with the same task instructions. Workers were shown ten examples whose true scores were evenly spread across 0 to 1. We estimated that the task would take 4 minutes and paid workers 80 cents ($12 / hour). Three reviews of the task on TurkerView indicated that workers hourly earnings were $22.15, $48.00, and $50.53, suggesting that workers were faster than anticipated.

[2] One potential drawback of this approach is that the filtering step may produce a biased sample of workers. That may be problematic for more subjective tasks, though with a large enough sample, responses could be weighted to make the results more representative.

[3] This was completed as part of a larger study approved by the Michigan IRB under study ID HUM00155689.

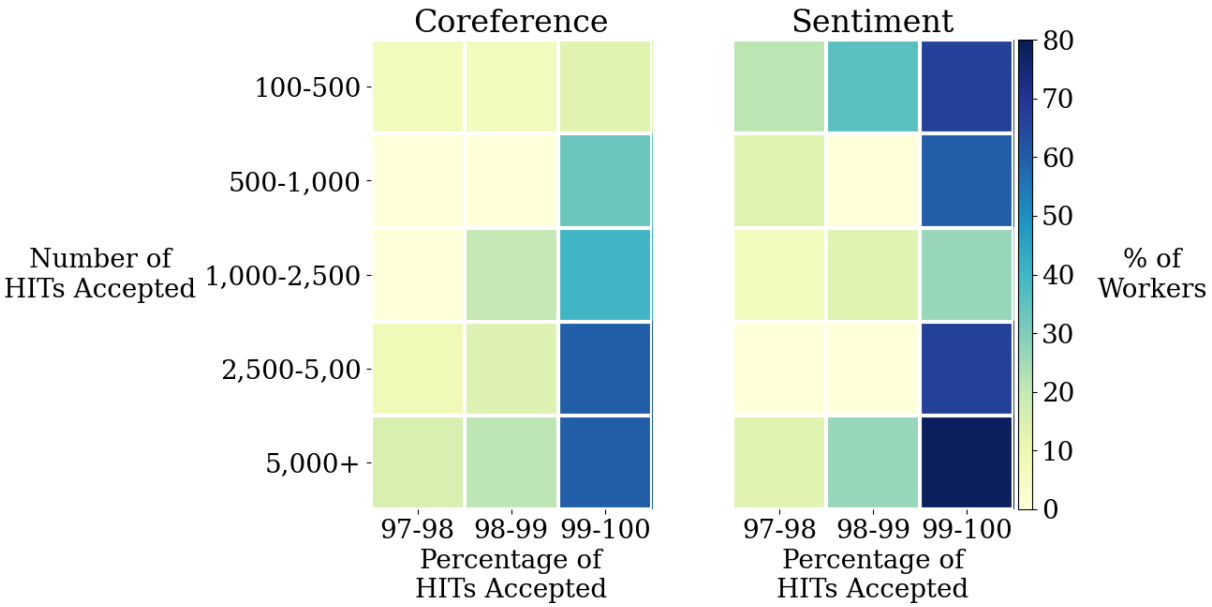

Figure 2: Results for all fifteen combinations of qualifications. Left (coreference): The percentage of workers scoring above 80 in each group. Right (sentiment): The percentage of workers whose average error was below 0.15 in each group. Each value is based on fifteen workers, except for sentiment there were fourteen for (98-99%, 500-1,000), and for coreference there were fourteen for (97-98%, 500-1,000), (97-98%, 1,000-2,500), (98-99%, 2,500-5,000), (98-99%, 5,000+), thirteen for (97-98%, 5,000+), and twelve for (97-98%, 2,500-5,000).

To evaluate, the labels are mapped to [0, 1] and compared with the STS values. An average value of below 0.15 was considered acceptable. This cutoff was chosen based on the scores achieved by two NLP students in our lab (0.11 and 0.09).

4.2 Recruitment

We considered 15 combinations of ranges for "Approved HITs" and "Percentage Approved", as shown by the axis labels in Figure 2. The ranges are based on the preset values provided by MTurk, with the addition of a boundary at 2,500 to provide slightly more detail in the shift between 1,000 and 5,000. Workers also had to be U.S.-based. We used Javascript-based checks to ensure each worker completed the task only once. 224 workers completed the sentiment task and 30 opened and returned it. 216 workers completed the coreference task and 657 opened and returned it. All but two conditions had 14 or 15 workers (the 97-98%, 5,000+ case for coreference had 13 and the 97-98%, 2,500-5,000 case for coreference had 12).

4.3 Results

The heatmap on the left of Figure 2 shows the percentage of workers scoring 80 or higher on the coreference resolution task. When the acceptance percentage is below 99, results are consistently poor, with fewer than 25% of workers scoring above 80. When the acceptance percentage is 99-100, groups with higher approved HITs have better scores. However, Figure 3 shows that more workers returned the HIT[4] in the groups with higher performance (see the last column of the rightmost plot), indicating that workers are self-selecting out.

This figure may be interpreted to suggest that a threshold of 2,500 is necessary. However, the distribution of workers is not uniform across these qualification groups. In a follow up experiment with constraints of 99-100% and 1,000+ using a relatively new requester account, 60 out of 92 workers scored 80 or above (65%), indicating that there are more workers in the higher approved HITs groups.

Figure 2 also shows results for the sentiment task. First, note that many more workers did well on the task. Comparing the left and right, the trend for percentage of HITs accepted is repeated, with consistently poor performance from workers with values below 99% (the left two columns). While the best result is the same in both cases (the bottom-right), the trend in the third column is somewhat different. Rather than a steady increase in performance as the approved HITs threshold increases, there is a U-shaped pattern. This shows that the pattern is somewhat task dependent.

[4] 'Returning' a task means a worker choose to stop working on it, receives no pay, but also receives no penalty in their profile for failing to complete the task.

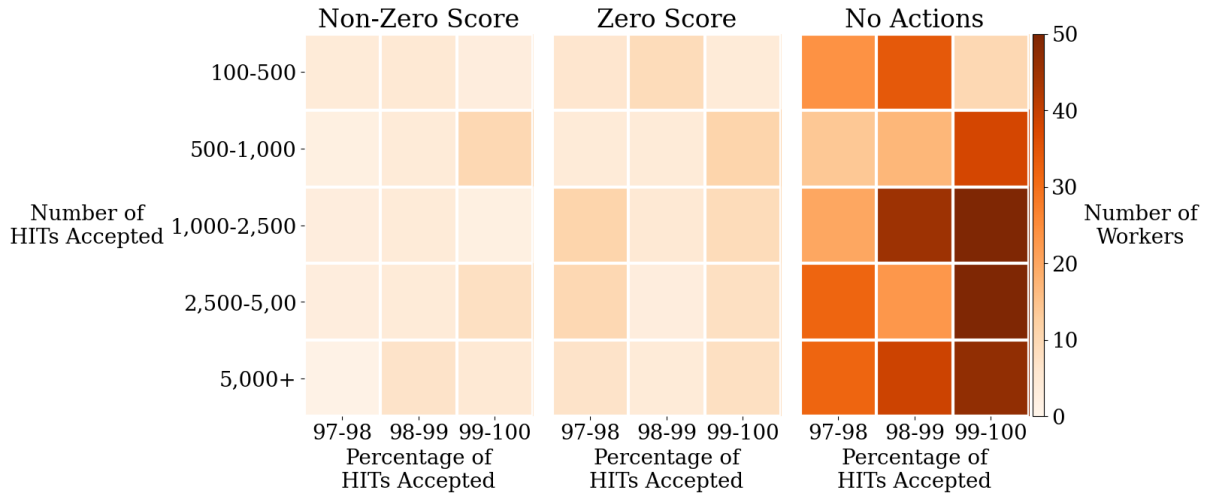

Figure 3: For coreference resolution, 657 workers opened and returned the HIT without completing it. These three heatmaps show the number of workers who: left partially correct annotations (Non-Zero Score), left entirely incorrect annotations (Zero Score), did not interact with the page (No Action). We do not include plots for sentiment analysis because only 30 workers opened and returned the HIT.

These results suggest that a lower qualification can be used without a substantial impact on work quality. In both tasks, the percentage HITs accepted qualification had a clear impact, with substantial decreases in quality from workers with a value below 99%. While that qualification does not directly force workers to do a substantial amount of work, it can be impacted by requesters who unfairly reject work. Our results also suggest that simply paying workers more will not lead to better work, as the sentiment analysis task paid considerably better and did not solve the issue.

5 Ethics and Impact Statement

This work involved consideration of several potential impacts. In terms of privacy, all data from workers is aggregated for the purpose of presenting results, and information from worker discussions were only sourced from publicly shared content. In terms of payment, we estimated the effort involved and aimed to pay workers $12 USD an hour. See the main text for worker reported values of hourly earnings on the two tasks. This was approved by the Michigan IRB under study ID HUM00155689. One potential harm of this work is that it may encourage higher values of the Percentage of HITs Accepted qualification, making workers more vulnerable to requesters who unfairly reject work.

6 Conclusion and Recommendations

This paper identifies the issue of Qualification Labour: the implied labour created by the qualifications we define. Based on a range of sources, we found that 5,000 approved tasks is one common threshold. That takes approximately two months to achieve and the tasks are poorly paid. We conducted a study of two tasks to understand how work quality correlates with these qualifications. We found that trends are task dependent, but lower thresholds can often be used.

We recommend either not using the ”HITs accepted” qualification, or running preliminary tests to identify the lowest suitable threshold for your task. This calibration is necessary because worker performance depends on many factors, including the task type, data (including which language), user interface, and instructions. One particularly promising method is to use controlled crowdsourcing (Roit et al., 2020) with a low threshold: run a short task with low or no qualifications to identify workers, then for the full task only allow those workers to participate. This reduces the burden on workers while maintaining high quality work.

Men Are Elected, Women Are Married: Events Gender Bias on Wikipedia

Jiao Sun[1,2] and **Nanyun Peng**[1,2,3]

Abstract

Human activities can be seen as sequences of events, which are crucial to understanding societies. Disproportional event distribution for different demographic groups can manifest and amplify social stereotypes, and potentially jeopardize the ability of members in some groups to pursue certain goals. In this paper, we present the first event-centric study of gender biases in a Wikipedia corpus. To facilitate the study, we curate a corpus of career and personal life descriptions with demographic information consisting of 7,854 fragments from 10,412 celebrities. Then we detect events with a state-of-the-art event detection model, calibrate the results using strategically generated templates, and extract events that have asymmetric associations with genders. Our study discovers that Wikipedia pages tend to intermingle personal life events with professional events for females but not for males, which calls for the awareness of the Wikipedia community to formalize guidelines and train the editors to mind the implicit biases that contributors carry. Our work also lays the foundation for future works on quantifying and discovering event biases at the corpus level.

1 Introduction

Researchers have been using NLP tools to analyze corpora for various tasks on online platforms. For example, Pei and Jurgens (2020) found that female-female interactions are more intimate than male-male interactions on Twitter and Reddit. Different from social media, open collaboration communities such as Wikipedia have slowly won the trust of public (Young et al., 2016). Wikipedia has been trusted by many, including professionals in work tasks such as scientific journals (Kousha and Thelwall, 2017) and public officials in powerful positions of authority such as court briefs (Gerken, 2010). Implicit biases in such knowledge sources could have a significant impact on audiences' perception of different groups, thus propagating and even amplifying societal biases. Therefore, analyzing potential biases in Wikipedia is imperative.

Name	Wikipedia Description
Loretta Young (F)	**Career**: In 1930, when she was 17, she eloped with 26-year-old actor Grant Withers; they were married in Yuma, Arizona. The marriage was annulled the next year, just as their second movie together (ironically entitled Too Young to Marry) was released .
Grant Withers (M)	**Personal Life**: In 1930, at 26, he eloped to Yuma, Arizona with 17-year-old actress Loretta Young. The marriage ended in annulment in 1931 just as their second movie together, titled Too Young to Marry, was released .

Table 1: The marriage events are under the *Career* section for the female on Wikipedia. However, the same marriage is in the *Personal Life* section for the male. yellow background highlights events in the passage.

In particular, studying events in Wikipedia is important. An event is a specific occurrence under a certain time and location that involves participants (Yu et al., 2015); human activities are essentially sequences of events. Therefore, the distribution and perception of events shape the understanding of society. Rashkin et al. (2018) discovered implicit gender biases in film scripts using events as a lens. For example, they found that events with female agents are intended to be helpful to other people, while events with male agents are motivated by achievements. However, they focused on the intentions and reactions of events rather than events themselves.

In this work, we propose to use events as a lens to study gender biases and demonstrate that events are more efficient for understanding biases in corpora than raw texts. We define *gender bias* as the

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 350–360
August 1–6, 2021. ©2021 Association for Computational Linguistics

asymmetric association of events with females and males,[1] which may lead to gender stereotypes. For example, females are more associated with domestic activities than males in many cultures (Leopold, 2018; Jolly et al., 2014).

To facilitate the study, we collect a corpus that contains demographic information, personal life description, and career description from Wikipedia.[2] We first detect events in the collected corpus using a state-of-the-art event extraction model (Han et al., 2019). Then, we extract gender-distinct events with a higher chance to occur for one group than the other. Next, we propose a calibration technique to offset the potential confounding of gender biases in the event extraction model, enabling us to focus on the gender biases at the corpus level. Our contributions are three-fold:

- We contribute a corpus of 7,854 fragments from 10,412 celebrities across 8 occupations including their demographic information and Wikipedia *Career* and *Personal Life* sections.
- We propose using events as a lens to study gender biases at the corpus level, discover a mixture of personal life and professional life for females but not for males, and demonstrate the efficiency of using events in comparison to directly analyzing the raw texts.
- We propose a generic framework to analyze event gender bias, including a calibration technique to offset the potential confounding of gender biases in the event extraction model.

2 Experimental Setup

In this section, we will introduce our collected corpus and the event extraction model in our study.

Dataset. Our collected corpus contains demographics information and description sections of celebrities from Wikipedia. Table 2 shows the statistics of the number of celebrities with *Career* or *Personal Life* sections in our corpora, together with all celebrities we collected. In this work, we only explored celebrities with *Career* or *Personal Life* sections, but there are more sections (e.g., *Politics* and *Background and Family*) in our collected corpus. We encourage interested researchers to further utilize our collected corpus and conduct studies from other perspectives. In each experiment, we select the same number of female and male celebrities from one occupation for a fair comparison.

	Career		Personal Life		Collected	
Occ	F	M	F	M	F	M

Table 2: Statistics showing the number of celebrities with *Career* section or *Personal Life* section, together with all celebrities we collected. Not all celebrities have *Career* or *Personal Life* sections.

Event Extraction. There are two definitions of events: one defines an event as the trigger word (usually a verb) (Pustejovsky et al., 2003b), the other defines an event as a complex structure including a trigger, arguments, time, and location (Ahn, 2006). The corpus following the former definition usually has much broader coverage, while the latter can provide richer information. For broader coverage, we choose a state-of-the-art event detection model that focuses on detecting event trigger words by Han et al. (2019).[3] We use the model trained on the TB-Dense dataset (Pustejovsky et al., 2003a) for two reasons: 1) the model performs better on the TB-Dense dataset; 2) the annotation of the TB-Dense dataset is from the news articles, and it is also where the most content of Wikipedia comes from.[4] We extract and lemmatize events e from the corpora and count their frequencies $|e|$. Then, we separately construct dictionaries $\mathcal{E}^m = \{e_1^m : |e_1^m|, ..., e_M^m : |e_M^m|\}$ and $\mathcal{E}^f = \{e_1^f : |e_1^f|, ..., e_F^f : |e_F^f|\}$ mapping events to their frequency for male and female respectively.

Event Extraction Quality. To check the model performance on our corpora, we manually annotated events in 10,508 sentences (female: 5,543,

[1] In our analysis, we limit to binary gender classes, which, while unrepresentative of the real-world diversity, allows us to focus on more depth in analysis.

[2] https://github.com/PlusLabNLP/ee-wiki-bias

[3] We use the code at https://github.com/rujunhan/EMNLP-2019 and reproduce the model trained on the TB-Dense dataset.

[4] According to Fetahu et al. (2015), more than 20% of the references are news articles on Wikipedia.

Metric	TB-D	S	S-F	S-M
Precision	89.2	93.5	95.3	93.4
Recall	92.6	89.8	87.1	89.8
F1	90.9	91.6	91.0	91.6

Table 3: The performance for off-the-shelf event extraction model in both common event extraction dataset TB-Dense (TB-D) and our corpus with manual annotation. `S` represents the sampled data from the corpus. `S-F` and `S-M` represent the sampled data for female career description and male career description separately.

male: 4,965) from the Wikipedia corpus. Table 3 shows that the model performs comparably on our corpora as on the TB-Dense test set.

3 Detecting Gender Biases in Events

Odds Ratio. After applying the event detection model, we get two dictionaries $\mathcal{E}^m$ and $\mathcal{E}^f$ that have events as keys and their corresponding occurrence frequencies as values. Among all events, we focus on those with distinct occurrences in males and females descriptions (e.g., `work` often occurs at a similar frequency for both females and males in *Career* sections, and we thus neglect it from our analysis). We use the Odds Ratio (OR) (Szumilas, 2010) to find the events with large frequency differences for females and males, which indicates that they might potentially manifest gender biases. For an event e_n, we calculate its odds ratio as the odds of having it in the male event list divided by the odds of having it in the female event list:

$$\frac{\mathcal{E}^m(e_n)}{\sum^{i}_{\substack{e_i^m \neq e_n \\ i\in[1,\ldots,M]}} \mathcal{E}^m(e_i^m)} \Big/ \frac{\mathcal{E}^f(e_n)}{\sum^{j}_{\substack{e_j^f \neq e_n \\ j\in[1,\ldots,F]}} \mathcal{E}^f(e_j^f)} \quad (1)$$

The larger the OR is, the more likely an event will occur in male than female sections by Equation 1. After obtaining a list of events and their corresponding OR, we sort the events by OR in descending order. The top k events are more likely to appear for males and the last k events for females.

Calibration. The difference of event frequencies might come from the model bias, as shown in other tasks (e.g., gender bias in coreference resolution model (Zhao et al., 2018)). To offset the potential confounding that could be brought by the event extraction model and estimate the actual event frequency, we propose a calibration strategy by 1) generating data that contains target events; 2) testing the model performance for females and males separately in the generated data, 3) and using the model performance to estimate real event occurrence frequencies.

We aim to calibrate the top 50 most skewed events in females' and males' *Career* and *Personal Life* descriptions after using the OR separately. First, we follow two steps to generate a synthetic dataset:

1. For each target event, we select all sentences where the model successfully detected the target event. For each sentence, we manually verify the correctness of the extracted event and discard the incorrect ones. For the rest, we use the verified sentences to create more ground truth; we call them *template sentences*.

2. For each template sentence, we find the celebrity's first name and mark it as a `Name Placeholder`, then we replace it with 50 female names and 50 male names that are sampled from the name list by Ribeiro et al. (2020). If the gender changes during the name replacement (e.g., Mike to Emily), we replace the corresponding pronouns (e.g., he to she) and gender attributes (Zhao et al., 2018) (e.g., Mr to Miss) in the template sentences. As a result, we get 100 data points for each template sentence with automatic annotations. If there is no first name in the sentence, we replace the pronouns and gender attributes.

After getting the synthetic data, we run the event extraction model again. We use the detection recall among the generated instances to calibrate the frequency $|e|$ for each target event and estimate the actual frequency $|e|^*$, following:

$$|e|^* = \frac{|e|}{TP(e)/(TP(e)+FP(e))} \quad (2)$$

Then, we replace $|e|$ with $|e|^*$ in Equation 1, and get k female and k male events by sorting OR as before. Note that we observe the model performances are mostly unbiased, and we have only calibrated events that have different performances for females and males over a threshold (i.e., 0.05).[6]

[5]ACE dataset: https://www.ldc.upenn.edu/collaborations/past-projects/ace

[5]We did not show the result for the `artists` and `musicians` due to the small data size.

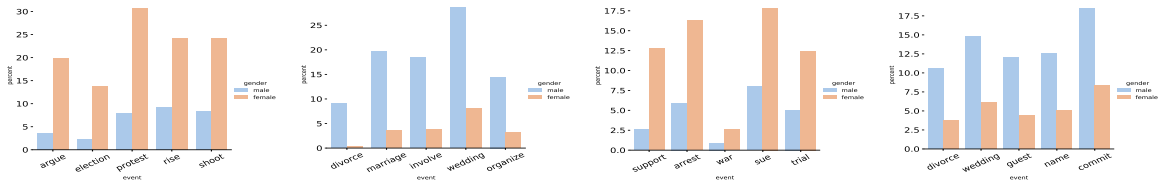
Table 4: Top 5 extracted events that occur more often for females and males in *Career* sections across 8 occupations. We predict event types by applying EventPlus (Ma et al., 2021) on sentences that contain target events and take the majority vote of the predicted types. The event types are from the ACE dataset.[5] We calculate WEAT scores with all tokens excluding stop words (WEAT* column) and only detected events (WEAT column) for *Career* sections.



(a) Male Writers (b) Female Writers (c) Actor (d) Actress

Figure 1: The percentile of extracted events among all detected events, sorted by their frequencies in descending order. The smaller the percentile is, the more frequent the event appears in the text. The extracted events are among the top 10% for the corresponding gender (e.g., extracted female events among all detected events for female writers) and within top 40% percent for the opposite gender (e.g., extracted female events among all detected events for male writers). The figure shows that we are not picking rarely-occurred events, and the result is significant.

WEAT score. We further check if the extracted events are associated with gender attributes (e.g., `she and her` for females, and `he and him` for males) in popular neural word embeddings like Glove (Pennington et al., 2014). We quantify this with the Word Embedding Association Test (WEAT) (Caliskan et al., 2017), a popular method for measuring biases in text. Intuitively, WEAT takes a list of tokens that represent a concept (in our case, *extracted events*) and verifies whether these tokens have a shorter distance towards female attributes or male attributes. A positive value of WEAT score indicates that female events are closer to female attributes, and male events are closer to male attributes in the word embedding, while a negative value indicates that female events are closer to male attributes and vice versa.[7]

To show the effectiveness of using events as a lens for gender bias analysis, we compute WEAT scores on the raw texts and detected events separately. For the former, we take all tokens excluding stop words.[8] Together with gender attributes from Caliskan et al. (2017), we calculate and show the WEAT scores under two settings as "WEAT*" for the raw texts and "WEAT" for the detected events.

4 Results

The Effectiveness of our Analysis Framework. Table 4 and Table 5 show the associations of both raw texts and the extracted events in *Career* and *Personal Life* sections for females and males across occupations after the calibration. The values in WEAT* columns in both tables indicate that there

[7]Details of WEAT score experiment in App. A.4.

[8]We use spaCy (`https://spacy.io/`) to tokenize the corpus and remove stop words.

Table 5: Top 5 events in *Personal Life* section across 6 occupations.[9] There are more `Life` events (e.g., "birth" and "marry") in females' personal life descriptions than males' for most occupations. While for males, although we see more life-related events than in the *Career* section, there are events like "awards" even in the *Personal Life* section. The findings further show our work is imperative and addresses the importance of not intermingling the professional career with personal life regardless of gender during the future editing on Wikipedia.

was only a weak association of words in raw texts with gender. In contrast, the extracted events are associated with gender for most occupations. It shows the effectiveness of the event extraction model and our analysis method.

The Significance of the Analysis Result. There is a possibility that our analysis, although it picks out distinct events for different genders, identifies the events that are infrequent for all genders and that the frequent events have similar distributions across genders. To verify, we sort all detected events from our corpus by frequencies in descending order. Then, we calculate the percentile of extracted events in the sorted list. The smaller the percentile is, the more frequent the event appears in the text. Figure 1 shows that we are not picking the events that rarely occur, which shows the significance of our result.[10] For example, Figure 1a and Figure 1b show the percentile of frequencies for selected male and female events among all events frequencies in the descending order for male and female writers, respectively. We can see that for the corresponding gender, event frequencies are among the top 10%. These events occur less frequently for the opposite gender but still among the top 40%.

Findings and Discussions. We find that there are more `Life` events for females than males in both *Career* and *Personal Life* sections. On the other hand, for males, there are events like "awards" even in their *Personal Life* section. The mixture of personal life with females' professional career events and career achievements with males' personal life events carries implicit gender bias and reinforces the gender stereotype. It potentially leads to career, marital, and parental status discrimination towards genders and jeopardizes gender equality in society. We recommend: 1) Wikipedia editors to restructure pages to ensure that personal life-related events (e.g., marriage and divorce) are written in the *Personal Life* section, and professional events (e.g., award) are written in *Career* sections regardless of gender; 2) future contributors should also be cautious and not intermingle *Personal Life* and *Career* when creating the Wikipedia pages from the start.

[10] See plots for all occupations in Appendix A.5.

5 Conclusion

We conduct the first event-centric gender bias analysis at the corpus level and compose a corpus by scraping Wikipedia to facilitate the study. Our analysis discovers that the collected corpus has event gender biases. For example, personal life related events (e.g., `marriage`) are more likely to appear for females than males even in *Career* sections. We hope our work brings awareness of potential gender biases in knowledge sources such as Wikipedia, and urges Wikipedia editors and contributors to be cautious when contributing to the pages.

Ethical Considerations

Our corpus is collected from Wikipedia. The content of personal life description, career description, and demographic information is all public to the general audience. Note that our collected corpus might be used for malicious purposes. For example, it can serve as a source by text generation tools to generate text highlighting gender stereotypes.

This work is subject to several limitations: First, it is important to understand and analyze the event gender bias for gender minorities, missing from our work because of scarce resources online. Future research can build upon our work, go beyond the binary gender and incorporate more analysis. Second, our study focuses on the Wikipedia pages for celebrities for two additional reasons besides the broad impact of Wikipedia: 1) celebrities' Wikipedia pages are more accessible than non-celebrities. Our collected Wikipedia pages span across 8 occupations to increase the representation of our study; 2) Wikipedia contributors have been extensively updating celebrities' Wikipedia pages every day. Wikipedia develops at a rate of over 1.9 edits every second, performed by editors from all over the world (wik, 2021). The celebrities' pages get more attention and edits, thus better present how the general audience perceives important information and largely reduce the potential biases that could be introduced in personal writings. Please note that although we try to make our study as representative as possible, it cannot represent certain groups or individuals' perceptions.

Our model is trained on TB-Dense, a public dataset coming from news articles. These do not contain any explicit detail that leaks information about a user's name, health, negative financial status, racial or ethnic origin, religious or philosophical affiliation or beliefs, trade union membership, alleged or actual crime commission.

A Appendix

A.1 Quality Check: Event Detection Model

To test the performance of the event extraction model in our collected corpus from Wikipedia. We manually annotated events in 10,508 (female: 5,543, male: 4,965) sampled sentences from the *Career* section in our corpus. Our annotators are two volunteers who are not in the current project but have experience with event detection tasks. We asked annotators to annotate all event trigger words in the text. During annotation, we follow the definition of events from the ACE annotation guideline.[11] We use the manual annotation as the ground truth and compare it with the event detection model output to calculate the metrics (i.e., precision, recall and F1) in Table 3.

A.2 Calibration Details

To offset the potential confounding that could be brought by the event extraction model and estimate the actual event frequency of $|e|^*$, we use the recall for the event e to calibrate the event frequency $|e|$ for females and males separately. Figure 2 shows the calibration result for the 20 most frequent events in our corpus. Please note that Figure 2 (a)-(h) show the quantitative result for extracted events in the *Career* sections across 8 occupations, and Figure 2 (i)-(n) for the *Personal Life* sections.

Example Sentence Substitutions for Calibration. After checking the quality of selected sentences containing the target event trigger, we use 2 steps described in Section 3 *Calibration* to compose a synthetic dataset with word substitutions. Here is an example of using `Name Placeholder`: for target event trigger "married" in `Carole Baskin`'s *Career* section, we have:

> At the age of 17, Baskin worked at a Tampa department store. To make money, she began breeding show cats; she also began rescuing bobcats, and used llamas for a lawn trimming business. In January 1991, she married her second husband and joined his real estate business.

First, we mark the first name Baskin as `Name Placeholder` and find all gender attributes and pronouns which are consistent with the celebrity's gender. Then, we replace Baskin with 50 female names and 50 male names from Ribeiro et al. (2020). If the new name is a male name, we change the corresponding gender attributes (none in this case) and pronouns (e.g., she to he, her to his).

Another example is for the context containing the target event trigger "married" in `Indrani Rahman`'s *Career* section, where there is no first name:

> In 1952, although married, and with a child, she became the first Miss India, and went on to compete in the Miss Universe 1952 Pageant, held at Long Beach, California. Soon, she was travelling along with her mother and performing all over the world...

We replace all pronouns (she to he, her to his) and gender attributes (Miss to Mr).

Interpret the Quantitative Calibration Result. We use the calibration technique to calibrate potential gender biases from the model that could have complicated the analysis. In Figure 2, we can see that there is little gender bias at the model level: the model has the same performance for females and males among most events.

Besides, we notice that the model fails to detect and has a low recall for few events in the generated synthetic dataset. We speculate that this is because of the brittleness in event extraction models triggered by the word substitution. We will leave more fine-grained analysis at the model level for future work. We focus on events for which the model performs largely different for females and males during our calibration. Thus, we select and focus on the events that have different performance for females and males over a threshold, which we take 0.05 during our experiment, to calibrate the analysis result.

A.3 Top Ten Extracted Events

Table 6 and Table 7 show the top 10 events and serves as the supplement of top 5 events that we reported for *Career* and *Personal Life* sections.

A.4 Details for Calculating WEAT Score

The WEAT score is in the range of -2 to 2. A high positive score indicates that extracted events for females are more associated with female attributes in the embedding space. A high negative score means that extracted events for females are more

Chef	death, serve, announce, describe, born, die, life, state, marriage, live	birth, lose, divorce, speak, meet, work, diagnose, wedding, write, engage

Table 7: The top 10 extracted events in *Personal Life* section.

associated with male attributes. To calculate the WEAT score, we input two lists of extracted events for females E_f and males E_m, together with two lists of gender attributes A and B, then calculate:

$$S(E_f, E_m, A, B) = \sum_{e_f \in E_f} s(e_f, A, B) - \sum_{e_m \in E_m} s(e_m, A, B), \tag{3}$$

where

$$s(w, A, B) = \text{mean}_{a \in A} cos(\vec{w}, \vec{a}) - \text{mean}_{b \in B} cos(\vec{w}, \vec{b}). \tag{4}$$

Following Caliskan et al. (2017), we have "female, woman, girl, sister, she, her, hers, daughter" as female attribute list A and "male, man, boy, brother, he, him, his, son" as male attributes list B. To calculate WEAT*, we replace the input lists E_f and E_m with all non-stop words tokens in raw texts from either *Career* section or *Personal Life* section.

A.5 Extracted Events Frequency Distribution

We sort all detected events from our corpus by their frequencies in descending order according to Equation 1. Figure 3 (a)-(l) show the percentile of extracted events in the sorted list for another 6 occupations besides the 2 occupations reported in Figure 1 for *Career* section. The smaller the percentile is, the more frequent the event appears in the text. These figures indicate that we are not picking events that rarely occur and showcase the significance of our analysis result. Figure 3 (m)-(x) are for *Personal Life* sections across 6 occupations, which show the same trend as for *Career* sections.

Abstract

Neural machine translation has achieved great success in bilingual settings, as well as in multilingual settings. With the increase of the number of languages, multilingual systems tend to underperform their bilingual counterparts. Model capacity has been found crucial for massively multilingual NMT to support language pairs with varying typological characteristics. Previous work increases the modeling capacity by deepening or widening the Transformer. However, modeling cardinality based on aggregating a set of transformations with the same topology has been proven more effective than going deeper or wider when increasing capacity. In this paper, we propose to efficiently increase the capacity for multilingual NMT by increasing the cardinality. Unlike previous work which feeds the same input to several transformations and merges their outputs into one, we present a Multi-Input-Multi-Output (MIMO) architecture that allows each transformation of the block to have its own input. We also present a task-aware attention mechanism to learn to selectively utilize individual transformations from a set of transformations for different translation directions. Our model surpasses previous work and establishes a new state-of-the-art on the large scale OPUS-100 corpus while being 1.31 times as fast.

1 Introduction

Multilingual translation between multiple language pairs with a single model (Firat et al., 2016a; Johnson et al., 2017; Aharoni et al., 2019) has some advantages compared to bilingual systems (Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017; Barrault et al., 2020), e.g., easy deployment, enabling transfer learning across languages and zero-shot translation.

Despite their advantages, multilingual systems tend to underperform their bilingual counterparts as the number of languages increases (Johnson et al., 2017; Aharoni et al., 2019). This is due to the fact that multilingual NMT must distribute its modeling capacity over different translation directions. Zhang et al. (2020) show that the model capacity is crucial for massively multilingual NMT to support language pairs with varying typological characteristics, and propose to increase the modeling capacity by deepening the Transformer.

However, compared to going deeper or wider, modeling cardinality based on aggregating a set of transformations with the same topology has been proven more effective when we increase the model capacity (Xie et al., 2017). In this paper, we efficiently increase the capacity of the multilingual NMT model by increasing the cardinality, i.e. stacking sub-layers that aggregate a set of transformations with the same topology.

Our main contributions are as follows:

- We propose to efficiently increase the capacity of the multilingual NMT model by increasing cardinality, and present a novel MIMO design that allows transformations in the subsequent layer to take different outputs from the current layer as their inputs, unlike previous studies (Xie et al., 2017; Yan et al., 2020) which feed the same input to several transformations and merge their outputs into one;
- We propose to learn a task-aware attention mechanism for the MIMO transformation, allowing the model to weigh different transformations of the set differently for specific translation directions;
- In our experiments on the OPUS-100 corpus, our approach outperforms previous work and

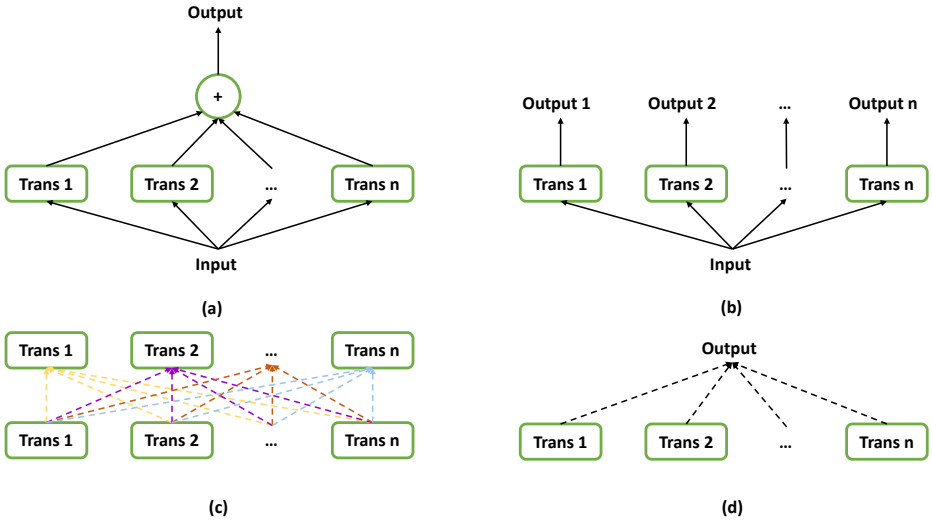

Figure 1: Block transformations. (a) takes the same input into a set of transformations, and adds up their outputs as the output of the block. (b) takes the same input and processes it with these transformations without merging their outputs. (c) is the MIMO architecture that combines weighted outputs of these transformations as inputs to the subsequent transformation set. (d) combines weighted outputs of these transformations into one. Dashed arrows indicate learned attention probabilities. Each "Trans" is a sub-layer that runs in the order of: transforming $\rightarrow$ dropout $\rightarrow$ residual connection $\rightarrow$ layer normalization, where the transforming unit can be either multi-head attention or FFN, as depicted in Figure 2. We aggregate the final output of layer normalization of each "Trans" in the block into the input fed to the next block in different ways (i.e., (a)-(d)).

achieves a new state-of-the-art while being 1.31 times as fast.

2 Preliminaries

Zhang et al. (2020) overcome the capacity bottleneck of multilingual NMT via deepening NMT architectures.

Xie et al. (2017) present a highly modularized network architecture for image classification. The network is constructed by repeating a building block that aggregates a set of transformations with the same topology. For a given input i, the block adopts n networks of the same topology $trans$ to process i and merges their outputs into the final output o of the layer:

$$o = \sum_{k=1}^{n} trans_k(i) \quad (1)$$

This design strategy exposes a new dimension, namely "cardinality" (the size of the set of transformations), as an essential factor in addition to the dimensions of depth and width. Xie et al. (2017) empirically show that increasing cardinality is more effective than going deeper or wider when we increase the capacity to improve classification accuracy.

Yan et al. (2020) present a multi-unit Transformer to efficiently improve the translation performance by increasing cardinality instead of depth. However, their work implements stacks of *input* $\rightarrow$ *performing multiple transformations* $\rightarrow$ *merging* blocks (as illustrated in Figure 1 (a)), is developed for bilingual sentence-level transformation, and requires the additional design of a biasing module and sequential dependency that guide and encourage complementariness among different units. By contrast, our work aims at efficiently increasing the capacity for multilingual translation, proposes the MIMO transformation (Figure 1 (c)) between stacked blocks, and naturally uses the translation task in attention form to guide individual transformations of the set to learn different representations for different translation directions.

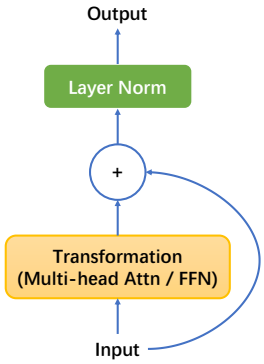

Figure 2: The "Trans" unit.

3 Our Approach

3.1 Multi-Input-Multi-Output (MIMO) Transformation

In contrast to previous approaches (Xie et al., 2017; Yan et al., 2020) that follow a stack of transformation-merging procedures (Figure 1 (a)) to increase cardinality, in our approach we allow our set of transformations to take different inputs. Compared to using the same input, this may encourage transformations to learn complementary representations. Furthermore, merging the outputs of different transformations into one is likely to incur information loss. This is avoided in our approach.

We employ a MIMO transformation between stacked layers (Figure 1 (c)) to enable each transformation of the block to selectively learn to operate on its own unique input.

Specifically, we keep n outputs of the set of transformations to produce multiple inputs for the next layer instead of merging them into one. The input i_k^j to the kth transformation of the jth layer $trans_k^j$ is a weighted accumulation of the outputs o^{j-1} of the layer $j-1$.

$$i_k^j = \sum_{m=1}^{n} p_m^j * o_m^{j-1} \tag{2}$$

where p_m^j are softmax-normalized learnable parameters to model translation task-aware attention for multilingual NMT described in Section 3.2.

o_k^j is produced by $trans_k^j$ with i_k^j as its input:

$$o_k^j = trans_k^j(i_k^j) \tag{3}$$

In the case of a Transformer for multilingual NMT, $trans_k^j$ can be either the multi-head attention or the feed-forward neural network. We adopt a one-to-many transformation (Figure 1 (b)) for the self-attention layer in the first encoder/decoder layer to project one input from the embedding layer to multiple inputs to subsequent layers, and perform a many-to-one transformation (Figure 1 (d)) with the outputs of the feed-forward layer of the last decoder layer to build a single input for the classifier.

3.2 Task-Aware Attention

Rather than separating the multilingual NMT model into 2 parts: 1) the shared part for all language pairs trained on the full dataset; 2) the language isolated part which will only be activated in the corresponding translation task and trained on the part of the whole dataset specifically for the language, we compute all transformations of each block regardless of the translation task, thus all model parameters can utilize and benefit from the whole training set. At the same time, we introduce a task-aware attention mechanism to utilize different transformations of the block differently for specific translation directions.

Specifically, we learn an embedding v for each translation direction (i.e., to X (e.g., en, zh, de)) for each transformation to weightedly aggregate multiple outputs of the block below. v is first normalized into a probability p:

$$p = \mathrm{softmax}(v) \tag{4}$$

Next, p is used in Equation 2 for weighted aggregation. p is expected to assign a higher weight to corresponding transformations of the block which are more important for the translation direction.

3.3 Discussion

Increasing model capacity via increasing cardinality is more efficient than deepening a model or widening it (Xie et al., 2017; Yan et al., 2020). Compared to widening a model, increasing cardinality removes connections between hidden units and reduces both parameters and computation. Compared to deepening a model, increasing cardinality allows to parallelize the computation of all transformations of a set, accelerating both training and decoding.

4 Experiments

4.1 Settings

We conducted our experiments on the challenging massively many-to-many translation task on the OPUS-100 corpus (Tiedemann, 2012; Aharoni et al., 2019; Zhang et al., 2020). We followed Zhang et al. (2020) for experiment settings. We implemented our approaches based on the Neutron implementation (Xu and Liu, 2019) of the Transformer translation model. Parameters were initialized under the Lipschitz constraint (Xu et al., 2020). We adopted BLEU (Papineni et al., 2002) for translation evaluation with the SacreBLEU toolkit (Post, 2018).[1] We report average BLEU over 94 language pairs BLEU_{94}, win ratio WR (%) compared

to Zhang et al. (2020), average BLEU over 4 selected typologically different target languages (de, zh, br, te) $BLEU_4$, and average BLEU for zero-shot translation $BLEU_{zero}$.

4.2 Main Results

For fair comparison, we use a 6-layer model where each attention/FFN block contains 4 transformations, which leads to a similar number of parameters compared to the 24-layer model of Zhang et al. (2020). Results are shown in Table 1.

Table 1 shows that our approach achieves better performance in all evaluations while being 1.31 times as fast.

4.3 Ablation Study

We study removing MIMO transformations and task-aware attention. Results are shown in Table 2.

Table 2 verifies that both mechanisms contribute to the performance.

We also examine different combinations of depth and cardinality. Results are shown in Table 3.

Table 3 shows that using 6 layers with 4 transformations in each block leads to the best performance.

Table 4: Languages with similar task-aware attention weights.

4.4 Task-Aware Attention Weight Analysis

To verify whether task-aware attention learns to aggregate similar languages together, we extract the learned task-aware attention probabilities, flatten them into vectors, and select the languages with the top-5 cosine similarity. Results for several languages are shown in Table 4.

Table 4 shows that close languages are aggregated together.

5 Related Work

Multilingual NMT includes one-to-many (Dong et al., 2015), many-to-many (Firat et al., 2016a) and zero-shot (Firat et al., 2016b) scenarios. A simple solution is to insert a target language token at the beginning of the input sentence (Johnson et al., 2017).

Multilingual NMT has to handle different languages in one joint representation space, neglecting their linguistic diversity, especially for massively multilingual NMT (Aharoni et al., 2019; Zhang et al., 2020; Freitag and Firat, 2020). Most studies focus on how to mitigate this representation bottleneck (Zoph and Knight, 2016; Blackwood et al., 2018; Wang et al., 2018; Platanios et al., 2018; Wang et al., 2019a; Tan et al., 2019b; Wang et al., 2019b; Tan et al., 2019a; Bapna and Firat, 2019; Zhu et al., 2020; Lyu et al., 2020).

There are also studies on the trade-off between

shared and language-specific parameters (Sachan and Neubig, 2018; Zhang et al., 2021), on the training of multilingual NMT (Al-Shedivat and Parikh, 2019; Siddhant et al., 2020; Wang et al., 2020b,a), and on analyzing translations from multilingual NMT (Lakew et al., 2018) or the trained model (Kudugunta et al., 2019; Oncevay et al., 2020). Transferring a pre-trained multilingual NMT model can help improve the performance of downstream language pairs (Kim et al., 2019; Lin et al., 2020), especially for low-resource scenarios (Dabre et al., 2019). Multilingual data also has been proven useful for unsupervised NMT (Sen et al., 2019; Sun et al., 2020).

6 Conclusion

We propose to efficiently increase the capacity for multilingual NMT by increasing the cardinality. We present a MIMO architecture that allows each transformation of the block to have its own input. We also present a task-aware attention mechanism to learn to selectively utilize individual transformations from a set of transformations for different translation directions.

Our model surpasses previous work and establishes a new state-of-the-art on the large scale OPUS-100 corpus while being 1.31 times as fast.

Abstract

kNN-MT, recently proposed by Khandelwal et al. (2020a), successfully combines pre-trained neural machine translation (NMT) model with token-level k-nearest-neighbor (kNN) retrieval to improve the translation accuracy. However, the traditional kNN algorithm used in kNN-MT simply retrieves a same number of nearest neighbors for each target token, which may cause prediction errors when the retrieved neighbors include noises. In this paper, we propose Adaptive kNN-MT to dynamically determine the number of k for each target token. We achieve this by introducing a light-weight *Meta-k Network*, which can be efficiently trained with only a few training samples. On four benchmark machine translation datasets, we demonstrate that the proposed method is able to effectively filter out the noises in retrieval results and significantly outperforms the vanilla kNN-MT model. Even more noteworthy is that the Meta-k Network learned on one domain could be directly applied to other domains and obtain consistent improvements, illustrating the generality of our method. Our implementation is open-sourced at https://github.com/zhengxxn/adaptive-knn-mt.

1 Introduction

Retrieval-based methods (Gu et al., 2018; Zhang et al., 2018; Bapna and Firat, 2019; Khandelwal et al., 2020a) are increasingly receiving attentions from the machine translation (MT) community recently. These approaches complement advanced neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017; Hassan et al., 2018) to alleviate the performance degradation when translating out-of-domain sentences (Dou et al., 2019; Wei et al., 2020), rare words (Koehn and Knowles, 2017), etc. The ability of accessing any provided datastore during translation makes them scalable, adaptable and interpretable.

kNN-MT, recently proposed in (Khandelwal et al., 2020a), equips a pre-trained NMT model with a kNN classifier over a datastore of cached context representations and corresponding target tokens, providing a simple yet effective strategy to utilize cached contextual information in inference. However, the hyper-parameter k is fixed for all cases, which raises some potential problems. Intuitively, the retrieved neighbors may include noises when the target token is relatively hard to determine (e.g., relevant context is not enough in the datastore). And empirically, we find that the translation quality is very sensitive to the choice of k, results in the poor robustness and generalization performance.

To tackle this problem, we propose Adaptive kNN-MT that determines the choice of k regarding each target token adaptively. Specifically, instead of utilizing a fixed k, we consider a set of possible k that are smaller than an upper bound K. Then, given the retrieval results of the current target token, we propose a light-weight *Meta-k Network* to estimate the importance of all possible k-Nearest Neighbor results, based on which they are aggregated to obtain the final decision of the model. In this way, our method dynamically evaluate and utilize the neighbor information conditioned on different target tokens, therefore improve the translation performance of the model.

We conduct experiments on multi-domain machine translation datasets. Across four domains, our approach can achieve 1.44$\sim$2.97 BLEU score improvements over the vanilla kNN-MT on average when $K \geq 4$. The introduced light-weight Meta-k Network only requires thousands of parameters and can be easily trained with a few training samples. In addition, we find that the Meta-k Net-

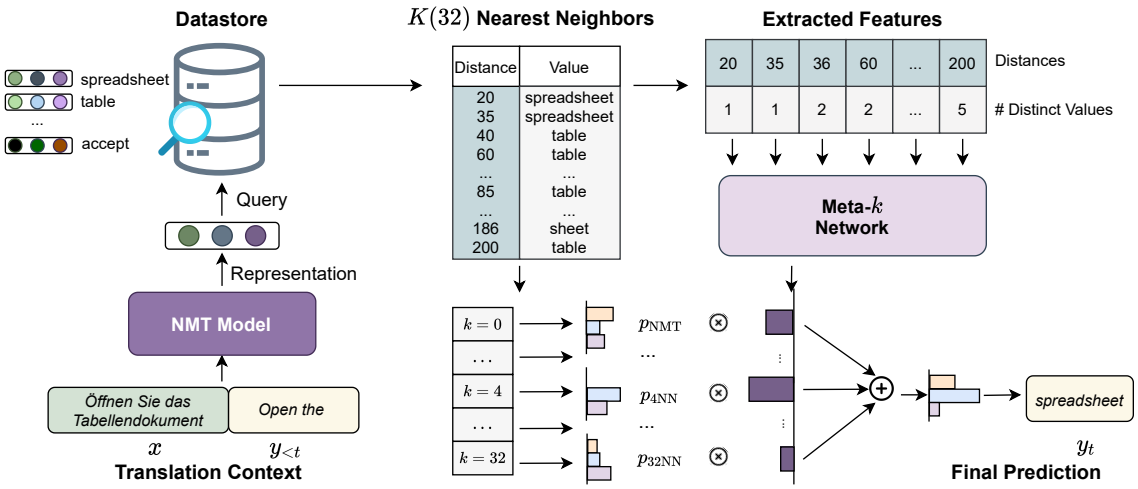

Figure 1: An overview of the proposed Adaptive kNN-MT, which could dynamically evaluate and aggregate a set of kNN predictions based on the distances as well as count of distinct values of retrieved neighbors.

work trained on one domain can be directly applied to other domains and obtain strong performance, showing the generality and robustness of the proposed method.

2 Background: kNN-MT

In this section, we will briefly introduce the background of kNN-MT, which includes two steps: creating a datastore and making predictions depends on it.

Datastore Creation. The datastore consists of a set of key-value pairs. Formally, given a bilingual sentence pair in the training set $(x, y) \in (\mathcal{X}, \mathcal{Y})$, a pre-trained autoregressive NMT decoder translates the t-th target token y_t based on the translation context $(x, y_{<t})$. Denote the hidden representations of translation contexts as $f(x, y_{<t})$, then the datastore is constructed by taking $f(x, y_{<t})$ as keys and y_t as values,

$$(\mathcal{K}, \mathcal{V}) = \bigcup_{(x,y)\in(\mathcal{X},\mathcal{Y})} \{(f(x, y_{<t}), y_t), \forall y_t \in y\}.$$

Therefore, the datastore can be created through a single forward pass over the training set $(\mathcal{X}, \mathcal{Y})$.

Prediction. While inference, at each decoding step t, the kNN-MT model aims to predict $\hat{y}_t$ given the already generated tokens $\hat{y}_{<t}$ as well as the context representation $f(x, \hat{y}_{<t})$, which is utilized to query the datastore for k nearest neighbors w.r.t the l_2 distance. Denote the retrieved neighbors as $N^t = \{(h_i, v_i), i \in \{1, 2, ..., k\}\}$, their distribution over the vocabulary is computed as:

$$p_{\text{kNN}}(y_t|x, \hat{y}_{<t}) \propto \sum_{(h_i,v_i)} \mathbb{1}_{y_t=v_i} \exp\left(\frac{-d(h_i, f(x, \hat{y}_{<t}))}{T}\right), \quad (1)$$

where T is the temperature and $d(\cdot, \cdot)$ indicates the l_2 distance. The final probability when predicting y_t is calculated as the interpolation of two distributions with a hyper-parameter λ:

$$p(y_t|x, \hat{y}_{<t}) = \lambda\, p_{\text{kNN}}(y_t|x, \hat{y}_{<t}) + (1 - \lambda)\, p_{\text{NMT}}(y_t|x, \hat{y}_{<t}), \quad (2)$$

where p_{NMT} indicates the vanilla NMT prediction.

3 Adaptive kNN-MT

The vanilla kNN-MT method utilizes a fixed number of translation contexts for every target token, which fails to exclude noises contained in retrieved neighbors when there are not enough relevant items in the datastore. We show an example with $k = 32$ in Figure 1. The correct prediction *spreadsheet* has been retrieved as top candidates. However, the model will finally predict *table* instead because it appears more frequently in the datastore than the correct prediction. A naive way to filter the noises is to use a small k, but this will also cause over-fitting problems for other cases. In fact, the optimal choice of k varies when utilizing different datastores in vanilla kNN-MT, leading to poor robustness and generalizability of the method, which is empirically discussed in Section 4.2.

To tackle this problem, we propose a dynamic method that allows each untranslated token to utilize different numbers of neighbors. Specifically,

we consider a set of possible ks that are smaller than an upper bound K, and introduce a light-weight *Meta-k Network* to estimate the importance of utilizing different ks. Practically, we consider the powers of 2 as the choices of k for simplicity, as well as $k = 0$ which indicates ignoring kNN and only utilizing the NMT model, i.e., $k \in \mathcal{S}$ where $\mathcal{S} = \{0\} \cup \{k_i \in \mathbb{N} \mid \log_2 k_i \in \mathbb{N}, k_i \leq K\}$. Then the Meta-$k$ Network evaluates the probability of different kNN results by taking retrieved neighbors as inputs.

Concretely, at the t-th decoding step, we first retrieve K neighbors N^t from the datastore, and for each neighbor (h_i, v_i), we calculate its distance from the current context representation $d_i = d(h_i, f(x, \hat{y}_{<t}))$, as well as the count of distinct values in top i neighbors c_i. Denote $d = (d_1, ..., d_K)$ as distances and $c = (c_1, ..., c_K)$ as counts of values for all retrieved neighbors, we then concatenate them as the input features to the Meta-k Network. The reasons of doing so are two-fold. Intuitively, the distance of each neighbor is the most direct evidence when evaluating their importance. In addition, the value distribution of retrieved results is also crucial for making the decision, i.e., if the values of each retrieved results are distinct, then the kNN predictions are less credible and we should depend more on NMT predictions.

We construct the Meta-k Network $f_{\text{Meta}}(\cdot)$ as two feed-forward Networks with non-linearity between them. Given $[d; c]$ as input, the probability of applying each kNN results is computed as:

$$p_{\text{Meta}}(k) = \text{softmax}(f_{\text{Meta}}([d; c])). \quad (3)$$

Prediction. Instead of introducing the hyper-parameter λ as Equation (2), we aggregate the NMT model and different kNN predictions with the output of the Meta-k Network to obtain the final prediction:

$$p(y_t|x, \hat{y}_{<t}) = \sum_{k_i \in \mathcal{S}} p_{\text{Meta}}(k_i) \cdot p_{k_i\text{NN}}(y_t|x, \hat{y}_{<t}), \quad (4)$$

where $p_{k_i\text{NN}}$ indicates the k_i Nearest Neighbor prediction results calculated as Equation (1).

Training. We fix the pre-trained NMT model and only optimize the Meta-k Network by minimizing the cross entropy loss following Equation (4), which could be very efficient by only utilizing hundreds of training samples.

4 Experiments

4.1 Experimental Setup

We evaluate the proposed model in domain adaptation machine translation tasks, in which a pre-trained general-domain NMT model is used to translate domain-specific sentences with kNN searching over an in-domain datastore. This is the most appealing application of kNN-MT as it could achieve comparable results with an in-domain NMT model but without training on any in-domain data. We denote the proposed model as Adaptive kNN-MT (A) and compare it with two baselines. One of that is vanilla kNN-MT (V) and the other is uniform kNN-MT (U) where we set equal confidence for each kNN prediction.

Datasets and Evaluation Metric. We use the same multi-domain dataset as the baseline (Khandelwal et al., 2020a), and consider domains including **IT**, **Medical**, **Koran**, and **Law** in our experiments. The sentence statistics of datasets are illustrated in Table 1. The Moses toolkit[1] is used to tokenize the sentences and split the words into subword units (Sennrich et al., 2016) with the bpe-codes provided by Ng et al. (2019). We use SacreBLEU[2] to measure all results with case-sensitive detokenized BLEU (Papineni et al., 2002).

Dataset	IT	Medical	Koran	Laws

Test	2000	2000	2000	2000

Table 1: Statistics of dataset in different domains.

Implementation Details. We adopt the fairseq toolkit[3](Ott et al., 2019) and faiss[4](Johnson et al., 2017) to replicate kNN-MT and implement our model. We apply the WMT'19 German-English news translation task winner model (Ng et al., 2019) as the pre-trained NMT model which is also used by Khandelwal et al. (2020a). For kNN-MT, we carefully tune the hyper-parameter λ in Equation (2) and report the best scores for each domain. More details are included in the supplementary materials. For our method, the hidden size of the two-layer FFN in Meta-k Network is set to 32. We

directly use the dev set (about 2k sents) to train the Meta-k Network for about 5k steps. We use Adam (Kingma and Ba, 2015) to optimize our model, the learning rate is set to 3e-4 and batch size is set to 32 sentences.

4.2 Main Results

The experimental results are listed in Table 2. We can observe that the proposed Adaptive kNN-MT significantly outperforms the vanilla kNN-MT on all domains, illustrating the benefits of dynamically determining and utilizing the neighbor information for each target token. In addition, the performance of the vanilla model is sensitive to the choice of K, while our proposed model is more robust with smaller variance. More specifically, our model achieves better results when choosing larger number of neighbors, while the vanilla model suffers from the performance degradation when $K = 32$, indicating that the proposed Meta-k Network is able to effectively evaluate and filter the noise in retrieved neighbors, while a fixed K cannot. We also compare our proposed method with another naive baseline, uniform kNN-MT, where we set equal confidence for each kNN prediction and make it close to the vanilla kNN-MT with small k. It further demonstrates that our method could really learn something useful but not bias smaller k.

Generality. To demonstrate the generality of our method, we directly utilize the Meta-k Network trained on the IT domain to evaluate other domains. For example, we use the Meta-k Network trained on IT domain and medical datastore to evaluate the performance on medical test set. For comparison, we collect the in-domain results from Table 2. We set $K = 32$ for both settings. As shown in Table 3, the Meta-k Network trained on the IT domain achieves comparable performance on all other domains which re-train the Meta-k Network with in-domain dataset. These results also indicate that the mapping from our designed feature to the confidence of retrieved neighbors is common across different domains.

Robustness. We also evaluate the robustness of our method in the domain-mismatch setting, where we consider a scenario that the user inputs an out-of-domain sentence (e.g. IT domain) to a domain-specific translation system (e.g. medical domain) to evaluate the robustness of different methods. Specifically, in IT ⇒ Medical setting, we firstly use medical dev set and datastore to tune hyper-parameter for vanilla kNN-MT or train the Meta-k Network for Adaptive kNN-MT, and then use IT test set to test the model with medical datastore. We set $K = 32$ in this experiment. As shown in Table 4, the retrieved results are highly noisy so that the vanilla kNN-MT encounters drastic performance degradation. In contrast, our method could effectively filter out noises and therefore prevent performance degradation as much as possible.

Case Study. Table 5 shows a translation example selected from the test set in **Medical** domain with

- distance feature	45.60

Table 6: Effect of different features in Meta-k Network.

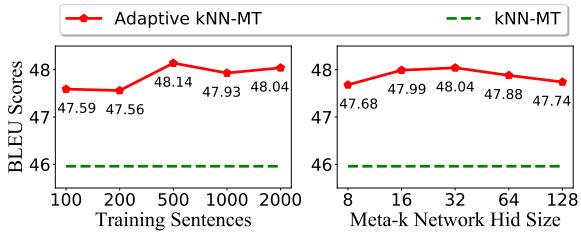

Figure 2: Effect of different number of training sentences and the hidden size of Meta-k Network.

$K = 32$. We can observe that the Meta-k Network could determine the choice of k for each target token respectively, based on which Adaptive kNN-MT leverages in-domain datastore better to achieve proper word selection and language style.

Analysis. Finally, we study the effect of two designed features, number of training sentences and the hidden size of the proposed Meta-k Network. We conduct these ablation study on IT domain with $K = 8$. All experimental results are summarized in Table 6 and Figure 2. It's obvious that both of the two features contribute significantly to the excellent performance of our model, in which the distance feature is more important. And surprisingly, our model could outperforms the vanilla kNN-MT with only 100 training sentences, or with a hidden size of 8 that only contains around 0.6k parameters, showing the efficiency of our model.

5 Conclusion and Future Works

In this paper, we propose Adaptive kNN-MT model to dynamically determine the utilization of retrieved neighbors for each target token, by introducing a light-weight *Meta-k Network*. In the experiments, on the domain adaptation machine translation tasks, we demonstrate that our model is able to effectively filter the noises in retrieved neighbors and significantly outperform the vanilla kNN-MT baseline. In addition, the superiority of our method on generality and robustness is also verified. In the future, we plan to extend our method to other tasks like Language Modeling, Question Answering, etc, which can also benefit from utilizing kNN searching (Khandelwal et al., 2020b; Kassner and Schütze, 2020).

A Appendix

A.1 Datastore Creation

We first use numpy array to save the key-value pairs over training sets as datastore. Then, faiss is used to build index for each datastore to carry out fast nearest neighbor search. We utilize faiss to learn $4k$ cluster centroids for each domain, and search 32 clusters for each target token in decoding. The size of datastore (count of target tokens), and hard disk space of datastore as well as faiss index are shown in Table 7.

A.2 Hyper-Parameter Tuning for kNN-MT

The performance of vanilla kNN-MT is highly related to the choice of hyper-parameter, i.e. k, T and λ. We fix T as 10 for IT, Medical, Law, and 100 for Koran in all experiments. Then, we tuned k and λ for each domain when using kNN-MT and the optimal choice for each domain are shown in Table 9. The performance of kNN-MT is unstable with different hyper-parameters while our Adaptive kNN-MT avoids this problem.

Dataset	IT	Medical	Koran	Laws
k	8	4	16	4
T	10	10	10	100
λ	0.7	0.8	0.8	0.8

Table 9: Optimal choice of hyper-parameters for each domain in vanilla kNN-MT.

A.3 Decoding Time

We compare the decoding time on IT test set of NMT, kNN-MT (our replicated) and Adaptive kNN-MT condition on different batch size. In decoding, the beam size is set to 4 with length penalty 0.6. The results are summarized in Table 8.

On Orthogonality Constraints for Transformers

Abstract

Orthogonality constraints encourage matrices to be orthogonal for numerical stability. These plug-and-play constraints, which can be conveniently incorporated into model training, have been studied for popular architectures in natural language processing, such as convolutional neural networks and recurrent neural networks. However, a dedicated study on such constraints for transformers has been absent. To fill this gap, this paper studies orthogonality constraints for transformers, showing the effectiveness with empirical evidence from ten machine translation tasks and two dialogue generation tasks. For example, on the large-scale WMT'16 En→De benchmark, simply plugging-and-playing orthogonality constraints on the original transformer model (Vaswani et al., 2017) increases the BLEU from 28.4 to 29.6, coming close to the 29.7 BLEU achieved by the very competitive dynamic convolution (Wu et al., 2019).

1 Introduction

Transformers (Vaswani et al., 2017) are a class of neural architectures that have made a tremendous transformative impact on modern natural language processing research and applications. Transformers have not only served as a powerful inductive bias for general-purpose sequence transduction (Ott et al., 2018) but also lived as the core of large pre-trained language models (Devlin et al., 2018; Radford et al., 2018; Dai et al., 2019). That said, the study of more effective training for this class of models is still an open research question, bearing great potential to impact a myriad of applications and domains.

To improve numerical stability during training, the trick of enforcing orthogonality constraints has surfaced recently. In the analysis of numerical stability, enforcing orthogonality constraints can upper-bound the Lipschitz constant of linear transformations. The Lipschitz constant is a measure that approximates the rate of change (variation) of representations. Theoretically, controlling the Lipschitz constant, which may be achieved via orthogonality constraints, yields representations that are robust and less sensitive to perturbations.

In view of this, orthogonality constraints have been studied for convolutional neural networks (CNNs) (Bansal et al., 2018; Huang et al., 2018) and recurrent neural networks (RNNs) (Arjovsky et al., 2016; Vorontsov et al., 2017; Rodríguez et al., 2016). Such plug-and-play constraints can be incorporated into model training without additional hassle. For example, CNN-based models incorporating orthogonality constraints have demonstrated empirical effectiveness for tasks such as person re-identification (Han et al., 2019) and keyword spotting (Lee et al., 2019), while RNN-based models that enforce such constraints have shown promising empirical results for response generation (Tao et al., 2018) and text classification (Wei et al., 2020; Krishnan et al., 2020). However, a dedicated study on orthogonality constraints for transformers has been absent so far.

To fill this research gap, we study orthogonality constraints for transformers, which are imposed on (i) linear transformations in self-attention and position-wise feed-forward networks and (ii) the affinity matrix in self-attention. Mathematically, orthogonality constraints on the weights of these linear transformations can be motivated by bounded Lipschitz constants. We also formally analyze the self-attention mechanism by bounding perturbations to the affinity matrix in the face of input changes.

Furthermore, we conduct extensive experiments on ten neural machine translation (both subword-

level and character-level) tasks and two dialogue generation tasks. Our experimental results are promising, demonstrating that the performance of transformers can be consistently boosted with orthogonality constraints. For example, on the large-scale WMT'16 En→De benchmark, simply plugging-and-playing orthogonality constraints on the original transformer model (Vaswani et al., 2017) increases the BLEU from 28.4 to 29.6, coming close to the 29.7 BLEU achieved by the very competitive dynamic convolution (Wu et al., 2019).

Notation For any vector $\mathbf{x}$ and any matrix $\mathbf{X}$, $\|\mathbf{x}\|$ and $\|\mathbf{X}\|$ denote their L_2-norm and spectral norm, respectively.

2 Orthogonality Constraints for Transformers

Recall that in the transformer architecture, keys, queries, and values all come from the same place in the self-attention module. They are linearly transformed for computing multiple attention heads, where all the heads are aggregated by another linear transformation. The position-wise feed-forward network is also built on two linear transformations with activations. In the following, we will describe orthogonality constraints for (i) linear transformations in self-attention and position-wise feed-forward networks and (ii) the affinity matrix in self-attention.

2.1 For Linear Transformations in Self-Attention and Position-wise Feed-Forward Networks

Note that linear transformations in self-attention and position-wise feed-forward networks are in the form:

$$\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{b},$$

where $\mathbf{y}$ is the output, $\mathbf{x}$ is an input, $\mathbf{W}$ is a linear transformation weight matrix, and $\mathbf{b}$ is an optional bias term. This form provides us with convenient tools for motivating the application of orthogonality constraints to the weights of such linear transformations.

Specifically, as described in Section 1, robustness of linear transformations to small perturbations can be measured by Lipschitz constants. Thus, we begin with motivating orthogonality constraints from the perspective of bounding Lipschitz constants of linear transformations.

Formally, the linear transformation (layer) of the aforementioned form $\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{b}$ has a Lipschitz constant equal to the largest singular value of the weight matrix $\mathbf{W}$. The linear layer is Lipschitz continuous with the constant L if for all $\mathbf{x}$ and $\mathbf{x}'$, it holds that

$$\|(\mathbf{W}\mathbf{x} + \mathbf{b}) - (\mathbf{W}\mathbf{x}' + \mathbf{b})\| \leq L\|\mathbf{x} - \mathbf{x}'\|,$$

which can be re-written as

$$\frac{\|\mathbf{W}(\mathbf{x} - \mathbf{x}')\|}{\|\mathbf{x} - \mathbf{x}'\|} \leq L,$$

where $\mathbf{x} \neq \mathbf{x}'$. Therefore, the smallest Lipschitz constant is

$$\sup_{\mathbf{x} \neq \mathbf{x}'} \frac{\|\mathbf{W}(\mathbf{x} - \mathbf{x}')\|}{\|\mathbf{x} - \mathbf{x}'\|}.$$

For numerical stability, our goal is to force the Lipschitz constant to be no greater than one at every linear transformation so that their multiplication throughout compositions of transformations is also upper bounded by one. Mathematically, we need to constrain the Lipschitz constant (the largest singular value) of $\mathbf{W}$ to be no greater than one, which requires the following orthogonality constraint:

$$\mathbf{W}^\top \mathbf{W} \approx \mathbf{I}.$$

Back to the context of multi-head self-attention of transformers, denote by $\mathbf{P}$ the concatenation of the linear transformation weights for the query, key, value, and the multi-head aggregation. To impose the orthogonality constraint for these linear transformations, we add the following loss to the transformer model for every layer:

$$L_{\text{LA}} = \lambda \|\mathbf{P}^\top \mathbf{P} - \mathbf{I}\|_F^2.$$

Likewise, for position-wise feed-forward network with two linear transformation weight matrices $\mathbf{M}_1$ and $\mathbf{M}_2$, the orthogonality constraint can be imposed with another additional loss:

$$L_{\text{LF}} = \lambda \left[\|\mathbf{M}_1^\top \mathbf{M}_1 - \mathbf{I}\|_F^2 + \|\mathbf{M}_2^\top \mathbf{M}_2 - \mathbf{I}\|_F^2 \right].$$

2.2 For the Affinity Matrix in Self-Attention

In transformers, given the query matrix $\mathbf{Q}$ and the key matrix $\mathbf{K}$ in the self-attention module, the affinity matrix

$$\mathbf{A} = \text{softmax}(\alpha \mathbf{Q}\mathbf{K}^\top), \tag{1}$$

where α is typically $\frac{1}{\sqrt{d}}$ (d is the dimension of the key and the query). Given the value matrix $\mathbf{V}$, the self-attention computes representations via the matrix multiplication $\mathbf{AV}$.

Within the context of sequence transduction, when an input word token is aligned with another semantically similar token, we would expect a small change in the behavior of the self-attention mechanism, rather than a huge change in the output. In the affinity matrix $\mathbf{A}$ as defined in (1), let $\mathbf{A}_{i,*}$ be the row vector indexed by i. Essentially, each $\mathbf{A}_{i,*}$ is a probability distribution over the tokens in the sequence that directs the alignment-based pooling operation. Intuitively, for a robust self-attention mechanism, noisy perturbations should have a limited effect on the affinity scores of the tokens.

More formally, let us analyze the self-attention mechanism by bounding perturbations to the affinity matrix in the face of input changes. Mathematically, changes to the affinity scores are bounded such that $\|\mathbf{A}'_{i,*} - \mathbf{A}_{i,*}\| \leq 2\alpha\|\mathbf{K}\|\epsilon$, where $\epsilon = \|\mathbf{Q}'_{i,*} - \mathbf{Q}_{i,*}\|$ is the noise from the query matrix. We can see this as the result of the following theorem.

Theorem 2.1 (Bounded Perturbations to the Affinity Matrix)**.** *Expressing $\mathbf{A}_{i,*}$ to be the i^{th} row of the affinity matrix $\mathbf{A}$ as defined in (1) and $\mathbf{Q}_{i,*}$ to be the i^{th} row of the query matrix $\mathbf{Q}$, the perturbation to the affinity matrix is bounded as such:*

$$\|\mathbf{A}'_{i,*} - \mathbf{A}_{i,*}\| \leq 2\alpha\|\mathbf{K}\|\epsilon,$$

where $\mathbf{A}' = softmax(\alpha\mathbf{Q}'\mathbf{K}^\top)$ and $\epsilon = \|\mathbf{Q}'_{i,*} - \mathbf{Q}_{i,*}\|$ is the L_2 perturbation value in $\mathbf{Q}_{i,*}$.

The detailed proof of Theorem 2.1 is provided in the appendix. In standard training, the spectral norm of the key matrix $\|\mathbf{K}\|$ or the noise ϵ from the query matrix may be large, and as a result the changes to affinity scores may become "unbounded". We speculate that this may hurt the generalization of the self-attention mechanism.

We impose orthogonality constraints on the affinity matrix $\mathbf{A}$. More concretely, we obtain an additional loss term for every layer of the transformer model using the Frobenius norm $\|\cdot\|_F$:

$$L_{\text{AM}} = \lambda\|\mathbf{A}^\top\mathbf{A} - \mathbf{I}\|_F^2,$$

where $\mathbf{I}$ is the identity matrix and λ is a scaling factor to control the ratio to the original task loss.

With orthogonally constrained affinity scores, each row vector of $\mathbf{A}$ is now orthonormal to all the other row vectors. Given that each row vector is a probability distribution over the tokens in the sequence that directs the alignment-based pooling operation, a diverse form of the self-attention mechanism would be more encouraged. This could be viewed as an additional quality of orthogonality constrained transformers.

3 Experiments

We evaluate the effectiveness of orthogonality constrained transformers (OC-transformers for brevity) on ten neural machine translation tasks and two dialogue generation tasks. Specifically, we assess three variants, largely pertaining to where orthogonality constraints are applied, i.e., (i) AM (for the affinity matrix in self-attention), (ii) LA (for the linear transformations in self-attention), and (iii) LF (for the linear transformations in position-wise feed-forward networks). We evaluate them in an incremental fashion with three main model labels: VAR-I (AM only), VAR-II (AM + LA), and VAR-III (AM + LA + LF). The scaling factor λ is tuned amongst $\{10^{-6}, 10^{-8}, 10^{-10}\}$.

3.1 Neural Machine Translation

For neural machine translation (NMT), we evaluate on both the subword-level and character-level tasks.

Experimental Setup For subword-level NMT, we evaluate our models on seven NMT datasets using the Tensor2Tensor[1] framework (Vaswani et al., 2018), namely IWSLT'14 De→En, IWSLT'14 Ro→En, IWSLT'15 En→Vi, IWSLT'17 En→Id, WMT'17 En→Et, SETIMES En→Mk, and the well-established large-scale WMT'16 En→De.

All the models are trained with the transformer-base setting. Owing to the smaller size, we use the transformer-small setting for IWSLT'14 datasets. For the WMT'16 En→De dataset, we train both the transformer-base and transformer-big settings on $4\times$ GPUs with gradient accumulation of $2\times$ to emulate $8\times$ GPU training. By determining improvement on approximate BLEU scores on the validation set, we train models for $2M$ steps for the transformer-base setting and $800K$ steps for the transformer-big setting. Note that between the standard transformer and OC-transformer, we maintain all the other hyperparameters to keep the comparisons as fair as possible. For character-level NMT, we evaluate on three language pairs, namely

WMT En→Fr, IWSLT'14 Ro→En, and IWSLT'15 De→En. The transformer-small setting is used for all the three language pairs and trained for $200K$ steps.

Experimental Results Table 1 reports experimental results on subword-level NMT datasets. Overall, we note that performance of transformers is consistently boosted by orthogonality constraints, ascertaining the effectiveness of adopting such plug-and-play tricks. More specifically, they are able to achieve $+1.0\%$ to $+7.3\%$ relative gain over the standard transformer. Notably, all the variants (VAR-I, VAR-II, and VAR-III) boost the performance of transformers: it demonstrates that orthogonality constraints are indeed useful. Moreover, orthogonal constraints on the self-attention affinity matrix are beneficial in general even if the rest of the model is not fully enforced with orthogonality constraints.

Table 2 reports the results on the large-scale WMT'16 En→De dataset. Orthogonality constraints boost the performance of the transformer-big setting based on (Vaswani et al., 2017), increasing the BLEU from 28.4 to 29.6. This result outperforms the more advanced transformer-ott-big proposed in (Ott et al., 2018) and comes close to 29.7 that was achieved by the very competitive dynamic convolution model (Wu et al., 2019). Likewise, orthogonality constraints also boost the performance of the transformer-base setting with the BLEU increased from 27.3 to 28.5.

Table 3 reports the results on character-level NMT. We observe that orthogonality constraints consistently boost the performance of standard transformers on all the three language pairs: En→Fr (+3.5%), Ro→En (+2.6%), and De→En (+1.6%).

3.2 Sequence-to-Sequence Dialogue Generation

We conduct experiments on the sequence-to-sequence dialog generation task whereby the goal is to generate the reply in a two-way conversation.

Experimental Setup We use two datasets: PersonaChat (Zhang et al., 2018) and DailyDialog (Li et al., 2017). We implement our task in Tensor2Tensor using the transformer-small setting in a sequence-to-sequence fashion (Sutskever et al., 2014). We train all the models for $20K$ steps, which we find sufficient for model convergence. Beam search of beam size 4 and length penalty 0.6 is adopted for decoding the output sequence. We evaluate all the models with the language generation evaluation suite in (Sharma et al., 2017).

Experimental Results Table 4 reports our results on the PersonaChat and DailyDialog datasets. The key observation is that all the variants of enforcing orthogonality constraints boost performance of standard transformers. The best results of OC-transformers make a substantial improvement in all

	DailyDialog				
BLEU-1	12.1	13.5	13.3	**14.0**	+15.7%
BLEU-4	6.22	6.70	6.52	**7.11**	+14.3%
Meteor	8.23	8.43	8.39	**8.72**	+6.0%
Rouge	21.1	21.4	**21.7**	**21.7**	+2.8%
CIDEr	79.3	79.2	79.6	**82.1**	+3.5%
SkipT	66.9	67.1	67.1	**67.2**	+0.4%
EmbA	84.9	**85.7**	85.6	85.5	+0.9%
VecE	53.1	53.3	**53.4**	53.2	+0.5%
GreedyM	72.1	72.3	**72.6**	72.2	+0.7%

the nine evaluation measures. Notably, on both datasets, the best variants are either VAR-II or VAR-III. VAR-I performs decently and boosts performance of standard transformers on both tasks, signifying that the orthogonality constrained affinity matrix in self-attention is sufficiently effective. This mirrors the results on neural machine translation and is consistent across the findings. The relative gain of applying orthogonality constraints is also promising, peaking at $+23.5\%$ on BLEU-1 scores and $+2.8\%$ to $+6.3\%$ on Rouge.

4 Conclusion

We studied orthogonality constraints for transformers, which are imposed on (i) linear transformations in self-attention and position-wise feed-forward networks and (ii) the affinity matrix in self-attention. We showed that such plug-and-play constraints, which can be conveniently incorporated, consistently boost performance of transformers on ten different machine translation tasks and two dialogue generation tasks. For example, on the large-scale WMT'16 En→De benchmark, simply plugging-and-playing orthogonality constraints on the original transformer model (Vaswani et al., 2017) increases the BLEU from 28.4 to 29.6, coming close to the 29.7 BLEU achieved by the very competitive dynamic convolution (Wu et al., 2019).

Broader Impact Given widespread adoptions of transformer models, the proposed plug-and-play orthogonal constraints could also be useful to computer vision, automatic speech recognition, time series analysis, and biological sequence analysis.

A Proof of Theorem 2.1

Proof. Let $\mathbf{x} = \mathbf{Q}_{i,*}$, $g(\mathbf{x}) = \mathbf{x}\mathbf{K}^\top$, and $f(\mathbf{y}) = \text{softmax}(\mathbf{y})$. Expressing each row in $\mathbf{A}$ as $\mathbf{A}_{i,*} = \text{softmax}(\alpha\mathbf{Q}_{i,*}\mathbf{K}^\top)$, we have

$$\mathbf{A}_{i,*} = f(\alpha g(\mathbf{x})). \tag{2}$$

We first consider bounding $g(\mathbf{x})$ with respect to $\|\mathbf{x}' - \mathbf{x}\|$:

$$\|g(\mathbf{x}') - g(\mathbf{x})\| = \|(\mathbf{x}' - \mathbf{x})\mathbf{K}^\top\|.$$

Recalling the definition of the spectral norm, $\|\mathbf{A}\| = \max_{\mathbf{x}\in\mathbb{R}^l\setminus\{\mathbf{0}\}} \frac{\|\mathbf{x}\mathbf{A}\|}{\|\mathbf{x}\|}$:

$$\|g(\mathbf{x}') - g(\mathbf{x})\| \leq \|\mathbf{K}\|\|\mathbf{x}' - \mathbf{x}\|. \tag{3}$$

Here, we can observe that the Lipschitz constant for g is $\|\mathbf{K}\|$.

Next, we bound $f(\mathbf{y}) = \text{softmax}(\mathbf{y})$ with respect to $\|\mathbf{y}' - \mathbf{y}\|$. Since f is a differentiable function, it holds that

$$\|f(\mathbf{y}') - f(\mathbf{y})\| \leq \|\mathbf{J}\|^*\|(\mathbf{y}' - \mathbf{y})\|, \tag{4}$$

where $\mathbf{J}$ is the Jacobian matrix of $f(\mathbf{y})$ with respect to $\mathbf{y}$, i.e., $\mathbf{J}_{i,j} = \frac{\partial f(\mathbf{y})_i}{\partial \mathbf{y}_j}$, and $\|\mathbf{J}\|^* = \max_{\mathbf{y}} \|\mathbf{J}\|$. Since $f(\mathbf{y})_i = \frac{e^{\mathbf{y}_i}}{\sum e^{\mathbf{y}_j}}$, for diagonal entries of $\mathbf{J}$ we have

$$\begin{aligned}\mathbf{J}_{i,i} &= \frac{\partial f(\mathbf{y})_i}{\partial \mathbf{y}_i} \\ &= \frac{e^{\mathbf{y}_i}}{\sum e^{\mathbf{y}_j}} - \frac{e^{2\mathbf{y}_i}}{(\sum e^{\mathbf{y}_j})^2} \\ &= f_i - {f_i}^2,\end{aligned}$$

where $f_i = f(\mathbf{y})_i$ for brevity. For non-diagonal entries of $\mathbf{J}$ where $i \neq j$, we have

$$\begin{aligned}\mathbf{J}_{i,j} &= \frac{\partial f(\mathbf{y})_i}{\partial \mathbf{y}_j} \\ &= -\frac{e^{\mathbf{y}_i}e^{\mathbf{y}_j}}{(\sum e^{\mathbf{y}_j})^2} \\ &= -f_i f_j.\end{aligned}$$

With this, we can express the Jacobian $\mathbf{J}$ as

$$\begin{aligned}\mathbf{J} &= \begin{bmatrix} f_1 - {f_1}^2 & \cdots & -f_1 f_n \\ \vdots & \ddots & \vdots \\ -f_n f_1 & \cdots & f_n - {f_n}^2 \end{bmatrix} \\ &= \text{diag}(f_i) - \mathbf{f}^\top\mathbf{f},\end{aligned}$$

where $\mathbf{f} = [f_1, .., f_n]$ and $\mathbf{f}^\top\mathbf{f}$ is the outer product of $\mathbf{f}$. We can then express the spectral norm of $\mathbf{J}$ as

$$\begin{aligned}\|\mathbf{J}\| &= \|\text{diag}(f_i) - \mathbf{f}^\top\mathbf{f}\| \\ &\leq \|\text{diag}(f_i)\| + \|\mathbf{f}^\top\mathbf{f}\|.\end{aligned} \tag{5}$$

Note that $\text{diag}(f_i)$ and $\mathbf{f}^\top\mathbf{f}$ are both symmetric matrices. The spectral norm of a symmetric matrix $\mathbf{M}$ is the largest absolute value of its eigenvalues λ:

$$\|\mathbf{M}\| = \max_i |\lambda_i(\mathbf{M})|. \tag{6}$$

For a diagonal matrix like $\text{diag}(f_i)$, its eigenvectors are the standard basis vector while its eigenvalues are the non-zero diagonal entries, i.e., $\lambda_i(\text{diag}(f_i)) = f_i$. Thus, we can get

$$\|\text{diag}(f_i)\| = \max_i f_i. \tag{7}$$

Next, we find $\|\mathbf{f}^\top\mathbf{f}\|$ through the eigenvalues of $\mathbf{f}^\top\mathbf{f}$. When we take the product of $\mathbf{f}^\top\mathbf{f}$ and $\mathbf{f}^\top$,

$$\begin{aligned}\mathbf{f}^\top\mathbf{f}\cdot\mathbf{f}^\top &= \begin{bmatrix} f_1 \\ \vdots \\ f_n \end{bmatrix} \begin{bmatrix} f_1 & \cdots & f_n \end{bmatrix} \begin{bmatrix} f_1 \\ \vdots \\ f_n \end{bmatrix} \\ &= \begin{bmatrix} f_1 \\ \vdots \\ f_n \end{bmatrix} \cdot \sum_i {f_i}^2 \\ &= \left(\sum_i {f_i}^2\right)\mathbf{f}^\top.\end{aligned}$$

From this, we know $\lambda_1(\mathbf{f}^\top\mathbf{f}) = \sum_i {f_i}^2$, with the corresponding eigenvector $\mathbf{v}_1 = \mathbf{f}^\top$. Since the remaining $n-1$ eigenvectors are orthogonal to $\mathbf{v}_1$, i.e., $\mathbf{v}_1^\top\mathbf{v}_i = \mathbf{f}\mathbf{v}_i = 0, \forall i \neq 1$, we have

$$\begin{aligned}\mathbf{f}^\top\mathbf{f}\cdot\mathbf{v}_i &= \mathbf{f}^\top(\mathbf{f}\cdot\mathbf{v}_i) \\ &= \mathbf{0}.\end{aligned}$$

This implies that $\sum_i {f_i}^2$ is the only non-zero eigenvalue of $\mathbf{f}^\top\mathbf{f}$. Thus, with (6), this gives

$$\|\mathbf{f}^\top\mathbf{f}\| = \sum_i {f_i}^2.$$

Combining this with (5) and (7), we get

$$\|\mathbf{J}\| \leq \max_i f_i + \sum_i {f_i}^2. \tag{8}$$

Recall that $\|\mathbf{J}\|$ is the largest possible spectral norm of $\mathbf{J}$, i.e., $\|\mathbf{J}\|^* = \max_{\mathbf{y}} \|\mathbf{J}\|$. Moreover, by

definition of probability, it holds that $f_i \leq 1$ and sum of probabilities $\sum f_i \leq 1$. Therefore,

$$\begin{aligned} \|\mathbf{J}\|^* &\leq \max_{i,\mathbf{y}} f_i + \max_{\mathbf{y}} \sum_i {f_i}^2 \\ &\leq 1 + 1 = 2. \end{aligned} \tag{9}$$

With (4) and (9), we get

$$\|f(\mathbf{y}') - f(\mathbf{y})\| \leq 2\|(\mathbf{y}' - \mathbf{y})\|. \tag{10}$$

Bounding $\|\mathbf{A}'_{i,*} - \mathbf{A}_{i,*}\|$ with (2), (10), and (3), this gives

$$\begin{aligned} \|\mathbf{A}'_{i,*} - \mathbf{A}_{i,*}\| &= \|f(\alpha g(\mathbf{x}')) - f(\alpha g(\mathbf{x}))\| \\ &\leq \|2\alpha g(\mathbf{x}') - 2\alpha g(\mathbf{x})\| \\ &= 2\alpha\|g(\mathbf{x}') - g(\mathbf{x})\| \\ &\leq 2\alpha\|\mathbf{K}\|\|\mathbf{x}' - \mathbf{x}\| \\ &= 2\alpha\|\mathbf{K}\|\epsilon. \end{aligned}$$

Abstract

Imagine you are in a supermarket. You have two bananas in your basket and want to buy four apples. How many fruits do you have in total? This seemingly straightforward question can be challenging for data-driven language models, even if trained at scale. However, we would expect such generic language models to possess some mathematical abilities in addition to typical linguistic competence. Towards this goal, we investigate if a commonly used language model, BERT, possesses such mathematical abilities and, if so, to what degree. For that, we fine-tune BERT on a popular dataset for word math problems, AQuA-RAT, and conduct several tests to understand learned representations better.

Since we teach models trained on natural language to do formal mathematics, we hypothesize that such models would benefit from training on semi-formal steps that explain how math results are derived. To better accommodate such training, we also propose new pretext tasks for learning mathematical rules. We call them (Neighbor) Reasoning Order Prediction (ROP or NROP). With this new model, we achieve significantly better outcomes than data-driven baselines and even on-par with more tailored models. We also show how to reduce positional bias in such models.

1 Introduction

Automatically solving math word problems has a long history dating back to the middle sixties (Bobrow, 1964). Early approaches were rule-based matching systems that solve the problem symbolically. Even though there are some impressive symbolic systems that operate in a relatively narrow domain, the inability to successfully scale them up is sometimes presented as a critique of the good-old-fashioned AI, or GOFAI (Dreyfus et al., 1992). One issue is to create a formalism that covers all the aspects needed to solve these problems. On the other hand, deep learning (LeCun et al., 2015) aims to develop artificial general intelligence that scales better to various problems.

However, despite many successes in computer vision and natural language processing (Devlin et al., 2018; He et al., 2016; Krizhevsky et al., 2012; Lan et al., 2019; Mikolov et al., 2013), data-driven methods evade our dream of building a system with basic, every-day, mathematical skills. As large-scale natural language models become more common (Devlin et al., 2018; Brown et al., 2020), we would expect them to also reason mathematically.

Since natural language understanding also involves symbolic manipulation (Liang, 2016), we treat mathematical reasoning as a language understanding and revisit the data-driven paradigm. For that, we rely on a recent language model, BERT (Devlin et al., 2019), and challenge it with math word problems (Ling et al., 2017). Even though such language models have initially shown promising results, more recent investigation shows they may rely on various biases in their predictions (Hendricks et al., 2018; Brown et al., 2020; Bhardwaj et al., 2020; Kurita et al., 2019). Here, we also follow that line of investigation and show these models can answer correctly without an understanding of the rationale behind it.

Furthermore, as directly predicting answers to math problems often requires multiple steps of reasoning, we show that we can improve BERT's generalization by exposing it to rationales (Ling et al., 2017; Hendricks et al., 2016; Lei et al., 2016). These are, however, only used during training similarly to a teacher that shows a student a justification for each answer. But then, the student is evaluated only on the ability to answer these questions during the college exam correctly with no access to rationales. Finally, to learn a better representation

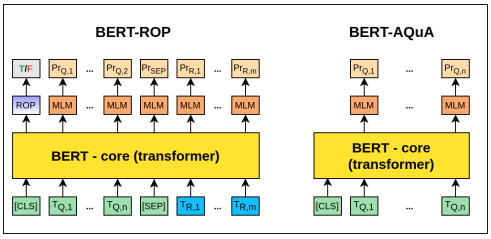

Figure 1: BERT (right) and our novel extension (left). We use shared architecture but we separate question tokens (green blocks) from rationales (blue blocks) using different segment and positional embeddings. We show all three losses. MLM predicts masked tokens (depicted here as $Pr_{Q,k}$). We use ROP or NROP to predict if the ordering of rationale steps is correct. For question-answering, we fine-tune the whole model with a classification layer using softmax. We use the embedding that corresponds to the [CLS] token as the input representation.

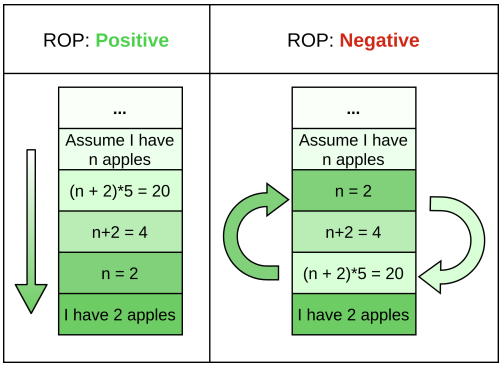

Figure 2: ROP or NROP with positive (left) and negative (right) labels. We randomly swap two rationales and classify if that change has happened.

from rationales and to improve the generalization even further, we introduce novel pretext tasks and corresponding losses, which we name (Neighbor) Reasoning Order Prediction (ROP or NROP). We also show that permutation invariant losses can lead to less biased representations. With that, we outperform other data-driven baselines, and are even on-par with methods that are more tailored to math-world problems and the AQuA-RAT dataset.

2 Methods

We use the following methods, each initialized with BERT-base pre-trained on Wikipedia and Books Corpus (Devlin et al., 2018; Zhu et al., 2015). Note that, in fine-tuning they all have the same number of parameters.

1) **BERT-base**. We fine-tune BERT to predict the correct answer and show its transfer to math word problems.

2) **BERT-AQuA**. We use the MLM loss on the AQuA-RAT questions before training to predict correct answer.

3) **BERT-AQuA-RAT**. We use the MLM loss on the AQuA-RAT questions and rationales and show if we can inject knowledge from rationales into BERT.

4) **BERT-(N)ROP**. We use the MLM loss and the novel (N)ROP loss for coherence prediction (defined later) and show if we can improve the results by focusing the model on rationales.

Later in this paper, we propose permutation invariant losses that additionally reduce positional biases of the BERT-base model, and can work with all the pretext tasks described above.

2.1 Architectures, pretext tasks and losses

We base our architecture on BERT (Devlin et al., 2019) that has 12 transformer blocks (Vaswani et al., 2017). As the core, we use the standard configuration described in (Devlin et al., 2019). We use three self-supervised losses. One is the standard Masked Language Modelling (MLM) but extended to work on rationales. Other two are our new losses, (Neighbour) Reasoning Order Prediction (ROP or NROP). Figure 1 shows two variants of our models. Note that, during fine-tuning, rationales and all the self-supervised losses are discarded.

MLM is the Masked Language Modelling (Devlin et al., 2019). We randomly mask 15% of the input tokens by a special token [MASK]. The objective of this loss is to predict the masked token using its context casted as a classification problem over the tokenizer vocabulary. Loss is calculated only on masked tokens. We extend this loss to rationales. First, we randomly choose whether we mask a question or rationale. Next, we follow the procedure above applied to either a question or rationale. However, to encourage binding between questions and rationales, we use the whole context for the predictions. Interestingly, there are parallels between masking numbers and solving mathematical equations, where it can be seen as solving the equation with unknown. For example, $2 + [\text{MASK}] = 4$ becomes $2 + x = 4$. As a consequence, models during training organically deal with mathematical calculations without defining a specific loss for mathematics allowing soft transitions between natural and more formal languages.

ROP is our novel coherence loss. Since rationales are sequences of consecutive reasoning steps, the order of the execution is critical as shown in Figure 2. Following this intuition, we introduce

Reasoning Order Prediction (ROP) that predicts whether the order of the rationale steps is preserved. Hence it encourages the network to pay more attention to rationales. The loss is similar to Sentence Order Prediction (SOP) (Lan et al., 2019), but ours is focused on learning reasoning steps.

NROP is an extension of ROP where only consecutive rationale steps are swapped making the prediction (swap or no swap) task more challenging and, hence, it can arguably lead to a better representation as understanding the correct ordering is more nuanced. Indeed, we observe that our models trained with NROP correctly predict if swap has occurred in about 75% cases, while with ROP in about 78% cases (both on the validation set). This indeed, confirms our hypothesis that NROP task is more challenging than ROP.

3 Results

Dataset. We use AQuA-RAT (Ling et al., 2017). It has about 100k crowd-sourced math questions with five candidate answers (one is correct). Each question has a rationale – a step-by-step explanation of how the answer is computed – that is only available during training. At test time answer predictions are based on questions. The train set has roughly 100k question-answer-rationale triples, while dev and test about 250 question-answer pairs each.

Main results. Table 1 shows our main results. We see that our method is the state-of-the-art among the models with minimal inductive biases and is very competitive to the other two models that are more specific to handle word math problems (e.g., requires programs). Moreover, even though BERT is already a stronger model than LSTM, it is better to use its MLM pretext task and loss on the AQuA-RAT questions (BERT-AQuA) or even better on questions and rationales (BERT-AQuA-RAT). However, models with our novel coherence prediction losses can better learn from rationales (BERT-ROP and BERT-NROP).

Moreover, we observe a highly sensitive relationship between dev and test sets (Figure 3, left), where small changes in the accuracies in the former set can lead to more dramatic changes at test time. Indeed, the correlation of results between both sets is only 0.082. As the validation set is quite small, we propose an extended dev consisting of 5000 randomly chosen samples from the training set extended by the whole dev set. Although not ideal, and the sensitive relationship is still present

Model	Accuracy
Random chance	20.0%
LSTM (Ling et al., 2017)	20.8%
BERT-base (ours)	28.3(±2.0)%
BERT-AQUA (ours)	29.1(±1.7)%
BERT-AQuA-RAT (ours)	32.3(±1.8)%
BERT-ROP (ours)	35.4(±1.0)%
BERT-NROP (ours)	37.0(±1.1)%
AQuA-RAT (Ling et al., 2017)	36.4%
MathQA (Amini et al., 2019)	**37.9%**

Table 1: Comparison of data-driven (first six rows) with two hybrid approaches that use stronger and hence more specific inductive biases (last two rows). Standard deviation estimates (over random initializations) is given in parentheses, where we see our losses can reduce the variability slightly.

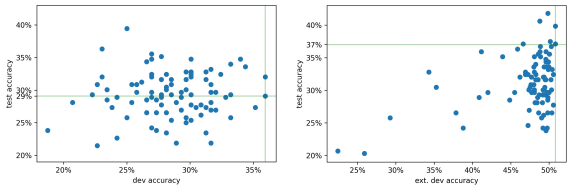

Figure 3: Accuracies for dev and test sets. Green lines show the iteration that maximizes validation accuracy. The image also shows the sensitivity of relationship between test and the original (left) or our extended (right) validation set.

(Figure 3, right), we have increased the correlation to 0.401. With such a new validation set, we report 37% test accuracy but we can also see that 40% is within the reach (Figure 3, right).

Rationales. We hypothesize that rationales contain information that is either missing or hard to extract from questions. For instance, their structure is different; they are more formal with emphasis on the logical steps. However, testing that hypothesis is non-trivial as there is a confounding factor – adding more rationales results in more data. Therefore, we artificially modify the dataset so that both models (one trained only on questions, and another one on questions and rationales) are trained on roughly the same number of data points. For that, we have estimated that rationales have 1.7 times more tokens than questions. This means that a question combined with rationale has around 3 times more tokens than just a question. If our hypothesis is valid, training on 20% questions and rationales should give better results than training on 60% questions (counting the number of tokens). We therefore created samples of respective sizes of just questions and questions combined with rationales. We show our results in Figure 4. The results suggest that adding more questions is insufficient and only slightly improves the overall performance.

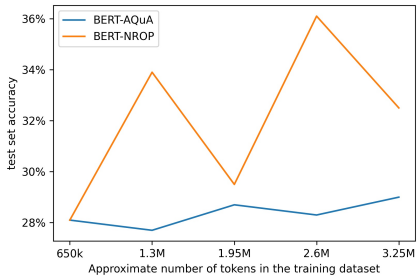

Figure 4: Accuracy scores conditioned on the number of tokens available for training. To support our argument that training on rationales is qualitatively different than questions, we align both together so that we have comparable number of tokens in both cases. Plot shows the progression of the dataset size. Starting with 650K of tokens - 20% dataset BERT-AQuA and 6.66% for BERT-NROP and ending with 3.25M - 100% of dataset for BERT-AQuA and 33.3% dataset for BERT-NROP. This shows that training with rationales leads to a better representation. Even better than training with more questions.

On the other hand, using rationales is more helpful.

Embeddings. To better understand the difference between BERT and BERT+NROP, we analyze their embeddings. For our analysis, we sample 2500 questions with a single operator in rationales, and next we visualise them with T-SNE (Van der Maaten and Hinton, 2008). We show both in Figure 5. We observe that BERT+NROP embeddings preserve more information about different operators.

Permutation consistency. Random guessing on AQuA-RAT yields 20%. With that in mind to separate questions that were solved by chance, we have constructed a new evaluation task – permutation consistency test – where each question gets 5 answers at different positions. Table 2 shows our procedure. Here, models only score a single point if they solve all 5 questions correctly. Hence, a random chance is 0.032% in such experiments.

Table 3 shows our results. BERT+NROP solves almost three times as many questions as BERT. Additionally, further inspection shows that BERT relies on choosing the answers that most stand out, e.g., numbers ending with zeros or floats while every other option is an integer. We didn't observe that simple patterns with BERT+NROP. Questions solved by BERT+NROP usually contain one or two operations and show that BERT+NROP better understands the problem. Below, we exemplify two math problems solved by both models.

Example of a problem solved by BERT+NROP: *8 man work for 6 days to complete a work. How many men are required to complete same work in 1/2 day?*
Answers: *A)93, B)94, C)95, D)96, E)97*

Original question	
How much is 27 / 3	A)13 **B)9** C)3 D)12 E)17
Generated questions	
How much is 27 / 3	**A)9** B)13 C)3 D)12 E)17
How much is 27 / 3	A)13 **B)9** C)3 D)12 E)17
How much is 27 / 3	A)13 B)3 **C)9** D)12 E)17
How much is 27 / 3	A)13 B)12 C)3 **D)9** E)17
How much is 27 / 3	A)13 B)17 C)3 D)12 **E)9**

Table 2: Our generation method for the permutation consistency test. Models get a point only if they solve all them.

Correct Option: *D*
Example of a problem solved by BERT *A ship went on a voyage. After it had traveled 180 miles a plane started with 10 times the speed of the ship. Find the distance when they meet from starting point.?*
Answers: *A)238, B)289, C)200, D)287, E)187*
Correct Option: *C*

Model	Score
Random chance	0.032%
BERT	4.33%
BERT+NROP	**11.02%**
BERT AUG	13.4%
BERT+NROP AUG	19.7%
BERT SEP-NC	15.0%
BERT+NROP SEP-NC	22.7%
BERT SEP-C	16.1%
BERT+NROP SEP-C	**23.9%**

Table 3: Our results for the permutation consistency test.

Drop from 37.0% to 11.02% (Table 3) suggests that models rely strongly on the order of answers. To reduce such a bias, we test several permutation invariant losses.

1) **AUG**. We sample randomly 25 permutations of all the possible answers and use them during training. Original ordering is not used, so there is no order bias. This is a data augmentation technique.

2) **SEP-NC**. The original models are trained on a 5-class classification task, where we build the representation by using questions and all the candidate answers, i.e., $\textbf{BERT}(Q||P)$. Here, $||$ denotes concatenation, Q is the question and P represents the sequence of all answers. In SEP-NC, we block the path between all the candidate answers and the BERT-base. Next, we use a late-fusion to predict if the given candidate answer matches with the question. That is, we use the following formulation $f(\textbf{BERT}(Q)||\textbf{BERT}(C))$, where $C \in P$ is a single candidate answer and f is a multi-layer perception (with two layers). At test time, the model

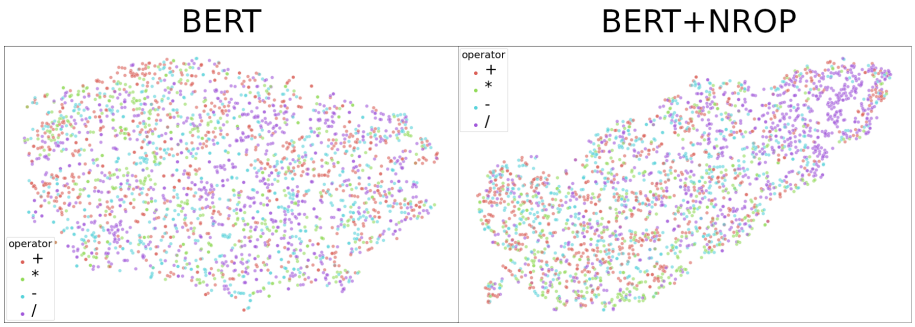

Figure 5: BERT and BERT+NROP embeddings. Colours represent different operators in rationales (T-SNE). BERT+NROP embeddings better separate operators.

is prompted to score all five candidate answers and select the one with the highest score. Appendix has more information about this method.

3) **SEP-C**. As models trained with SEP-NC do not have access to all the possible answers, their biases to answer positions are significantly reduced. However, these models cannot compare each answer to all other candidate answers. Here, we use the following formulation $f(\textbf{BERT}(Q||P)||\textbf{BERT}(C))$ to measure the compatibility of the input (question Q and all the candidate answers P) with the given candidate answer $C \in P$. We also reset the positional encoding between every possible answer in P. In such a way, we hypothesise the network can learn a less biased representation, and on the other hand, use relationship between the candidate answers. Table 3 shows SEP-NC and SEP-C vastly outperform the original model on the permutation consistency test. Details are in the appendix.

SEP-NC and SEP-C improve permutation consistency tests. Yet, they give similar results to original methods in accuracy measuring task. They achieve respectively 33.5% (SEP-NC) and 35.4% (SEP-C).

Questions difficulty. To better understand the models' performance, we check which questions are difficult for the model. We categorize questions by their difficulty for BERT-NROP and BERT. To estimate a question's difficulty, we have ranked the candidate answers according to the model's uncertainties. For instance, if the correct answer has the 2nd largest probability, we assign to that question difficulty two. With that, we group questions into 5 difficulty categories, from the easiest: $D_1, .., D_5$.

Manual inspection shows that for BERT+NROP: D_5 requires additional knowledge or implicitly defined numbers (e.g., adding first 100 numbers), D_4 requires geometry or non-linear equations and systems, D_3 requires solving linear systems with a few basic operations, D_2 requires solving simple equations, and D_1 has one or two basic operations with clearly written numbers. We show an example from each group in the supplementary material. We didn't observe a similar pattern for BERT with the exception of the easiest group D_1 where the model chooses the answer that is somewhat different from other candidates. We provide an example of each group in the supplementary materials.

Finally, we also compare the difficulty of questions with the difficulty perceived by humans. For that, we have conducted a small-group human study, where we have asked participants to solve some AQuA-RAT questions and rate their difficulty. We find a positive correlation between the difficulty measured by our models (as described above) to the difficulty judged by humans. We give more details in the appendix.

Conclusions. We have investigated if BERT (Devlin et al., 2019) – a pre-trained, large language model – can deal with mathematical reasoning. We find that its representation is biased (Brown et al., 2020; Bhardwaj et al., 2020; Kurita et al., 2019) also in mathematics. We investigate and describe that bias. Our novel pretext tasks and losses reduce that bias, but the network still finds shortcuts. We hope our work will spark interest of the community in developing language models capable of mathematical reasoning.

Acknowledgements. We thank Wang Ling (DeepMind) for his comments and suggestions on our draft. Also, we thank Piotr Biliński and all participants of the 2020 Machine Learning Project course at the University of Warsaw for the conversations about the project. All experiments were performed using the Entropy cluster funded by NVIDIA, Intel, the Polish National Science Center grant UMO-2017/26/E/ST6/00622 and ERC Starting Grant TOTAL. The work of Henryk Michalewski was supported by the Polish National Science Center grant UMO-2018/29/B/ST6/02959.

Impact Statement

Our research follows the data-driven paradigm for creating general-purpose language models with some mathematical skills. We expect that mathematically aware language models will broaden the spectrum of topics they can understand, increasing their reliability and making them more useful.

Improving mathematical abilities and coherence in language models is likely to affect question-answering or dialogue systems, search engines or text summarization systems.

One considerable risk in developing language models at scale is that they could use various workarounds and biases to achieve their results. We have shown that issues in the context of mathematical reasoning. Such problems can become hazardous when wrong numbers could lead to bad decisions. Additionally, a person could easily fall into the fallacy that the order of magnitude is correct even if the answer is incorrect. As we showed, the model can favour round numbers over the ones close to the right answer. To mitigate the risk, we encourage considering additional tests and investigating the models more rigorously.

A AQuA-RAT example

Question: *A starts a business with Rs.40,000. After 2 months, B joined him with Rs.60,000. C joined them after some more time with Rs.120,000. At the end of the year, out of a total profit of Rs.375,000, C gets Rs.150,000 as his share. How many months after B joined the business, did C join?*
Options: *A) 30, B) 32, C) 35, D) 36, E) 40*
Rationale:

Assume that C was there in the business for x months

$$A : B : C = 40000 * 12 : 60000 * 10 : 120000 * x$$
$$= 40 * 12 : 60 * 10 : 120x = 40 : 5 * 10 : 10x$$
$$= 8 : 10 : 2x$$
$$= 4 : 5 : x$$
$$\textit{C's share} = 375000 * x/(9 + x) = 150000$$
$$=> 375x/(9 + x) = 150$$
$$=> 15x = 6(9 + x)$$
$$=> 5x = 18 + 2x$$
$$=> 3x = 18$$
$$=> x = 18/3 = 6$$

It means C was there in the business for 6 months. Given that B joined the business after 2 months. Hence C joined after 4 months after B joined
Answer is B

Additional examples are in the supplementary material.

B Input representation

All BERT variants use the representation that corresponds to a special token [CLS] that we put at the beginning of the whole input sequence consisting of question tokens followed by rationale tokens, and in the downstream, question-answering task, rationale tokens are replaced by the answer options. With that, the classification uses the contextual embedding of [CLS] that captures the entire input. MLM classifies over the entire vocabulary of possible words while the other two losses use a binary cross-entropy loss for the predictions.

C Training protocol

We train all our architectures on AQuA-RAT using the following training phases. In all cases, we choose our best model based on the performance on the validation set (dev set), and report the final performance on the test set.

Pre-training. Each model is pre-trained on a large corpus of texts written in natural language sampled from English Wikipedia and BooksCorpus (Devlin et al., 2018; Zhu et al., 2015). We use this as the base (BERT-base) model that is also used in all other variants of BERT. In practice, we initialize all the models with the weights using the HuggingFace library (Wolf et al., 2019) and don't keep final layer for fine-tuning. Our model therefore has the same number of weights as BERT-base.

Self-supervision. Here, we use our newly introduced losses, ROP and NROP, where our models use questions and possibly rationales from the AQuA-RAT dataset. Both questions and rationales use the same word embeddings. However, to distinguish between both modalities we use two segment embeddings. The first one for all the question tokens, and the second one for all the rationale tokens. That is, the segment embedding is shared among all the question tokens, and separately among all the rationale tokens. We use dynamic masking (Liu et al., 2019). Here, tokens are randomly masked for each batch. We naturally extend this approach to other losses that we use in this phase. That is, ROP and NROP negative examples are randomly recreated every k epochs, where $k = 2$ in our case.

Fine-tuning is the last training phase. Here, once our models have learnt the representation during the self-supervised phase, we tune such a representation to the question-answering downstream task. In this task, our input consists of question tokens and possible answer options. There are five such options that comes with the dataset. Like other methods, we tread this as a five-class classification task where the classification head is added on top of the final embedding of the input. We consider the embedding corresponding to the first (from the left) [CLS] token as such the final representation.

D Implementation details

In our experiments, we use four TITAN V GPUs. We use a multi-gpu setup. In the pre-training phase, we use batch size equals to four for each GPU device. Therefore the effective batch size equals to sixteen. We use the learning rate $5 \cdot 10^{-5}$ and trained the models for 24 epochs. In the fine-tuning phase, we use early stopping criteria, based on the accuracy score on the validation set. We use the following criteria. If the model does not improve the performance in 15 consecutive epochs, we stop training, and evaluate a model that yields the highest validation performance. We use ADAM optimizer with learning rate 10^{-5} and gradient clipping that sets the maximal gradient's norm to one. All our settings use the same hyper-parameters but they differ due to the random initialization of our self-supervised networks (during the self-supervised training phase) and the classification networks (during the fine-tuning phase). Self-supervision phase takes around 4 days on 4 GPUs, whereas fine-tuning takes 8 hours on a single GPU.

E Permutation invariant methods

In the main paper, we have shown that typical models can use positional biases in achieving answers. This results in a low permutation consistency score (Table 3 in the main paper). To handle that issue, we have defined extra variants that do not use positional encodings for the answer options and instead they rely on the retrieval mechanics where input representations are matched against the candidate answers. Here, we describe two such variants.

E.1 Original methods

Original models create an embedding of a sentence extended by possible questions. This embedding is then transformed by a linear layer to predict the correct answer. That is,

$$o_1 = f_1(\textbf{BERT}(Q||P))$$

where o_1 is a 5-dimensional vector with probabilities for each possible answer, Q is a question, P are all possible answers, $||$ represents concatenation, f_1 is a single fully connected layer from 768-dimensional space to 5-dimensional space with the softmax activation. **BERT** is a BERT-base sentence embedding. The same approach is used for BERT+(N)ROP.

E.2 SEP-NC

In SEP-NC and SEP-C, we use separate embeddings for a question and **SEP**arate embedding for a candidate answer. They differ, however, in the fact that SEP-C has access to all five possible answers, while SEP-NC has access only to one prompted candidate answer. Therefore NC stands for ńo candidates", while C stands for ćandidates".

We train the SEP-NC model on a binary classification task to predict whether each candidate answer C is correct. The method produces two embeddings, one for question and another one for a candidate answer $C \in P$, and next concatenates them. That is,

$$o_2 = f_2(\textbf{BERT}(Q)||\textbf{BERT}(C))$$

where o_2 is an estimated probability that C is a correct answer, P is the sequence of all possible answers, f_2 is a single fully connected layer from 1536 (768 * 2) dimensional space to 1-dimensional space with the sigmoid activation. Note that, all candidate answers are independent of the question. That is, BERT cannot use positional biases in deriving an answer. At test time, the model is prompted to score all five candidate answers and select the one with the highest score. We naturally extended that approach to BERT+ROP and BERT+NROP. Table 3 (the main paper) shows a significant improvement over the baseline method.

E.3 SEP-C

SEP-NC method could be too restrictive as it does not allow the model to compare against different answers. Therefore, we propose another approach that 1) alleviate the issue with positional biases, but 2) can compare between different answer options. We call that approach SEP-C.

Originally for each token, a positional encoding is assigned based on its position. In SEP-C, before assigning positional encoding, we artificially reset the position at the beginning of each possible answer. For example, if possible answers are: $a)10, b)20, c)30, d)40, e)50$ they are changed into $10; 20; 30; 40; 50$ and after the tokenization, we get the following list of tokens: ['1','0', ';', '2', '0', ';', '3', '0', ';' ,'4', '0', ';', '5', '0']. Modified positional encoding will assign value based only on the relative position to the beginning of the current possible answer. Therefore, in the example above, each '0' will receive the same positional encoding, and '1' will get the same positional encoding as '2', '3', and so on.

Formally, we have

$$o_3 = f_3(\textbf{BERT}(Q||P_m)||\textbf{BERT}(C))$$

where P_m is the sequence of all the possible answers but modified as explained above. Note that, in this formulation, the model can use the information for all the possible answer options, but their order is not taken into account. Table 3 (the main paper) shows a significant improvement over the baseline method.

E.4 Human study

We carried an initial human study on the group of 16 volunteers from University of Warsaw. Volunteers were Mathematics and Informatics students from the Faculty of Mathematics, Informatics and Mechanics. We asked the participants to solve questions sampled from the AQuA-RAT dataset. We are interested in the relation between BERTs difficulty, BERT+NROP difficulty and human difficulty. Therefore to have a full image we would like to have 2 questions for each question difficulty pair, for example (D_1 BERT, D_2**:** BERT+NROP)

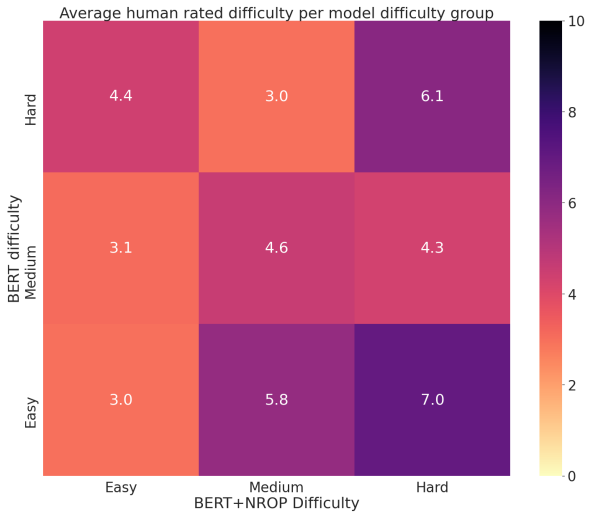

Figure 6: The average human-judged difficulty for questions from each model difficulty group.

. However, that would give 25 combinations and 50 questions if we wanted to have 2 questions per combination. That would be too much to ask from a volunteer participant. In order to reduce the number of questions, we group our 5 difficulty groups into 3 categories as follows.

- Easy: D_1
- Medium: D_2 and D_3 combined
- Hard: D_4 and D_5 combined

Because of that we have only 9 possible combinations and by sampling 2 questions from each combination we still have a feasible number of questions (18).

Apart from solving the question, we asked to rate question difficulty on a scale from 1 (the simplest) to 10 (the most challenging). In general, our participants were knowledgeable in math and solved all the questions correctly. With that grouping we now

The average human-rated difficulty for each of 9 combinations is presented in Figure 6. The results show that the progression of human difficulty is correlated with the difficulty judged by the models. Additionally, the human difficulty seems to be more sensitive to BERT+NROP difficulty than to BERTs. In other words, increasing the difficulty of BERT+NROP will increase the human difficulty more than the increasing difficulty of BERT. This observation fits our previous observations that BERT+NROP solves the most straightforward questions while BERT is looking for some leaks, like looking for the roundest answer.

dataset	A	B	C	D	E
train	21.03%	22%	22.87%	19.95%	14.15%
dev	27.17%	25.98%	16.93%	19.69%	10.24$
test	24.80%	22.83%	20.87%	18.11%	13.38%

Table 4: Answer distribution in each dataset.

F Distribution of answers

Table 4 shows the distribution of the answers in the AQuA-RAT (Ling et al., 2017) dataset in all the folds. Imbalance in distributions could potentially be used by models to find easy, shortcut solutions. For instance, a constant classifier that always choose the first answer (A) gets about 24% test accuracy.

G Negative results

While developing our self-supervised losses, we have developed another loss that turned out to be unhelpful. Here, we describe that loss as some its parts could be insightful for others. (N)ROP is a local loss focusing on rationales but not on the connections between questions and rationales. For that, we have developed Question Rationale Alignment (QRA). QRA changes a rationale with 50% probability to a randomly chosen rationale from the current batch. However, simply changing rationales would result in trivially solvable task in most cases. All the model would have to do is check whether numbers in the rationale and the question match. Hence, we mask number tokens with a special token QRA alone or QRA combined with NROP does not improve the results, it gives it gives 33.9% accuracy on the test in the best combination, so we didn't include it in the main results.

H Related work

We are inspired by the following research.

BERTology. We use BERT (Devlin et al., 2019) as our core. It uses Transformers (Vaswani et al., 2017); powerful neural architectures that applies a trainable function to all the pairs of input embeddings. It also uses masking that covers a fraction of the input words and requires the network to predict the hidden words based on the context. With both ingredients, the meaning (representation) of a word emerges from the "company it keeps" (Firth, 1961). In practice, often, such representations are pre-trained on large textual corpora with no need for annotations, and next fine-tuned on the downstream tasks. BERT's strong performance has resulted in the Cambrian explosion of studies of the

inner working mechanisms and various modifications (Clark et al., 2019; de Vries et al., 2019; Lan et al., 2019; Liu et al., 2019; Sanh et al., 2019; Radford et al.; Raffel et al., 2019; Yang et al., 2019). Finally, our Reasoning Order Prediction (ROP) is inspired by Sentence Order Prediction (SOP) (Lan et al., 2019). However, ROP works with multiple rationale sentences, where by changing the order we force the network to understand the consecutive "reasoning" steps. We have also further extended ROP to a more difficult Neighbor Reasoning Order Prediction (NROP).

Language and math. Development psychologists (Cocking et al., 1988; Mestre, 2013) often argue for the necessity of learning languages and point out that those with limited language skills are in danger of under-performing at school. Moreover, it is also believed that language studies involve discipline in learning and manipulating formal structures, and thus may promote the development of the organization of thoughts also required in mathematical reasoning. The similarity between linguistic competence and mathematics is especially pronounced when solving math word problems (Fuchs et al., 2006, 2008; Wang et al., 2016). Interestingly, attention appears to be crucial in problem solving (Fuchs et al., 2006; Pasolunghi et al., 1999). (Crossley et al., 2017) show that language skills are correlated with the performance in mathematical tests also among the university students. In particular, they pointed out that ability to use complex syntactic structures and cohesion devices are linked to better scores in a blended discrete mathematics course. We take inspiration from all such studies and decide to build our mathematical model based on language models.

Math word problems. Solving math word problems is a significant component of the mathematics curriculum and is taught very early, thoroughly, and universally. Such the emphasize is often motivated by that solving them is among the best predictors of employability, and is considered as a distinct area of mathematical competence (Murnane et al., 2001; Wang et al., 2016). Since solving such problems is unique to human intelligence, math word problems are also interesting for the AI community. This results in various approaches, more traditional symbolic methods, neural networks, and neuro-symbolic methods. (Bobrow, 1964; Charniak, 1969; Shi et al., 2015; Ling et al., 2017; Amini et al., 2019; Parisotto et al., 2016; Wang et al., 2018; Zou and Lu, 2019) as well as datasets (Ling et al., 2017; Amini et al., 2019; Huang et al., 2016; Saxton et al., 2019) An interesting approach is proposed in (Rabe et al., 2020), in which authors use self-supervised tasks on parsing trees of formal expressions. This approach requires syntax trees, and hence we would have to use an external parser. As our goal was to make an end to end model, we did not experiment with it, but there are no obstacles against using it in symbiosis with our methods. (Geva et al., 2020) also proposes self-supervised training for improving mathematical abilities in language models. We, however, focused on a data-driven approach to exclude choice biases and therefore restricted ourselves from using generated data.

Rationales. In human communication, we always expect there is some rationale behind each decision. Hence, we set the same expectations to our artificial agents. Symbolic or semi-symbolic architectures naturally produce justifications as a sequence of formulas in some formal language (Lane et al., 2005; Core et al., 2006; Lomas et al., 2012; Johnson; Liang, 2016; Malinowski and Fritz, 2014). Ideally, such rationales would also be shared and communicated to us through some language. The latter approach is especially appealing when applied to black-box neural networks. For instance, (Hendricks et al., 2016) propose a system that classifies the input image as well as it produces a textual explanation on "why this class is suitable for the given image".

Systems that produce explanations either in the form of the language (Ling et al., 2017; Hendricks et al., 2016), attention (Bahdanau et al., 2014; Mnih et al., 2014; Gulcehre et al., 2016; Malinowski et al., 2018; Xu and Saenko, 2016; Yang et al., 2016), phrase selection (Lei et al., 2016), distillation into programs (Hajipour et al., 2020), or decision trees (Alaniz and Akata, 2019) can potentially increase the transparency of the black-box neural networks. However, most of these approaches create rationales posthoc where the justification is conditioned on answers or by querying the network. In our work, we use rationales to learn a finer representation that can potentially lead to better decisions. In this sense, our technique is conceptually closer to methods that derive answers based on the program and use rationales paired with questions to guide the program induction process (Ling et al., 2017).

Happy Dance, Slow Clap: Using Reaction GIFs to Predict Induced Affect on Twitter

Abstract

Datasets with *induced emotion* labels are scarce but of utmost importance for many NLP tasks. We present a new, automated method for collecting texts along with their *induced reaction* labels. The method exploits the online use of reaction GIFs, which capture complex affective states. We show how to augment the data with *induced emotions* and *induced sentiment* labels. We use our method to create and publish ReactionGIF, a first-of-its-kind affective dataset of 30K tweets. We provide baselines for three new tasks, including induced sentiment prediction and multilabel classification of induced emotions. Our method and dataset open new research opportunities in emotion detection and affective computing.

1 Introduction

Affective states such as emotions are an elemental part of the human condition. The automatic detection of these states is thus an important task in affective computing, with applications in diverse fields including psychology, political science, and marketing (Seyeditabari et al., 2018). Training machine learning algorithms for such applications requires large yet task-specific emotion-labeled datasets (Bostan and Klinger, 2018).

Borrowing from music (Gabrielsson, 2001) and film (Tian et al., 2017), one can distinguish between two reader perspectives when labeling emotions in text: *perceived* emotions, which are the emotions that the reader recognizes in the text, and *induced* emotions, which are the emotions aroused in the reader. However, with the exception of Buechel and Hahn (2017), this distinction is mostly missing from the NLP literature, which focuses on the distinction between author and reader perspectives (Calvo and Mac Kim, 2013).

The collection of perceived emotions data is considerably simpler than induced emotions data, and presently most human-annotated emotion datasets are labeled with perceived emotions (e. g., Strapparava and Mihalcea, 2008; Preoţiuc-Pietro et al., 2016; Hsu and Ku, 2018; Demszky et al., 2020). Induced emotions data can be collected using physiological measurements or self-reporting, but both methods are complex, expensive, unreliable and cannot scale easily. Still, having well-classified induced emotions data is of utmost importance to dialogue systems and other applications that aim to detect, predict, or elicit a particular emotional response in users. Pool and Nissim (2016) used distant supervision to detect induced emotions from Facebook posts by looking at the six available emoji reactions. Although this method is automatic, it is limited both in emotional range, since the set of reactions is small and rigid, and accuracy, because emojis are often misunderstood due to their visual ambiguity (Tigwell and Flatla, 2016).

To overcome these drawbacks, we propose a new method that innovatively exploits the use of reaction GIFs in online conversations. Reaction GIFs are effective because they "display emotional responses to prior talk in text-mediated conversations" (Tolins and Samermit, 2016). We propose a fully-automated method that captures in-the-wild texts, naturally supervised using *fine-grained*, *induced reaction* labels. We also augment our dataset with sentiment and emotion labels. We use our method to collect and publish the ReactionGIF dataset.[1]

2 Automatic Supervision using GIFs

Figure 1a shows a typical Twitter thread. User *A* writes *"I can't take this any more!"*. User *B* replies with a reaction GIF depicting an embrace. Our method automatically infers a *hug* reaction, signaling that *A*'s text induced a feeling of love and caring. In the following, we formalize our method.

(a) A root tweet ("I can't take...") with a *hug* reaction GIF reply.

(b) The reaction categories menu offers 43 categories (*hug*, *kiss*, ...).

(c) The top reaction GIFs offered to the user from the *hug* category.

Figure 1: How reaction GIFs are used (left) and inserted (middle, right) on Twitter.

2.1 The Method

Let (t, g) represent a 2-turn online interaction with a root post comprised solely of text t, and a reply containing only reaction GIF g. Let $R = \{R_1, R_2, ..., R_M\}$ be a set of M different *reaction categories* representing various affective states (e. g., *hug*, *facepalm*). The function $\mathfrak{R}$ maps a GIF g to a reaction category, $g \mapsto \mathfrak{R}(g)$, $\mathfrak{R}(g) \in R$. We use $r = \mathfrak{R}(g)$ as the label of t. In the Twitter thread shown in Figure 1a, the label of the tweet *"I can't take this any more!"* is $r = \mathfrak{R}(g) =$ *hug*.

Inferring $\mathfrak{R}(g)$ would usually require humans to manually view and annotate each GIF. Our method automatically determines the reaction category conveyed in the GIF. In the following, we explain how we automate this step.

GIF Dictionary We first build a dictionary of GIFs and their reaction categories by taking advantage of the 2-step process by which users post reaction GIFs. We describe this process on Twitter; other platforms follow a similar approach:

Step 1: The user clicks on the GIF button. A menu of reaction categories pops up (Figure 1b). Twitter has 43 pre-defined categories (e. g., *high five*, *hug*). The user clicks their preferred category.

Step 2: A grid of reaction GIFs from the selected category is displayed (Figure 1c). The user selects one reaction GIF to insert into the tweet.

To compile the GIF dictionary, we collect the first 100 GIFs in each of the $M = 43$ reaction categories on Twitter. We save the 4300 GIFs, along with their categories, to the dictionary. While in general GIFs do not necessarily contain affective information, our method collects *reaction* GIFs that depict corresponding affective states.

Computing $\mathfrak{R}(g)$ Given a (t, g) sample, we label text t with reaction category r by mapping reaction GIF g back to its category $r = \mathfrak{R}(g)$. We search for g in the GIF dictionary and identify the category(ies) in which it is offered to the user. If the GIF is not found, the sample is discarded. For the small minority of GIFs that appear in two or more categories, we look at the positions of the GIF in each of its categories and select the category with the higher position.

2.2 Category Clustering

Because reaction categories represent overlapping affective states, a GIF may appear in multiple categories. For example, a GIF that appears in the *thumbs up* category may also appear in the *ok* category, since both express approval. Out of the 4300 GIFs, 408 appear in two or more categories. Exploiting this artefact, we propose a new metric: the pairwise *reaction similarity*, which is the number of reaction GIFs that appear in a pair of categories.

To automatically discover affinities between reaction categories, we use our similarity metric and perform hierarchical clustering with average linkage. The resulting dendrogram, shown in Figure 2, uncovers surprisingly well the relationships between common human gesticulations. For example, *shrug* and *idk* (**I d**on't **k**now) share common emotions related to uncertainty and defensiveness. In particular, we can see two major clusters capturing negative sentiment (left cluster: *mic drop* to *smh* [**s**hake **m**y **h**ead]) and positive sentiment (right cluster: *hug* to *slow clap*), which are useful for downstream sentiment analysis tasks. The two rightmost singletons, *popcorn* and *thank you*, lack sufficient similarity data.

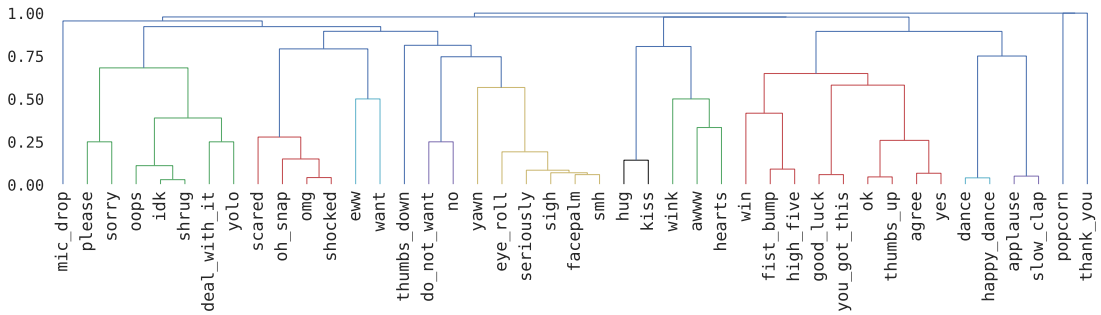

Figure 2: Hierarchical clustering (average linkage) of reaction categories shows relationships between reactions.

3 ReactionGIF Dataset

We applied our proposed method to 30K English-language (t, g) 2-turn pairs collected from Twitter in April 2020. t are text-only root tweets (not containing links or media) and g are pure GIF reactions. We label each tweet t with its reaction category $r = \mathfrak{R}(g)$. See Appendix A for samples. The resulting dataset, ReactionGIF, is publicly available.

Figure 3 shows the category distribution's long tail. The top seven categories (*applause* to *eye-roll*) label more than half of the samples (50.9%). Each of the remaining 36 categories accounts for between 0.2% to 2.8% of the samples.

Label Augmentation Reaction categories convey a rich affective signal. We can thus augment the dataset with other affective labels. We add **sentiment labels** by using the positive and negative reaction category clusters, labeling each sample according to its cluster's sentiment (§2.2). Furthermore, we add **emotion labels** using a novel reactions-to-emotions mapping: we asked 3 annotators to map each reaction category onto a subset of the 27 emotions in Demszky et al. (2020) — see Table 1. Instructions were to view the GIFs in each category and select the expressed emotions. Pairwise Cohen's kappa indicate moderate interrater agreements with $\kappa_{12} = 0.512$, $\kappa_{13} = 0.494$, $\kappa_{23} = 0.449$, and Fleiss' kappa $\kappa_F = 0.483$. We use the annotators' majority decisions as the final many-to-many mapping and label each sample according to its category's mapped emotions subset.

GIFs in Context As far as we know, our dataset is the first to offer reaction GIFs with their eliciting texts. Moreover, the reaction GIFs are labeled with a reaction category. Other available GIF datasets (TGIF by Li et al., 2016, and GIFGIF/GIFGIF+, e. g., Jou et al., 2014) lack both the eliciting texts and the reaction categories.

Admiration	Curiosity	Fear	Pride
Amusement	Desire	Gratitude	Realization
Anger	Disappointment	Grief	Relief
Annoyance	Disapproval	Joy	Remorse
Approval	Disgust	Love	Sadness
Caring	Embarrassment	Nervousness	Surprise
Confusion	Excitement	Optimism	

Table 1: The 27 emotions in Demszky et al. (2020).

4 Baselines

As this is the first dataset of its kind, we aim to promote future research by offering baselines for predicting the reaction, sentiment, and emotion induced by tweets. We use the following four models in our experiments:

- **Majority**: A simple majority class classifier.
- **LR**: Logistic regression classifier (L-BFGS solver with $C = 3$, maximum iterations 1000, stratified K-fold cross validation with $K = 5$) using TF-IDF vectors (unigrams and bigrams, cutoff 2, maximum 1000 features, removing English-language stop words).
- **CNN**: Convolutional neural network (100 filters, kernel size 3, global max pooling; 2 hidden layers with 0.2 dropout; Adam solver, 100 epochs, batch size 128, learning rate 0.0005) with GloVe embeddings (Twitter, 27B tokens, 1.2M vocabulary, uncased, 100d) (Pennington et al., 2014).
- **RoBERTa**: Pre-trained transformer model (base, batch size 32, maximum sequence length 96, 3 training epochs) (Liu et al., 2019).

We hold out 10% of the samples for evaluation. The code is publicly available along with the dataset for reproducibility. The experiment results are summarized in Table 2.

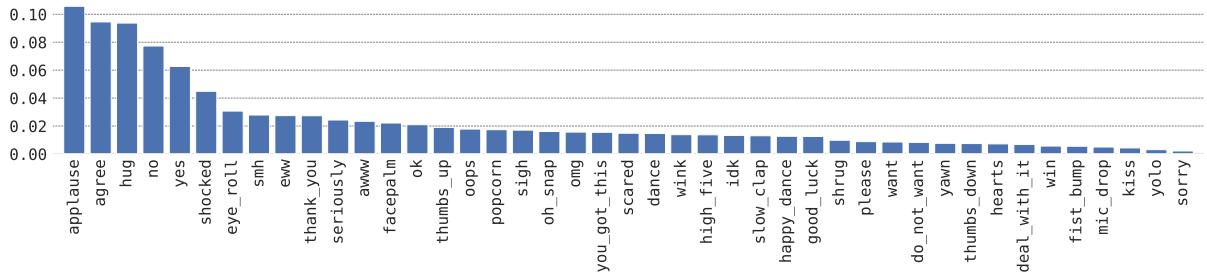

Figure 3: Distribution of the 43 reaction categories in ReactionGIF

Task →	Reaction				Sentiment				Emotion
Model ↓	Acc	P	R	F_1	Acc	P	R	F_1	LRAP
Majority	10.4	1.1	10.4	2.0	58.0	33.7	58.0	42.6	0.445
LR	22.7	19.5	22.7	18.0	64.7	64.4	64.7	62.4	0.529
CNN	25.5	17.3	25.5	19.1	67.1	66.8	67.1	66.3	0.557
RoBERTa	**28.4**	**23.6**	**28.4**	**23.9**	**70.0**	**69.7**	**70.0**	**69.8**	**0.596**

Table 2: Baselines for the reaction, sentiment, and emotion classification tasks. All metrics are weight-averaged. The highest value in each column is emboldened.

Affective Reaction Prediction is a multiclass classification task where we predict the reaction category r for each tweet t. RoBERTa achieves a weight-averaged F_1-score of 23.9%.

Induced Sentiment Prediction is a binary classification task to predict the sentiment induced by tweet t by using the augmented labels. RoBERTa has the best performance with accuracy 70.0% and F_1-score of 69.8%.

Finally, **Induced Emotion Prediction** uses our reaction-to-emotion transformation for predicting emotions. This is a 27-emotion *multilabel* classification task, reflecting our dataset's unique ability to capture complex emotional states. RoBERTa is again the best model, with Label Ranking Average Precision (LRAP) of 0.596.

5 Discussion

Reaction GIFs are ubiquitous in online conversations due to their uniqueness as lightweight and silent moving pictures. They are also more effective and precise[2] when conveying affective states compared to text, emoticons, and emojis (Bakhshi et al., 2016). Consequently, the reaction category is a new type of label, not yet available in NLP emotion datasets: existing datasets use either the discrete emotions model (Ekman, 1992) or the dimensional model of emotion (Mehrabian, 1996). The new labels possess important advantages, but also present interesting challenges.

Advantages The new reaction labels provide a rich, complex signal that can be mapped to other types of affective labels, including sentiment, emotions and possibly feelings and moods. In addition, because reaction GIFs are ubiquitous in online conversations, we can automatically collect large amounts of inexpensive, naturally-occurring, high-quality affective labels. Significantly, and in contrast with most other emotion datasets, the labels measure *induced* (as opposed to *perceived*) affective states; these labels are of prime importance yet the most difficult to obtain, with applications that include GIF recommender systems, dialogue systems, and any other application that requires predicting or inducing users' emotional response.

Challenges The large number of reaction categories (reflecting the richness of communication by gestures) makes their prediction a challenging task. In addition, the category distribution has a long tail, and there is an affective overlap between the categories. One way to address these issues is by accurately mapping the reactions to emotions. Precise mapping will require a larger GIF dictionary (our current one has 4300 GIFs), a larger dataset, and new evaluation metrics. A larger GIF dictionary will also improve the *reaction similarity*'s accuracy, offering new approaches for studying relationships between reactions (§2.2).

[2]For example, the *facepalm* reaction is "a gesture in which the palm of one's hand is brought to one's face, as an expression of disbelief, shame, or exasperation.", Oxford University Press, lexico.com/en/definition/facepalm

6 Conclusion

Our new method is the first to exploit the use of reaction GIFs for capturing in-the-wild *induced* affective data. We augment the data with induced sentiment and emotion labels using two novel mapping techniques: reaction category clustering and reactions-to-emotions transformation. We used our method to publish ReactionGIF, a first-of-its-kind dataset with multiple affective labels. The new method and dataset offer opportunities for advances in emotion detection.

Moreover, our method can be generalized to capture data from other social media and instant messaging platforms that use reaction GIFs, as well as applied to other downstream tasks such as multimodal emotion detection and emotion recognition in dialogues, thus enabling new research directions in affective computing.

Ethical Considerations and Implications

Data Collection

The ReactionGIF data was collected from Twitter using the official API in full accordance with their Development Agreement and Policy (Twitter, 2020). Similar to other Twitter datasets, we include the tweet IDs but not the texts. This guarantees that researchers who want to use the data will also need to agree with Twitter's Terms of Service. It also ensures compliance with section III (Updates and Removals) of the Developer Agreement and Policy's requirement that when users delete tweets (or make them private), these changes are reflected in the dataset (Belli et al., 2020).

Annotation

Annotation work was performed by three adult students, two males and one female, who use social media regularly. The labeling involved viewing 43 sets of standard reaction GIFs, one for each reaction category. These reaction GIFs are the standard offering by the Twitter platform to all its users. As a result, this content is highly familiar to users of social media platforms such as Facebook or Twitter, and thus presents a very low risk of psychological harm. Annotators gave informed consent after being presented with details about the purpose of the study, the procedure, risks, benefits, statement of confidentiality and other standard consent items. Each annotator was paid US$18. The average completion time was 45 minutes.

Applications

The dataset and resulting models can be used to infer readers' induced emotions. Such capability can be used to help online platforms detect and filter out content that can be emotionally harmful, or emphasize and highlight texts that induce positive emotions with the potential to improve users' well-being. For example, when a person is in grief or distress, platforms can give preference to responses which will induce a feeling of caring, gratitude, love, or optimism. Moreover, such technology can be of beneficial use in assistive computing applications. For example, people with emotional disabilities can find it difficult to understand the emotional affect in stories or other narratives, or decipher emotional responses by third parties. By computing the emotional properties of texts, such applications can provide hints or instructions and provide for smoother and richer communication. However, this technology also has substantial risks and peril. Inducing users' affective response can also be used by digital platforms in order to stir users into specific action or thoughts, from product purchase and ad clicking to propaganda and opinion forming. Deployers must ensure that users understand and agree to the use of such systems, and consider if the benefit created by such systems outweigh the potential harm that users may incur.

A Dataset Samples

Figure 4 includes four samples from the dataset. For each sample, we show the record ID within the dataset, the text of the tweet, a thumbnail of the reaction GIF, the reaction category of the GIF, and the two augmented labels: the sentiment and the emotions.

Exploring Listwise Evidence Reasoning with T5 for Fact Verification

Kelvin Jiang, Ronak Pradeep, and **Jimmy Lin**
David R. Cheriton School of Computer Science
University of Waterloo
{kelvin.jiang, rpradeep, jimmylin}@uwaterloo.ca

Abstract

This work explores a framework for fact verification that leverages pretrained sequence-to-sequence transformer models for sentence selection and label prediction, two key sub-tasks in fact verification. Most notably, improving on previous pointwise aggregation approaches for label prediction, we take advantage of T5 using a listwise approach coupled with data augmentation. With this enhancement, we observe that our label prediction stage is more robust to noise and capable of verifying complex claims by jointly reasoning over multiple pieces of evidence. Experimental results on the FEVER task show that our system attains a FEVER score of 75.87% on the blind test set. This puts our approach atop the competitive FEVER leaderboard at the time of our work, scoring higher than the second place submission by almost two points in label accuracy and over one point in FEVER score.

1 Introduction

In recent years, the Internet has become an effective platform for creating and sharing content to large audiences. Unfortunately, there have been occurrences of bad actors taking advantage of this to propagate manipulative information for their benefit, often to the point of spreading misinformation. With the large amount of data being generated on the Internet each day, it is infeasible to manually verify it all, motivating recent research into automated fact verification.

In this work, we explore a fact verification framework built with the pretrained sequence-to-sequence transformer T5 (Raffel et al., 2020) as its backbone which we call LisT5. Within a standard three-stage architecture, we focus mostly on the label prediction problem. We adopt a "listwise approach", where all candidate sentences that form the evidence set of a claim are considered together. Our main contribution is a data augmentation technique that involves deliberately introducing noise into training data to combat data sparsity and produce a more robust model. At its introduction, a full pipeline using our techniques represents the state of the art, achieving the top scoring run on the FEVER leaderboard. An additional minor contribution exploits named entities during the sentence selection phase, which has a small but noticeable effect on generating a better candidate set for downstream label prediction. We believe that these techniques can be potentially valuable to a broader range of NLP tasks that also involve aggregation of information from upstream retrieval models.

2 Background and Related Work

As this work focuses on the Fact Extraction and VERification (FEVER) task (Thorne et al., 2018),[1] we begin by briefly describing the task setup. We are given a textual claim q, to be verified against a corpus comprised of a subset of Wikipedia. Each claim is associated with a three-way veracity label $v(q) \in \{\text{SUPPORTS}, \text{NOINFO}, \text{REFUTES}\}$ and a set of reference sentences $S(q)$ that provide support.[2] An example claim q, its label $v(q)$, and supporting evidence $S(q)$ are given in Figure 1.

The primary evaluation metric, FEVER score, is computed as the proportion of claims where the system has predicted the correct veracity label conditioned on also having retrieved a complete set of reference sentences. Most current systems adopt a three-stage approach to this task, comprising document retrieval, sentence selection, and label prediction. In this work, our contributions are focused on the second and third sub-tasks; for document retrieval, we simply augment current best practices with BM25 (Yang et al., 2017; Lin et al., 2021).

[1] Details of the FEVER sets are included in Appendix A.1.
[2] Each claim may have multiple different sets of reference sentences, any of which is sufficient as the support set.

Claim: The Rodney King riots took place in the most populous county in the USA.
Evidence 1 (`wiki/Los_Angeles_Riots`): The 1992 Los Angeles riots, also known as the Rodney King riots were a series of riots, lootings, arsons, and civil disturbances that occurred in Los Angeles County, California in April and May 1992.
Evidence 2 (`wiki/Los_Angeles_County`): Los Angeles County, officially the County of Los Angeles, is the most populous county in the USA.
Label: SUPPORTS

Figure 1: An example claim and its corresponding evidence and label from the FEVER dataset.

By construction, the veracity of each claim is determined by the (candidate) supporting sentences, taken together. One simple and popular approach to fact extraction and verification is to consider the veracity of the claim with respect to each candidate *independently* (i.e., classification), and then aggregate the evidence (Hanselowski et al., 2018; Zhou et al., 2019; Soleimani et al., 2019; Liu et al., 2020; Pradeep et al., 2021b). For convenience, we refer to these as "pointwise approaches", borrowing from the learning to rank literature (Li, 2011).

As an alternative, researchers have proposed approaches that consider multiple candidates at once to *jointly* arrive at a veracity prediction (Thorne et al., 2018; Nie et al., 2019a; Zhou et al., 2019; Stammbach and Neumann, 2019; Pradeep et al., 2021a). For convenience, we refer to these as "listwise approaches", also borrowing from the learning to rank literature (Li, 2011). Such listwise approaches have also been used for information aggregation in other NLP tasks such as question answering (Wang et al., 2018; Nie et al., 2019b). At a high level, this strategy suffers from a number of challenges, including data sparsity and a high level of sensitivity to noisy inputs. Following this thread of work, we adopt the listwise approach and improve it by training with a data augmentation technique that involves deliberately introducing noise into the training data to produce a more robust model.

3 Methods

Our work adopts a three-stage pipeline comprising document retrieval, sentence selection, and label prediction, which we detail in this section.

3.1 Document Retrieval

Given a claim q, our first step is to retrieve the top K most relevant documents $\hat{D}(q) = \{d_1, ..., d_K\}$. Since the corpus contains over 5.4M documents, we first perform document retrieval to narrow our search space. We leverage the Pyserini toolkit (Yang et al., 2017; Lin et al., 2021), which is based on the popular Lucene search engine, using the BM25 scoring function (Robertson and Zaragoza, 2009) to rank documents. Additional document retrieval details are described in Appendix A.3. We also incorporate document retrieval using the MediaWiki API, which has been shown in previous work to form a strong baseline (Hanselowski et al., 2018). We combine the results of the two methods by alternating through the two ranked lists of documents, skipping duplicates and keeping the top K unique documents.

3.2 Sentence Selection

Given a claim q and retrieved documents $\hat{D}(q)$, the next stage in the pipeline selects the top L most relevant evidence sentences $\hat{S}(q) = \{s_{k_1,i_1}, ..., s_{k_L,i_L}\}$, where $s_{k,i}$ is the i-th sentence from document d_k. Similar to how Soleimani et al. (2019) and Subramanian and Lee (2020) frame this stage as a semantic matching problem using BERT-based models, we use T5 to rank the similarities between the claim and the sentences in each document. Introduced by Nogueira et al. (2020), like Pradeep et al. (2021a), we use T5 (Raffel et al., 2020) as a pointwise reranker, which they dub monoT5. Empirically, T5 has been found to be more effective at ranking than BERT-based models across a wide variety of domains.

As a sequence-to-sequence model, ranking is performed using the following input template:

`Query:` q `Document:` $s_{k,i}$ `Relevant:`

where q and $s_{k,i}$ are the claim and evidence sentence, respectively. To provide a broader context and to resolve ambiguities, we prepend each sentence $s_{k,i}$ with the title of document d_k.

We fine-tune the model to generate the token "true" if $s_{k,i} \in S(q)$ and "false" otherwise. In terms of training data for fine-tuning, we use the gold evidence in the evidence sets in $S(q)$ for "true" samples, but for the "false" samples, we sample negatives from the sentences in $\hat{D}(q)$.

At inference time, we construct a candidate set comprised of sentences from each document in $\hat{D}(q)$ in its retrieved order. Using the same input

format, for each sentence, we probe the logits of the "true" and "false" tokens and apply the softmax function to produce a relevance probability score between 0 and 1; these scores are used to select the top L (= 5) sentences. For efficiency, instead of reranking all sentences in $\hat{D}(q)$, we take the first 200 sentences and only rerank this subset. Since there is an average of five non-empty sentences per document, we are roughly considering the top 40 documents from $\hat{D}(q)$.

On top of the basic reranking input template of Nogueira et al. (2020), we introduce a novel enhancement where we append any named entities found within the claim to the input of monoT5. The intuition here is to prompt monoT5 to promote sentences that come from documents with titles that are similar to those entities, which tend to contain information that is relevant to verifying the claims. During fine-tuning, we use the names of the documents that contain the gold evidence as entities, but during inference, we extract named entities from the claims using the named entity recognition (NER) module built into spaCy's `en_core_web_sm` model.[3] We append these entities, denoted as $e_1, ..., e_j$, to our monoT5 input template as follows:

`Query:` q `Document:` $s_{k,i}$ `Entity1:` e_1 $\cdots$ `Entity`j`:` e_j `Relevant:`

Additional details are described in Appendix A.3.

3.3 Label Prediction

Given claim q and evidence $\hat{S}(q)$, the final stage of the pipeline is to predict a veracity label $\hat{v}(q)$.

Pointwise Aggregation One common method in the literature for label prediction is to combine the claim and each evidence sentence individually as the inputs to some model and aggregate those model outputs to obtain a veracity prediction. With the sequence-to-sequence nature of T5, we achieve this by fine-tuning the model with samples of the following input sequence:

`query:` q `sentence:` $s_{k,i}$ `relevant:`

There are many different methods to aggregate the outputs: Soleimani et al. (2019) assumes NOINFO unless there are unanimous outputs of SUPPORTS or REFUTES, while Zhou et al. (2019) chooses the most frequently occurring label as well as attending over the outputs with the vector representations of each claim and evidence pair. Assume that the input sequence with evidence sentence $s_{k,i}$, after passing through T5 and applying the softmax function to the logits of the three classes, produces the probabilities $\Pr(\text{S} \mid q, s_{k,i})$ for SUPPORTS, $\Pr(\text{R} \mid q, s_{k,i})$ for REFUTES, and $\Pr(\text{N} \mid q, s_{k,i})$ for NOINFO. We experiment with two aggregation schemes that achieves the best results for us, which we denote by `sum` and `max`, as follows:

$$\texttt{sum} : \hat{v}(q) = \underset{l \in \{\text{S,R,N}\}}{\text{argmax}} \sum_{s_{k,i} \in \hat{S}(q)} \Pr(l \mid q, s_{k,i})$$

$$\texttt{max} : \hat{v}(q) = \underset{l \in \{\text{S,R,N}\}}{\text{argmax}} \max_{s_{k,i} \in \hat{S}(q)} \Pr(l \mid q, s_{k,i})$$

For fine-tuning, we use $S(q)$ as the evidence for SUPPORTS and REFUTES samples. Similar to sentence selection, for NOINFO samples, we sample negatives from the top predicted sentences from upstream, which in this case, is sentence selection, using the full reranked candidate list instead of just the top L sentences in $\hat{S}(q)$.

Listwise Concatenation Another common strategy for label prediction is to concatenate all L sentences into a single input to some model and have the model directly classify the claim and list of evidence $\hat{S}(q)$ as one of SUPPORTS, NOINFO, and REFUTES. Again, with T5, we use the following input sequence:

`query:` q `sentence1:` s_{k_1,i_1} $\cdots$ `sentence`L`:` s_{k_L,i_L} `relevant:`

To obtain fine-tuning training data, we use the same method as for pointwise aggregation.

Listwise Data Augmentation To make label prediction more tolerant to noisy evidence in the top L sentences, we fine-tune T5 with augmented, noisy evidence sets: this mimics the model during inference more closely as there usually exists some non-gold evidence in $\hat{S}(q)$. To accomplish this, instead of fine-tuning directly with the gold evidence sets $S(q)$, we fine-tune using $I(S(q))$, which "infuses" $S(q)$ with $\hat{S}(q)$. Specifically, we define the transformation I as:

- If $v(q) \in \{\text{SUPPORTS}, \text{REFUTES}\}$, we check if $S(q) \subseteq \hat{S}(q)$. For each $s \in S(q)$ such that $s \notin \hat{S}(q)$, we randomly select an index k of $\hat{S}(q)$ where $\hat{S}(q)[k] \notin S(q)$ and insert s at $\hat{S}(q)[k]$. This is repeated iteratively, and so $I(S(q))$ returns the resulting list of sentences $\hat{S}(q)$.
- If $v(q) = \text{NOINFO}$, $I(S(q)) = \hat{S}(q)$.

Table 1: Label prediction results on the FEVER development set and blind test set. LA refers to label accuracy and FS refers to FEVER score. Other top submissions on the FEVER leaderboard at the time of our work are denoted with the symbol *.

Note that we use the same T5 input format as listwise concatenation. Training details for the label prediction stage can be found in Appendix A.3.

4 Results

We report the overall results of LisT5 on the FEVER development and blind test sets in Table 1, comparing the label prediction variations presented in Section 3.3. We also include the oracle FEVER score for our retrieved $\hat{S}(q)$ on line (2a). For reference, we compare LisT5 against several baselines and state-of-the-art techniques (drawn from the leaderboard) at the time of our work, shown in lines (1a)–(1h).

From the results in Table 1, it is clear that the different label prediction strategies lead to vastly different FEVER scores. The top-performing method, according to both label accuracy and FEVER score, is trained with augmented data in a listwise manner, found on line (2e). This run represents the state of the art atop the FEVER leaderboard at the time of our work. The other methods that fine-tune with only gold evidence data, found on lines (2b) to (2d), seem to trail by over 10 points. These results suggest the importance of training with augmented listwise evidence sets, which is presented in Section 3.3.

Contrary to the results reported in some papers, our concatenation methods consistently outperform corresponding aggregation methods: this suggests that T5 is able to capture inter-sentence semantics and use information from multiple, possibly diverse, pieces of evidence to come to veracity conclusions. Specifically, the T5 variant on line (2e) achieves 78.02%[4] (174/223) label accuracy on claims in the development set that require retrieving at least two pieces of evidence in conjunction to verify, which is close to our overall label accuracy of 81.26%. This finding suggests that T5 is capable of incorporating and corroborating the information contained in multiple pieces of evidence, which is one of the most common needed areas of improvement described in previous papers.

Table 2 compares the LisT5 sentence selection results of the monoT5 variations described in Section 3.2. We include some results from baselines, using recall at five as the primary sentence selection metric, which by definition is an upper-bound for the downstream FEVER score. We format the results for LisT5 as an ablation analysis focused on sentence selection. Line (2a) shows the results of the full monoT5 model with NER and fine-tuned on the FEVER dataset; monoT5 without NER features but fine-tuned on the FEVER dataset is shown on line (2b). Finally, we have zero-shot monoT5 on line (2c) to show the results of monoT5 without fine-tuning on the FEVER dataset, i.e., directly from the model checkpoints of Nogueira

[4]These only include claims where an entire gold evidence set is contained in the sentence selection output $\hat{S}(q)$.

(2a)	monoT5 w/ NER (full model)	25.66	**90.54**	37.17	**85.62**
(2b)	monoT5 w/o NER (fine-tuned)	25.50	90.08	36.94	84.87
(2c)	monoT5 w/o NER (zero-shot)	22.70	85.39	33.86	76.87

Table 2: Comparison of sentence selection methods on the FEVER development set.

et al. (2020). We explain this in more detail in Appendix A.3. From these results, it is clear that monoT5 supplemented with named entities – on line (2a) – performs the best, achieving the highest recall and mean average precision, better than the other monoT5 variations or any of the baselines. It is worth noting that the full monoT5 model on line (2a) achieves 90.53 recall on the blind test set, consistent with the development set results.

While document retrieval is not our focus, our pipeline performs competitively compared to prior work and is further discussed in Appendix A.4.

5 Error Analysis

We randomly select 200 incorrectly predicted claims by LisT5 and summarize the most common issues, hoping to identify areas of improvement for future fact verification systems.

One common issue is failing to distinguish between similar but semantically different words or phrases. An example of this is the claim "Shane McMahon officially retired on the first day of 2010" to which our document retrieval and sentence selection stages retrieve the sentence "In 2009, McMahon announced his resignation from WWE which went into effect January 1, 2010". Here, retirement and resignation are semantically similar words that both describe individuals leaving their positions. These similarities may have been learned by the pretrained transformer, but it is not always the case that the words imply one another, leading to an incorrect prediction for this claim.

Another frequent issue is incorrectly labelled claims in the FEVER dataset, often due to missing evidence in $S(q)$. An example of this is the claim "Mickey Rourke appeared in a sequel" to which our document retrieval and sentence selection stages retrieve the sentence "Since then, Rourke has appeared in several commercially successful films including the 2010 films Iron Man 2 and The Expendables and the 2011 film Immortals". However, the claim was labelled NOINFO in the dataset, which is incorrect due to Iron Man 2 indeed being a sequel. In short, we are bumping into data quality issues in the annotations themselves.

6 Conclusion

In this paper, we present the LisT5 framework for automated fact verification. LisT5 consists of a three-stage pipeline – document retrieval, sentence selection, and label prediction. For document retrieval, we combine two strong document retrieval baselines. For sentence selection, we fine-tune a T5 model as a reranker with named entities provided as additional features. For label prediction, we present evidence in a listwise manner to a T5 model, trained on augmented data. Our experimental results indicate that LisT5 achieves the state of the art on the FEVER task, which we attribute to the framework's ability to reason jointly over multiple pieces of evidence.

A Appendix

A.1 FEVER Dataset

The dataset used for training and evaluating our fact verification system is FEVER (Thorne et al., 2018), a large-scale dataset consisting of 185K claims with evidence taken from Wikipedia. We include the label distribution of the dataset across its training, development, and blind test set in Table 3.

Split	SUPPORTS	REFUTES	NOINFO
Train	80,035	29,775	35,639
Dev	6,666	6,666	6,666
Test	6,666	6,666	6,666

Table 3: Label distribution of the FEVER dataset.

A.2 Baseline Details

As discussed in Section 3, most fact verification systems, especially for the FEVER task, consist of a three-stage pipeline similar to the one used in LisT5. The stages are as follows:

Document Retrieval Many systems use the document retrieval component of DrQA (Chen et al., 2017a), which performs retrieval with TF-IDF feature vectors along with bigram features. Some other systems leverage external search APIs, such as Hanselowski et al. (2018), who use the MediaWiki API, Wikipedia's own search engine, and Chakrabarty et al. (2018), who use the Google Search API.

Sentence Selection When the FEVER task was introduced in 2018, many of the initial top-scoring systems (Nie et al., 2019a; Hanselowski et al., 2018) employed variations of the Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017b), which consists of Bidirectional Long Short-Term Memory networks (BiLSTMs) (Schuster and Paliwal, 1997) as its primary building block. However, with the advent of the transformer architecture (Vaswani et al., 2017), most systems today (Soleimani et al., 2019; Subramanian and Lee, 2020) use transformers to perform semantic matching between the claim and each candidate sentence.

Label Prediction Framing the problem as that of natural language inference (NLI), Nie et al. (2019a), Yoneda et al. (2018), and Hanselowski et al. (2018) again use variations of ESIM for label prediction. Similar to the sentence selection stage, many recent systems use transformers for this stage as well. However, there has also been active research into graph-based models for knowledge aggregation by modelling evidence sentences as nodes in a graph (Zhou et al., 2019; Liu et al., 2020; Zhong et al., 2020).

A.3 Implementation and Training Details

Document Retrieval We retrieve with BM25 using the parameters $k_1 = 0.6$ and $b = 0.5$. These parameters are tuned by running a grid search over parameter values in 0.1 increments over a subset of the training set.

Sentence Selection Whenever we fine-tune monoT5, we use the T5-3B variant, which as its name suggests, contains three billion parameters. We fine-tune the model with batch size 128 over one epoch, using the configurations prescribed by Raffel et al. (2020), except that we use learning rate 0.0001 instead of 0.001. While training, we save checkpoints at evenly spaced iteration intervals, usually around 1000 iterations per checkpoint depending on the size of the training data. Thus, whenever we report the results of a model, we use the results of the best performing checkpoint on the FEVER development set. We fine-tune on TPU v3-8 nodes on the Google Cloud Platform, which takes around 24 hours.

Note that we first fine-tune a pretrained T5 model on the MS MARCO passage dataset (Bajaj et al., 2018) for 10000 iterations, following best practices reported in previous work (Akkalyoncu Yilmaz et al., 2019; Nogueira et al., 2020; Zhang et al., 2020; Pradeep et al., 2020, 2021c,b), which has shown that this leads to improved effectiveness. This procedure also gives us a zero-shot setting for fact verification, which we experiment with before fine-tuning on the FEVER dataset directly.

In our experiments, we note that negative sampling sentences from highly-ranked documents in $\hat{D}(q)$ leads to poorly performing models. This may be due to false negatives in the data, where some claims are labelled as NOINFO but are actually verifiable, with relevant evidence retrieved by our document retrieval stage. To avoid negative sampling such false negative evidence, we negative sample sentences ranked between 50 and 200.

Label Prediction Again, we use the T5-3B variant as the model for label prediction. We use similar settings for fine-tuning T5 as before for monoT5, except that we use the default learning rate 0.001.

Method	R@1000 (%)
MediaWiki API	89.56
Anserini	94.76
Anserini + MediaWiki API	**96.87**

Table 4: Comparison of document retrieval methods on the FEVER development set. The code for retrieval using the MediaWiki API is courtesy of Hanselowski et al. (2018).

We also fine-tune on TPU v3-8 nodes on the Google Cloud Platform, which takes around 8 hours.

To avoid similar negative sampling issues encountered in fine-tuning models for sentence selection, we sample from sentences ranked between 10 and 25 here.

A.4 Document Retrieval Results

We report the importance of combining the two document retrieval methods described in Section 3.1 by comparing their recall at rank 1000 in Table 4. These figures show that combining the two techniques results in being only a few points away from perfectly retrieving all relevant documents.

DefSent: Sentence Embeddings using Definition Sentences

Hayato Tsukagoshi **Ryohei Sasano** **Koichi Takeda**

Abstract

Sentence embedding methods using natural language inference (NLI) datasets have been successfully applied to various tasks. However, these methods are only available for limited languages due to relying heavily on the large NLI datasets. In this paper, we propose DefSent, a sentence embedding method that uses definition sentences from a word dictionary, which performs comparably on unsupervised semantics textual similarity (STS) tasks and slightly better on SentEval tasks than conventional methods. Since dictionaries are available for many languages, DefSent is more broadly applicable than methods using NLI datasets without constructing additional datasets. We demonstrate that DefSent performs comparably on unsupervised semantics textual similarity (STS) tasks and slightly better on SentEval tasks to the methods using large NLI datasets. Our code is publicly available at https://github.com/hpprc/defsent.

1 Introduction

Sentence embeddings represent sentences as dense vectors in a low dimensional space. Recently, sentence embedding methods using natural language inference (NLI) datasets have been successfully applied to various tasks, including semantic textual similarity (STS) tasks. However, these methods are only available for limited languages due to relying heavily on the large NLI datasets. In this paper, we propose DefSent, a sentence embedding method that uses definition sentences from a word dictionary. Since dictionaries are available for many languages, DefSent is more broadly applicable than the methods using NLI datasets without constructing additional datasets.

Defsent is similar to the model proposed by Hill et al. (2016) in that it generates sentence embeddings so that the embeddings of a definition sentence and the word it represents are similar. However, while Hill et al. (2016)'s model is based on recurrent neural network language models, DefSent is based on pre-trained language models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), with a fine-tuning mechanism as well as Sentence-BERT (Reimers and Gurevych, 2019). Sentence-BERT is one of the state-of-the-art sentence embedding models, which is based on pre-trained language models that are fine-tuned on NLI datasets. Overviews of Sentence-BERT and DefSent are depicted on Figure 1.

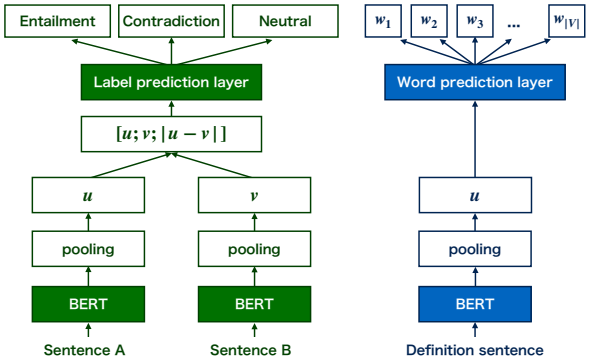

Figure 1: Sentence-BERT (left) and DefSent (right).

2 Sentence Embedding Methods

In this section, we introduce BERT, RoBERTa, and Sentence-BERT, followed by a description of DefSent, our proposed sentence embedding method.

2.1 BERT and RoBERTa

BERT is a pre-trained language model based on the Transformer architecture (Vaswani et al., 2017). Utilizing masked language modeling and next sentence prediction, BERT acquires linguistic knowledge and outputs contextualized word embeddings. In masked language modeling, a specific proportion of input tokens is replaced with a special token [MASK], and the model is trained to predict these

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 411–418
August 1–6, 2021. ©2021 Association for Computational Linguistics

masked tokens. Next sentence prediction is a task to predict whether two sentences connected by a sentence separator token [SEP] are consecutive sentences in the original text data. BERT uses the output embedding of the unique token [CLS] at the beginning of each such sentence for prediction.

RoBERTa has the same structure as BERT. It attempts to improve BERT by removing the next sentence prediction from pre-training objectives and increasing the data size and batch size. While both Sentence-BERT and DefSent are applicable to BERT and RoBERTa, we use BERT for the explanations in this paper.

2.2 Sentence-BERT

Conneau et al. (2017) proposed InferSent, a sentence encoder based on a Siamese network structure. InferSent trains the sentence encoder such that similar sentences are distributed close to each other in the semantic space. Reimers and Gurevych (2019) proposed Sentence-BERT, which also uses a Siamese network to create BERT-based sentence embeddings. An overview of Sentence-BERT is depicted on the left side of Figure 1. Sentence-BERT first inputs the sentences to BERT and then constructs a sentence embedding from the output contextualized word embeddings by pooling. They utilize the following three types of pooling strategy.

CLS Using the [CLS] token embedding.; When using RoBERTa, since the [CLS] token does not exist, the beginning-of-sentence token <s> is used as an alternative.

Mean Using the mean of the contextualized embeddings of all words in a sentence.

Max Using the max-over-time of the contextualized embeddings of all words in a sentence.

Let u and v be the sentence embeddings for each of the sentence pairs obtained by pooling. Then compose a vector $[u; v; |u - v|]$ and feed it to the label prediction layer, which has the same number of output dimensions as the number of classes. For fine-tuning, Reimers and Gurevych uses the SNLI dataset (Bowman et al., 2015) and the Multi-Genre NLI dataset (Williams et al., 2018), which together contain about one million sentences.

2.3 DefSent

Since they have the same meaning, we focus on the relationship between a definition sentence and the word it represents. To learn how to embed sentences in the semantic vector space, we train the sentence embedding model by predicting the word from definitions. An overview of DefSent is depicted on the right side of Figure 1. We call the layer that predicts the original token from the [MASK] embeddings used in the masked language modeling during BERT pre-training a word prediction layer. Also, we use w_k to denote the word corresponding to a given definition sentence X_k.

DefSent inputs the definition sentence X_k to BERT and derives the sentence embedding u by pooling the output embeddings. As in Sentence-BERT, three types of pooling strategy are used: CLS, Mean, and Max. Then, the derived sentence embedding u is input to the word prediction layer to obtain the probability $P(w_k|X_k)$. We use cross-entropy loss as a loss function and fine-tune BERT to maximize $P(w_k|X_k)$.

In DefSent, the parameters of the word prediction layer are fixed. This setting allows us to fine-tune models without training an additional classifier, as is the case with both InferSent and Sentence-BERT. Additionally, since our method uses a word prediction layer that has been pre-trained in masked language modeling, the sentence embedding u is expected to be similar to the contextualized word embedding of w_k when w_k appears as the same meaning as X_k.

3 Word Prediction Experiment

To evaluate how well DefSent can predict words from sentence embeddings, we conducted an experiment to predict a word from its definition.

3.1 Dataset

DefSent requires pairs of a word and its definition sentence. We extracted these from the Oxford Dictionary dataset used by Ishiwatari et al. (2019). Each entry in the dataset consists of a word and its definition sentence, and a word can have multiple definitions. We split this dataset into train, dev, and test sets in the ratio of 8:1:1 word by word to evaluate how well the model can embed unseen definitions of unseen words. It is worth noting that since DefSent utilizes the pre-trained word prediction layer of BERT and RoBERTa, it is impossible to obtain probabilities for out-of-vocabulary (OOV) words. Therefore, we cannot calculate losses of these OOV words in a straightforward way.[1] In our

[1] Although we could substitute the mean of subwords as OOV word embeddings, we opted to filter out OOV words for

experiments, we only use words and their respective definitions in the dataset, as contained by the model vocabulary. The statistics of the datasets are listed in Table 1.

3.2 Settings

We used the following pre-trained models: BERT-base (bert-base-uncased), BERT-large (bert-large-uncased), RoBERTa-base (roberta-base), and RoBERTa-large (roberta-large) from Transformers (Wolf et al., 2020). The batch size was 16, a fine-tuning epoch size was 1, the optimizer was Adam (Kingma and Ba, 2015), and we set a linear learning rate warm-up over 10% of the training data. For each respective model and pooling strategy, the learning rate was chosen based on the highest recorded Mean Reciprocal Rank (MRR) for the dev set in the range of $2^x \times 10^{-6}, x \in \{0, 0.5, 1, ..., 7\}$. We conducted experiments with ten different random seeds, and their mean was used as the evaluation score. Top-k accuracy (the percentage of correct answers within the first, third, and tenth positions) and MRR were calculated from the output word probabilities when a definition sentence was fed into the model. Also, we evaluated the performance of BERT-base without fine-tuning for comparison.

3.3 Results

Table 2 shows the experimental results.[2] `Max` was the best pooling strategy for BERT-base without fine-tuning, but its top-1 accuracy was extremely low at 0.0157. This indicates that it is not adequate for predicting words from definitions without fine-tuning. DefSent performed higher for larger models. In the case of BERT, `CLS` was the best pooling strategy for both base and large models. `CLS` was also the best pooling strategy for RoBERTa-base but `Mean` was the best for RoBERTa-large.

4 Extrinsic Evaluations

Next, to evaluate the general quality of the constructed sentence embedding, we conducted evaluations on semantic textual similarity (STS) tasks and SentEval tasks (Conneau and Kiela, 2018).

simplicity and intuitiveness.

[2]We report the fine-tuning time and computing infrastructure in Appendix A, and report the learning rate, means, and standard deviations on the word prediction experiment in Appendix B. We also show the actual predicted words when definition sentences and other sentences are given as inputs in Appendices C and D, respectively.

Table 2: Results of word prediction experiments.

4.1 Settings

We compared the performance of DefSent with several existing sentence embedding methods including InferSent (Conneau et al., 2017), Universal Sentence Encoder (Cer et al., 2018), and Sentence-BERT (Reimers and Gurevych, 2019). For the pooling strategies, we used the strategy that achieved the highest MRR in the word prediction task for each pre-trained model.[3] The performance of the existing methods was taken from Reimers and Gurevych (2019).

4.2 Semantic textual similarity tasks

We evaluated DefSent on unsupervised STS tasks. In these tasks, we compute semantic similarities of given sentence pairs and calculate Spearman's rank correlation ρ between similarities and gold scores of sentence similarities. In the unsupervised setting, none of the models are optimized on the STS datasets. Instead, the similarities of the given sentence embeddings are calculated using common similarity measures such as negative Manhattan distance, negative Euclidean distance, and cosine-similarity. In this study, we used cosine-similarity.

[3]We report the means and standard deviations on the unsupervised STS tasks and SentEval tasks for each respective model and pooling strategy in Appendices E and F.

Model	STS12	STS13	STS14	STS15	STS16	STS-B	SICK-R	Avg.

Table 4: Accuracy (%) for each task in SentEval.

We performed experiments on unsupervised STS tasks using the STS12-16 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS Benchmark (Cer et al., 2017), and SICK-Relatedness (Marelli et al., 2014) datasets. These datasets contain sentence pairs and their similarity scores, which is a real number from 0 to 5 assigned by human evaluations. Experiments were conducted with ten different random seeds, and the mean was used as the evaluation score.

Table 3 shows the experimental results. Although the training data size used in DefSent was only about 5% that of Sentence-BERT, DefSent-BERT-base and DefSent-RoBERTa-base performed comparably to Sentence-BERT-base and Sentence-RoBERTa-base. In particular, DefSent-RoBERTa models showed high performance in the STS Benchmark.

4.3 SentEval

SentEval (Conneau and Kiela, 2018) is a popular toolkit for evaluating the quality of universal sentence embeddings that aggregates various tasks, including binary and multi-class classification, natural language inference, and sentence similarity. For the SentEval evaluations, we trained a logistic regression classifier using sentence embeddings as input features to evaluate the extent to which each sentence embedding contained the important information for each task. We used the same tasks and settings as Reimers and Gurevych (2019) and performed a 10-fold cross-validation. We conducted experiments with three different random seeds, and the mean was used as the evaluation score.

Table 4 shows the results.[4] DefSent-RoBERTa-large achieved the best average score among all models. Also, increasing the model size improved the performance consistently. The performances of DefSent-BERT-large, DefSent-RoBERTa-base, and DefSent-RoBERTa-large were better than the performances of Sentence-BERT-based methods. These results indicate that DefSent embeds useful information that can be applied to various tasks.

5 Conclusion

In this paper, we proposed DefSent, a new sentence embedding method using a dictionary, and demonstrated its effectiveness through a series of experiments. Its performance was comparable to or even slightly better than existing methods using

[4] Reimers and Gurevych (2019) reported that there were minor difference from Sentence-BERT, so we omitted the results of Sentence-RoBERTa.

large NLI datasets. DefSent is based on dictionaries developed for many languages, so it does not require new language resources when applied to other languages. Since the model is trained with the same word prediction process as the masked language modeling, sentence embeddings derived by DefSent are expected to be similar to contextualized word embeddings of a word when it appears with the same meaning as the definition.

In future work, we will evaluate the performance of DefSent when it is applied to languages other than English and when it is applied to a broader range of downstream tasks, such as document classification tasks. We will also analyze the relationship between the sentence embeddings by DefSent and the contextualized word embeddings in the semantic vector space and investigate how model architecture and size influence the embeddings.

A Average Runtime and Computing Infrastructure

Fine-tuning for DefSent-BERT-base and DefSent-RoBERTa-base took about 5 minutes on a single NVIDIA GeForce GTX 1080 Ti. Fine-tuning for DefSent-BERT-large and DefSent-RoBERTa-large took about 15 minutes on a single Quadro GV100.

B Full Results of the Word Prediction Experiment

Table 5 shows the experimental results on the word prediction experiment for each model and pooling strategy with learning rate.

C Predictions for definition sentences

Table 6 shows the predicted words when the embeddings of definition sentences are input. We used BERT-large as a model and `CLS` as a pooling strategy for the experiment. For prediction, sentences were first input into the model to obtain sentence embeddings. Then the sentence embeddings were input into the pre-trained word prediction layer to obtain word probabilities. We show the top five words with the highest probability.

D Predictions for sentences other than definition sentences

Table 7 shows the predicted words when the embeddings of sentences other than definition sentences are input. We used BERT-large as a model and `CLS` as a pooling strategy for the experiment. The evaluation procedure is the same as for Appendix C.

E Full Results of the STS Evaluation

Table 8 shows the experimental results on STS tasks for each model and pooling strategy.

F Full Results of the SentEval Evaluation

Table 9 shows the experimental results on SentEval tasks for each model and pooling strategy.

Abstract

Modern sentence encoders are used to generate dense vector representations that capture the underlying linguistic characteristics for a sequence of words, including phrases, sentences, or paragraphs. These kinds of representations are ideal for training a classifier for an end task such as sentiment analysis, question answering and text classification. Different models have been proposed to efficiently generate general purpose sentence representations to be used in pretraining protocols. While averaging is the most commonly used efficient sentence encoder, Discrete Cosine Transform (DCT) was recently proposed as an alternative that captures the underlying syntactic characteristics of a given text without compromising practical efficiency compared to averaging. However, as with most other sentence encoders, the DCT sentence encoder was only evaluated in English. To this end, we utilize DCT encoder to generate universal sentence representation for different languages such as German, French, Spanish and Russian. The experimental results clearly show the superior effectiveness of DCT encoding in which consistent performance improvements are achieved over strong baselines on multiple standardized datasets.

1 Introduction

Recently, a number of sentence encoding representations have been developed to accommodate the need of sentence-level understanding; some of these models are discussed in (Hill et al., 2016; Logeswaran and Lee, 2018; Conneau et al., 2017), yet most of these representations have focused on English only.

To generate sentence representations in different languages, the most obvious solution is to train monolingual sentence encoders for each language. However, training a heavily parameterized monolingual sentence encoder for every language is inefficient and computationally expensive, let alone the impact on the environment. Thus, utilizing a non-parameterized model with ready-to-use word embeddings is an efficient alternative to generate sentence representations in various languages.

A number of non-parameterized models have been proposed to derive sentence representations from pre-trained word embeddings (Rücklé et al., 2018; Yang et al., 2019; Kayal and Tsatsaronis, 2019). However, most of these models, including averaging, disregard structure information, which is an important aspect of any given language. Recently, Almarwani et al. (2019) proposed a structure-sensitive sentence encoder, which utilizes Discrete Cosine Transform (DCT) as an efficient alternative to averaging. The authors show that this approach is versatile and scalable because it relies only on word embeddings, which can be easily obtained from large unlabeled data. Hence, in principle, this approach can be adapted to different languages. Furthermore, having an efficient, ready-to-use language-independent sentence encoder can enable knowledge transfer between different languages in cross-lingual settings, empowering the development of efficient and performant NLP models for low-resource languages.

In this paper, we empirically investigate the generality of DCT representations across languages as both a single language model and a cross-lingual model in order to assess the effectiveness of DCT across different languages.

2 DCT as sentence Encoder

In signal processing domain DCT is used to decompose signal into component frequencies revealing dynamics that make up the signal and transitions within (Shu et al., 2017). Recently, DCT has been adopted as a way to compress textual information

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 419–426

(Kayal and Tsatsaronis, 2019; Almarwani et al., 2019). A key observation in NLP is that word vectors obey laws of algebra King – Man + Woman = (approx.) Queen (Mikolov et al., 2013). Thus, given word embeddings, cast a sentence as a multi-dimensional signal over time, in which DCT is used to summarize the general feature patterns in word sequences and compress them into fixed-length vectors (Kayal and Tsatsaronis, 2019; Almarwani et al., 2019).

Mathematically, DCT is an invertible function that maps an input sequence of N real numbers to the coefficients of N orthogonal cosine basis functions of increasing frequencies (Ahmed et al., 1974). The DCT components are arranged in order of significance. The first coefficient (c[0]) represents the sum of the input sequence normalized by the square length, which is proportional to the average of the sequence (Ahmed et al., 1974). The lower-order coefficients represent lower signal frequencies which correspond to the overall patterns in the sequence. For example, DCT is used for compression by preserving only the coefficients with large magnitudes. These coefficients can be used to reconstruct the original sequence exactly using the inverse transform (Watson, 1994).

In NLP, Kayal and Tsatsaronis (2019) applied DCT at the word level to reduce the dimensionality of the embeddings size, while Almarwani et al. (2019) applied it along the sentence length as a way to compress each feature in the embedding space independently. In both implementations, the top coefficients are concatenated to generate the final representation for a sentence. As shown in (Almarwani et al., 2019), applying DCT along the features in the embeddings space renders representations that yield better results. Also, Zhu and de Melo (2020) noted that similar to vector averaging the DCT model proposed by (Almarwani et al., 2019) yields better overall performance compared to more complex encoders, thus, in this work, we adopt their implementation to extract sentence-level representations.

Specifically, given a sentence matrix $N \times d$, a sequence of DCT coefficients $c[0], c[1], ..., c[K]$ are calculated by applying the DCT type II along the d-dimensional word embeddings, where $c[K] = \sqrt{\frac{2}{N}} \sum_{n=0}^{N-1} v_n \cos \frac{\pi}{N}(n + \frac{1}{2})K$ (Shao and Johnson, 2008). Finally, a fixed-length sentence vector of size Kd is generated by concatenating the first K DCT coefficients, which we refer to as $c[0 : K]$.[1]

Task	Description
SentLen	Length prediction
WC	Word Content analysis
BShift	Word order analysis
TreeDepth	Tree depth prediction
Tense	Verb tense prediction
CoordInv	Coordination Inversion
SubjNum	Subject number prediction
ObjNum	Object number prediction
SOMO	Semantic odd man out

Table 1: Probing Tasks as described in (Conneau et al., 2018; Ravishankar et al., 2019).

3 Multi-lingual DCT Embeddings

3.1 Experimental Setups and Results

In our study, DCT is used to learn a separate encoder for each language from existing monolingual word embeddings. To evaluate DCT embeddings across different languages, we used the probing benchmark provided by Ravishankar et al. (2019), which includes a set of multi-lingual probing datasets.[2] The benchmark covers five languages: English, French, German, Spanish and Russian, derived from Wikipedia. The task set comprises 9 probing tasks, summarized in Table 1, that address varieties of linguistic properties including surface, syntactic, and semantic information (Conneau et al., 2018; Ravishankar et al., 2019). Ravishankar et al. (2019) used the datasets to evaluate different sentence encoders trained by mapping sentence representations to English. Unlike Ravishankar et al. (2019), we use the datasets to evaluate DCT embeddings for each language independently. As a baseline, in addition to the DCT embeddings, we use vector averaging to extract sentence representations from the pre-trained embeddings.

For model evaluations, we utilize the SentEval framework introduced in (Conneau and Kiela, 2018). In all experiments, we use a single-layer MLP on top of DCT sentence embeddings with the following parameters: kfold=10, batch_size=128, nhid=50, optim=adam, tenacity=5, epoch_size=4.

[1] Unlike (Almarwani et al., 2019), we note no further improvements with larger coefficients, thus, we only report the results of $1 \leq K \leq 4$.

[2] Refer to (Conneau et al., 2018) and (Ravishankar et al., 2019) for more details about the probing tasks.

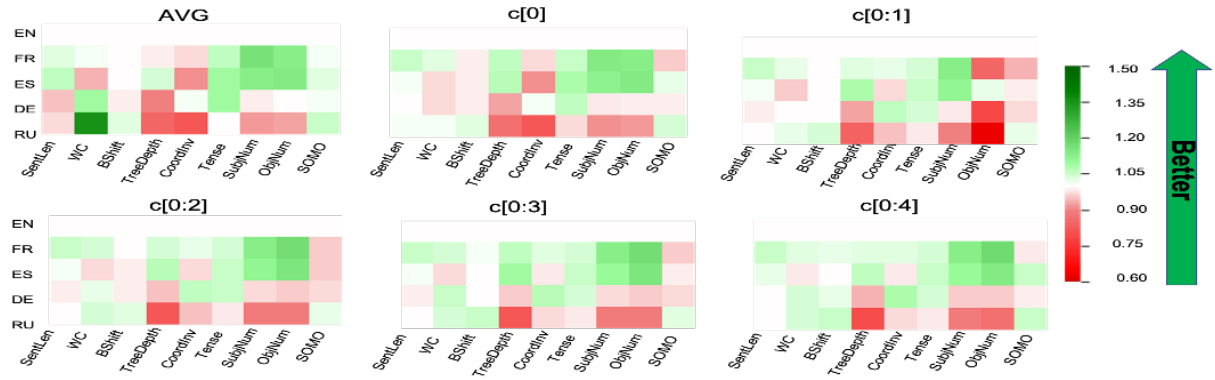

Figure 1: Results of the probing tasks comparing XX languages performance relative to English. White indicates a value of 1, demonstrating parity in performance with English. Red indicates better English performance while green indicates better XX Lang results.

For the word embeddings, we relied on the publicly available pre-trained FastText embeddings introduced in (Grave et al., 2018).[3]

Results: Figure 1 shows a heat-map reflecting the probing results of the different languages relative to English. Overall, French (FR) seems to be the closest to English (EN) followed by Spanish (ES) then German (DE) and then finally Russian (RU) across the various DCT coefficients. Higher coefficients reflect majority better performance across most tasks for FR, ES and DE. We see the most variation with worse results than English on the syntactic tasks of TreeDepth, CoordInv, Tense, SubjNum and ObjNum for RU. SOMO stands out for RU where it outperforms EN. The variation in Russian might be due to the nature of RU being a more complex language that is morphologically rich with flexible word order (Toldova et al., 2015).

In terms of the performance per number of DCT coefficients, we observe consistent performance gain across different languages that is similar to the English result trends. Specifically, for the surface level tasks, among the DCT models the $c[0]$ model significantly outperforms the AVG with an increase of $\sim$30 percentage points in all languages. The surface level tasks (SentLen and WC) show the most notable variance in performance, in which the highest results are obtained using the $c[0]$ model. However, the performance decreases in all languages when K is increased. On the other hand, for all languages, we observe a positive effect on the model's performance with larger K in both the syntactic and semantic tasks. The complete numerical results are presented in the Appendix in Table 5.

4 Cross-lingual Mapping based on DCT Encoding

4.1 Approach

Aldarmaki and Diab (2019)proposed sentence-level transformation approaches to learn context-aware representations for cross-lingual mappings. While the word-level cross-lingual transformations utilize an aligned dictionary of word embeddings to learn the mapping, the sentence-level transformations utilize a large dictionary of parallel sentence embeddings. Since sentences provide contexts that are useful for disambiguation for the individual word's specific meaning, sentence-level mapping yields a better cross-lingual representation compared to word-level mappings.

A simple model like sentence averaging can be used to learn transformations between two languages as shown in (Aldarmaki and Diab, 2019). However, the resulting vectors fail to capture structural information such as word order, which may result in poor cross-lingual alignment. Therefore, guided by the results shown in (Aldarmaki and Diab, 2019), we further utilize DCT to construct sentence representations for the sentence-level cross-lingual modeling.

4.2 Experiments Setups and Results

For model evaluation, we use the same cross-lingual evaluation framework introduced in (Aldarmaki and Diab, 2019). Intuitively, sentences tend to be clustered with their translations when their vectors exist in a well-aligned cross-lingual space. Thus, in this framework, cross-lingual mapping ap-

proaches are evaluated using sentence translation retrieval by calculating the accuracy of correct sentence retrieval. Formally, the cosine similarity is used to find the nearest neighbor for a given source sentence from the target side of the parallel corpus.

4.3 Evaluation Datasets and Results

To demonstrate the efficacy of cross-lingual mapping using the sentence-level representation generated by DCT models, similarly to Aldarmaki and Diab (2019), we used the WMT'13 data set that includes EN, ES and DE languages (Bojar et al., 2013). We further used five language pairs from the WMT'17 translation task to evaluate the effectiveness of DCT-based embeddings. Specifically, we used a sample of 1 million parallel sentences from WMT'13 common-crawl data; this subset is the same one used in (Aldarmaki and Diab, 2019).[4] To assess efficacy of the DCT models for the cross-lingual mapping, we reported the performances of the sentence translation retrieval task within the WMT'13 test set, which includes EN, ES, and DE as test languages (Bojar et al., 2013). Specifically, we first used the 1M parallel sentences for the alignment between source languages (ES and DE) to a target language (EN) independently. We evaluated the translation retrieval performance in all language directions, from source languages to English: ES-EN and DE-EN, as well as between the sources languages: ES-DE.

Similarly, we conduct a series of experiments on 5 different language pairs from the WMT'17 translation task, which includes DE, Latvian (LV), Finnish (FI), Czech (CS), and Russian (RU), each of which is associated with an English translation (Zhang et al., 2018).[5] For each language pair, we sampled 1M parallel sentences from their training corpus for the cross-lingual alignment between each source language and EN. Also, we used the test set available for each language pair to evaluate the translation retrieval performances.

In our experiments, we evaluate the translation retrieval performance in all language directions using three type of word embeddings: 1- a publicly available pre-trained word embeddings in which we show the performance of DCT against averaging, which we refer to hereafter as out-of-domain embeddings as shown in Table 2. 2- Also, we ran additional experiments in which we used a domain specific word embedding (that we trained on genre that is similar to the translation task) and 3-contextualized word embedding, which we refer to hereafter as in-domain embeddings as shown in Table 3.

Lang pair	AVG	$c[0]$	$c[0:1]$	$c[0:2]$	$c[0:3]$
Lang→EN

ES→DE	57.67	56.46	**60.53**	59.83	57.87

Table 2: Sentence translation retrieval accuracy based on out of domain pre-trained Fasttext embeddings. Arrows indicate the direction, with English (EN), Spanish (ES), German (DE), Russian (RU), Czech (CS), Finnish (FI) , Turkish (TR), and Latvian (LV).

Out-of-domain embeddings: For all language pairs, DCT-based models outperform AVG and c[0] models in the sentence translation retrieval task. In the direction $\rightarrow EN$, while the c[0:2] model achieve the highest accuracy for ES, DE, RU, and FI languages, the c[0:3] model achieved the highest accuracy for CS and LV languages. Specifically, the c[0:2] model yields increases of 5.59%-30% in the direction from source languages (ES, DE, RU, and FI) to English compared to the AVG model. Also, while the c[0:3] model yielded an increase of 13% gains over the baseline for CS, it provides the most notable increase of 38% for LV. For the opposite directions $EN \rightarrow source$, the DCT-based embeddings model also outperformed AVG and c[0] models. In particular, we observed accuracy gains of at least 3.81% points using more coefficients in DCT-based models compared to the AVG and c[0] models for all languages. A similar trend is observed in the zero-shot translation retrieval between the two non English languages (ES and DE), in which DCT-based models outperform the AVG and c[0] models.

[4]Evaluation scripts and WMT'13 dataset as described in (Aldarmaki and Diab, 2019) are available in https://github.com/h-aldarmaki/sent_translation_retrieval

[5]The pre-processed version of the WMT'17 dataset was used. For more information refer to (Zhang et al., 2018).

Table 3: Accuracy using in-domain FastText (FT) and Contextualized mBERT embeddings. The best results for each row in **Bold** & for each direction in **gray**.

Model	**Average Accuracy**
FastText (dict) [ALD2019]	69.04
ELMo (word) [ALD2019]	82.23
FastText (word) [ALD2019]	74.00
FastText AVG (sent) [ALD2019]	76.92
ELMo AVG (sent) [ALD2019]	84.03
FastText $c[0]$ (sent)	76.33
FastText $c[0:1]$ (sent)	80.39
FastText $c[0:2]$ (sent)	79.42
FastText $c[0:3]$ (sent)	77.99
mBERT AVG (sent)	90.38
mBERT $c[0]$ (sent)	90.34
mBERT $c[0:1]$ (sent)	**91.83**
mBERT $c[0:2]$ (sent)	91.62
mBERT $c[0:3]$ (sent)	90.56

Table 4: The average accuracy of various models across all language retrieval directions as reported in (Aldarmaki and Diab, 2019), refer to as [ALD2019] in the table, along with the different DCT-based models in this work, in which (word) refers to word-level mapping, (sent) refers to sentence-level mapping, and (dict) refers to the baseline (using a static dictionary for mapping). **Bold** shows the best overall result.

In-domain embeddings: To ensure comparability to state-of-the-art results, we further utilized in-domain FastText embeddings as those used in (Aldarmaki and Diab, 2019) as well as contextualized-based word embeddings. For the in-domain FastText embeddings, the FastText (Bojanowski et al., 2017) is utilized to generate word embeddings from 1 Billion Word benchmark (Chelba et al., 2014) for English, and equivalent subsets of about 400 million tokens from WMT'13 (Bojar et al., 2013) news crawl data. For the contextualized-based embeddings, we utilized multilingual BERT (mBERT) introduced in (Devlin et al., 2019) as contextual word embeddings, in which representations from the last BERT layer are taken as word embeddings. As shown in Table 3, using in-domain word embeddings yields stronger results compared to the pre-trained embeddings we use in the previous experiments as illustrated in Table 2. On the other hand, we observe additional improvements using mBERT as word embeddings on all models. Furthermore, increasing K has positive effect on both embeddings, in which $c[0:1]$ demonstrate performance gains compared to other models in all language directions. This trend is clearly observed in the zero-shot performance between the non English languages.

Furthermore, as shown in Table 4, we obtained a state-of-the-art result using mBERT $c[0:1]$ with **91.83%** average accuracy across all translation directions compared to the 84.03% average accuracy of ELMo as reported in (Aldarmaki and Diab, 2019).

5 Conclusion

In this paper, we extended the application of DCT encoder to multi- and cross-lingual settings. Experimental results across different languages showed that similar to English using DCT outperform the vector averaging. We further presented a sentence-level-based approach for cross-lingual mapping without any additional training parameters. In this context, the DCT embedding is used to generate sentence representations, which are then used in the alignment process. Moreover, we have shown that incorporating structural information encoded in the lower-order coefficients yields significant performance gains compared to the AVG in sentence translation retrieval.

Acknowledgments

We thank Hanan Aldarmaki for providing us the in-domain FastText embeddings and for sharing many helpful insights. We would also like to thank 3 anonymous reviewers for their constructive feedback on this work.

Abstract

High-quality alignment between movie scripts and plot summaries is an asset for learning to summarize stories and to generate dialogues. The alignment task is challenging as scripts and summaries substantially differ in details and abstraction levels as well as in linguistic register. This paper addresses the alignment problem by devising a fully unsupervised approach based on a global optimization model. Experimental results on ten movies show the viability of our method with 76% F1-score and its superiority over a previous baseline. We publish alignments for 914 movies to foster research in this new topic.

1 Introduction

Motivation and Problem. An important aspect of language understanding is the ability to produce a concise and fluent summary of stories, dialogues and other textual contents. Automatic text summarization is a long-standing topic in natural language processing (Nenkova and McKeown, 2012; Dey and Das, 2020), with numerous approaches for a variety of inputs, largely focusing on news articles and scholarly publications (e.g., See et al. (2017); Hardy et al. (2019); Lev et al. (2019)).

In this paper, our focus is on less explored *narrative* texts such as books and movie scripts. Our goal is to automatically align scenes from movie scripts with sentences from plot summaries. Such alignments support story browsing and explorative search over screenplays (e.g., find all love scenes), and can also be an asset towards improving summarization and text-generation models for dialogues and other narratives.

Figure 1 shows an example: a scene snippet from the movie script of *Shrek*, and its corresponding sentence from the plot description of the movie's Wikipedia article. Establishing this alignment is challenging for three reasons:

- *Input Length:* Movies have many scenes (often more than a hundred), with longer dialogues or multi-person conversations. Plot summaries, on the other hand, are much shorter (e.g., 700 words for *Shrek* on Wikipedia).
- *Disparate Registers:* Scripts and summaries have fundamentally different registers (i.e., language styles, vocabulary and structure). Scripts are dominated by direct speech in dialogues, whereas plot summaries consist of, often complex, descriptive sentences and may introduce abstractions (e.g. *"fell in love ..."* instead of giving details on dating, kissing etc.).
- *Disparate Granularities:* Scripts contain every detail of the screenplay, whereas summaries focus on salient points and can leave out less important sub-stories. Thus, the units in scripts–*scenes*–and the units in plot summaries–*sentences*–are difficult to match.

Narrative Alignment Task: Given a *script* S consisting of a sequence of m scenes $\{s_1, s_2, ..., s_m\}$ and a *summary* U of n sentences $\{u_1, u_2, ..., u_n\}$, the narrative alignment task is to find a mapping between S and U, where both sides can be partial (i.e., some scenes and some sentences are not mapped) and certain constraints are satisfied.

Prior Work and its Limitations. The task of aligning narratives across different registers, like script dialogues and plot summaries, has not received much attention before. Gorinski and Lapata (2015) proposed a graph-based summarization method for movie scripts, exploiting given alignments between script scenes and plot sentences, to select a chain of scenes representing a film's story. Their focus was on the generation of the textual summary, and the alignment itself was addressed merely by simple best-match heuristics based on Nelken and Shieber (2006). Nevertheless, as this work is the relatively closest to ours, it is treated as

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 427–433

Script:

Suddenly the magic of the spell pulls Fiona away. She's lifted up into the air and she hovers there while the magic works around her. Suddenly Fiona's eyes open wide. She's consumed by the spell and then is slowly lowered to the ground.

SHREK: (going over to her) Fiona? Fiona. Are you all right?
FIONA: (standing up, she's still an ogre) Well, yes. But I don't understand. I'm supposed to be beautiful.
SHREK: But you ARE beautiful.

Summary:

Fiona is bathed in light as her curse is broken but is surprised that she is still an ogre, as she thought she would become beautiful, to which Shrek replies that she is beautiful

Figure 1: Snippet from *Shrek*'s script, and its summary sentence from *Shrek*'s Wikipedia article.

the baseline against which we evaluate our method. Tapaswi et al. (2015) used a graph-based method to compute an alignment between book chapters and video scenes using matching dialogues and characters as cues. As far as we know, our work is the first in-depth investigation of the narrative alignment task between movie scripts and plot summaries.

Approach and Contributions. We model the narrative alignment task as a global optimization over the possible pairs of scene-sentence mappings. To cope with disparate language registers, we devise embedding-based similarity measures. To cope with the length issue and different granularities, we design this for partial mappings where not all scenes and not all sentences need to be mapped. Typically, a notable subset of scenes is left out, but most sentences are aligned. To keep the alignments concise, we constrain the number of scenes that a sentence can be mapped to, and vice versa. Furthermore, we assume that script and summary both follow the chronology of events in the movie. This is modeled as a constraint for approximate order-preservation. All these considerations are cast into an Integer Linear Program (ILP).

The salient contributions of our work are:

- a fully unsupervised methodology using ILP for aligning two narratives, and
- an aligned corpus of movie scripts and plot summaries for 914 movies, which can serve as training data for text summarization and story generation tasks.

2 Approach

Our alignment method, AligNarr, has three steps: *(i) pre-processing*, which includes linking names found in both inputs, *(ii) building a similarity matrix* between the text units of the two narratives, and *(iii) constructing the alignment mapping* given the similarity matrix as input.

2.1 Pre-Processing

Given a movie script S and its summary U, we first segment them into corresponding units s_i and u_j, which are *scenes* and *sentences* respectively. An interior or exterior indicator 'INT.' or 'EXT.' is commonly used to mark a *scene heading*–separating different scenes–followed by a location or setting. A scene usually contains narrative descriptions as well as dialogue lines, as shown in Figure 1.

Linking Story Entities. We retrieve all phrases that are capitalized, as well as speaker names that start the dialogue lines in a given script, as *candidate names*, excluding the beginning of sentences. However, in movie scripts it is often the case that words are in all-capitals for emphasis, e.g., 'ARE' in Figure 1. Therefore, we first ran *Truecaser*[1] (Lita et al., 2003) to avoid having such words identified as candidate names.

For each pair of collected candidate names, we compute string similarity based on Levenshtein distance using *FuzzyWuzzy*[2]. Given the distance matrix between pairs of names, we then cluster the names using the DBSCAN algorithm (Ester et al., 1996) in order to have a cluster of names representing one *story entity*, e.g., E_{40}: {'Fiona', 'FIONA', 'Princess Fiona'}.

To resolve pronouns, we run *AllenNLP coreference resolution*[3], an end-to-end neural model (Lee et al., 2017) leveraging SpanBERT embeddings (Joshi et al., 2020). All occurrences of clustered names in the script and summary are then replaced with the corresponding entity identifier (e.g., E_{40}). Note that we only consider linking story entities appearing in the summary, since they represent a subset of story entities that are central to the story.

[2] github.com/seatgeek/fuzzywuzzy
[3] demo.allennlp.org/coreference-resolution

2.2 Similarity Matrix

We investigate three methods to measure similarity between units of script S and summary U:

Document Relevance Score. After removing stop words and punctuation, we compute the relevance scores of script units $\{s_1, ..., s_m\}$ (as the document collection D), for a given summary unit u_j (as the query q), using a ranking function. In this work, we use BM25 (Robertson and Zaragoza, 2009), a TF-IDF-based ranking function.

Word Overlap Score. We consider the sum of intersecting story entities and words (excluding stop words) that are similar (e.g., 'married' in s_i and 'wedding' in u_j), weighted by their similarity scores. As the similarity score between two words, we take the cosine similarity of word2vec embeddings (Mikolov et al., 2013); words are considered to be similar if their cosine similarity is above 0.5.

Sentence Similarity Score. We first compute sentence embeddings for a given summary unit u_j and all sentences in a script unit s_i, using RoBERTa (Liu et al., 2019) in *Sentence-Transformers*[4] (Reimers and Gurevych, 2019) optimized for the task of Semantic Textual Similarity (stsb-roberta-large). Taken as the similarity score is the highest cosine similarity between u_j's embeddings and embeddings of sentences in s_i. For practical reasons, we only compute sentence similarity scores for pairs of script and summary units with non-zero word overlap scores.

2.3 Alignment Mapping

Given a similarity matrix between units of script $S = \{s_1, ..., s_m\}$ and summary $U = \{u_1, ..., u_n\}$, we devise an Integer Linear Programming (ILP) model to optimize the overall alignment mapping as follows:

Objective Function. We want to maximize the story coherence between S and U in terms of textual similarity between the units: $\max \sum_i \sum_j sim(s_i, u_j) \cdot X_{ij}$, where $sim(s_i, u_j)$ is a numeric feature indicating the similarity or relatedness of s_i and u_j resulting from the previous step, and X_{ij} is a decision variable: $X_{ij} = 1$ if s_i and u_j are aligned, 0 otherwise.

Constraints. We define the following constraints to make sure that the alignment mapping follows the linear constraint of both narratives:

- Each summary sentence can only be aligned with at most r scenes: $\sum_j X_{*j} \leq r$.
- Each summary sentence can only be aligned with a block of r consecutive scenes: $\sum_i \sum_j \sum_k X_{ij} + X_{kj} \leq 1$ if $k \geq i + r$ and $\sum_i \sum_j \sum_k X_{ij} + X_{kj} \leq 1$ if $k \leq i - r, i \geq r$.
- The next summary sentence can only be about the same or the next scenes: $\sum_i \sum_j \sum_k X_{ij} + X_{kj+1} \leq 1$ if $k < i, j < n - 1$.
- The previous summary sentence can only be about the same or the previous scenes: $\sum_i \sum_j \sum_k X_{ij} + X_{kj-1} \leq 1$ if $k > i, j > 0$.

Candidate Space Pruning. To speed up the ILP inference, we exclude pairs of script and summary units, s_i and u_j, which are unlikely to be aligned. We employ the following pruning conditions:

- Given a summary unit u_j, we only consider scenes that yield similarity scores above θ in the ranked list of scenes.
- Given the most similar scene s_{top} to a summary unit u_j, we only consider scenes s_i in which $sim(s_{top}, u_j) - sim(s_i, u_j) < \sigma$.
- The candidate pairs (s_i, u_j) are within the diagonal line boundaries as depicted in Figure 2, by considering only (i, j) pairs that satisfy $j < ni/m + \tau n$ and $i < mj/n + \tau m$ with hyper-parameter τ.

3 Experiments

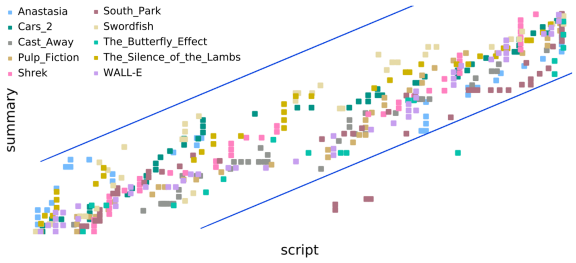

Figure 2: Ground truth alignment for ten movies.

Dataset. We used the ScriptBase corpus[5] (Gorinski and Lapata, 2015, 2018) that contains preprocessed scripts (with various automatic annotations and scene segmentation), along with the corresponding plot summaries taken from Wikipedia. Data statistics are given in Table 3. Two annotators manually created the alignment mappings for ten movies with varying script lengths, yielding inter-annotator agreement of 0.79 Fleiss' κ. The

ground-truth alignments (for which both annotators agree) are shown in Figure 2. These mappings confirm our intuition that a summary normally follows the corresponding script narration in a linear manner, with very few exceptions.

Hyper-Parameters. We defined r (in Section 2.3) as the average ratio of scenes to summary sentences $\lceil m/n \rceil$ based on ten movies, setting it to $r = 5$. θ was set to the 50^{th} percentile (i.e., the median). σ was set to the standard deviation of similarity scores for all scenes given the summary sentence u_j. Hyper-parameter τ, for pruning elements outside the diagonal line boundaries, was set to 0.3.

Baseline. Gorinski and Lapata (2015) used a classifier with sentence-level features (lemma overlap and word stem similarity) to compute sentence-to-sentence alignments. These aligned sentences were then used to identify aligned scene-sentence pairs forming the "gold chain" of scenes in this work (which focused more on the subsequent summarization task), in which a scene contains at least one sentence aligned with a summary sentence. They reported a precision of .53 at a recall rate of .82 for four movies. We re-ran their aligner (provided by the authors) on ten movies in our dataset.

4 Results and Discussion

We report macro-averaged precision (P), recall (R) and F1 results in Table 1. The best performing AligNarr variant, which runs ILP on the combination of document relevance and sentence similarity scores (AligNarr $_{\text{bm25·sts}}$) outperforms the baseline by a large margin on precision and F1-score.

Ablation Study. Document relevance scores alone (AligNarr $_{\text{bm25}}$) already yield very good performance with .737 F1-score averaged over ten movies. When combined with word overlap scores (AligNarr $_{\text{bm25·w2v}}$), the overall performance is further improved to .746 F1-score. Word overlap scoring using word embeddings is particularly useful when the summary uses different vocabulary, for example, using "...a *growing seedling*" for describing a scene with "...a small *plant* in its early stage of *growth*." Combining document relevance scores with sentence similarity scores (AligNarr $_{\text{bm25·sts}}$) results in the best performance with .756 F1 score. Adding word overlap scores on top of that (AligNarr $_{\text{bm25·sts·w2v}}$) yields higher precision of .808 but unfortunately at a lower recall rate of .720. Detailed comparisons and runtime are available in Appendix A and B.

We explored different strategies to combine the similarity matrices, and found element-wise matrix multiplication to perform the best.

Global vs. Local Alignments. To assess the benefit of using ILP, we devised an alignment algorithm focusing on finding the best scene alignment per summary sentence, that is, locally without using the ILP. Given a ranked list of scenes for a given summary sentence, we greedily pick scene-sentence pairs while observing the constraints on at most r consecutive scenes and the diagonal boundary for order-preservation. This local alignment algorithm results in .702 F1-score (AligNarr $_{\text{bm25·sts non-ILP}}$), showing the advantage of computing alignment mappings via global optimization.

Principal Limitation. The ILP constraints and diagonal line boundaries for candidate space pruning (presented in Section 2.3) are too restrictive to allow for 100% F1-score. Considering only candidate pairs that are within the diagonal line boundaries yields in reduced recall of .993, leading to F1-score of .997. If we also take into account all constraints employed by the ILP, recall is further reduced to .944, leading to F1-score of .969.

Contextual Embeddings. We also investigate the utility of contextual embeddings for computing word overlap scores. Specifically, we utilized a pretrained BERT model (bert-large-uncased) from Huggingface (https://huggingface.co/

movie	#scenes	#summary sentences	ratio	P	R	F1
Shrek	35	38	0.9	.89	.89	.89
Pulp Fiction	85	30	2.8	.89	.88	.88

Table 3: AligNarr $_{\text{bm25·sts}}$'s performance on ten movies.

transformers/model_doc/bert.html) to embed sentences from a given pair of script and summary units. We then retrieved individual vectors for each token (i.e., wordpiece) by summing together the outputs of BERT's last four layers.

For each token in the summary unit u_j, we look for similar tokens in the script unit s_i by computing cosine similarity of their embeddings, and take the highest one from each sentence as our intersecting tokens (only if their cosine similarity is above 0.7). Finally, BERT-based word overlap scores are the sum of overlapping tokens (excluding stop words) weighted by their cosine similarity.

Replacing word2vec embeddings with BERT embeddings (AligNarr $_{\text{bm25·sts·bert}}$ in Table 2) yields better performance for some movies like *Shrek*, *Cars 2* and *Anastasia*), which interestingly belong to the same genre (animation). The better performance may be attributed to the ability of BERT to better represent less common words (e.g., *ogre*) using contextual information. However, the overall performance is comparable with the performance of AligNarr $_{\text{bm25·sts·w2v}}$, which requires much less computing time (see Appendix B).

Movie Comparison. AligNarr's performance per movie is shown in Table 3. We observed a trend that the higher the ratio of scenes to summary sentences, the worse the alignment performance, particularly for three movies with ratio above r (average ratio, $r = 5$). This is potentially useful for estimating AligNarr's performance on other movies, which is negatively correlated to the compression rate of a given summary. The most difficult movie to align is *Cast Away*, where *(i)* there was only one active *story entity* throughout the narration, *(ii)* the summary is highly abstract (e.g., *"He also has regular conversations and arguments with Wilson."*), and *(iii)* the story plots and entity names do not fully match, possibly due to the outdated script version.

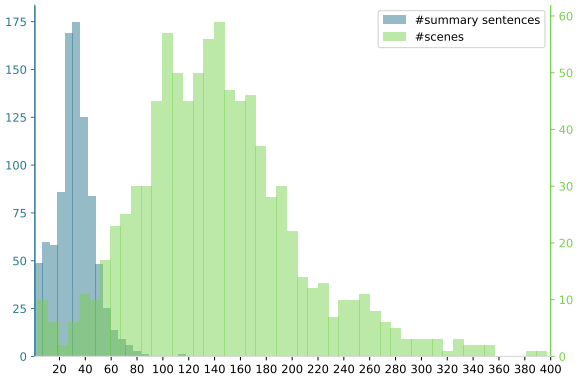

Figure 3: Histograms of number of scenes and summary sentences in ScriptBase movies.

Data and Code. We provide alignments by AligNarr for ten movies at d5demos.mpi-inf.mpg.de/alignarr/experiments; the same platform was used to manually annotate the alignment mappings. The code for producing the alignments is published at github.com/paramitamirza/AligNarr.

We applied the best performing AligNarr $_{\text{bm25·sts}}$ on the ScriptBase corpus[6] (Gorinski and Lapata, 2015, 2018), leveraging the XML version of movie scripts in *ScriptBase-J* and Wikipedia plot summaries from *ScriptBase-alpha*, totaling to 914 movies. Figure 3 shows the histograms of number of scenes and summary sentences in the corpus, with most summaries containing 20-40 sentences and most scripts consisting of around 100-180 scenes. The alignment mappings for those movies are made available for viewing and downloading at d5demos.mpi-inf.mpg.de/alignarr/scriptbase.

Table 5: AligNarr's runtime (in seconds).

A Detailed Ablation Study

We report in Table 4 the ablation study on AligNarr's performance using different similarity matrices on ten movies. In general, leveraging word-based (w2v) and sentence-based (sts) semantic similarity scores via embeddings, in addition to document relevance scores (bm25), results in significantly higher precision for some movies, while recall remains more or less stable.

B AligNarr's Runtime

In Table 5 we detail the average runtime of the best performing AligNarr $_{bm25\cdot sts}$, along with the computing infrastructure used.

Note that to compute sentence similarity scores (sts) we need word overlap scores via word2vec embeddings (w2v) to filter out scene-sentence pairs that are unlikely to be similar, in order to speed up the runtime. Computing word overlap scores using BERT embeddings (bert) requires almost 13 times the time of computing the scores with word2vec embeddings.

An Exploratory Analysis of Multilingual Word-Level Quality Estimation with Cross-Lingual Transformers

Abstract

Most studies on word-level Quality Estimation (QE) of machine translation focus on language-specific models. The obvious disadvantages of these approaches are the need for labelled data for each language pair and the high cost required to maintain several language-specific models. To overcome these problems, we explore different approaches to multilingual, word-level QE. We show that multilingual QE models perform on par with the current language-specific models. In the cases of zero-shot and few-shot QE, we demonstrate that it is possible to accurately predict word-level quality for any given new language pair from models trained on other language pairs. Our findings suggest that the word-level QE models based on powerful pre-trained transformers that we propose in this paper generalise well across languages, making them more useful in real-world scenarios.

1 Introduction

Quality Estimation (QE) is the task of assessing the quality of a translation without having access to a reference translation (Specia et al., 2009). Translation quality can be estimated at different levels of granularity: word, sentence and document level (Ive et al., 2018). So far the most popular task has been sentence-level QE (Specia et al., 2020), in which QE models provide a score for each pair of source and target sentences. A more challenging task, which is currently receiving a lot of attention from the research community, is word-level quality estimation. This task provides more fine-grained information about the quality of a translation, indicating which words from the source have been incorrectly translated in the target, and whether the words inserted between these words are correct (good vs bad gaps). This information can be useful for post-editors by indicating the parts of a sentence on which they have to focus more.

Word-level QE is generally framed as a supervised ML problem (Kepler et al., 2019; Lee, 2020) trained on data in which the correctness of translation is labelled at word-level (i.e. good, bad, gap). The training data publicly available to build word-level QE models is limited to very few language pairs, which makes it difficult to build QE models for many languages. From an application perspective, even for the languages with resources, it is difficult to maintain separate QE models for each language since the state-of-the-art neural QE models are large in size (Ranasinghe et al., 2020b).

In our paper, we address this problem by developing multilingual word-level QE models which perform competitively in different domains, MT types and language pairs. In addition, for the first time, we propose word-level QE as a zero-shot cross-lingual transfer task, enabling new avenues of research in which multilingual models can be trained once and then serve a multitude of languages and domains. The main contributions of this paper are the following:

i We introduce a simple architecture to perform word-level quality estimation that predicts the quality of the words in the source sentence, target sentence and the gaps in the target sentence.

ii We explore multilingual, word-level quality estimation with the proposed architecture. We show that multilingual models are competitive with bilingual models.

iii We inspect few-shot and zero-shot word-level quality estimation with the bilingual and multilingual models. We report how the source-target direction, domain and MT type affect the predictions for a new language pair.

iv We release the code and the pre-trained models as part of an open-source framework[1].

2 Related Work

Quality Estimation Early approaches in word-level QE were based on features fed into a traditional machine learning algorithm. Systems like QuEst++ (Specia et al., 2015) and MARMOT (Logacheva et al., 2016) were based on features used with Conditional Random Fields to perform word-level QE. With deep learning models becoming popular, the next generation of word-level QE algorithms were based on bilingual word embeddings fed into deep neural networks. Such approaches can be found in OpenKiwi (Kepler et al., 2019). However, the current state of the art in word-level QE is based on transformers like BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) where a simple linear layer is added on top of the transformer model to obtain the predictions (Lee, 2020). All of these approaches consider quality estimation as a language-specific task and build a different model for each language pair. This approach has many drawbacks in real-world applications, some of which are discussed in Section 1.

Multilinguality Multilinguality allows training a single model to perform a task from and/or to multiple languages. Even though this has been applied to many tasks (Ranasinghe and Zampieri, 2020, 2021) including NMT (Nguyen and Chiang, 2017; Aharoni et al., 2019), multilingual approaches have been rarely used in QE (Sun et al., 2020). Shah and Specia (2016) explore QE models for more than one language where they use multitask learning with annotators or languages as multiple tasks. They show that multilingual models led to marginal improvements over bilingual ones with a traditional black-box, feature-based approach. In a recent study, Ranasinghe et al. (2020b) show that multilingual QE models based on transformers trained on high-resource languages can be used for zero-shot, sentence-level QE in low-resource languages. In a similar architecture, but with multi-task learning, Sun et al. (2020) report that multilingual QE models outperform bilingual models, particularly in less balanced quality label distributions and low-resource settings. However, these two papers are focused on sentence-level QE and to the best of our knowledge, no prior work has been done on multilingual, word-level QE models.

3 Architecture

Our architecture relies on the XLM-R transformer model (Conneau et al., 2020) to derive the representations of the input sentences. XLM-R has been trained on a large-scale multilingual dataset in 104 languages, totalling 2.5TB, extracted from the CommonCrawl datasets. It is trained using only RoBERTa's (Liu et al., 2019) masked language modelling (MLM) objective. XML-R was used by the winning systems in the recent WMT 2020 shared task on sentence-level QE (Ranasinghe et al., 2020a; Lee, 2020; Fomicheva et al., 2020). This motivated us to use a similar approach for word-level QE.

Our architecture adds a new token to the XLM-R tokeniser called <GAP> which is inserted between the words in the target. We then concatenate the source and the target with a [SEP] token and we feed them into XLM-R. A simple linear layer is added on top of word and <GAP> embeddings to predict whether it is "Good" or "Bad" as shown in Figure 1. The training configurations and the system specifications are presented in the supplementary material.

Table 1: Information about the language pairs used to predict word-level quality. The **Language Pair** column lists the language pairs we used in ISO 639-1 codes. **Source** stands for the domain of the sentence and **MT System** is the Machine Translation system used to translate the sentences. **Competition** refers to the quality estimation competition in which the data was released and the last column indicates the number of instances the train dataset has for each language pair respectively.

4 Experimental Setup

4.1 QE Dataset

We used several language pairs for which word-level QE annotations were available: English-Chinese (En-Zh), English-Czech (En-Cs), English-German (En-De), English-Russian (En-Ru), English-Latvian (En-Lv) and German-English (De-En). The texts are from a variety of domains and the translations were produced using both neural and statistical machine translation systems. More details about these datasets can be found in Table 1 and in (Specia et al., 2018; Fonseca et al., 2019; Specia et al., 2020).

4.2 Evaluation Criteria

For evaluation, we used the approach proposed in the WMT shared tasks in which the classification performance is calculated using the multiplication of F1-scores for the 'OK' and 'BAD' classes against the true labels independently: words in the target ('OK' for correct words, 'BAD' for incorrect words), gaps in the target ('OK' for genuine gaps, 'BAD' for gaps indicating missing words) and source words ('BAD' for words that lead to errors in the target, 'OK' for other words) (Specia et al., 2018). In recent WMT shared tasks, the most popular category was predicting quality for words in the target. Therefore, in Section 5 we only report the F1-score for words in the target. Other results are presented in the supplementary material. Prior to WMT 2019, organisers provided separate scores for gaps and words in the target, while after WMT 2019 they produce a single result for target gaps and words. We follow this latter approach.

5 Results

The values displayed diagonally across section I of Table 2 show the results for supervised, bilingual, word-level QE models where the model was trained on the training set of a particular language pair and tested on the test set of the same language pair. As can be seen in section V, the architecture outperforms the baselines in all the language pairs and also outperforms the majority of the best systems from previous competitions. In addition to the target word F1-score, our architecture outperforms the baselines and best systems in target gaps F1-score and source words F1-score too as shown in Tables 5 and 6. In the following sections we explore its behaviour in different multilingual settings.

5.1 Multilingual QE

We combined instances from all the language pairs and built a single word-level QE model. Our results, displayed in section II ("All") of Table 2, show that multilingual models perform on par with bilingual models or even better for some language pairs. We also investigate whether combining language pairs that share either the same domain or MT type can be more beneficial, since it is possible that the learning process is better when language pairs share certain characteristics. However as shown in sections III and IV of Table 2, for the majority of the language pairs, specialised multilingual models built on certain domains or MT types do not perform better than multilingual models which contain all the data.

Table 2: Target F1-Multi between the algorithm predictions and human annotations. Best results for each language by any method are marked in bold. Sections I, II and III indicate the different evaluation settings. Section IV shows the results of the state-of-the-art methods and the best system submitted for the language pair in that competition. **NR** implies that a particular result was *not reported* by the organisers. Zero-shot results are coloured in grey and the value shows the difference between the best result in that section for that language pair and itself.

5.2 Zero-shot QE

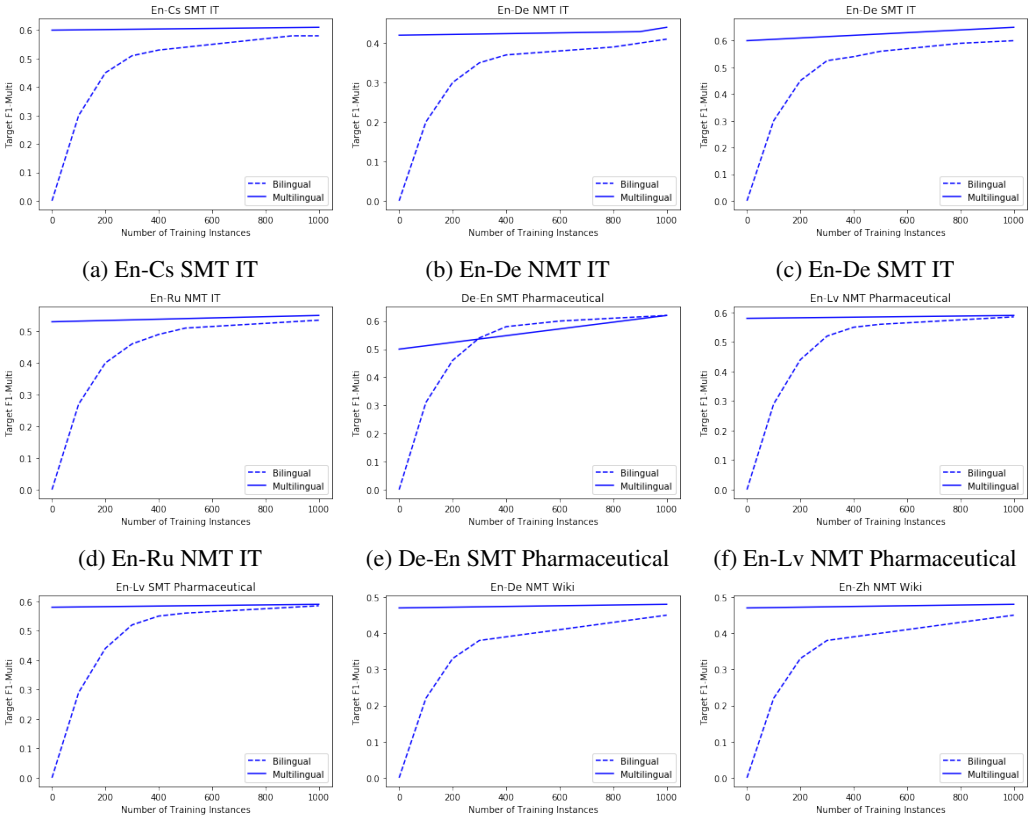
To test whether a QE model trained on a particular language pair can be generalised to other language pairs, different domains and MT types, we performed zero-shot quality estimation. We used the QE model trained on a particular language pair and evaluated it on the test sets of the other language pairs. Non-diagonal values of section I in Table 2 show how each QE model performed on other language pairs. For better visualisation, the non-diagonal values of section I of Table 2 show by how much the score changes when the zero-shot QE model is used instead of the bilingual QE model. As can be seen, the scores decrease, but this decrease is negligible and is to be expected. For most pairs, the QE model that did not see any training instances of that particular language pair outperforms the baselines that were trained extensively on that particular language pair. Further analysing the results, we can see that zero-shot QE performs better when the language pair shares some properties such as domain, MT type or language direction. For example, En-De SMT $\Rightarrow$ En-Cs SMT is better than En-De NMT $\Rightarrow$ En-Cs SMT and En-De SMT $\Rightarrow$ En-De NMT is better than En-Cs SMT $\Rightarrow$ En-De NMT.

We also experimented with zero-shot QE with multilingual QE models. We trained the QE model in all the pairs except one and performed prediction on the test set of the language pair left out. In section II ("All-1"), we show its difference to the multilingual QE model. This also provides competitive results for the majority of the languages, proving it is possible to train a single multilingual QE model and extend it to a multitude of languages and domains. This approach provides better results than performing transfer learning from a bilingual model.

One limitation of the zero-shot QE is its inability to perform when the language direction changes. In the scenario where we performed zero-shot learning from De-En to other language pairs, results degraded considerably from the bilingual result. Similarly, the performance is rather poor when we test on De-En for the multilingual zero-shot experiment as the direction of all the other pairs used for training is different. This is in line with results reported by Ranasinghe et al. (2020b) for sentence level.

5.3 Few-shot QE

We also evaluated how the QE models behave with a limited number of training instances. For each language pair, we initiated the weights of the bilingual model with those of the relevant All-1 QE and trained it on 100, 200, 300 and up to 1000 training instances. We compared the results with those obtained having trained the QE model from scratch for that language pair. The results in Figure 2 show



(a) En-Cs SMT IT (b) En-De NMT IT (c) En-De SMT IT

(d) En-Ru NMT IT (e) De-En SMT Pharmaceutical (f) En-Lv NMT Pharmaceutical

(g) En-Lv SMT Pharmaceutical (h) En-De NMT Wiki (i) En-Zh NMT Wiki

Figure 2: Target F1-Multi scores with Few-shot learning

that All-1 or the multilingual model performs well above the QE model trained from scratch (Bilingual) when there is a limited number of training instances available. Even for the De-En language pair, for which we had comparatively poor zero-shot results, the multilingual model provided better results with a few training instances. It seems that having the model weights already fine-tuned in the multilingual model provides an additional boost to the training process which is advantageous in a few-shot scenario.

6 Conclusions

In this paper, we explored multilingual, word-level QE with transformers. We introduced a new architecture based on transformers to perform word-level QE. The implementation of the architecture, which is based on Hugging Face (Wolf et al., 2020), has been integrated into the TransQuest framework (Ranasinghe et al., 2020b) which won the WMT 2020 QE task (Specia et al., 2020) on sentence-level direct assessment (Ranasinghe et al., 2020a)[2].

In our experiments, we observed that multilingual QE models deliver excellent results on the language pairs they were trained on. In addition, the multilingual QE models perform well in the majority of the zero-shot scenarios where the multilingual QE model is tested on an unseen language pair. Furthermore, multilingual models perform very well with few-shot learning on an unseen language pair when compared to training from scratch for that language pair, proving that multilingual QE models are effective even with a limited number of training instances. While we centered our analysis around the F1-score of the target words, these findings are consistent with the F1-score of the target gaps and the F1-score of the source words too. This suggests that we can train a single multilingual QE model on as many languages as possible and apply it on other language pairs as well. These findings can be beneficial to perform QE in low-resource languages for which the training data is scarce and when maintaining several QE models for different language pairs is arduous.

Exploration and Exploitation: Two Ways to Improve Chinese Spelling Correction Models

Abstract

A sequence-to-sequence learning with neural networks has empirically proven to be an effective framework for Chinese Spelling Correction (CSC), which takes a sentence with some spelling errors as input and outputs the corrected one. However, CSC models may fail to correct spelling errors covered by the confusion sets, and also will encounter unseen ones. We propose a method, which continually identifies the weak spots of a model to generate more valuable training instances, and apply a task-specific pre-training strategy to enhance the model. The generated adversarial examples are gradually added to the training set. Experimental results show that such an adversarial training method combined with the pre-training strategy can improve both the generalization and robustness of multiple CSC models across three different datasets, achieving state-of-the-art performance for CSC task.[1]

1 Introduction

Chinese Spelling Correction (CSC) aims to detect and correct spelling mistakes in Chinese texts. Many Chinese characters are visually or phonologically similar, while their semantic meaning may differ greatly. Spelling errors are usually caused by careless writing, automatic speech recognition, and optical character recognition systems. The CSC task has received steady attention over the past two decades (Chang, 1995; Xin et al., 2014; Wang et al., 2018; Hong et al., 2019). Unlike English, Chinese texts are written without using whitespace to delimit words, and it is hard to identify whether and which characters are misspelled without the information of word boundaries. The context information should be taken into account to reconstruct the word boundaries when correcting spelling mistakes, which makes CSC a long-standing challenge for Chinese NLP community.

Many early CSC systems follow the same recipe with minor variations, adopting a three-step strategy: detect the positions of spelling errors; generate candidate characters for these positions; and select a most appropriate one from the candidates to replace the misspelling (Yeh et al., 2013; Yu and Li, 2014; Zhang et al., 2015; Wang et al., 2019). Recently, a sequence-to-sequence (seq2seq) learning framework with neural networks has empirically proven to be effective for CSC, which transforms a sentence with errors to the corrected one (Zhang et al., 2020; Cheng et al., 2020b).

However, even if training a CSC model with the seq2seq framework normally requires a huge amount of high-quality training data, it is still unreasonable to assume that all possible spelling errors have been covered by the *confusion* sets (i.e. a set of characters and their visually or phonologically similar characters which can be potentially confused) extracted from the training samples. New spelling errors occur everyday. A good CSC model should be able to exploit what it has already seen in the training instances in order to achieve reasonable performance on easy spelling mistakes, but it can also explore in order to generalize well to possible unseen misspellings.

In this study, we would like to pursue both the *exploration* (unknown misspellings) and *exploitation* (the spelling errors covered by the confusion sets) when training the CSC models. To encourage a model to explore unknown cases, we propose a character substitution-based method to pre-train the model. The training data generator chooses about 25% of the character positions at random for prediction. If a character is chosen, we replace it with the character randomly selected from its confusion set (90% of the time) or a random character (10%

of the time). Then, the model is asked to predict the original character.

Because of the combination of spelling errors and various contexts in which they occur, even though the confusion sets are given and fixed, models may still fail to correct characters that are replaced by any character from its confusion set. To better exploit what the models has experienced during the training phase, we generate more valuable training data via adversarial attack (i.e. tricking models to make false prediction by adding imperceptible perturbation to the input (Szegedy et al., 2014)), targeting the weak spots of the models, which can improve both the quality of training data for fine-tuning the CSC models and their robustness against adversarial attacks. Inspired by adversarial attack and defense in NLP (Jia and Liang, 2017; Zhao et al., 2018; Cheng et al., 2020a; Wang and Zheng, 2020), we propose a simple but efficient method for adversarial example generation: we first identify the most vulnerable characters with the lowest generation probabilities estimated by a pre-trained model, and replace them with characters from their confusion sets to create the adversarial examples.

Once the adversarial examples are obtained, they can be merged with the original clean data to train the CSC models. The examples generated by our method are more valuable than those already existed in the training set because they are generated towards to the weak spots of the current models. Through extensive experimentation, we show that such adversarial examples can improve both generalization and robustness of CSC models. If a model pre-trained with our proposed character substitution-based method is further fine-tuned by adversarial training, its robustness can be improved about 3.9% while without suffering too much loss (less than 1.1%) on the clean data.

2 Method

2.1 Problem Definition

Chinese Spelling Correction aims to identify incorrectly used characters in Chinese texts and giving its correct version. Given an input Chinese sentence $X = \{x_1, ..., x_n\}$ consisting of n characters, which may contain some spelling errors, the model takes X as input and outputs an output sentence $Y = \{y_1, ..., y_n\}$, where all the incorrect characters are expected to be corrected. This task can be formulated as a conditional generation problem by modeling and maximizing the conditional probability of $P(Y|X)$.

2.2 Base Models

We use vanilla BERT (Devlin et al., 2019) and two recently proposed BERT-based models (Cheng et al., 2020b; Zhang et al., 2020) as our base models. When applying BERT to the CSC task, the input is a sentence with spelling errors, and the output representations are fed into an output layer to predict target tokens. We tie the input and output embedding layer, and all the parameters are fine-tuned using task-specific corpora. Soft-Masked BERT (Zhang et al., 2020) uses a Bi-GRU network to detect errors, and applies a BERT-based network to correct errors. SpellGCN (Cheng et al., 2020b) utilizes visual and phonological similarity knowledge through a specialized graph convolutional network and substitutes parameters of the output layer of BERT with the final output of it.

These models achieved state-of-the-art or close to state-of-the-art performance on the CSC task. However, we found that their performance and robustness could be further improved through pre-training and adversarial training, which help models explore unseen spelling errors and exploit weak points of themselves.

2.3 Pre-training Method

We collected unlabeled sentences from Wikipedia and Weibo corpora (Shang et al., 2015), covering both formal and informal Chinese texts. Training example pairs are generated by substituting characters in clean sentences, and models are trained to predict the original character. According to Chen et al. (2011), a sentence contains no more than two spelling errors on average, so we select and replace 25% characters in a sentence. The chosen Chinese character will be substituted by a character randomly selected from its confusion set (90% of the time) or a random Chinese character (10% of the time). The latter helps models to explore unknown misspellings not covered by the confusion sets.

2.4 Adversarial Example Generation and Adversarial Training

To efficiently identify and alleviate the weak spots of trained CSC models, we designed an adversarial attack algorithm for CSC tasks, which replaces the tokens in a sentence with spelling mistakes.

The adversarial examples generation algorithm in this paper can be divided into two main steps:

(1) determine the vulnerable tokens to change (2) replace them with the spelling mistakes that most likely to occur in the contexts (Algorithm 1).

For the i-th position of input sentence X, the positional score s_i can be obtained by the logit output o_i as follows:

$$s_i = o_i^{y_i} - o_i^{m_i}(o_i^{m_i} = max\{o_i^r, r \neq y_i\}) \quad (1)$$

where o_i^r denotes the logit output of character r in the i-th position, and y_i denotes the i-th character of ground truth sentence Y. The lower the positional score, the less confident the model is in predicting the position. Attacking this position makes the model output more likely to change. Once the positional score of each character in the input sentence is calculated, we sort these positions in ascending order according to the positional scores. This process can reduce the substitutions and maintain the original semantics as much as possible.

Once a vulnerable position is determined, the token at that position is replaced with one of its phonologically or visually similar characters. Confusion set D contains a set of visually or phonologically similar characters. In order to fool the target CSC model while maintaining the context, the character with the highest logit output in the confusion set is used as a replacement.

Given a sentence in training sets, its adversarial examples are generated by substituting a few characters based on the algorithm mentioned above. Adversarial training was conducted with these examples, improving the robustness of CSC models by alleviating their weak spots, and exploiting knowledge about easy spelling mistakes from confusion sets to help models generalize better.

Algorithm 1 Adversarial Attack Algorithm

Input:
$X = \{x_1, x_2, \ldots, x_n\}$, input Chinese sentence;
$Y = \{y_1, y_2, \ldots, y_n\}$, the corresponding ground truth;
λ, proportion of characters can be changed;
f, a target CSC model;
D, a confusion set created based on visually or phonologically similar characters;
Output:
$\widehat{X} = \{\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_n\}$, adversarial example;

$\widehat{X} \leftarrow X$
if $f(X) \neq Y$ **then**
  return $\widehat{X}$
else
  $num \leftarrow 0$
  while $f(\widehat{X}) = Y$ && $num \leq \lambda \cdot n$ **do**
    $O = \{o_1, o_2, ..., o_n\} \leftarrow$ Logit output of $f(\widehat{X})$
    $P = \{p_1, p_2, ..., p_k\} \leftarrow$ Sort the position p_i in ascending order based on s_{p_i} ($1 \leq p_i \leq n$ and y_{p_i} is a Chinese character)
    for each $i \in [1, k]$ **do**
      if $\hat{x}_{p_i} \neq y_{p_i}$ **then**
        continue
      end if
      $\hat{x}_{p_i} \leftarrow m_{p_i}$, where $m_{p_i} \in D(x_{p_i})$ and $p_i^{m_{p_i}} = max\{p_i^r, p_i^r \in D(x_{p_i})\}$
      break
    end for
    $num \leftarrow num + 1$
  end while
end if
return $\widehat{X}$

3 Experiments

3.1 Datasets

Statistics of the datasets used are shown in Table 1.

Pretraining data We generated a large corpus by a character substitution-based method. Models were first pre-trained on these nine million sentence pairs, and then fine-tuned using the training data mentioned below.

Training data The training data contained three human-annotated training datasets, SIGHAN 2013 (Wu et al., 2013), SIGHAN 2014 (Yu et al., 2014), and SIGHAN 2015 (Tseng et al., 2015). We also utilized an automatically generated dataset (Wang et al., 2018).

Table 1: Statistics information on the used data resources. A subset of the Wikipedia corpus and Weibo corpus, denoted by Wikipedia* and Weibo* respectively, was sampled from the entire corpus.

Pre-Training Data	#Line	Avg. Length
Wikipedia*	4,531,007	40.2
Weibo*	4,770,015	16.3

Training Data	#Line	Avg. Length	#Errors
(Wang et al., 2018)	271,329	42.6	381,962
SIGHAN 2013	350	49.3	339
SIGHAN 2014	3,437	49.6	5,136
SIGHAN 2015	2,339	31.3	3,048

Test Data	#Line	Avg. Length	#Errors
SIGHAN 2013	1,000	74.3	1,221
SIGHAN 2014	1,062	50.0	771
SIGHAN 2015	1,100	30.7	705

Test data Models' performance in detection and correction stage was evaluated in sentence level on three benchmark datasets, in the metrics of F1 scores (detection and correction). Characters in these datasets were transferred into simplified Chinese characters using OpenCC[2]. We revised the processed datasets for one simplified Chinese character may correspond to multiple traditional Chinese characters.

[2]https://github.com/BYVoid/OpenCC

Table 2: Performance of three models trained with the proposed pretraining strategy and adversarial training method. "**CLEAN**" stands for the testing results on the clean data, and "**ATTACK**" denotes the F1 scores under test-time attacks. "**DET**" and "**COR**" denote the F1 scores of detection and correction. The F1 scores were increased 4.1% on average by our pre-training method across the various models on the different datasets. Models' robustness was also improved about 3.9% while without suffering too much loss (less than 1.1%) on the clean data.

3.2 Models and Hyper-parameter Settings

For BERT and Soft-Masked BERT, we used the BERT model pre-trained on Chinese text provided by transformers[3] and fine-tuned it. Adam optimizer was used and the learning rate was 2e-5, except when adversarial training on SIGHAN 13 dataset, which was 1e-5. We followed Zhang et al. (2020) to set our hyper-parameters. The size of the hidden state in Bi-GRU in Soft-Masked BERT was 256.

Similarly, we followed the hyper-parameters settings of SpellGCN (Cheng et al., 2020b) except the batch size. Batch size was reduced to eight due to GPU memory. The BERT model used in SpellGCN was provided by the repository of BERT[4].

We conducted adversarial training on base models gained through pre-training and fine-tuning. The threshold λ was tuned on the validation set for each dataset. The number of sentence pairs directly used for training was twice that that used to generate adversarial examples.

3.3 Results and Analysis

As shown in Table 2, through pre-training particularly designed for CSC, the models achieve better results on three benchmark datasets. The average improvement of correction F1 score was 4.3% over base CSC models, which proves that our pre-training method has significant contribution to improving the model. Notably, BERT achieves state-of-the-art results on three datasets through our method.

[3]https://github.com/huggingface/transformers

[4]https://github.com/google-research/bert

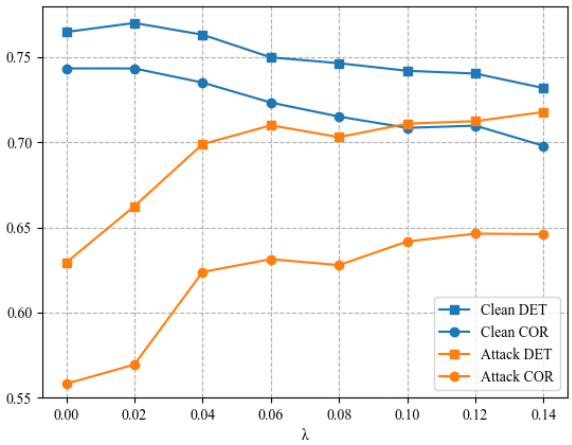

Figure 1: Trade-off between generalization and robustness. The blue and orange lines respectively denote the average F1 scores of BERT on the SIGHAN-2015 data set and the adversarial examples generated ($\lambda = 0.05$).

Figure 1 shows the trade-off between generalization and robustness during adversarial training. As the threshold increases, the robustness of BERT also increases with a slight performance decrease on clean dataset (less than 0.7%).

The experiments of the models under adversarial attacks were conducted with the base, pre-trained and adversarially trained models ($\lambda = 0.02$). We found that CSC models are vulnerable to adversarial examples as expected. The average drop in F1 score of three base models was 51.6%. Under the attacks, the F1 scores of adversarially trained model decreased less (44.1%), which indicates the adversarial training can substantially improve the robustness of CSC models. Compared with other models, BERT is more robust against adversarial attack (-41.2%). The reason for the more serious

robustness issues of other models may be related to the modules added to BERT, which increases the number of parameters, therefore it is more likely to overfit on the CSC data set.

4 Conclusion

In this paper, we have described a character substitution-based method to create large pseudo data to pre-train the models by encouraging them to explore unseen misspellings. We also proposed a data augmentation method for training the CSC models by continually adding the adversarial examples, particularly generated to alleviate the weak spot of the current model, to the training set. By the proposed pre-training strategy and adversarial training method, we can pursue both the exploration and exploitation when training the CSC models. Experimental results demonstrate that the CSC models trained with the data augmented by these pseudo data and adversarial examples can substantially be improved in both generalization and robustness.

Abstract

Adaptive Computation (AC) has been shown to be effective in improving the efficiency of Open-Domain Question Answering (ODQA) systems. However, current AC approaches require tuning of all model parameters, and training state-of-the-art ODQA models requires significant computational resources that may not be available for most researchers. We propose *Adaptive Passage Encoder*, an AC method that can be applied to an existing ODQA model and can be trained efficiently on a single GPU. It keeps the parameters of the base ODQA model fixed, but it overrides the default layer-by-layer computation of the encoder with an AC policy that is trained to optimise the computational efficiency of the model. Our experimental results show that our method improves upon a state-of-the-art model on two datasets, and is also more accurate than previous AC methods due to the stronger base ODQA model. All source code and datasets are available at https://github.com/uclnlp/APE.

1 Introduction

Open-Domain Question Answering (ODQA) requires finding relevant information for a given question and aggregating the information to produce an answer. The retriever-reader architecture, popularised by Chen et al. (2017), has shown great success in this task. The retriever acquires a set of documents from external sources (e.g., Wikipedia) and the reader extracts the answer spans from these documents (Clark and Gardner, 2018; Yang et al., 2019; Wang et al., 2019; Min et al., 2019; Asai et al., 2020). Recently, Min et al. (2020); Lewis et al. (2020b); Izacard and Grave (2020b) showed that generative reader models that exploit an encoder-decoder architecture can significantly outperform previous extractive models, thanks to their better capability in aggregating and combining evidence from multiple passages. However, these generative models are much more computationally expensive than extractive models, and often need to be trained with a large number of passages, making it hard to train these models for most researchers (Schwartz et al., 2020a).

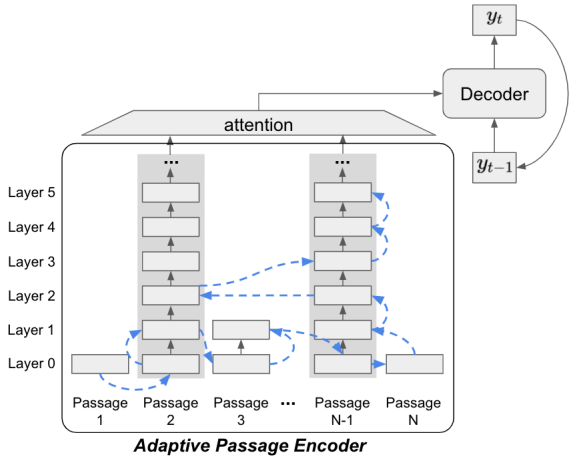

Figure 1: Overview of our approach. The adaptive passage encoder overrides the layer-by-layer computation of the encoder with an adaptive computation policy (indicated in blue dash arrows).

Wu et al. (2020) show that Adaptive Computation (AC) can significantly improve the efficiency of extractive ODQA models at inference time. However, it requires fine-tuning all model parameters with a multitask learning objective, making it computationally challenging to apply this method to current state-of-the-art models.

In this work, we explore an efficient approach to apply adaptive computation to large generative ODQA models. We introduce the *Adaptive Passage Encoder* (APE), a module that can be added to the encoder of an existing ODQA model, which has the following features: *1*) it efficiently reuses the encoder's hidden representations for calculating

Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Short Papers), pages 447–453
August 1–6, 2021. ©2021 Association for Computational Linguistics

the AC priorities; *2*) it does not require tuning of the base model and hence allows efficient training under limited resource; *3*) it does not require confidence calibration. Our experimental results on NaturalQuestions and TriviaQA show that our method improves the performance of the state-of-the-art model FiD (Izacard and Grave, 2020b), while also producing more accurate results (12.4% EM) than the AC method proposed by Wu et al. (2020).

2 Related Work

Open Domain Question Answering ODQA is a task that aims to answer a factoid question given a document corpus. Most works in this domain follow a *retriever-reader* design first proposed by Chen et al. (2017). The retriever collects a set of relevant passages, then the reader comprehends and aggregates the information from multiple passages to produce the answer. Depending on the design of the reader model, these systems could be further categorised into *extractive models* and *generative models*. Extractive models (Min et al., 2019; Yang et al., 2019; Wang et al., 2019; Asai et al., 2020; Karpukhin et al., 2020) exploit an answer extraction model to predict the probabilities of answer spans, and use global normalisation (Clark and Gardner, 2018) to aggregate the answer probabilities across multiple passages.

However, thanks to recent advances in sequence-to-sequence pretrained language models (Raffel et al., 2020; Lewis et al., 2020a), generative ODQA models (Min et al., 2020; Lewis et al., 2020b; Izacard and Grave, 2020b) achieve significant improvement upon extractive models, demonstrating stronger capability in combining evidence from multiple passages. We focus on generative models in this work.

Passage Retrieval and Re-Ranking Passage retrievers in ODQA systems are initially based on sparse vector representations. Chen et al. (2017) use TF-IDF, whereas Yang et al. (2019); Karpukhin et al. (2020); Wang et al. (2019) rely on BM25 for ranking passages (Robertson, 2004). Recently, Karpukhin et al. (2020); Lewis et al. (2020b); Izacard and Grave (2020a) achieved substantial increase in retrieval performance using dense representations. Our work is based on the retrieval results from a dense retriever (Izacard and Grave, 2020b), but we show that the proposed method can still improve the quality of the support passages despite the strong retrieval performance.

Nogueira and Cho (2019); Qiao et al. (2019); Mao et al. (2021) show that adding a separate cross-encoder re-ranker can improve the performance, but that comes with a significant increase of the computation at train or inference time. Despite that our proposed adaptive passage encoder can be viewed as an encoder with an integrated re-ranker, the focus of our work is to improve the computational efficiency, namely, enhancing the performance without a substantial increase in computation.

Adaptive Computation Adaptive computation allows the model to condition the computation cost on the input. For example, Schwartz et al. (2020b); Liu et al. (2020); Xin et al. (2020) propose models that can dynamically decide to early exit at intermediate layers when the confidence at the layer exceeds a threshold. They show that adaptively early exiting can significantly reduce the computational cost for various sequence classification tasks. Closest to our work, Wu et al. (2020) introduced adaptive computation for extractive ODQA models. We extend adaptive computation to generative ODQA models, and our approach can be incorporated in existing generative ODQA models without finetuning the base model.

3 Method

In this section, we will introduce the base model and how our proposed adaptive passage encoder works with it.

3.1 Base Model

Large generative ODQA models (Lewis et al., 2020b; Izacard and Grave, 2020b) share a similar encoder-decoder architecture. They first concatenate the question with all retrieved passages. Then the encoder encodes all passages and produces their hidden representations $h_1^L, \cdots, h_N^L$, where L is the number of encoder layers and N is the number of retrieved passages. We denote the hidden representation of the i-th passage at its j-th encoder layer as h_i^j. The decoder will attend to these hidden representations and generate the answer tokens sequentially.

3.2 Adaptive Passage Encoder

As shown in Fig. 1, the adaptive passage encoder overrides the layer-by-layer computation of the encoder of the base model with an adaptive computation policy. It adds two components on top of the

base encoder to define the policy: an answerability prediction model HasAnswer and a scheduler.

The HasAnswer model predicts the probability that a passage contains an answer to the question, given its hidden representation h_i^j. It first pools hidden representation h_i^j into a vector, then feeds the pooled representation to a multi-layer perceptron to produce the probability p_i^j.

The scheduler is then responsible for the selection and prioritisation of passages that are likely to contain the answer (Wu et al., 2020). As shown by the blue arrows in Fig. 1, the scheduler learns a scheduling policy to allocate encoder layer computation to passages. The scheduler will exit in early layers for those spurious passages while allocating more layers to the ones that it finds promising.

To achieve this goal, the scheduler produces a *priority* score q_n for each passage:

$$q_n = \sigma(g(p_n^{l_n}, n, l_n))p_n^{l_n} + f(p_n^{l_n}, n, l_n) \quad (1)$$

where n is the passage rank by the retriever, l_n is the index of its current encoder layer, g and f are two multi-layer perceptrons that learn the weight and bias respectively. Starting at the initial layer for all passages, the scheduler will select a passage with the maximum priority, forward one encoder layer for it $l'_n = l_n + 1$, and updates its priorities q_n with its new hidden representation $h_n^{l'_n}$ and has-answer probability $p_n^{l'_n}$. This process will iterate for B (budget) steps, and only k passages with the most layers computed are retained in the end.

3.3 Training the Adaptive Passage Encoder

Differently from Wu et al. (2020), our method does not require tuning the underlying base model. Since the number of parameters introduced by the HasAnswer model and the scheduler is less than 4% of the base model, APE can be trained very efficiently. The HasAnswer model is first trained with cross-entropy loss, supervised by the has-answer labels of the passages. Then we fix HasAnswer and train the scheduler with REINFORCE algorithm (Williams, 1992) to maximise the expected return, which is defined to encourage selection and prioritisation of passages that contain the answer. The selection action gains a positive reward $(1 - c)$ if it selects a relevant passage, otherwise a negative reward $-c$. Since the weight g and bias f in Eq. (1) are automatically learned during the training of the scheduler, our method does not require confidence calibration of the HasAnswer model, unlike the method proposed by Wu et al. (2020).

TriviaQA	78,785	8,837	11,313

Table 1: Number of samples of the evaluated datasets.

4 Experiments

4.1 Experimental Setup

Datasets Following (Lee et al., 2019; Izacard and Grave, 2020b), we evaluate our method on NaturalQuestions (Kwiatkowski et al., 2019) and TriviaQA (Joshi et al., 2017) whose statistics are shown in Table 1.

Evaluation Metrics Following Wu et al. (2020), we conduct the evaluation under different computational costs at inference time. Since the number of passages k is almost linearly correlated with memory consumption and number of operations, we evaluate the performances with various number of passages $k \in \{5, 10, 20\}$. To evaluate the end performance of ODQA models, we use the standard Exact Match (EM) score, which is the proportion of questions whose predicted answer matches exactly with the ground truth. We also include the unrestricted setting to compare the best performances of different models.

Technical Details We use FiD (Izacard and Grave, 2020b) as our base model. FiD-base and FiD-large contain $L = 12$ and 24 layers respectively, and we set the budget $B = Lk$. For the pooling operation in the HasAnswer model, we found max-pooling works better than mean-pooling and the [CLS] token, so max-pooling is used in all our experiments. We use discount factor $\gamma = 0.8$ and step penalty $c = 0.1$ during the REINFORCE training of the scheduler. More hyperparameters are presented in Appendix A.1.

Computational Feasibility Tuning a FiD-base model with $k = 20$ or a FiD-large model with $k = 10$ (batch size=1) would yield out-of-memory errors on a V100 (16GB) GPU. Hence, it is infeasible to train FiD with the previous AC method (Wu et al., 2020) in our setting. However, training with our proposed approach can be done in the same setting with a batch size 4 or larger within 8-15

hours.

4.2 Experimental Results

As shown in Table 2 under restricted top-k, our proposed method improves upon the FiD model on both datasets, and by a statistically significant margin on TriviaQA. It also outperforms the previous AC method (Wu et al., 2020) by 12.4% when $k = 10$ due to the stronger base model. The addition of APE allows FiD to significantly outperform RAG (Lewis et al., 2020b) on NaturalQuestions when $k \in \{10, 20\}$.

Previous adaptive computation methods (Wu et al., 2020; Schwartz et al., 2020b) was reported to have plateaued or degraded performances in the unrestricted setting. However, Table 2 shows that our approach does not have this issue.

4.3 Analysis of Passage Quality

To understand how APE outperforms the baselines, we analyse the quality of the final top-k passages retained by APE. Table 3 reports the top-k retrieval accuracy of the top-k passages. The results show that the top-k accuracy of the selected collection of documents by APE is significantly better than BM25, DPR, and FiD, which are strong retrieval baselines for ODQA. Combined with Table 2, it indicates that the better passage quality yielded by APE helps to improve the end ODQA performance of the model.

5 Conclusions

In this work, we explore an adaptive computation method that can be efficiently applied to an existing generative ODQA model. We find that, by replacing the encoder of generative ODQA models with our proposed adaptive passage encoder, we can train an effective adaptive computation policy without tuning the base model. This allows applying adaptive computation to large state-of-the-art generative models, which was previously challenging computation-wise. Our experimental results show that our method produces more accurate results than a state-of-the-art generative model on both NaturalQuestions and TriviaQA, and it outperforms the previous AC method by a large margin. The analysis also shows that our approach achieves better passage quality that leads to improvements in ODQA performance.
