Message from the General Chair

Welcome to the 17th Conference of the European Chapter of the Association for Computational Linguistics (EACL). This is the flagship European conference dedicated to European and international researchers, covering a broad spectrum of research areas of Computational Linguistics and Natural Language Processing.

Organizing a scientific conference of the prestige and size of EACL is always a great honor associated with several challenges. Our team had to tackle unusual complexities: this conference was one of the first scheduled to be in person after the long period of online conferences forced by COVID pandemic. The bidding process for a location, which typically takes place several years before the actual start of the conference, is mainly driven by the aim of expanding and involving the science community of all European countries: EACL selected Kyiv, Ukraine, as the physical location. As you all know, in February 2022, an unpredictable and dramatic event happened, the war between Russian and Ukraine, which made the organization in Kyiv impossible.

Considering the importance of physical interaction among researchers, especially after the restrictions imposed by the COVID pandemic, we worked hard with the EACL and ACL boards to find an alternative location, able to delight our attendees. Our team achieved this seemingly impossible goal of organizing a conference in a new location a few months before its start: we selected Dubrovnik, Croatia, while preserving the original aim of strengthening the connection with the Ukrainian community. In this respect, the Ukraine local committee will feature a dedicated panel session, “Low-resource languages in NLP products”, and a workshop to highlight work on Ukrainian language technologies. Following the latest conference, EACL 2023 will be “hybrid,” serving both virtual and in-person participants. As our official local chairs are not from the physical location, we needed a local team from Croatia for helping with the logistics. As a result, the main unexpected novelty of EACL 2023 is to have two local organizing committees from two different European countries.

In the remainder of this preface, I would like to thank EACL contributors chronologically with respect to my work timeline for EACL: Roberto Basili and Shuly Wintner, the new and former Presidents of ACL, along with the EACL board – thanks for having trusted me to manage the organization of the conference in rather complicated times. I started to be confident that we would have done a good job after Isabelle Augenstein and Andreas Vlachos accepted the role of PC Chairs. They have performed amazing work, creating an outstanding program, and also helping me in recruiting our fantastic organization team. A special thank is due to Preslav Nakov (EACL officer) for his support: thanks to his action, the proactiveness of David Yarowsky, and the fairless effort of Jennifer Rachford (our new secretary of the ACL business office), we successfully implemented the apparently unrealistic idea of switching from the already planned online conference to a hybrid setting with a physical location in Dubrovnik. Regarding the online side of our hybrid conference, we partnered with Underline (Sol Rosenberg, Damira Mrcic and Luka Simic), who also gave us support for managing the entire conference. While finalizing the location, we started to activate the different sections of the conference, for which my acknowledgements are again in chronological order:

- Ukraine Local Committee, Viktoriya Kolomiets, Mariana Romanyshyn, Oleksii Molchanovskiy, Oles Dobosevych, was instrumental in preserving our initial goal of connecting the Ukraine research community, organizing a panel and a workshop.
- The website chairs, Pepa Atanasova and Julius Cheng, started immediately to design our website, even when almost no information was available.
- The workshop chairs, Zeerak Talat and Antonio Toral, selected our conferences and led the selection of workshops for the joint ACL call.

- The tutorial chairs, Sameer Pradhan and Fabio Massimo Zanzotto, together with the ACL chairs, took care of the tutorial selection for the ACL related conferences.
- The demonstration chairs, Danilo Croce and Luca Soldaini, created a parallel conference program to select exciting demos.
- The Publicity Chairs, Laura Biester, Leshem Choshen and Joel Tetrault, have been our interface with the science community through social media platforms.
- The Publication Chairs, Carolina Scarton and Ryan Cotterell, produced high-quality proceedings, thanks to their competence and experience.
- The diversity and inclusion chairs, Sara Tonelli, Elena Cabrio, Verena Rieser, Spandana Gella, took care of DI and performed an amazing job, also working on hundreds applications.
- The Local Organising Committee of Croatia, Marko Tadić, Krešimir Šojat, and Daša Farkaš, gave essential help for the logistics, Visa, and student volunteers.
- Student Research Workshop Chairs, Matthias Lindemann, Alban Petit, and Elisa Bassignana, along with their faculty advisors Valerio Basile and Natalie Schluter, helped in setting the bases for forming great NLP researchers of the future.
- Our entire program committee, Senior Area Chairs, Area Chairs, reviewers, and best paper committee, was essential for obtaining our high-quality scientific program.
- The ACL's sponsorship director Chris Callison-Burch took care of our sponsorships.
- The student volunteers, as usual, are essential for a successful conference execution.
- Priscilla Rasmussen, our former ACL business office secretary, continued to provide us with useful advice.

Finally, I would like to thank our sponsors for helping us to fund scholarships and DI initiatives.

Alessandro Moschitti

 EACL 2023 General Chair

ACL Statement on the Ukraine situation

March 11, 2022

The Association for Computational Linguistics (ACL) condemns in the strongest possible terms the actions of the Russian Federation government in invading the sovereign state of Ukraine and engaging in war against the Ukrainian people. We stand together with Ukrainian NLP colleagues, the Ukrainian people, Russian NLP colleagues and Russian people who condemn the actions of the Russian Federation government, and all those around the world who have been impacted by the invasion.

As a small token of our solidarity with the Ukrainian people, the ACL has decided to temporarily sever its ties with Russia-based organizations, while at the same time allowing Russian scientists to remain part of the ACL community. In practice, this means that the ACL will refrain from accepting any sponsorship or allowing any exhibits from Russian-headquartered entities at ACL-run events. Russian scholars are still welcome to participate in ACL events and publish at ACL venues.

The ACL is committed to peace and condemns any form of violence and harassment. We are also committed to peaceful co-operation, mutual understanding, and tolerance across borders. NLP scholars from both Ukraine and Russia are welcome to get in touch with the ACL with any concerns.

Tim Baldwin, on behalf of the ACL Executive

Message from the Program Chairs

Welcome to the 17th Conference of the European Chapter of the Association for Computational Linguistics (EACL). After the last edition in 2021 having been held fully online due to the COVID pandemic, EACL 2023 is being held in “hybrid” mode this year, serving both virtual and in-person participants in Dubrovnik, Croatia. While the original plan was to hold the conference in Kyiv (which was the plan originally for EACL 2021), the ongoing war made the organisation in Ukraine impossible. In order to ensure that the original aim of strengthening the connections with the Ukrainian community is still served, our program features a dedicated session and a workshop to highlight work on Ukrainian language technologies.

Submission and Acceptance

EACL 2023 accepted direct submissions, as well as submissions via ARR. For direct submissions, abstracts were needed to be registered one week prior to the submission date.

In total, EACL 2023 received 1550 submissions, the largest number to date, with the 2021 edition having received 1400 submissions. Out of those, 1045 were long and 505 were short paper submissions. 81 were ARR papers that were committed to EACL. 249 submissions were withdrawn throughout the reviewing process, including before the full paper submission deadline. 55 papers were desk rejected for various reasons (missing the limitations section, anonymity policy, multiple submission policy, plagiarism or formatting violations).

By the time we as the programme chairs made acceptance decisions, 1166 submissions were still active in the system. We kept the acceptance rate in line with previous *ACL conferences, resulting in 281 papers accepted to the main conference (24.1%), and 201 papers accepted to the Findings of EACL (17.2%), with the remaining 58.7% being rejected. One paper accepted to the main conference and four papers accepted to Findings were subsequently withdrawn. Out of the final set of accepted main conference papers, we invited 178 to be presented orally, and all 281 papers accepted to the main conference to be presented during in-person sessions, as well as a plenary virtual poster session. The EACL 2023 program also features six papers from the Transactions of the Association for Computational Linguistics (TACL) journal, and one from the Computational Linguistics (CL) journal.

Limitations Section

Following EMNLP 2022, we required that each submitted paper must include an explicitly named Limitations section, discussing the limitations of the work. This was to counterbalance the practice of over-hyping the take-away messages of papers, and to encourage more rigorous and honest scientific practice. This discussion did not count towards the page limit, and we asked reviewers to not use the mentioned limitations as reasons to reject the paper, unless there was a really good reason to.

Areas

To ensure a smooth process, the submissions to EACL 2023 were divided into 21 areas. The areas mostly followed these of previous EACL, and more broadly *ACL conferences, reflecting the typical divisions in the field. We also had a special area for papers for which both SACs had a conflict of interest. Those papers were reviewed by the reviewers and ACs in their original areas, but the paper recommendations were made by a dedicated SAC, who was a senior member of the NLP community. The most popular areas with over 100 submissions were “Generation and Summarization”, “Language Resources and Evaluation”, and “Machine Learning in NLP”.

Best Paper Awards

From the papers submitted to EACL 2023, we selected 25 papers accepted to the main conference as candidates for a Best Paper award, based on nominations by the reviewers. These papers were assessed by the Best Paper Award Committee, who also determined the types of paper awards, following the ACL Conference Awards Policy. The selected best papers and runner-ups will be announced in a dedicated plenary session for Best Paper Awards on 4 May 2023.

Programme Committee Structure and Reviewing

Similar to prior NLP conferences, we adopted the hierarchical program committee structure, where for each area we invited 1-2 Senior Area Chairs (SACs), who worked with a team of Area Chairs (ACs), and a larger team of reviewers. We relied on statistics from prior years to estimate how many SACs, ACs and reviewers would be needed and ended up with 43 SACs, 118 ACs and 1634 reviewers. For identifying ACs and reviewers, we used the reviewer lists from prior *ACL conferences, and also encouraged all EACL 2023 authors to serve as reviewers, using a mandatory form requesting further information on their ability to serve as ACs, reviewers or emergency reviewers, which authors had to fill in on Softconf when registering their abstracts. We passed this information on to SACs, who were responsible for recruiting ACs and reviewers.

Rather than making assignments using a matching algorithm, we asked ACs and reviewers to bid on registered abstracts within their areas, to achieve a better fit. We went with this solution as the number of papers per area was relatively small, and we wanted to avoid poor reviewing assignments as much as possible. We then made an initial paper assignment, in which we ensured that each paper would be reviewed by at least one reviewer who bid “yes” for the submission, and by no reviewers who bid “no” for the submission.

Afterwards, we asked the SACs to fine-tune the allocations, and ensure each paper had one AC and three reviewers assigned to it.

To ensure the review quality, we provided detailed guidelines about what reviewers should and shouldn’t do in a review, based on the EMNLP 2022 guidelines. We also asked reviewers to flag papers for potential ethical concerns.

For pre-reviewed ARR papers, we asked SACs to not rely mainly on the reviewer scores, but to make their recommendations based on the text of the reviews, meta-reviews and the papers themselves. For making acceptance decisions, we mostly followed SAC recommendations, though also taking into account the overall quality of papers submitted to the conference. Where recommendations seemed overly harsh or lenient given the reviewers’ scores, reviews, author responses, or discussions amongst reviewers, we engaged in a dialogue with the respective SACs to make the final decision about the papers in question.

Ethics Committee

We also formed an Ethics Committee (EC) dedicated to ethical issues. The ethics committee considered 21 papers that were flagged by the technical reviewing committee for ethical concerns. Out of these, 10 were conditionally accepted, meaning the ethics issues had to be addressed in the camera-ready version, to be verified by the EC prior to final acceptance, and the other 11 were accepted as is. The authors of all conditionally accepted papers submitted the camera-ready version and a short response that explained how they had made the changes requested by the EC. The EC double-checked these revised submissions and responses, and confirmed that the ethical concerns had been addressed. As a result, all conditionally accepted papers were accepted to the main conference or Findings.

ACL Rolling Review

ACL Rolling Review (ARR) is an initiative of the Association for Computational Linguistics, where the reviewing and acceptance of papers to publication venues are done in a two-step process: (1) centralized rolling review and (2) the ability to commit the reviewed papers to be considered for publication by a publication venue. For EACL 2023, we decided to follow EMNLP 2022’s example and run a process which is separate from ARR, but also allows for ARR submissions. Specifically, authors could either submit papers to EACL 2023 directly, or commit ARR reviewed papers by a certain date. We coordinated with the ARR team to extract the submission, review and meta-review from the OpenReview system, according to a submission link that the author provided when committing their ARR submission to EACL. The ARR commitment deadline was set one month after the direct submission deadline since the ARR submissions already have their reviews and meta-recommendation. These ARR papers were then ranked by the SACs together with the direct submissions in the track, and based on the reviews and meta-reviews from ARR. Overall, EACL had 81 papers committed from ARR, of these 24 were accepted to the main conference and 20 were accepted to Findings of EACL.

Presentation Mode

We made the decision on which papers would be invited for oral poster presentations based on several factors: the relative rank of the paper according to SAC recommendation, whether the paper had been recommended for a best paper award by at least one reviewer, and for TACL and CL papers, the authors’ preference of presentation mode.

Keynotes and Panel

Another highlight of our program are the plenary sessions, for which we scheduled three talks, as well a panel:

- a keynote talk by Joyce Chai (University of Michigan) on “Language Use in Embodied AI!”
- a keynote talk by Edward Greffentette (Cohere AI and University College London) on “Going beyond the benefits of scale by reasoning about data”
- a keynote talk by Kevin Munger (Penn State University) on Chatbots for Good and Evil”
- a panel on “low-resource languages in NLP products” led by Mariana Romanyshyn with Viktoria Kolomiets (Grammarly), Mariana Romanyshyn (Grammarly), Oleksii Molchanovskiy (Ukrainian Catholic University) and Oles Doboşevych (Ukrainian Catholic University)

Thank You

EACL 2023 is the result of a collaborative effort and a supportive community, and we want to acknowledge the efforts of so many people with whom we worked directly and made significant efforts in putting together the programme for EACL 2023!

- Our General Chair, Alessandro Moschitti, who led the whole organising team, and helped with many of the decision processes;
- Our 43 Senior Area Chairs, who were instrumental in every aspect of the review process, from recruiting Area Chairs, correcting reviewer assignments, to making paper acceptances;
- Our 118 Area Chairs, who had the role of interacting with the reviewers, leading paper review discussions, and writing meta-reviews;

- The 1634 reviewers, who provided valuable feedback to the authors; The emergency reviewers, who provided their support at the last minute to ensure a timely reviewing process;
- Our Best Paper Selection Committee, who selected the best papers and the outstanding papers: Jonathan Kummerfeld (chair), Joakim Nivre, Bonnie Webber, Tamar Solorio and Hanna Hajishirzi;
- Our Ethics Committee, chaired by Zeerak Talat, for their hard work to ensure that all the accepted papers addressed the ethical issues appropriately, under a very tight schedule;
- Our amazing Publication Chairs, Carolina Scarton and Ryan Cotterell for compiling the proceedings in good time for the conference;
- Our Publicity Chairs, Laura Biester, Leshem Choshen and Joel Tetrault, for their work on managing the communications on social media platforms;
- Our website chairs, Pepa Atanasova and Julius Cheng for putting together the website for the conference and keeping it up to date;
- Damira Mrsic from Underline, for her support in developing the virtual conference platform;
- Jennifer Rachford, who has worked tirelessly online and on-site to ensure that EACL 2023 is a success.

We're looking forward to a great EACL 2023!

Table of Contents

<i>Using Punctuation as an Adversarial Attack on Deep Learning-Based NLP Systems: An Empirical Study</i>	
Brian Formento, Chuan Sheng Foo, Luu Anh Tuan and See Kiong Ng	1
<i>Self-Supervised Unimodal Label Generation Strategy Using Recalibrated Modality Representations for Multimodal Sentiment Analysis</i>	
Yewon Hwang and Jong-Hwan Kim	35
<i>Fighting FIRE with FIRE: Assessing the Validity of Text-to-Video Retrieval Benchmarks</i>	
Pedro Rodriguez, Mahmoud Azab, Becca Silvert, Renato Sanchez, Linzy Labson, Hardik Shah and Seungwhan Moon	47
<i>Improving Numeracy by Input Reframing and Quantitative Pre-Finetuning Task</i>	
Chung-Chi Chen, Hiroya Takamura, Ichiro Kobayashi and Yusuke Miyao	69
<i>Visualize Before You Write: Imagination-Guided Open-Ended Text Generation</i>	
Wanrong Zhu, An Yan, Yujie Lu, Wenda Xu, Xin Wang, Miguel Eckstein and William Yang Wang	78
<i>ImaginE: An Imagination-Based Automatic Evaluation Metric for Natural Language Generation</i>	
Wanrong Zhu, Xin Wang, An Yan, Miguel Eckstein and William Yang Wang	93
<i>Entity-Aware Dual Co-Attention Network for Fake News Detection</i>	
Sin-han Yang, Chung-chi Chen, Hen-Hsen Huang and Hsin-Hsi Chen	106
<i>CIKQA: Learning Commonsense Inference with a Unified Knowledge-in-the-loop QA Paradigm</i>	
Hongming Zhang, Yintong Huo, Yanai Elazar, Yangqiu Song, Yoav Goldberg and Dan Roth .	114
<i>Data-Efficient Methods For Improving Hate Speech Detection</i>	
Sumegh Roychowdhury and Vikram Gupta	125
<i>Learning the Effects of Physical Actions in a Multi-modal Environment</i>	
Gautier Dagan, Frank Keller and Alex Lascarides	133
<i>FVQA 2.0: Introducing Adversarial Samples into Fact-based Visual Question Answering</i>	
Weizhe Lin, Zhilin Wang and Bill Byrne	149
<i>Revisiting Intermediate Layer Distillation for Compressing Language Models: An Overfitting Perspective</i>	
Jongwoo Ko, Seungjoon Park, Minchan Jeong, Sukjin Hong, Euijai Ahn, Du-Seong Chang and Se-Young Yun	158
<i>Implicit Temporal Reasoning for Evidence-Based Fact-Checking</i>	
Liesbeth Allein, Marlon Saelens, Ruben Cartuyvels and Marie-Francine Moens	176
<i>Active PETs: Active Data Annotation Prioritisation for Few-Shot Claim Verification with Pattern Exploiting Training</i>	
Xia Zeng and Arkaitz Zubiaga	190
<i>Plan-then-Seam: Towards Efficient Table-to-Text Generation</i>	
Liang Li, Ruiying Geng, Chengyang Fang, Bing Li, Can Ma, Binhua Li and Yongbin Li	205
<i>A corpus of metaphors as register markers</i>	
Markus Egg and Valia Kordoni	220

<i>Translate First Reorder Later: Leveraging Monotonicity in Semantic Parsing</i>	
Francesco Cazzaro, Davide Locatelli, Ariadna Quattoni and Xavier Carreras	227
<i>PePe: Personalized Post-editing Model utilizing User-generated Post-edits</i>	
Jihyeon Lee, Taehee Kim, Yunwon Tae, Cheonbok Park and Jaegul Choo	239
<i>Infusing Context and Knowledge Awareness in Multi-turn Dialog Understanding</i>	
Ting-Wei Wu and Biing-Hwang Juang	254
<i>MCoNaLa: A Benchmark for Code Generation from Multiple Natural Languages</i>	
Zhiruo Wang, Grace Cuenca, Shuyan Zhou, Frank F. Xu and Graham Neubig	265
<i>Augmenting pre-trained language models with audio feature embedding for argumentation mining in political debates</i>	
Rafael Mestre, Stuart Middleton, Matt Ryan, Masood Gheasi, Timothy Norman and Jiatong Zhu	274
<i>Improving Retrieval Augmented Neural Machine Translation by Controlling Source and Fuzzy-Match Interactions</i>	
Cuong Hoang, Devendra Sachan, Prashant Mathur, Brian Thompson and Marcello Federico .	289
<i>CALM-Bench: A Multi-task Benchmark for Evaluating Causality-Aware Language Models</i>	
Dhairya Dalal, Paul Buitelaar and Mihael Arcan	296
<i>ezCoref: Towards Unifying Annotation Guidelines for Coreference Resolution</i>	
Ankita Gupta, Marzena Karpinska, Wenlong Zhao, Kalpesh Krishna, Jack Merullo, Luke Yeh, Mohit Iyyer and Brendan O’Connor	312
<i>PREME: Preference-based Meeting Exploration through an Interactive Questionnaire</i>	
Negar Arabzadeh, Ali Ahmadvand, Julia Kiseleva, Yang Liu, Ahmed Hassan Awadallah, Ming Zhong and Milad Shokouhi	331
<i>Sentence Identification with BOS and EOS Label Combinations</i>	
Takuma Udagawa, Hiroshi Kanayama and Issei Yoshida	343
<i>Gauging the Gap Between Human and Machine Text Simplification Through Analytical Evaluation of Simplification Strategies and Errors</i>	
Daichi Yamaguchi, Rei Miyata, Sayuka Shimada and Satoshi Sato	359
<i>Bridging the Gap between Pre-Training and Fine-Tuning for Commonsense Generation</i>	
Haoran Yang, Yan Wang, Piji Li, Wei Bi, Wai Lam and Chen Xu	376
<i>LED: A Dataset for Life Event Extraction from Dialogs</i>	
Yi-Pei Chen, An-Zi Yen, Hen-Hsen Huang, Hideki Nakayama and Hsin-Hsi Chen	384
<i>Reading and Reasoning over Chart Images for Evidence-based Automated Fact-Checking</i>	
Mubashara Akhtar, Oana Cocarascu and Elena Simperl	399
<i>Causal Reasoning of Entities and Events in Procedural Texts</i>	
Li Zhang, Hainiu Xu, Yue Yang, Shuyan Zhou, Weiqiu You, Manni Arora and Chris Callison-Burch	415
<i>Few-Shot Structured Policy Learning for Multi-Domain and Multi-Task Dialogues</i>	
Thibault Cordier, Tanguy Urvoy, Fabrice Lefèvre and Lina M. Rojas Barahona	432

<i>Transfer Knowledge from Natural Language to Electrocardiography: Can We Detect Cardiovascular Disease Through Language Models?</i>	
Jielin Qiu, William Han, Jiacheng Zhu, Mengdi Xu, Michael Rosenberg, Emerson Liu, Douglas Weber and Ding Zhao	442
<i>Practical Takes on Federated Learning with Pretrained Language Models</i>	
Ankur Agarwal, Mehdi Rezagholizadeh and Prasanna Parthasarathi	454
<i>Paper Bullets: Modeling Propaganda with the Help of Metaphor</i>	
Daniel Baleato Rodríguez, Verna Dankers, Preslav Nakov and Ekaterina Shutova	472
<i>Lexical Semantics with Large Language Models: A Case Study of English break"</i>	
Erika Petersen and Christopher Potts	490
<i>SWING: Balancing Coverage and Faithfulness for Dialogue Summarization</i>	
Kung-Hsiang Huang, Siffi Singh, Xiaofei Ma, Wei Xiao, Feng Nan, Nicholas Dingwall, William Yang Wang and Kathleen McKeown	512
<i>Language-Aware Multilingual Machine Translation with Self-Supervised Learning</i>	
Haoran Xu, Jean Maillard and Vedanuj Goswami	526
<i>Cloze Quality Estimation for Language Assessment</i>	
Zizheng Zhang, Masato Mita and Mamoru Komachi	540
<i>Bag of Tricks for In-Distribution Calibration of Pretrained Transformers</i>	
Jaeyoung Kim, Dongbin Na, Sungchul Choi and Sungbin Lim	551
<i>Fine-Tuning Deteriorates General Textual Out-of-Distribution Detection by Distorting Task-Agnostic Features</i>	
Sishuo Chen, Wenkai Yang, Xiaohan Bi and Xu Sun	564
<i>A Question of Style: A Dataset for Analyzing Formality on Different Levels</i>	
Elisabeth Eder, Ulrike Krieg-Holz and Michael Wiegand	580
<i>Task-specific Compression for Multi-task Language Models using Attribution-based Pruning</i>	
Nakyeong Yang, Yunah Jang, Hwanhee Lee, Seohyeong Jeong and Kyomin Jung	594
<i>Zero-shot Transfer of Article-aware Legal Outcome Classification for European Court of Human Rights Cases</i>	
Santosh T.Y.S.S, Oana Ichim and Matthias Grabmair	605
<i>Abstractive Document Summarization with Summary-length Prediction</i>	
Jingun Kwon, Hidetaka Kamigaito and Manabu Okumura	618
<i>Hierarchical Label Generation for Text Classification</i>	
Jingun Kwon, Hidetaka Kamigaito, Young-In Song and Manabu Okumura	625
<i>Active Learning for Multilingual Semantic Parser</i>	
Zhuang Li and Gholamreza Haffari	633
<i>Joint Word and Morpheme Segmentation with Bayesian Non-Parametric Models</i>	
Shu Okabe and François Yvon	640
<i>Cross-Lingual Transfer of Cognitive Processing Complexity</i>	
Charlotte Pouw, Nora Hollenstein and Lisa Beinborn	655
<i>Does Transliteration Help Multilingual Language Modeling?</i>	
Ibraheem Muhammad Moosa, Mahmud Elahi Akhter and Ashfia Habib	670

<i>A Multilingual Dataset of Racial Stereotypes in Social Media Conversational Threads</i>	
Tom Bourgeade, Alessandra Teresa Cignarella, Simona Frenda, Mario Laurent, Wolfgang Schmeisser-Nieto, Farah Benamara, Cristina Bosco, Véronique Moriceau, Viviana Patti and Mariona Taulé . . .	686
<i>Detecting Contextomized Quotes in News Headlines by Contrastive Learning</i>	
Seonyeong Song, Hyeonho Song, Kunwoo Park, Jiyoung Han and Meeyoung Cha	697
<i>Zero-Shot On-the-Fly Event Schema Induction</i>	
Rotem Dror, Haoyu Wang and Dan Roth	705
<i>BanglaNLG and BanglaT5: Benchmarks and Resources for Evaluating Low-Resource Natural Language Generation in Bangla</i>	
Abhik Bhattacharjee, Tahmid Hasan, Wasi Uddin Ahmad and Rifat Shahriyar	726
<i>It's about Time: Rethinking Evaluation on Rumor Detection Benchmarks using Chronological Splits</i>	
Yida Mu, Kalina Bontcheva and Nikolaos Aletras	736
<i>MUTANT: A Multi-sentential Code-mixed Hinglish Dataset</i>	
Rahul Gupta, Vivek Srivastava and Mayank Singh	744
<i>Bridging the Gap between Native Text and Translated Text through Adversarial Learning: A Case Study on Cross-Lingual Event Extraction</i>	
Pengfei Yu, Jonathan May and Heng Ji	754
<i>Scalable Prompt Generation for Semi-supervised Learning with Language Models</i>	
Yuhang Zhou, Suraj Maharjan and Beiye Liu	770
<i>Novel Feature Discovery for Task-Oriented Dialog Systems</i>	
Vinh Thinh Ho, Mohamed Soliman and Abdalghani Abujabal	782
<i>Context Generation Improves Open Domain Question Answering</i>	
Dan Su, Mostofa Patwary, Shrimai Prabhumoye, Peng Xu, Ryan Prenger, Mohammad Shoeybi, Pascale Fung, Anima Anandkumar and Bryan Catanzaro	793
<i>RedHOT: A Corpus of Annotated Medical Questions, Experiences, and Claims on Social Media</i>	
Somin Wadhwa, Vivek Khetan, Silvio Amir and Byron Wallace	809
<i>Paparazzi: A Deep Dive into the Capabilities of Language and Vision Models for Grounding Viewpoint Descriptions</i>	
Henrik Voigt, Jan Hombeck, Monique Meuschke, Kai Lawonn and Sina Zarriß	828
<i>PLACES: Prompting Language Models for Social Conversation Synthesis</i>	
Maximillian Chen, Alexandros Papangelis, Chenyang Tao, Seokhwan Kim, Andy Rosenbaum, Yang Liu, Zhou Yu and Dilek Hakkani-Tur	844
<i>FedPerC: Federated Learning for Language Generation with Personal and Context Preference Embeddings</i>	
Andrew Silva, Pradyumna Tambwekar and Matthew Gombolay	869
<i>A Neural CRF-based Hierarchical Approach for Linear Text Segmentation</i>	
Inderjeet Nair, Aparna Garimella, Balaji Vasani Srinivasan, Natwar Modani, Niyati Chhaya, Srikrishna Karanam and Sumit Shekhar	883
<i>MultiFin: A Dataset for Multilingual Financial NLP</i>	
Rasmus Jørgensen, Oliver Brandt, Mareike Hartmann, Xiang Dai, Christian Igel and Desmond Elliott	894

<i>MLASK: Multimodal Summarization of Video-based News Articles</i> Mateusz Krubiński and Pavel Pecina	910
<i>Going beyond research datasets: Novel intent discovery in the industry setting</i> Aleksandra Chrabrowa, Tsimur Hadeliya, Dariusz Kajtoch, Robert Mroczkowski and Piotr Rybak	925
<i>DATScore: Evaluating Translation with Data Augmented Translations</i> Moussa Kamal Eddine, Guokan Shang and Michalis Vazirgiannis	942
<i>How do decoding algorithms distribute information in dialogue responses?</i> Saranya Venkatraman, He He and David Reitter	953
<i>Benchmarking Long-tail Generalization with Likelihood Splits</i> Ameya Godbole and Robin Jia	963
<i>Exploring Enhanced Code-Switched Noising for Pretraining in Neural Machine Translation</i> Vivek Iyer, Arturo Oncevay and Alexandra Birch	984
<i>XQA-DST: Multi-Domain and Multi-Lingual Dialogue State Tracking</i> Han Zhou, Ignacio Iacobacci and Pasquale Minervini	999
<i>Improving Prediction Backward-Compatibility in NLP Model Upgrade with Gated Fusion</i> Yi-An Lai, Elman Mansimov, Yuqing Xie and Yi Zhang	1010
<i>AmbiCoref: Evaluating Human and Model Sensitivity to Ambiguous Coreference</i> Yuewei Yuan, Chaitanya Malaviya and Mark Yatskar	1023
<i>Improving Unsupervised Out-of-domain detection through Pseudo Labeling and Learning</i> Byoungchan Lee, Jaesik Kim, Junekyu Park and Kyung-Ah Sohn	1031
<i>How Many Data Samples is an Additional Instruction Worth?</i> Ravsehaj Singh Puri, Swaroop Mishra, Mihir Parmar and Chitta Baral	1042
<i>[MASK] Insertion: a robust method for anti-adversarial attacks</i> Xinrong Hu, Ce Xu, Junlong Ma, Zijian Huang, Jie Yang, Yi Guo and Johan Barthelemy ...	1058
<i>ViDeBERTa: A powerful pre-trained language model for Vietnamese</i> Cong Dao Tran, Nhut Huy Pham, Anh Tuan Nguyen, Truong Son Hy and Tu Vu	1071

Abstract

This work empirically investigates punctuation insertions as adversarial attacks on NLP systems. Data from experiments on three tasks, five datasets, and six models with four attacks show that punctuation insertions, when limited to a few symbols (apostrophes and hyphens), are a superior attack vector compared to character insertions due to 1) a lower after-attack accuracy ($A_{aft-atk}$) than alphabetical character insertions; 2) higher semantic similarity between the resulting and original texts; and 3) a resulting text that is easier and faster to read as assessed with the Test of Word Reading Efficiency (TOWRE)). The tests also indicate that 4) grammar checking does not mitigate punctuation insertions and 5) punctuation insertions outperform word-level attacks in settings with a limited number of word synonyms and queries to the victim’s model. Our findings indicate that inserting a few punctuation types that result in easy-to-read samples is a general attack mechanism. In light of this threat, we assess the impact of punctuation insertions, potential mitigations, the mitigation’s tradeoffs, punctuation insertion’s worst-case scenarios and summarize our findings in a qualitative casual map, so that developers can design safer, more secure systems.

1 Introduction

The goal of an attack is to disrupt a natural language processing (NLP) model’s classification accuracy. The motivation behind researching these adversarial attacks is to create a toolbox of methods to attack systems while also pointing out flaws to improve the models’ robustness. Previous work on adversarial research showed that deep learning-based NLP models are sensitive to slight changes in the input (Ebrahimi et al., 2018) such as character perturbations or word substitutions. However, these attack vectors have three major flaws: 1) letter perturbations can be detected by grammar checkers; 2) these attacks may change the meaning or, worse,

the human label of the sentence (e.g., ‘she’ to ‘he’ with a character deletion for a gender classification system (Zang et al., 2020)); 3) they can make a sample unreadable. Although word-level attacks that change words to a perturbing synonym make these perturbations almost invisible to humans, the cumulative effect of multiple synonym substitutions in a sentence can make the sample harder to understand. Furthermore, the attack must find perturbing word synonyms when attacking samples in a specific domain, such as biology or law, which may be challenging if the algorithm uses general word embeddings with no domain knowledge.

Punctuation insertions, on the other hand, may be a feasible attack vector that is unaffected by the limitations of character perturbations/word substitutions, since it is hard for grammar checkers to detect punctuation (Section 5.5) while also not drastically changing the meaning of the sentence (Sections 5.7, 5.8). Removing punctuation causes deep learning models to perform worse (Ek et al., 2020), as punctuation contains critical information that models require to function correctly (Jones, 1994). Furthermore, punctuation can hold adversarial downstream information (Formento et al., 2021) that may be exploited by malicious users. Punctuation attacks remain an understudied area: Previous works on the topic (Hosseini et al., 2017; Eger and Benz, 2020; Formento et al., 2021) only casually explored punctuation and ignored whether it can generalize or show which punctuation symbols are best suited for intrusion attacks.

Contributions: Through extensive empirical studies, we have determined that punctuation insertions can outperform, in terms of $A_{aft-atk}$, alphabetical character insertions (as shown in Section 5.1) and, under certain conditions, word substitution (5.2), allowing for a user-controllable tradeoff between after-attack accuracy ($A_{aft-atk}$), sample quality, and attack time efficiency when used together in a multi-level attack (5.3). Specifically,

hyphen (Hy) and apostrophe (Ap) insertions are the most effective at avoiding straightforward defense mechanisms (as shown in Sections 5.4, 5.5) while preserving the original meaning, as evidenced by achieving 100% semantic similarity in our tests (as shown in Section 5.7). Additionally, by using the TOWRE test, we have demonstrated that inserting only one punctuation type significantly increases attack readability by increasing reading speeds by 800% compared to character insertions, and 96.8% compared to using multiple types of punctuation (as shown in Section 5.8) without compromising the attack performance (Section 5.9). To aid in the understanding of our findings, we have also introduced a casual map in Figure 5.

2 Related Work

Adversarial attacks on NLP systems can be categorized in terms of the level of granularity of the perturbation. **Character-level** attacks (Ebrahimi et al., 2018; Eger and Benz, 2020; Eger et al., 2019; Belinkov and Bisk, 2018; Sun et al., 2020; Boucher et al., 2021) modify individual characters in words to force the tokenizer to process multiple unrelated embeddings instead of the original, resulting in decreased performance. **Word-level** attacks (Jin et al., 2020; Li et al., 2020; Maheshwary et al., 2020) employ a search algorithm to locate useful perturbing embeddings (Jin et al., 2020; Li et al., 2020; Maheshwary et al., 2020) or operations (Tan et al., 2020; Li et al., 2021) that are clustered close to the candidate attack word’s embedding given a similarity constraint (such as the Universal Sentence Encoder (Cer et al., 2018)). **Multi-level** attacks combine multiple types of perturbations, making the attack cumulative. Textbugger (Li et al., 2019), which uses both character-level and word-level attacks, is an example of a multi-level attack.

Although previous research has investigated character and word-level attacks, few have studied the use of punctuation attacks. To the best of our knowledge, only Zéro (Eger and Benz, 2020), Perspective Atk (Hosseini et al., 2017) and SSTA (Formento et al., 2021) have researched punctuation as an attack vector. While the former two randomly insert symbols within a word, the third revealed that symbols contain adversarial information and can be inserted as padding with little further optimization. Zéro, in particular, is a benchmark of ten different character attacks. Out of these ten, Zéro Intrude is the only one focusing on punctua-

tion and is thus used as one of the gold standards in this paper.

Our work builds on these previous works by further exploring Zéro Intrude and the concept, introduced initially in SSTA, that model-specific symbols can attack binary classifiers when used as padding. Our work contributes to the discussion on punctuation symbols being a general mechanism to attack deep learning models while also improving readability through the novel use of the TOWRE metric, which tracks how quickly someone can read the adversarial text.

3 Methodology

3.1 Overview

Suppose we have a sequence classifier $f : \mathcal{X} \mapsto \mathcal{Y}$, that takes an input sequence of words $x = (\tau_1, \dots, \tau_n) \in \mathcal{X}$ with ground truth label y and outputs a prediction $\hat{y} = f(x)$. An adversarial attack on input x and classifier f would perturb τ , for example, using character manipulations or word substitutions, to produce a new adversarial sample \hat{x} that is misclassified by f such that $f(\hat{x}) \neq y$.

We investigate punctuation and multi-level attacks in gray-box and black-box settings. Specifically, we explore the effects of inserting punctuation when the victim’s model classification logit is leaked (**gray-box**) and when it is not (**black-box**). We use a variation of DeepWordBug (DWB) and the original Zéro Intrude (ZI) attack in these settings. In addition, we combine punctuation together with word substitutions in a gray-box setting (**multi-level**) to evaluate if punctuation can augment word-level attacks. We provide a more detailed description of the respective attacks used in the following sections.

3.2 Attack foundations and baselines

We build upon and compare our results to the following four attack baselines: 1) *Zéro Intrude (ZI)*, a simple black-box attack (see Section 3.5 (Eger and Benz, 2020)); 2) *DeepWordBug (DWB)*, which uses four-character level perturbations including delete, swap, insert, and nearby character swap (Gao et al., 2018); 3) *TextFooler*, a popular baseline that uses word synonyms from counterfeited embeddings to perturb the sample perturbation (Jin et al., 2020); and 4) *SememePSO*, a recent method that uses a seme (e.g., a morpheme) to create a word substitution together with PSO (Zang et al., 2020).

3.3 Gray-box punctuation attack

As a representative gray-box punctuation attack, we implement a variant of DWB through the TextAttack framework that performs only punctuation insertions instead of alphabetical insertions, swaps, deletions, and substitutions. We denote this punctuation variant as DeepWordBugPunc (DWBP). DWBP has three main steps:

- Step 1: Determine the essential words with set $\tau_R = \{\tau_1 \dots \tau_k\}$ for an NLP model f using a word delete schema, ranking them from highest to lowest in terms of output logit change. A delete schema, popularized by BERT-Attack (Li et al., 2020), analyzes the logit change when a word is removed from a sample.
- Step 2: Use user-defined set γ (e.g. $\gamma = \{-'\}$) and the RPos (Random Position) and RPunc (Random Punctuation) flags to return a set of transformations $\{\tau_k\}$ from highest-ranking word τ_k from Step 1.
- Step 3: Search over the attack space by querying the victim’s model with samples modified with the transformations from Step 2. Keep the best transformation with regard to the logit and semantic similarity score. The next word from τ_R is then perturbed. This is repeated until either $f(x) \neq f(\hat{x})$ or the algorithm iterates through τ_R . This process is called Greedy Search with Word Replacement (GSRW).

In summary, for a sample x , the algorithm identifies the top words in τ_R . It gradually modifies them by inserting one punctuation symbol and making calls to the victim’s model through the GSRW Algorithm 1. Optimizing over τ_R results in GSRW being a time-efficient query alternative to the greedy search algorithm. It gradually replaces τ_R in x with transformations from Step 2 by calling Algorithm 2.

Algorithm 2 takes a word and decides the location and punctuation type to insert with the **RPos** and **RPunc** flags. These two flags, when set to false, allow the algorithm to explore the entire attack space. This in turn creates many transformation variations with γ , therefore allowing GSRW to check the adversarial performance of each symbol in γ at each position within the word τ_k . GSRW keeps the transformation if the change creates a successful reduction in logit score. After an adversarial candidate \hat{x} is found, the semantic similarity

between x and \hat{x} with $S' = Sim(x, \hat{x})$ is calculated with a deep learning model (Cer et al., 2018). GSRW will reject all perturbations that miss a semantic similarity threshold, set at 0.8, which ensures a good tradeoff between sample quality and adversarial strength (Li et al., 2019). The algorithm repeats this procedure until the end condition.

The difference between DWBP and DWB is that DWB transforms a word with a composition of transformations (letter substitution, deletion, swap, or insertion), and all the transformed words are added to $\{\hat{\tau}_k\}$. Appendix D.1 gives an extended description for the three steps. We tested all variants of RPos and RPunc when applicable.

Algorithm 1 τ_k Transform Function with GSRW

Input: Word ranking τ_R , Sample x , Symbols γ

Output: Adversarial sentence \hat{x}

```

1: Initialize  $\hat{x} = x$ 
2: for each  $\tau_k$  in  $\tau_R$  do

3.4 Gray-box multi-level attack

We also evaluated the performance of punctuation insertions when used in conjunction with word-level attacks. To conduct this assessment, we employed two baselines TextFooler and SememePSO.

- TextFooler/DWBP: This variant uses the same word scoring function and the GSWR search algorithm. However, $\hat{\tau}_k$ will be a mix of word synonym and punctuation insertion transformations of τ_k .
- SememePSO/DWBP: This variant uses the same word scoring function but with particle swarm optimization (PSO) as a search technique. PSO uses a population-based evolutionary algorithm that exploits the interactions between individuals in a population to find a solution in a search space. $\hat{\tau}_k$ will be a mix of sememes (a type of word substitution) and punctuation insertion transformations of τ_k .

See Section D.5 in the Appendix for details on TextFooler/DWBP and SememePSO/DWBP.

3.5 Black-box punctuation attack

As a representative black-box attack, we implement a variant of the ZI algorithm instead of DWB, as the latter requires access to logits that are absent in this setting. ZI is a simple black-box attack that randomly perturbs a word in a sample with probability p . It then adds a random symbol from this list—!@#\$%^&'()*+,-./:;<=>?@[\\]^_{|}—between two letters with the same probability p , which we define as baseline ZI. In our variant, ZI perturbs a word with probability p (defined as ZIP) but uses the same predefined symbol.

4 Experimental Setup

4.1 Backbone models and tasks

We evaluated the *BERT* (Devlin et al., 2019), *RoBERTa* (Liu et al., 2019), *XLNet* (Yang et al., 2019), *DistilBERT* (Sanh et al., 2020) models on classification (*MR*), entailment (*MNLI*, *SNLI*), and question answering (*QNLI*, *QQP*) tasks. We also used a *CNN* and *LSTM* for *MR* (details are provided in Appendix C).

4.2 Evaluation metrics

We use the evaluation framework previously proposed in (Morris et al., 2020), where an evaluation set is perturbed and out of the Total At-

tacked Samples (*TAS*) set the Number of Successful Attacks ($N_{succ-atk}$), Number of Failed Attacks ($N_{fail-atk}$) and Number of Skipped Attacks ($N_{skp-atk}$) are recorded. *After attack accuracy* ($A_{aft-atk} = \frac{N_{fail-atk}}{TAS}$), the most important metric, represents how well the attacker can fool the model across a dataset. Lower values of $A_{aft-atk}$ indicate that the attacker can fool the model better. *After success rate* ($A_{succ-rte} = \frac{N_{succ-atk}}{TAS - N_{skp-atk}}$), is similar to $A_{aft-atk}$ but ignores previously misclassified samples. *Percentage of perturbed words* refers to the percentage of words the algorithm perturbs out of the number of words in the sample. This metric should be as low as possible, as perturbing more words makes the sample’s perturbation more detectable. *Semantic similarity* (Jin et al., 2020; Maheshwary et al., 2020) is an automatic similarity index that describes the visual difference between two samples using a deep learning model. In this case, the Universal Sentence Encoder (Cer et al., 2018) is used, along with a cosine similarity measure between the output embeddings. A value of 1 indicates that the two inputs are semantically equivalent, while 0 represents no similarity. *Average number of queries* represents the number of times the algorithm must invoke the model to perform inference. This metric should be kept low to avoid detection.

4.3 Human evaluation

To evaluate the quality of adversarial samples, we conducted four human studies. The first three are the same tests used in TextFooler (Jin et al., 2020), and Hard-Label (Maheshwary et al., 2020). These tests analyzed the adversarial sample for 1) *grammatical correctness*, where reviewers rate the grammatical correctness of the original and adversarial samples on a scale from 1–5, where 1: many grammatical mistakes and 5: no grammatical mistakes; 2) *reviewer classification accuracy*, where reviewers predict the label of each sample; and 3) *similarity*, where reviewers rate if the two samples are similar (1), dissimilar (0), or ambiguous (0.5); 4) *readability*, where the novel application of TOWRE (Tarar et al., 2015) was used to analyze the quality of adversarial words in character-level black-box attacks. TOWRE is a widely used test that measures an individual’s reading accuracy and speed. We adapted TOWRE to record the quality of adversarial examples. Specifically, the reviewer pronounces a list of words, where each word was modified with

one out of four different perturbation types introduced with the ZI algorithm. We record the words per minute (WPM) and error rates. All tests had two reviewers who reviewed 100 samples in the first three tests and 36 in the fourth. Agreement between the reviewers was assessed with Krippendorff’s alpha, where a score of 1 indicates complete agreement and -1 indicates complete disagreement. Further implementation details on the human testing method and details on Krippendorff’s alpha are in Appendix F.

4.4 Defense Baselines

We evaluate fine-tuning and adversarial training as baseline defenses. In detail, it is possible to remove all punctuation during training, fine-tune the model for further epochs on this new punctuationless dataset, and at inference, always strip all punctuation (Table 18). We also experimented with adversarial training (Table 15 in Section 5.6) by using a standard technique (Morris et al., 2020) that is further described in Appendix E.3.

5 Experiments

We use the methodology in Section 3 and experimental setup to explore how punctuation insertions compare to character manipulations (Section 5.1). In Section 5.4, 5.5 and 5.6 we demonstrate how straightforward defence techniques fail and succeed and Sections 5.7, 5.8, and 5.9 highlight the advantages of punctuation insertions where no defence technique is present. The γ choices for each test are summarized and justified in Appendix E.2.

5.1 Punctuation vs character manipulations

How does an attack change when using punctuation insertions instead of letter manipulations? Punctuation insertions can degrade NLP model performance while preserving semantic similarity. The system’s $A_{aft-atk}$ is overall reduced (see Figure 1) while semantic similarity remains at 0.96–1.00 when using punctuation insertions (DWBP) compared to 0.87–0.90 when using DWB. Each DWBP box represents the $A_{aft-atk}$ for a dataset across all models with RPos = False. The lower the $A_{aft-atk}$ the more perturbing the attack.

Hyphen, apostrophe, full stop, or comma insertions lower $A_{aft-atk}$ more than any other letter in the alphabet (Figure 2). Values in Figure 2 reflect the after-attack difference [%] between using a letter or punctuation type in an intrusion attack.

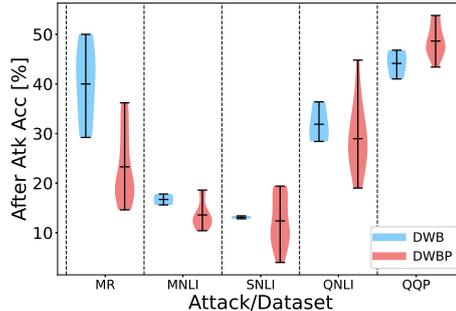

Figure 1: Gray box attack performance

Green/positive values represent an improvement and purple/negative values a decrease between the punctuation symbol on the x-axis and the letters on the y-axis when using DWBP. Each attack in Figure 2 has a constant number of queries, [%] of perturbed words, and query time. The extended results are in Appendix L.

Observation This experiment clarifies that if **any** internal punctuation is present, the system **is vulnerable** and that it is more susceptible to such insertions than other character manipulations and alphabet insertions. We limit our reporting to BERT on MR because other model results are consistent. Full tabular results for other Models and datasets for Figure 1 are in Appendix I in Tables 6 and 7 (“Without Grammar”). While Figure 2 has the other model’s results in Appendix L.

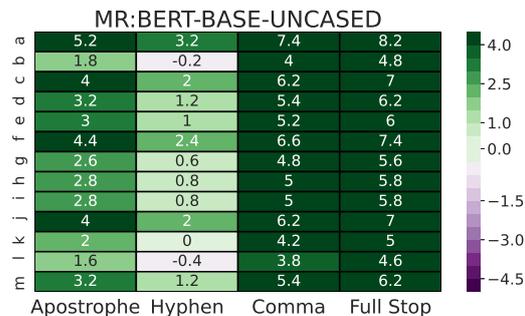

Figure 2: Punctuation vs character insertions. Green indicates positive values; purple indicates negative values

5.2 Punctuation vs word-level attacks

Are there advantages in using punctuation insertions instead of word substitutions? DWBP can also be compared to TextFooler since, with DWBP, a punctuation symbol is mapped to an embedding when using a word piece tokenizer. Figures 3 and 4 each show increasing numbers of unique punctuation symbols from γ (DWBP) or synonyms per word (TextFooler), ranging from 1 to 10. For

DWBP, γ is set to . for $N = 1$, . for $N = 2$, up to . for $N = 10$. In TextFooler, N represents the number of synonyms per word. Figure 3 displays the relationship between N (represented by the points and the x-axis) and improvement in $A_{succ-rte}$ (y-axis). Figure 4 displays the relationship between N (represented by the points), number of queries (x-axis), and the effect on $A_{aft-atk}$ (y-axis). Both experiments used all variations of RPunc/RPos on BERT-MR.

Observation The effectiveness of punctuation insertions is demonstrated DWBP when constrained on N and queries, as seen by the higher $A_{succ-rte}$ with low N in Figure 3 and the low $A_{aft-atk}$ with few queries in Figure 4. Similar results for MNLI can be found in Appendix H.

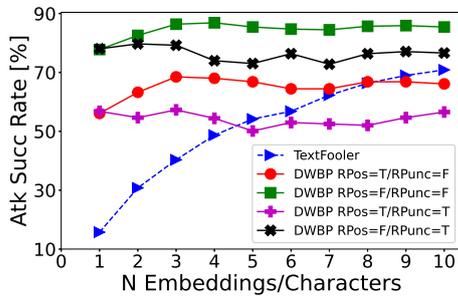

Figure 3: Punctuation embedding efficiency.

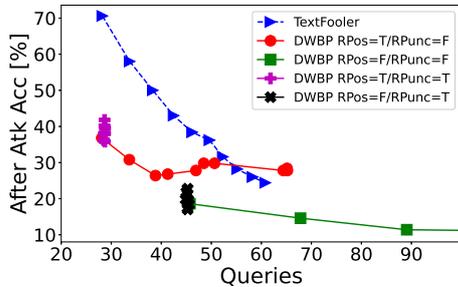

Figure 4: Punctuation query efficiency.

5.3 Punctuation as a multi-level attack

We investigate a composite experiment where τ_k is composed of word substitutions and punctuation insertions. The methodology is introduced in Section 3.4 and the details are given in Appendix D.5. We set RPunc = False, RPos = False, and $\gamma = -$.

Observation: The results in Table 1 indicate that incorporating punctuation insertions into the optimization process enhances TextFooler and SememePSO on BERT trained on MR. The additional findings in Section G.1 of the appendix present re-

sults for all tasks and models, and provide further observations.

Dataset	Model (Orig Acc)	Method	After Attack Acc [%]	Perturbed Words [%]	Semantic Sim	Avg Time Taken [s]	Avg Number Queries
MR	BERT (83.8)	DWBP	17.4	18.32	1	0.721	74.7
		TextFooler	9.4	17.54	0.82	1.3072	118.5
		TextFooler/DWBP	7.6	18.31	0.89	1.122	105.35
		SememePSO	7	16.52	0.81	16.1811	4950.71
		SememePSO/DWBP	6	9.99	0.89	7.3252	988.44

Table 1: Multi-level DWBP. Full results in Appendix J

5.4 Removing punctuation as a defense

How does removing punctuation perform as a defense? In this section, we sought to evaluate the effectiveness of simple defenses in countering punctuation attacks by examining the impact of various forms of punctuation removal on attack performance. To aid in this assessment, we employed the use of a casual map in Figure 5, which allows for tracking of the defender’s behavior in response to the attacker’s changing strategy.

The casual map, presented in the blue quadrant, begins with the "Base Model" on the right-hand side, representing the unchanged finetuned model from Hugging Face, in this instance, specifically BERT finetuned on MR. Adjacent to this model is a large red table, which represents the significant performance drop when utilizing punctuation insertions. For the sake of simplicity, in this map, we limited ourselves to the use of full stops (FS), commas (Co), which are common external punctuation types, and apostrophes (Ap) and hyphens (Hy), which are common internal punctuation types. Given this threat, we identified and explored three options for the defender to take. Beneath the "Base Model," the first option is to remove all punctuation ("All"), which secures the system but leads to an original performance drop of -2.6%. The second option, just beneath "All" is to remove all punctuation found inside of words. While this approach solves the problem, it becomes challenging to identify if a punctuation was inserted by mistake by a user or to prevent the attacker from inserting a whitespace before or after the punctuation insertion. If the attacker adds a whitespace, the attack defaults to the large red table. Furthermore, removing all internal punctuation has a noticeable original performance drop of -1.2%. An alternative to this is to remove all internal punctuation but make an exception for Hy and Ap, reducing the original performance drop to 0%, however, the system remains vulnerable to Ap and Hy. Given the persistent vulnerability to Ap and Hy, the defender may employ a grammar checker to reject all

samples that do not meet a certain grammatical correctness level. When implemented, the robustness of the model increases dramatically, resulting in a semi-secure model.

The blue quadrant also shows "Finetune with punctuation." This base model was further trained and then compared to further training the model when all the punctuation is removed (See "All + Finetune"). As previously highlighted, removing all punctuation can secure the system, the reduced performance drop of -0.6% now indicates that this approach has less of a trade-off between securing the system and original accuracy drop.

In addition, we also explored adversarial training. We discuss the findings of this quadrant in Section 5.6 and it's experimental setup in Section E.3 in the Appendix.

Observation Using a grammar checker increases the robustness of this task. However, as pointed out in the next section in Figure 6, the red candlesticks representing DWBP have a large attack variance depending on the dataset, symbol used, and model. Hence, for a task that results in a semi-secure model, another task may result in a semi-broken model. This reasoning also applies to black box punctuation attacks with ZIP, as pointed out by the large variance in the red candlesticks in Figure 7. Another aspect to consider is the original accuracy drop in performance experienced in the yellow boxes. Depending on the application, this may be acceptable/negligible or unacceptable/too high.

5.5 Grammar checkers as a defense

If a grammar checker preprocesses an input, how does the attack performance change? Another common idea is that character-level attacks are easy to defend against using a grammar checker (Zang et al., 2020). Although adding a grammar checker before processing the input lowers the effectiveness of the attack, punctuation is nonetheless a successful insertion technique with RPos = False, particularly when compared to DWB (Figure 6). Punctuation insertions are also effective in black-box settings (ZIP) and are **as competitive** as alphabetical character manipulations in gray-box settings (DWB) (Figure 7). The high variance of ZIP means that inserting some symbols can lower performance comparably, if not more than any character manipulation technique introduced in DWB. For example, ZIP Ap achieves a 7.8% lower $A_{aft-atk}$ than DWB.

The full results can be found in Appendix I (column "With Grammar" in Tables 6 and 7, and the performance of ZIP in Table 10).

Observation DWBP is more successful with the attack, except on the [%] of perturbed words. These results show a curious property of punctuation attacks by highlighting that the [%] of perturbed words is not necessarily aligned with semantic similarity. Therefore, it is possible to have a highly perturbed sample (in terms of [%] of perturbed words) that is nonetheless readable and potentially preserves the original information.

5.6 Adversarial training as a defense

How does adversarial training benefit learning? In this section, we aimed to robustify the model by experimenting with adversarial training on the MR dataset. To test this, we employed the use of the DWBP with hyphens and apostrophes (Hy and Ap). Our findings suggest that adversarial training for language models improves $A_{aft-atk}$. Specifically, $A_{aft-atk}$ increased by 7.4% with Hy and 6.4% with Ap on BERT, as shown in Figure 5. This is demonstrated in the "Adv Training" quadrant, where this model was further finetuned for 4 epochs on the base dataset, while the models beneath it were trained for 4 epochs where the base dataset was extended by 20% with adversarial samples containing either apostrophes or hyphens. The effects of adversarial training were minimal, but did result in an improvement to the model not undergoing any adversarial training. This can be observed by comparing the values in the Broken model to the left of "Adv Training" and to the Broken models that have been adversarially trained beneath "Adv Training". On LSTM, $A_{aft-atk}$ increased by 2.4% with Hy and 1.6% with Ap, with negligible drops/increases in original accuracy, as shown in Table 15 in the appendix.

Observation Our findings are in agreement with previous works, which highlight that adversarial training on large language models, such as BERT or LSTMs, can improve both original and adversarial accuracy (Zhu et al., 2020; Miyato et al., 2017; Cheng et al., 2019; Yoo and Qi, 2021). However, other studies suggest that robustness and generalization may be at odds with one another (Li et al., 2021; Eger and Benz, 2020; Meng and Wattenhofer, 2020). Our experiments also indicate that although adversarial training improves the $A_{aft-atk}$, there is still a large drop in performance.

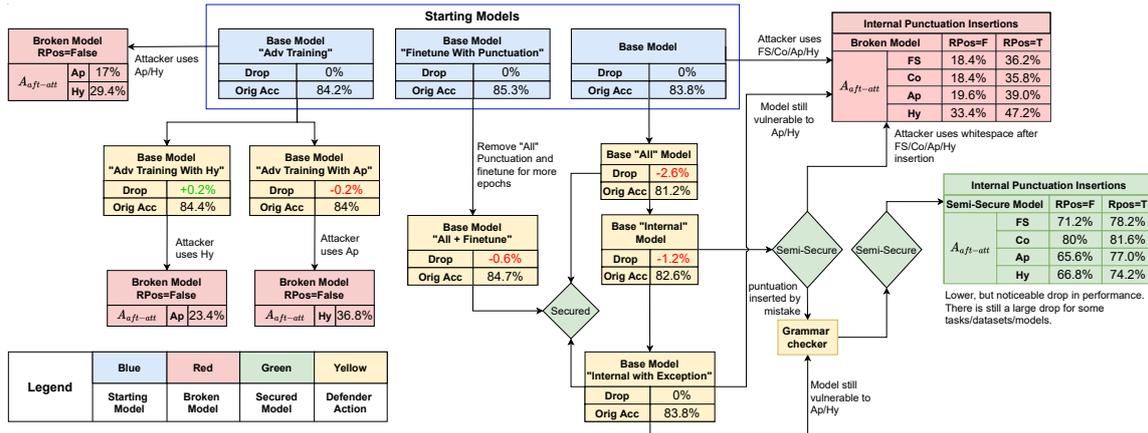

Figure 5: Qualitative casual map for defender/attacker strategy (Section 5.4), values represent BERT-MR.

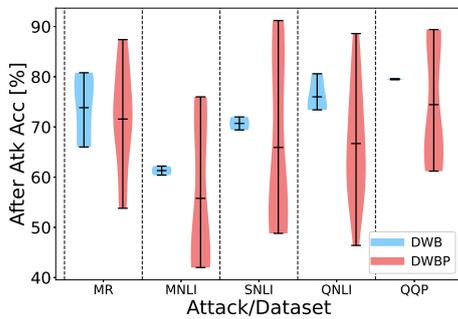

Figure 6: Gray-box attacks against grammar checker

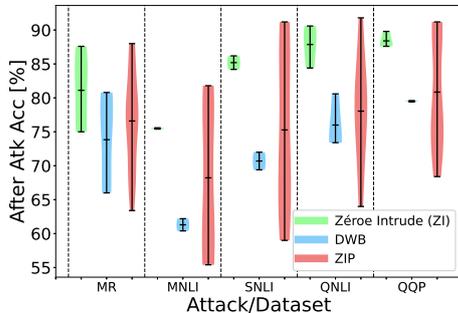

Figure 7: Black-box attacks against grammar checker

5.7 Semantic similarity of punctuation attacks

How similar are samples that have been perturbed with punctuation to the originals? Earlier tests concluded that removing punctuation is an impractical defense technique. We now evaluate the perturbation quality. Apostrophe and hyphen insertions attained a perfect score of 1 for similarity across all samples (in both human and automatic evaluations), a 98% on reviewer classification accuracy (nominal Krippendorff’s alpha = 0.960), and a grammatical correctness score difference of 1.29 between the original samples (3.14/5) and adversarial sam-

ples (4.43/5), with ordinal Krippendorff’s alphas of 0.459 and -0.004 for the original and adversarial samples, respectively. We provide qualitative examples in Table 2 to highlight how the sample changes with punctuation insertions.

MR	A dark comedy that goes for sick and demented (Negative Sentiment)
TextFooler	A dark comedy that goes for psychopathic and coot humor honestly to do so . the film is without object .
DWBP	A dark comedy that goes for sick and demented humor simply to do so . the movie is withou’t intent .

Table 2: Qualitative examples of DWBP and TextFooler. **Bold** words represent a perturbed word

Observation The grammar test is widely used (Jin et al., 2020; Maheshwary et al., 2020). However, the low Krippendorff’s alphas for grammatical correctness suggest the low reliability of the test in indicating grammatical correctness. Analyzing the visual effect of inserting punctuation makes it possible to observe that the semantics remained unchanged. However, such changes are very noticeable to a human (Table 2).

5.8 Limiting punctuation and readability

Does limiting the punctuation types improve readability? Our tests suggest that focusing on a few types of punctuation facilitate meaning preservation (Section 5.7). Another reason to limit punctuation insertions is to improve readability. To test readability, we used TOWRE, where a reviewer pronounces a list of words with four different perturbations in the test using the Zéro algorithm with $p = 0.8$ (high perturbation strength). The four types

are: 1) no perturbation (original); 2) ZIP with apostrophe (ZIP Ap), 3) ZI; and 4) character insertions. ZI uses all punctuation symbols from Section 3.5 and character insertions uses all alphabetic characters. Our ZIP Ap method has the fastest reading speeds. Specifically, Table 4 shows an improvement in WPM from 7 WPM (character insertion) to 32 WPM (ZI) to 63 WPM (ZIP Ap), with a ratio Krippendorff’s alpha of 0.977 and a consistent error rate reduction from character insertions (71.43) to ZI (6.17) to ZIP Ap insertions (1.43). In terms of reading speeds, ZIP Ap is an improvement over character insertions by 800% and by 96% over ZI.

Observation Compared to character insertions and ZI, apostrophe insertions by ZIP Ap are easier and faster to read, as seen with the perfect semantic similarity, WPM improvement, and error reduction. We also show, for the first time, that an attacker cannot use alphabetical character insertions in a high perturbation black-box setting as the samples become too scrambled (Table 3).

MNLI		
Original	Premise	Not only that but they don't pay the money either
	Hypothesis	They also do not contribute financially.
Character Insertions	Hypothesis	Th zezy also do not contribute fdiunlavnyckiawulvlwyv .
Zéro	Hypothesis	Th jely also do not contribute
Intrude	Hypothesis	fj i^ n>a l n{c-i{a}l*{y' .
Insertions (Full Stop)	Hypothesis	Th .e.y also do not contribute f.i.n.a.n.c.i.a.l.l.y.

Table 3: Qualitative examples of FS Insertions vs ZI vs Ch. **Bold** words represent a perturbed word

TOWRE	Method			
	Original	ZIP Ap	Zéro Intrude	Character Insertions
Time [s]	24.54	33.60	60.00	60.00
WPM	86.64±9.6	63.35±7.3	32.50±1.5	7.00±0
Errors	0.00±0	0.50±0.5	2.00±0	5.00±1
Error Rate [%]	0.00±0	1.43±1.4	6.17±0.2	71.43±14.3
Self-Corrections	1.00±0	0.50±0	1.50±0	0.50±0.5
Self-Correction Rate [%]	2.86±0	1.43±1.4	4.55±1.3	7.14±7.1

Table 4: Reading efficiency for the four perturbations

5.9 Limiting punctuation types

Is the attack still effective when using a limited punctuation set? Despite limiting the types of punctuation, ZIP performs similarly to ZI and better than character insertions (Figure 8). The test in Figure 8 explores the ability of ZIP with Ap (apostrophe), Hy (hyphen), Co (comma), and FS (full stop) insertions to generalize to black-box attacks. We compare these ZIP intrusions to ZI with all punctuation types and character insertions (Ch) with all alphabet letters using the ZI algorithm on MR-BERT.

Figure 8 shows the delta change in $A_{aft-atk}$ for each attack technique against the others for $p = 0.8$. Each square represents the $A_{aft-atk}$ from the x-axis attack method minus the $A_{aft-atk}$ from the y-axis attack method. Table 14 in the Appendix displays the $A_{aft-atk}$ [%] and semantic similarity (S) values for Figure 8. Limiting punctuation with ZIP also avoids grammar checking better than using all punctuation types with ZI (Figure 7) as ZIP can focus on one highly perturbing symbol.

Observation ZIP Ap achieved comparable results to that of Ch and ZI (Figure 8) where the difference is even smaller when comparing with other models. Using character insertions can thus be deemed counterproductive and should be avoided. Attacks should instead focus on only one punctuation type, such as Ap, since, compared to Ch and ZI as Section 5.8 highlighted, readability is preserved.

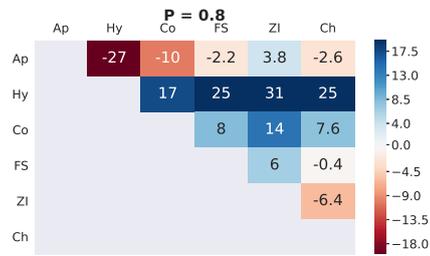

Figure 8: X-Axis $A_{aft-atk}$ minus Y-Axis $A_{aft-atk}$. ZIP (Ap, Hy, Co, FS) vs ZI, Ch

6 Conclusion

Researching adversarial attacks aims to create a toolbox to identify flaws and improve model robustness. Results show that punctuation insertions as an attack are more effective than character manipulations (Figure 1) and alphabetical character insertions (Figure 2) and better evade grammar checkers (Figures 6, 7). Punctuation insertions preserve more information and are faster to read (Section 5.7, 5.9). Simple defenses and adversarial training are not necessarily effective (Section 5.4, 5.6). The information-preserving characteristic of this attack could potentially evade censorship. Conversely, this highlights that a system deployed to combat fake news and offensive language propagation can potentially be compromised by this use of punctuation. Our defense findings are summarized in Figure 5. We hope this inspires further research in the under-explored area of punctuation and how to process it. The code is available¹.

7 Limitations

This work considers only classification tasks, which raises questions on whether such punctuation types can generalize to research tasks such as fake news, offensive content detection, and seq-to-seq tasks such as translation. From our experiments, we can conclude that punctuation insertion attacks (DWBP) with one symbol (apostrophe or hyphen), given our evaluation metrics work better in terms of after-attack accuracy, readability, and defense avoidance than alphabetical character insertions. However, We’ve found some limitations and cases where punctuation insertions with apostrophes or hyphens don’t work better than the alternative. For example, ZI with all punctuation symbols can achieve on some datasets and models a lower after-attack accuracy, therefore, a better attack success rate Figure 8 than using ZIP with an apostrophe of 3.8%. This increase in performance, however, has a cost since the sample will be harder to read. We only tested on English language, punctuation insertions on other languages are mostly unexplored.

A Future Work

How punctuation attacks can augment an effective adversarial learning schema is still an open question. Our punctuation insertion serve as a foundation for future punctuation manipulation. Hyphens, for example, can be used to s-p-e-l-l out words, syl-la-bi-fi-ca-tion, or to indicate s-stammering or so-so-sobbing in a sentence. There is no research exploring whether stammering or sobbing punctuation perturbations could generate a high-quality adversarial attack on NLP without compromising the meaning.

Exploring whether the identified punctuation types and attacks generalize to more complex prediction tasks like fake news, offensive content detection, and seq-to-seq tasks such as translation is an interesting topic for future work.

B Appendix: Ethics Statement

This research was conducted in accordance with the ACM Code of Ethics.

C Appendix: Task and Datasets

MR: The Rotten Tomatoes movie review dataset holds a sentiment classification task with positive/negative reviews. **QNLI:** Is a question-answering dataset where an annotator extracts the answer from a reference text. The task is to allow the model to predict whether the context sentence holds the answer to the question. **QQP:** Is a duplicate question detection task, where the model is required to detect if the two questions are asking the same thing. **SNLI:** Is composed of human-written sentence pairs where each annotator generates an entailing for each given premise. **MNLI:** It is similar to SNLI but covers multiple genres.

Task	Dataset	Train	Test	Avg Len (Test)	Classes
Sentiment Classification	MR	8.5k	1k	18.7	2
Entailment	MNLI	392k	9.8k	29.2	3
	SNLI	550k	10k	21.4	3
Question Answering	QNLI	105k	5.4k	37.6	2
Duplicate Question	QQP	363k	40k	22.2	2

Table 5: Overview of datasets used in experiments

D Appendix: Methodology Details

Each attack composition has three components, a word scoring function, a set of transformation func-

tions, and a search algorithm.

D.1 Gray-box

D.2 Step 1: Word scoring function

The original DeepWordBug paper introduces four word scoring functions: Replace-1 Score, Temporal Head Score, Temporal Tail Score, and Combination Score. All of which are now outdated. Therefore, for the Gray-Box tests, we use the same schema as that of TextFooler, popularized by BERT-Attack (Li et al., 2020). BERT-Attack records the original sentence’s inference logit. Then for each word in the input, the word is deleted. BERT-Attack then extracts a new logit with the remainder of the sample, tracking the difference in value between the original logit and the new logit for each word. It then regards the words with the most significant output change as the most important to f . The original input sentence x with τ_n words is turned to z_L tokens through a tokenizer function F_t in $z \in (z_1 \dots z_L)$ tokens. To find the set of most important words, which we call $\tau_R = \{\tau_1 \dots \tau_k\}$, that need to be perturbed to attack f , the delete schema associates a rank value R_k for each x_{τ_k} , or sample x without top word τ_k . R_k . Calculate τ_k with:

$$R_i = f(F_t(x))_{x_{Score}} - f(F_t(x_{x \cap x_{\setminus \tau_k}}))_{x_{Score}} \quad (1)$$

where $x_{\setminus \tau_k} = (\tau_1, \dots, \tau_{k-1}, \tau_{k+1}, \dots, \tau_k)$. Thereafter $\forall R_k \in R$ each word τ_i are ranked highest to lowest, resulting in τ_R , x_{Score} represents the output logit from model f .

D.3 Step 2: Transformation

For every top word in step 1, the second step finds ‘transformation’ candidates.

DeepWordBug returns four total candidates. The first candidate has a random letter character inserted in a random position. The second has a random letter deleted. The third has a random letter substituted with another, and the fourth changes the position of two adjacent letters.

DeepWordBugPunc adds punctuation symbols in the sentence to create candidates. The number of candidates depends on γ , RPos, and RPunc. γ is user-specific and is the punctuation types that can be inserted. An example is $\gamma = \{ - ' \}$. With RPos and RPunc It is possible to choose whether to insert a γ_{random} punctuation symbol at a random location, or return candidates for all possible punctuation insertions and position of such insertions.

D.4 Step 3: Optimization

For every word, Algorithm 2 returns a set of transformations. To choose which transformation is best and whether to keep it, we explore Greedy Search with Word Replacement (GSRW). GSRW is a time-efficient query modification applied to the greedy search algorithm. It replaces with a transformation only words strongly correlated with a change in the output when removed from the input. GSRW keeps the transformation if the change creates a successful perturbation. After an adversarial candidate is found the semantic similarity is calculated, with a deep learning model (Cer et al., 2018), between x and \hat{x} with $S' = Sim(x, \hat{x})$. GSRW will reject all perturbations that do not meet a semantic similarity threshold (set at 0.8).

If $|\tau_k| = 1$ or the word is part of a predefined set of stop words, the algorithm does not do the operation. As the algorithm perturbs top words τ_k , it checks for: if the i perturbation was successful at reducing the logit score, if so, the algorithm keeps the perturbation with γ_i , we define this new sample as \hat{x} . This is repeated until either $f(x) \neq f(\hat{x})$ or the algorithm runs out of τ_k .

D.5 Multi-level extension

We also evaluated the performance of punctuation insertions when used in conjunction with word-level attacks. To conduct this assessment, we employed two baselines: 1) TextFooler, a popular method that utilizes word synonyms from counterfeited embeddings to perturb the sample (Jin et al., 2020); and 2) SememePSO, a recent approach that employs a sememe (e.g., a morpheme) to create a word substitution, in conjunction with the use of PSO (Zang et al., 2020).

D.5.1 Gray-box multi-level attack

We explored two multi-level attacks based on TextFooler and SememePSO respectively:

- TextFooler/DWBP: This variant uses the same word scoring function and the GSRW search algorithm. However, $\hat{\tau}_k$ will be a mix of word synonym and punctuation insertion transformations of τ_k .
- SememePSO/DWBP: This variant uses the same word scoring function but with particle swarm optimization (PSO) as a search technique. PSO uses a population-based evolutionary algorithm that exploits the interactions

between individuals in a population to find a solution in a search space. $\hat{\tau}_k$ will be a mix of sememes (a type of word substitution) and punctuation insertion transformations of τ_k .

We performed multi-level attacks to explore their effect on deep learning models. The TextFooler/DWBP and SememePSO/DWBP methods result in $\{\hat{\tau}_k\}$ having both word substitutions and punctuation insertion candidates. For TextFooler/DWBP, TextFooler returns 20-word substitutions, and since RPunc and RPos are both false, DWBP returns K transformations. K is proportionate to the number of letters in the word and the length of γ . In our tests, $\gamma = \{-'\}$. Appendix D.5 gives an extended description for the two multi-level attacks and the TextFooler/SememePSO baselines.

To be clear, although we change SememePSO in the SememePSO/DWBP test and TextFooler in the TextFooler/DWBP, we compare SememePSO/DWBP and TextFooler/DWBP to their **unaltered baselines**.

D.5.2 TextFooler

Where Line 6 returns only TextFooler’s word synonym substitutions. For τ_k , the algorithm will return 50-word substitutions. This baseline uses GSRW.

D.5.3 TextFooler/DWBP

Line 6 in Algorithm 2 is changed to both call TextFooler’s word substitution and DeepWordBugPunc’s punctuation insertion functionality and concatenating the resulting transformations in Transformation Set $\hat{\tau}_k$. For TextFooler/DWBP, TextFooler returns 20-word substitutions, and since RPunc and RPos are both False, DWBP returns N number of transformations. N is proportionate to the number of letters in the word and the length of γ . In our Tests $\gamma = \{ ' - \}$. This baseline uses GSRW. Hyperparameter-wise, we reduce TextFooler/DeepWordBugPunc word embeddings for TextFooler from 50 to 20 on all tasks.

D.5.4 SememePSO

uses word substitutions based on sememes together with a different search algorithm based on particle swarm optimization (PSO). We use an existing implementation of SememePSO from the TextAttack library. PSO exploits a swarm composed of individual samples called particles that interact within a space to find a solution iteratively. Every particle,

which in the case of SememePSO is a sample with a sememe word substitution, has a position in the search space and a velocity. Multiple samples with a sememe word substitution form a swarm. Each particle in the swarm is initialized with a random velocity and position. PSO, after that, records for each particle its own best position in the search space and a global best position. This best position is calculated using an optimization score, which is the victim’s output logit for a classification task. If one of the samples achieves the desired optimization score, the algorithm is terminated since this sample can attack the model. Otherwise, each particle has its position and velocity updated with values from the individual best position, global best position, the inertia weight, two acceleration coefficients, and two random coefficients. The PSO components would replace lines 10-13 in Algorithm 2.

D.5.5 SememePSO/DWBP

uses both sememe word substitutions and punctuation insertions to construct $\{\tau_k\}$ and uses PSO to find the best substitution out of this set. Hyperparameter-wise for SememePSO/DWBP, the attack is changed by reducing the SememePSO population size from 60 to 5 (MR, QNLI) to 2 (MNLI, SNLI, and QQP) and reducing the number of iterations from 20 to 2 for all tasks.

E Appendix: Implementation Details

E.1 Attack detail

All tests were carried out with the TextAttack (Morris et al., 2020) framework to ensure repeatability, standardization, and ease of future integration. The DeepWordBug baseline, for fairness comparison, has a cosine semantic similarity constraint set to 0.8 with (Cer et al., 2018) to ensure the perturbed sample does not differ too much from the original sample and is comparable to other baselines. For TextFooler, SememePSO we keep the default implementation from TextAttack when comparing them with DWBP in Table 1, Tables in Appendix J and Figure 4,3.

For each sample, we keep the After attack accuracy, the number of queries, semantic similarity, and [%] of perturbed words. These metrics are then averaged across 500 samples to complete each test. All data was sourced from the test set of their respective dataset and sampled under a common/standard seed $\in 755$, which is the standard

seed used in the TextAttack framework. For DeepWordBugPunc the tests in Section 5.2 have been conducted on one punctuation symbol and with RPos = False while $\gamma = \{ ' - \}$, RPos = True and RPunc = True for tests in section 5.3.

We used BERT, XLNET, and RoBERTa with 110 million parameters and DistilBERT with 66 million parameters. Every test has been run on a 32GB NVIDIA Tesla V100. The TextFooler and DeepWordBugPunc tests took approximately between 30 min and 1 hour to run, while PSO took between 5 and 10 hours. Regarding the human studies, the participants were not paid and were sourced from a lab at a university. All the participants were made aware verbally of how the data would be used. All scientific artifacts from this paper will be made available on GitHub under an MIT license.

It is possible to keep the perturbed words %, semantic similarity, the average time taken, and the average number of queries to concentrate on changes in $A_{aft-atk}$ by adding a word limit constraint on the % of words perturbed in the input. We use this strategy to construct Figure 2.

E.2 Choice of symbols

The experiments in 5 narrow down a choice for γ . We focus on the most frequent punctuation for each dataset (Table 16 in the Appendix) and find that the distribution of common punctuation is similar across datasets. We therefore use all punctuation for Section 5.1 and 5.5 and the ten most popular symbols for Section 5.2, while the other tests focus on apostrophes, hyphens, commas, and full stops (the two most common internal and non-internal symbols; Figure 2, Section 5.9; Figure 8). We use the results from Sections 5.1 and 5.2 to justify multi-level attacks with apostrophes and hyphens. $\gamma = \{ - ' \}$ is a good choice since they are internal punctuation and create added problems to the defender (see Sections 5.4 and 5.5). The human studies in Sections 5.7 and 5.8 tested $\gamma = \{ - ' \}$ and $\gamma = \{ ' \}$; we did not do human tests on other punctuation insertions as they are visually similar. Nonetheless, we believe the results will be similar regardless of the punctuation type inserted (full stop, comma, apostrophe, or hyphen).

E.3 Adversarial training details

The standard adversarial technique in (Morris et al., 2020; Yoo and Qi, 2021) works by, at each epoch, finding the adversarial sample for each datapoint

(if it exists). It then extends the base dataset by 20% using the adversarial data. For MR, we do fine-tuning and adversarial training for 4 epochs with a batch size of 16 and a learning rate of $2e^{-5}$. We compare this by fine-tuning the same model using the same hyperparameters but on the base dataset.

F Appendix: Human Evaluation Details

F.1 Appendix: Gray-box and multi-level human evaluation

We follow the evaluation strategy used in TextFooler (Jin et al., 2020) and Hard-Label (Maheshwary et al., 2020). Therefore evaluate the quality of the generated samples across three metrics; Grammatical Correctness: Measures in the Likert scale, between 1 and 5. The reviewer compares the adversarial sentence to the grammar of the original as a reference. Classification: Asks the reviewer to classify the sample. We then check if the human classification matches the true label, Similarity: The user inputs a number representing one of three choices where dissimilar is 0, ambiguous 0.5, and 1 similar. The three tests were conducted with two native English-speaking students from India and the UK who have a tertiary university education. They were trained using 3 test samples. We sampled 100 samples at random from MR targeting BERT for this test.

F.2 Appendix: Black-box human evaluation

Finally, we introduce a novel application of TOWRE (Tarar et al., 2015). To generate the word list, we extract all words from the NLTK python package and pick six words randomly for each word length between 4 and 9. The reviewer pronounces 36 words as accurately and fast as possible. The test reports the number of words correctly pronounced, the number of errors, self-corrections, and the time to pronounce the 36 words or the number correctly pronounced in 1 minute. The WPM (Words Per Minute) metric extrapolates from the time or the correct number of words. The reviewers conducting TOWRE are from Singapore and Brazil. Both hold tertiary education. All the tests were conducted in one sitting and took 15 minutes each. To ensure no duplicates existed in the word list, we manually checked the 145 words across the 4 tests and found no duplicates. TOWRE was initially introduced to measure sight word reading fluency. It is widely used in clinical practices to diagnose

dyslexia or reading difficulties in children.

F.3 Krippendorff’s alpha

We use the Krippendorff’s Alpha reliability metric to detect whether a test has statistical significance. Krippendorff’s Alpha extracts a value between -1 and 1 after highlighting the agreement between multiple reviewers in a trial. This metric can calculate statistical reliability for nominal (classification, semantic similarity), ordinal (grammar test), and ratio (WPM) data types. A value close to -1 represents complete disagreement between reviewers normalizing by chance, 0 represents neither statistical agreement nor disagreement, and 1 is perfect agreement.

G Extra Findings

G.1 Punctuation as a multi-level attack

Extra Observation We find an interesting trade-off between $A_{aft-atk}$, sample quality, and attack time efficiency depending on the influence of punctuation insertions over the word-level attacks. Hyperparameter-wise, the changes in Section D.5.1 increase the attack effectiveness of punctuation insertions by decreasing classification accuracy after the attack ($A_{aft-atk}$) while increasing the quality/meaning/readability of the text. These changes are also more efficient compared to other hyperparameters because the number of queries and amount of time taken to optimize the sample are decreased.

Other hyperparameters can achieve lower $A_{aft-atk}$ but at the cost of time, queries, and sample quality. We hypothesize that this interesting behavior derives from punctuation insertions being unconstrained by a similarity constraint. These attacks can inject information from different parts of the embedding space by inserting punctuation and avoiding word substitutions. Analyzing the visual effect of inserting punctuation makes it possible to observe that the semantics remained unchanged. However, such changes are more noticeable than word substitutions (Table 2).

H Appendix: Extended Budget Study

Figure 9 illustrates how the $A_{succ-rte}$ improves as each word in the sample can be either replaced with N synonyms (TextFooler) or have one of N punctuation characters inserted in the word (DWBP) in four different ways according to how the flags RPos/RPunc are set. The behaviour of RPos and

RPunc changes DWBP, as previously explained in Section 3.3.

Increasing the number of word synonyms in TextFooler or potential punctuation symbols in DWBP results in more transformations ($\hat{\tau}_k$) that the GSWR algorithm needs to evaluate by performing queries to the victim model, therefore searching for the optimal transformation. The query response is shown in Figure 10. Both tests suggest that DWBP performs better with limited word synonyms and limited queries from the attacker. On the other hand, TextFooler performs better when the algorithm has many synonym candidates to chose from for each word.

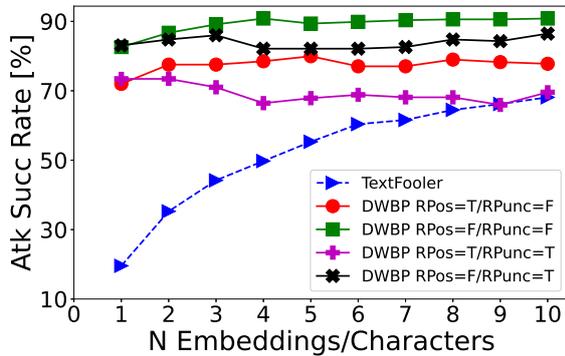

Figure 9: After Success Rate (higher is better) as the number of characters in γ is increased for DWBP vs the number N of synonyms is increased for TextFooler

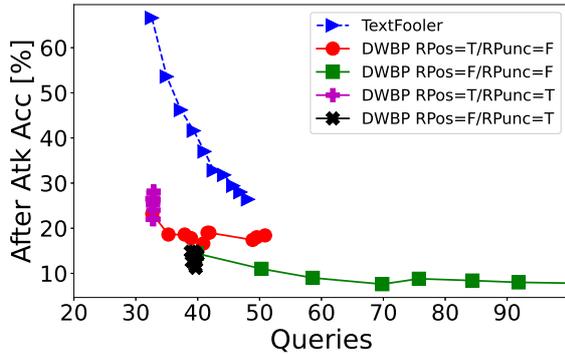

Figure 10: After Attack Accuracy (Lower is better) vs the number of queries required to find an adversarial solution. Each point represents the number of unique punctuation symbols (for DWBP) or synonyms (for TextFooler) from 1 to 10

I Appendix: Extended Non-Grammar/Grammar Checker Attack Results

The extended results of DWBP when a model employs a grammar checker (Language Tool) as a

defense technique are in Table 6. The table is with RPos = False. With RPos = True (Table 8), although it requires less queries the attack is not as effective, especially when there is a grammar checker (Figure 11 and 12). We also report the results for the most frequent non internal punctuation with RPos = False (Table 7) and with RPos = True (Table 9). Limiting punctuation is also effective against a grammar checker. The findings in fact generalize to a black box attack (Table 10). This table shows that Zeroe with all characters is ineffective and limiting punctuation is competitive with a gray-box character attack technique.

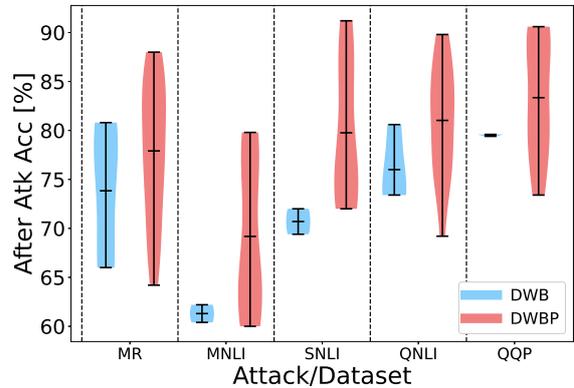

Figure 11: Summary of 'With Grammar Checker' (Table 8 and 9) $A_{aft-atk}$ across datasets with RPos = True

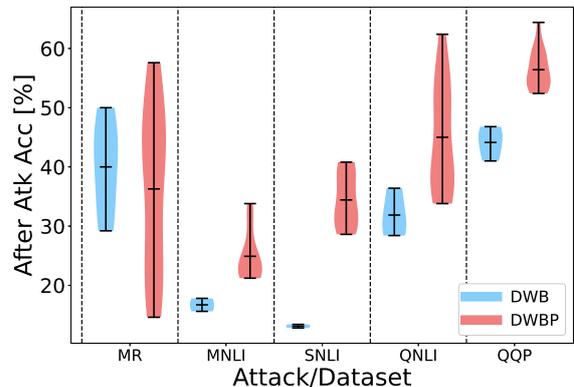

Figure 12: Summary of 'Without Grammar Checker' (Table 8 and 9) $A_{aft-atk}$ across datasets with RPos = True

J Appendix: Extended Multi-level Attack Results

The results for multi-level DWBP and DWBP on MR, MNLI, SNLI, QQP and QNLI across all models is shown in Table 11,12,13

Table 6: Results without (Original) and when using the LanguageTool grammar checker with RPos=False and internal punctuation

K Appendix: Black-Box Heatmaps

The extended results for the performance difference between ZIP (apostrophe (Ap), hyphen (Hy), comma (Co), full stop (FS) and for QQP question mark (Qu)), character insertions, Zéroé on MR, MNLI, SNLI, QQP and QNLI are in Figure 14 for LSTM on MR, Figure 13 for BERT on MR, Figure 16 for DistilBERT on MNLI, Figure 15 for BERT on MNLI, 18 for DistilBERT on SNLI, Figure 17 for BERT on SNLI, 20 for DistilBERT on QNLI, Figure 19 for BERT on QNLI, 22 for DistilBERT on QQP, Figure 21 for BERT on QQP. For BERT on MR we present the values to construct figure 13 in Table 14 as an example.

L Appendix: Punctuation vs Characters

The extended results for the performance increase in terms of after attack accuracy between inserting letters and punctuation (apostrophe, hyphen, comma, full stop), character insertions, Zéroé on MR, MNLI, SNLI, QQP and QNLI are in Figure 23 for LSTM on MR, Figure 24 for BERT on MR, Figure 25 for DistilBERT on MNLI, Figure 26 for BERT on MNLI, 27 for DistilBERT on SNLI, Figure 28 for BERT on SNLI, 29 for DistilBERT on QNLI, Figure 30 for BERT on QNLI, 31 for DistilBERT on QQP, Figure 32 for BERT on QQP.

The results show a constant improvement across all tasks except for QQP when inserting punctuation. Interestingly the strongest punctuation inser-

Table 7: Results without (Original) and when using the LanguageTool grammar checker with RPos=False and most frequent non internal punctuation from Table 16

tion appears to vary between tasks. For example, the comma is the strongest in MNLI for BERT, while the full stop is strongest for SNLI on BERT. Moreover, whether there are character insertions or punctuation insertions in the QQP task seems to have little to no difference; at times, character insertions are better, for example, when inserting a hyphen in QQP when trained on BERT. We speculate that QQP is hard to attack, whether using character or punctuation insertions. It could be hard to attack because a model is sensitive to samples with similar question pairs. Hence, it is easy to perturb them to become unsimilar by adding character or punctuation symbols. However, to perturb a nonsimilar question pair to become similar is harder, and neither character nor punctuation sym-

bols can do this. Future research to prove this can investigate this phenomenon by plotting the ROC and Precision/Recall graphs. However, the high $A_{aft-atk}$ in 13 and Table 6 in the Appendix, especially compared to other tasks, is a good indication of this theory being correct. Exploring the reasons behind these phenomena, and introducing a novel attack that can further decrease the $A_{aft-atk}$ of QQP, could be an interesting entry point for future research.

M Appendix: Adversarial training results

See Table 15 for the results of adversarial training using DWBP with hyphen insertions.

Table 8: Results without (Original) and when using the LanguageTool grammar checker with RPos=True and internal punctuation

N Appendix: Analysis

N.1 Empirical punctuation counts across datasets

The variance of symbols within each dataset is high. Table 16 shows the number of punctuation symbols and their proportion as a percentage of other characters for each dataset. The table is subdivided into ‘Total Punctuation’ and ‘Internal punctuation’ or the punctuation only appearing within words, such as apostrophes and hyphens. This distinction is essential, as Section 5 empirically motivates why punctuation can be used as an attack vector and cannot be easily defended.

N.2 Removing Punctuation

Table 17 shows the impact on all models across all datasets of removing either all punctuation, only internal punctuation, or just removing internal punctuation except the apostrophe and hyphen, which the two punctuation characters over-represented within words, as seen from Table 16. On the other hand, Table 18 shows how the original accuracy changes if the models are finetuned on data with no punctuation.

N.3 Most frequent punctuation in dataset attack

Table 19 highlights the drop in performance by the type of punctuation symbol used in the attack. The attack uses the most frequent symbols in a sample

Self-Supervised Unimodal Label Generation Strategy Using Recalibrated Modality Representations for Multimodal Sentiment Analysis

Yewon Hwang and Jong-Hwan Kim
School of Electrical Engineering, KAIST
Daejeon, Republic of Korea
{ywhwang, johkim}@rit.kaist.ac.kr

Abstract

While multimodal sentiment analysis (MSA) has gained much attention over the last few years, the main focus of most work on MSA has been limited to constructing multimodal representations that capture interactions between different modalities in a single task. This was largely due to a lack of unimodal annotations in MSA benchmark datasets. However, training a model using only multimodal representations can lead to suboptimal performance due to insufficient learning of each uni-modal representation. In this work, to fully optimize learning representations from multimodal data, we propose SUGRM which jointly trains multimodal and unimodal tasks using recalibrated features. The features are recalibrated such that the model learns to weight the features differently based on the features of other modalities. Further, to leverage unimodal tasks, we auto-generate unimodal annotations via a unimodal label generation module (ULGM). The experiment results on two benchmark datasets demonstrate the efficacy of our framework.¹

1 Introduction

These days, we can easily spot AI systems in our society that serve or assist humans. Understanding human emotions has become a critical factor for these AI systems to seamlessly integrate into human’s life (Castillo et al., 2018; De Graaf and Allouch, 2013). However, understanding humans’ emotions is not a trivial task. This is because humans tend to express their feelings through multiple cues in a complex form. Emotions can be expressed simply through language, but they can also be manifested through facial expression, behaviors or even tone of voice (Morency et al., 2011). Moreover, sometimes these cues signal a compatible emotion, while other times they signal conflicting emotions,

e.g., positive language with a condescending tone of voice indicates sarcasm (Robins et al., 2009).

Taking this nature into account, multimodal sentiment analysis (MSA) has become an active field of research which aims to understand the affective state of humans through visual, acoustic, and textual features. In general, when working with multimodal data like in MSA, each modality contains both supplementary and complementary information to each other, providing richer information about the data. This leads to improved performance over using only one modality (Vaezi Joze et al., 2020). However, capturing information in each modality as well as modeling the interactions between different modalities still remain challenging tasks to unravel (Hazarika et al., 2020).

Most of the existing works on MSA revolve around learning a joint representation which encompasses information from all modalities through sophisticated fusion methods varying from tensor-based (Zadeh et al., 2017) to attention-based methods (Tsai et al., 2019; Rahman et al., 2020), where the learning process happens in a single task. Single task learning was a dominant learning framework in MSA particularly due to the nature of the benchmark datasets: CMU-MOSI (Zadeh et al., 2016) and CMU-MOSEI (Bagher Zadeh et al., 2018). Considering all modalities, only one comprehensive sentiment intensity value (i.e., multimodal label, y_m) is annotated in both datasets due to the laborious labeling process. Meaning, unimodal labels (y_t, y_a, y_v) are omitted in the datasets. However, a recent study (Yu et al., 2021) argued the absence of unimodal annotations hinders capturing modality-specific information and proposed a module that auto-generates unimodal annotations from the multimodal labels.

In this work, we propose a novel framework, SUGRM, which leverages a self-supervised unimodal label generation strategy using recalibrated modality representations for MSA. First, we recal-

¹Our code is available at: <https://github.com/skystarhyw/SUGRM>

brate modality representations using Modality Recalibration Module (MRM). This allows the model to dynamically adjust features based on the features of other modalities. Further, motivated by (Yu et al., 2021), we propose a new unimodal label generation module (ULGM), which generates unimodal annotations (y_t, y_a, y_v) based on the multimodal annotation (y_m) in a self-supervised manner.

Different from (Yu et al., 2021), which preserves feature space of each modality, we project features of each modality into a common semantic feature space. Thus, our ULGM hypothesizes the distance between two features in a common semantic feature space is proportional to the distance between the corresponding labels in a label space. This not only allows simpler calculation of the offset (see section 3.3), but also avoids the problem in (Yu et al., 2021); that is, when two distances from a multimodal feature 1) to the center of negative multimodal features and 2) to the center of positive multimodal features are approximately equal, the generated unimodal label diverges. This could lead to unstable learning, potentially causing the model to fall into a local minima.

Our experiment results not only empirically validate our hypothesis, but also prove that using recalibrated modality representation as well as our ULGM lead to enhanced performance. The main contributions of our work can be summarized as follows:

- We introduce Modality Recalibration Module (MRM) for MSA which recalibrates modality features based on features of other modalities.
- We design a novel unimodal label generation module (ULGM) to expand MSA to multi-task learning and jointly train unimodal and multimodal tasks.
- Not only does our method outperform the previous SOTA results, but the experiment results validate the effectiveness of our framework.

2 Related Work

Prior works of MSA mainly focused on improving fusion between multi-modalities as well as learning joint representations. In earlier works, early fusion (Pérez-Rosas et al., 2013; Poria et al., 2016) and late fusion (Zadeh et al., 2016) were popular fusion methods to combine the multiple modalities. Later, more sophisticated methods of

fusion were proposed using a multi-dimensional tensor (Zadeh et al., 2017), attention mechanism (Zadeh et al., 2018a,b), multi-stage fusion (Liang et al., 2018) and low rank tensors to improve efficiency of fusion (Liu et al., 2018). In (Wang et al., 2019), the authors dynamically adjusted a word representation by calculating a shift caused by accompanying nonverbal information. More recent works have focused on applying Transformer architecture to better capture interactions between modalities and learn feature representations. For instance, (Rahman et al., 2020) was directly built upon (Wang et al., 2019), but used pretrained Transformer based language models to improve the performance. (Tsai et al., 2019) proposed cross-modal attention to latently adapt a target modality from source modalities. (Cheng et al., 2021) reduced the computational burden in (Tsai et al., 2019), by generating sparse attention matrices and compressing a long sequence to a short sequence. Further, a multi-task learning approach has been applied in recent MSA (Akhtar et al., 2019; Yu et al., 2021) to increase data efficiency.

Taking inspiration from the previous work (Yu et al., 2021), we expand a learning framework of MSA to multi-task learning. The benefits of multi-task learning is that each task helps a learning process of other tasks. This allows the model to learn better generalized representations that are shared across the tasks. Further, we recalibrate features of each modality and efficiently model inter-, intra-modality relationships by adopting the work of (Hu et al., 2018; Vaezi Joze et al., 2020; Cheng et al., 2021).

3 Methodology

3.1 Problem Definition

We define the input to the model as $I_{s \in \{t,a,v\}}$ which is composed of three types of modalities-text, audio, and video. The goal of our model is to take I_s as input and predict a sentiment intensity $\hat{y} \in \mathbb{R}$. To aid the learning process, our model generates labels for each modality $y_s \in \mathbb{R}$ during training.

3.2 Overall Architecture

Our framework consists of multimodal and unimodal tasks where they share modality representations as shown in Figure 1.

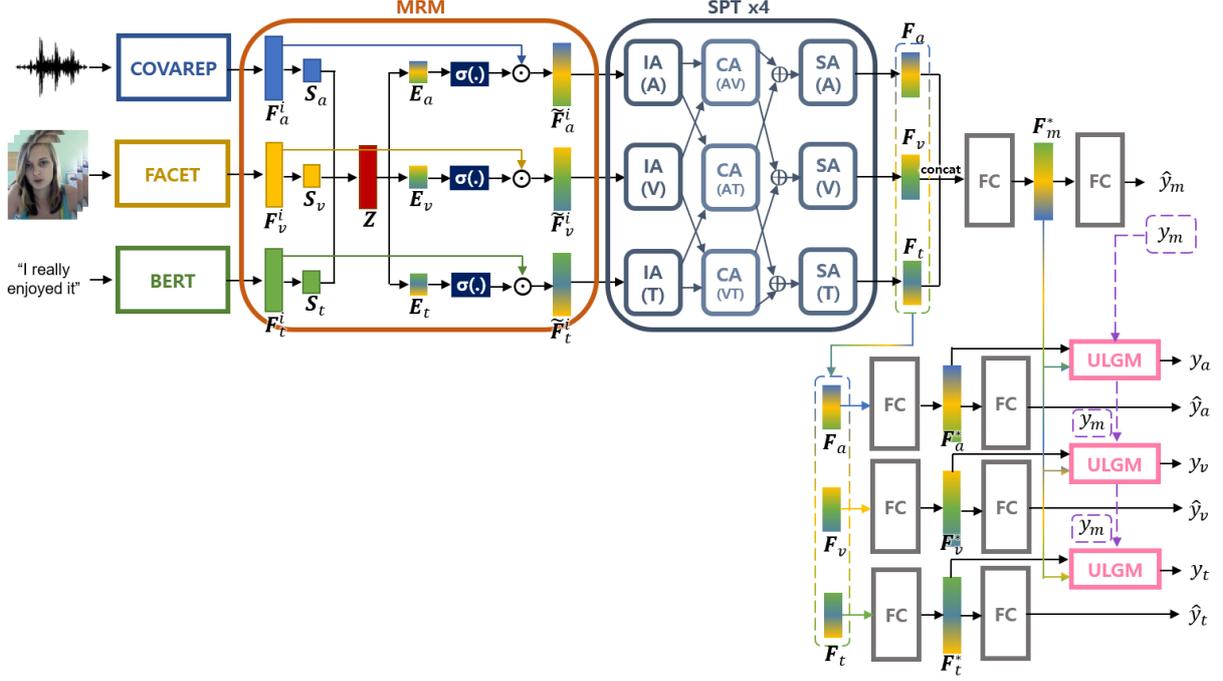

Figure 1: The overall architecture of SUGRM. The y_a , y_v , and y_t are the unimodal annotations generated from our ULGM based on the human-annotated multimodal label y_m to enable supervised learning of the unimodal tasks. The \hat{y}_a , \hat{y}_v , \hat{y}_t , and \hat{y}_m are the predicted sentiment values from the unimodal and multimodal tasks.

3.2.1 Multimodal Task

In the multimodal task, modality features ($\mathbf{F}_{s \in \{t, a, v\}}^i$) are initially extracted from pretrained BERT (Devlin et al., 2019), COVAREP (Degottex et al., 2014), and FACET (iMotions, 2013) for textual, acoustic, and visual information, respectively. Then these features are passed through Modality Recalibration Module (MRM) for feature recalibration. After the features are recalibrated, the final feature representation of each modality is captured using Sparse Phased Transformer (SPT).

Modality Recalibration Module. MRM recalibrates modality features using squeeze and excitation (SE) technique (Hu et al., 2018). This particular idea was studied in the case of CNN in (Vaezi Joze et al., 2020). Here, we show how SE can be expanded to the MSA application. MRM receives $\mathbf{F}_s^i \in \mathbb{R}^{l_s \times d_s}$ as input, where l_s is the sequence length and d_s is the feature dimension of s -modality, and squeeze the input along the sequence length using global average pooling:

$$\mathbf{S}_s(d) = \frac{1}{l_s} \sum_{l=1}^{l_s} \mathbf{F}_s^i(l, d),$$

where $s \in \{t, a, v\}$ and $d = 1, \dots, d_s$. Then the excitation process is performed to apply different weight calibrations for each modality. First,

squeezed features are concatenated and fed into a series of a fully connected network and ReLU to learn a global multimodal embedding \mathbf{Z} :

$$\mathbf{Z} = \text{ReLU}(\mathbf{W}_z[\mathbf{S}_t; \mathbf{S}_a; \mathbf{S}_v] + \mathbf{b}_z).$$

Here, the fully connected network reduces feature dimension. Then we compute excitation signals using another fully connected network as follows:

$$\mathbf{E}_s = \mathbf{W}_s \mathbf{Z} + \mathbf{b}_s.$$

The second fully connected network restores the original feature dimension, adopting bottleneck architecture. The reason for this is to reduce the number of computations and improve generalization (Hu et al., 2018). Finally, the input features are recalibrated through a following gating mechanism:

$$\tilde{\mathbf{F}}_s^i = 2 \times \sigma(\mathbf{E}_s) \odot \mathbf{F}_s^i,$$

where $\sigma(\cdot)$ is the sigmoid function and \odot is the element-wise product along the feature dimension. Since the numbers returned by sigmoid function (between 0 and 1) are multiplied by the original features, each feature is rescaled based on its importance. Finally, the textual, acoustic, and visual features after MRM can be described as follows:

$$\tilde{\mathbf{F}}_s^i = \text{MRM}(\mathbf{F}_s^i; \theta^{\text{mrm}}) \in \mathbb{R}^{l_s \times d_s},$$

where θ^{mrm} are the parameters of MRM.

Sparse Phased Transformer. SPT (Cheng et al., 2021) extracts the final feature representation of each modality using the recalibrated features. The motivation behind SPT is twofold: to extract more informative features by modeling intra- and inter-modalities (preferred over LSTM²) and to build a more efficient and lighter model (preferred over (Cheng et al., 2021)²). SPT alleviates the computational burden of the self-attention mechanism in the vanilla Transformer. Instead of generating a full attention matrix, SPT generates a sparse attention matrix to reduce computational complexity.³ Multimodal SPT is composed of input attention, cross attention, and self attention. Input attention (IA) compresses input sequence into hidden states. Then the hidden states of two different modalities are interacted through cross attention (CA). Finally, self attention (SA) refines the feature representations of each modality. For the technical details of SPT, refer to (Cheng et al., 2021) on which our implementation of SPT is based.

We denote the final feature representation for each modality as follows:

$$\mathbf{F}_s = SPT(\tilde{\mathbf{F}}_s^i; \theta^{spt}) \in \mathbb{R}^{d_s},$$

where SPT is the process of [IA→CA→SA] repeated 4 times and θ^{spt} are the parameters of SPT. Finally, the last element of the sequence is selected as a sequence representation.

To obtain a fusion representation, we concatenate each modality representation and project into a lower-dimensional feature space \mathbb{R}^{d_c} as follows:

$$\mathbf{F}_m^* = ReLU(\mathbf{W}_1^m [\mathbf{F}_t; \mathbf{F}_a; \mathbf{F}_v] + \mathbf{b}_1^m).$$

Lastly, the multimodal sentiment is predicted as follows:

$$\hat{y}_m = \mathbf{W}_2^m \mathbf{F}_m^* + b_2^m.$$

3.2.2 Unimodal Task

For the unimodal task, we use the feature representation of each modality obtained from the multimodal task ($\mathbf{F}_{s \in \{t, a, v\}}$). Then we map each feature representation into the same feature space as \mathbb{R}^{d_c} (i.e., a common semantic feature space) as follows:

$$\mathbf{F}_s^* = ReLU(\mathbf{W}_1^s \mathbf{F}_s + \mathbf{b}_1^s).$$

²Three options were considered as a final feature extractor: LSTM, multimodal Transformer (Cheng et al., 2021), and SPT (See Table 4).

³The authors of SPT (Cheng et al., 2021) claim that the number of parameters is reduced to 10% of (Tsai et al., 2019) which utilizes the vanilla Transformer encoder.

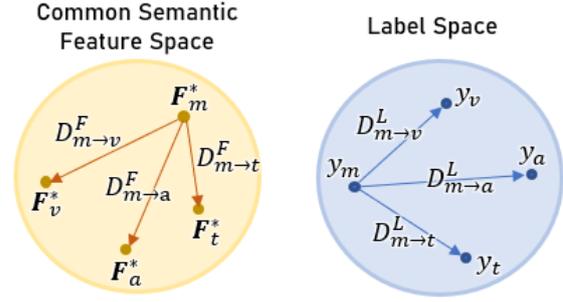

Figure 2: The distance from multimodal feature (\mathbf{F}_m^*) to s -modal feature (\mathbf{F}_s^*) in a common semantic feature space: $D_{m \rightarrow s}^F$, and the distance from multimodal label (y_m) to s -modal label (y_s) in a label space: $D_{m \rightarrow s}^L$.

Then the final sentiment prediction from each modality is obtained through an independent fully-connected layer:

$$\hat{y}_s = \mathbf{W}_2^s \mathbf{F}_s^* + b_2^s.$$

The unimodal tasks are trained using supervised learning, where labels for each modality are obtained via non-parametric Unimodal Label Generation Module (ULGM):

$$y_s = ULGM(y_m, \mathbf{F}_m^*, \mathbf{F}_s^*).$$

Finally, the multimodal task and three unimodal tasks are jointly trained.

3.3 ULGM

The goal of ULGM is to generate labels for each unimodality based on multimodal labels and modality representations. As shown in Figure 2, our ULGM is designed based on the notion that the distance between two features in a common semantic feature space is proportional to the distance between the corresponding labels in a label space:

$$D_{m \rightarrow s}^F \propto D_{m \rightarrow s}^L,$$

where $s \in \{t, a, v\}$. Our ULGM computes the offset of unimodal label y_s with respect to the multimodal label y_m based on the distance from the multimodal feature to each unimodal feature. We consider two factors when computing the offset: the magnitude and the direction.

Magnitude of offset. To calculate the offset, we argue that the maximum distance within the common semantic feature space is proportional to the maximum distance within the label space. In CMU-MOSI and -MOSEI datasets, the multimodal

labels range from -3 to +3, meaning the distance between multimodal features with labels -3 (\mathbf{F}_m^{*-3}) and +3 (\mathbf{F}_m^{*+3}) must correspond to the maximum distance within the common semantic feature space. Therefore, any $D_{m \rightarrow s}^F$ greater than the maximum distance is clipped to $D_{max}^F = \|\overline{\mathbf{F}_m^{*+3}} - \overline{\mathbf{F}_m^{*-3}}\|$:

$$D_{m \rightarrow s}^F = \begin{cases} \|\mathbf{F}_m^* - \mathbf{F}_s^*\|, & \text{if } D_{m \rightarrow s}^F \leq D_{max}^F, \\ D_{max}^F, & \text{otherwise,} \end{cases}$$

where $\overline{\mathbf{F}_m^{*+3}}$ and $\overline{\mathbf{F}_m^{*-3}}$ are the mean of \mathbf{F}_m^{*+3} and \mathbf{F}_m^{*-3} , respectively, and $\|\cdot\|$ is L2 normalization.

Based on our notion and the above argument, we can consider the following relationship from which we can obtain the magnitude of the offset from a multimodal label to an unimodal label:

$$D_{m \rightarrow s}^F / D_{max}^F = D_{m \rightarrow s}^L / D_{-3 \rightarrow +3}^L,$$

$$D_{m \rightarrow s}^L = \frac{D_{m \rightarrow s}^F}{D_{max}^F} D_{-3 \rightarrow +3}^L.$$

Direction of offset. In order to determine the direction of the offset, we identify the position of the s -modal feature with respect to the multimodal feature. To do that, we first take the average of the multimodal features with positive annotations ($\overline{\mathbf{F}_m^{*+}}$) and negative annotations ($\overline{\mathbf{F}_m^{*-}}$). Then we locate the multimodal and the s -modal features within this realm of feature space as shown in Figure 3. Using the distance from modality representations ($\mathbf{F}_{x \in \{m, t, a, v\}}^*$) to $\overline{\mathbf{F}_m^{*+}}$ and $\overline{\mathbf{F}_m^{*-}}$, we can determine the direction of the offset as follows:

$$Direction = \begin{cases} +, & \text{if } \frac{D_s^p}{D_s^n} < \frac{D_m^p}{D_m^n}, \\ -, & \text{if } \frac{D_s^p}{D_s^n} > \frac{D_m^p}{D_m^n}, \\ 0, & \text{if } \frac{D_s^p}{D_s^n} = \frac{D_m^p}{D_m^n}, \end{cases}$$

where $D_s^p = \|\mathbf{F}_s^* - \overline{\mathbf{F}_m^{*+}}\|$, $D_s^n = \|\mathbf{F}_s^* - \overline{\mathbf{F}_m^{*-}}\|$, $D_m^p = \|\mathbf{F}_m^* - \overline{\mathbf{F}_m^{*+}}\|$, and $D_m^n = \|\mathbf{F}_m^* - \overline{\mathbf{F}_m^{*-}}\|$. Finally, we obtain the unimodal label y_s as follows:

$$y_s = \begin{cases} y_m + D_{m \rightarrow s}^L, & \text{if direction is +,} \\ y_m - D_{m \rightarrow s}^L, & \text{if direction is -,} \\ y_m, & \text{if direction is 0.} \end{cases}$$

Unimodal Label Update Scheme. We update the generated unimodal labels using a momentum-based update policy (Yu et al., 2021) as follows:

$$y_s^e = \begin{cases} y_m & \text{for } e = 1, \\ \frac{e-1}{e+1} y_s^{(e-1)} + \frac{2}{e+1} y_s^e & \text{for } e > 1, \end{cases}$$

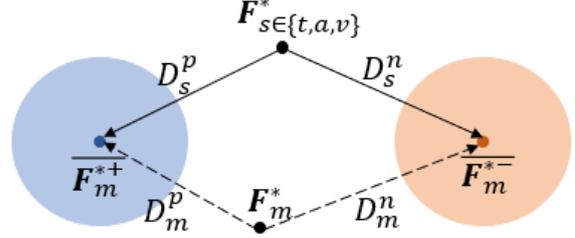

Figure 3: An illustration of positions of modality representations with respect to the mean of multimodal representations with positive labels ($\overline{\mathbf{F}_m^{*+}}$) and negative labels ($\overline{\mathbf{F}_m^{*-}}$) in the common semantic feature space.

where $s \in \{t, a, v\}$ and e is epoch. This scheme is used to mitigate the instability of labels that are generated at the beginning of epochs in which the learning of the modality features is trivial. This update scheme allows the labels generated in later epochs to have greater impact than the ones generated in earlier epochs. After a sufficient number of iterations, unimodal labels become stabilized, resulting in a stable training process of unimodal tasks. As can be seen in Figure 4, the labels stabilize within 15 epochs.

3.4 Objective Function for Training

For the objective function, we investigated three loss functions that are widely used in regression tasks: L1 loss, L2 loss, and Huber loss. Based on our loss ablation study (see Table 8 in Appendix), we use L1 loss as the objective function for both multimodal and unimodal tasks. We minimize the sum of the two loss functions over N training samples to optimize the entire model as follows:

$$L = \frac{1}{N} \sum_i (|\hat{y}_m^i - y_m^i| + \sum_{s \in \{t, a, v\}} w_s^i * |\hat{y}_s^i - y_s^i|),$$

where the first term corresponds to the multimodal task, and the second term corresponds to the unimodal tasks optimization. Note the loss functions for the unimodal tasks are weighted by w_s^i , where $w_s^i = \tanh(|y_s^i - y_m^i|)$ (Yu et al., 2021) such that the model can target the samples with larger difference between the multimodal label and the generated unimodal label more rigorously during training.

4 Experimental Settings

4.1 Datasets

We use the two most popular English benchmark datasets for MSA: CMU-MOSI (Zadeh et al., 2016) and CMU-MOSEI (Bagher Zadeh et al., 2018). CMU-MOSI dataset consists of 2,199 labeled video clips taken from 93 videos by 89 speakers. The videos were crawled from YouTube and encompass opinions on movies, books, and products. Each video is annotated with sentiment on a [-3,3] range. CMU-MOSEI dataset is the most comprehensive dataset for sentiment analysis and emotion recognition which comprises more than 65 hours worth of 23,453 annotated video segments from 1,000 speakers addressing 250 different topics. Each video is annotated with sentiment on a [-3,3] range as well as six discrete emotions: happy, sadness, anger, disgust, surprise, and fear. We only utilize sentiment values from CMU-MOSEI in this task. See Table 6 in Appendix for the dataset split.

4.2 Baselines

We compare the performance of our model with previous state-of-the-art MSA models. The superscript A indicates the proposed method only works on the aligned settings, while UA indicates the proposed method works on both unaligned and aligned settings.⁴

EF-LSTM.^A Early Fusion LSTM concatenates the multimodal features at the input level.

LF-LSTM.^{UA} Late Fusion LSTM combines modality-wise decisions using a voting mechanism.

TFN.^A The Tensor Fusion Network (Zadeh et al., 2017) models intra- and inter-modality dynamics through multi-dimensional tensors.

RAVEN.^A The Recurrent Attended Variation Embedding Network (Wang et al., 2019) models nonverbal sequences and dynamically shifts word representations based on nonverbal cues.

MCTN.^A The Multimodal Cyclic Translation Network (Pham et al., 2019) learns robust joint representations via multimodal cyclic translations using a cycle consistency loss.

⁴Multimodal data in CMU-MOSI and MOSEI are loaded from different sources which come at different frequencies, making the multimodal data “unaligned” in terms of sequence length. (The lengths of text, audio, video segments are 50, 375, 500, respectively for the unaligned dataset.) These unaligned data have been preprocessed through CMU-Multimodal SDK (<https://github.com/A2Zadeh/CMU-MultimodalSDK>) to align different modalities such that they have the same sequence length of 50. Note, our method works on both aligned and unaligned settings.

MULT.^{UA} The Multimodal Transformer (Tsai et al., 2019) uses cross-modal attention to model interactions between asynchronous modalities and latently adapt one modality to another.

MAG-BERT.^A The Multimodal Adaptation Gate for BERT (Rahman et al., 2020) is an improvement of RAVEN which applies multimodal adaptation gate at the first layer of the BERT model.

SPT.^{UA} The multimodal Sparse Phased Transformer (Cheng et al., 2021) is an improvement of MulT in terms of efficiency by using a sampling function to generate a sparse attention matrix.

Self-MM.^{UA} The Self-Supervised Multi-task Multimodal sentiment analysis network (Yu et al., 2021) generates a unimodal label for each modality and jointly trains multimodal and unimodal tasks.

4.3 Implementation Details

We trained our framework using NVIDIA TITAN Xp and Intel i7-9700K. We use the batch size of 32 and Adam as the optimizer for both datasets. For more implementation details such as hyperparameters for each dataset, see Table 7 in Appendix.

4.4 Evaluation Metrics

We evaluate our model using four metrics: weighted binary F1 score (F1-Score), binary classification accuracy (Acc₂), Mean Absolute Error (MAE), and Pearson correlation (Corr). For F1-Score and Acc₂, we report the model performance in two ways: negative/non-negative (Zadeh et al., 2017) and negative/positive (Tsai et al., 2019).

5 Results and Analysis

5.1 Quantitative Results

Tables 1 and 2 show the experiment results on the aligned and unaligned MOSI and MOSEI datasets, respectively. Our model outperformed all of the previous SOTA baseline models on all metrics for the MOSI dataset, and achieved either SOTA or comparable-to-SOTA results on the MOSEI dataset for both the aligned and unaligned datasets. Note, CTC (Graves et al., 2006) was introduced to allow some models (Wang et al., 2019; Pham et al., 2019) that originally only work on the aligned dataset to work on the unaligned dataset in Table 2. Unlike the previous observation (Tsai et al., 2019), our model shows greater strength in the unaligned dataset than the aligned dataset. This is beneficial in that it allows omission of extra data alignment

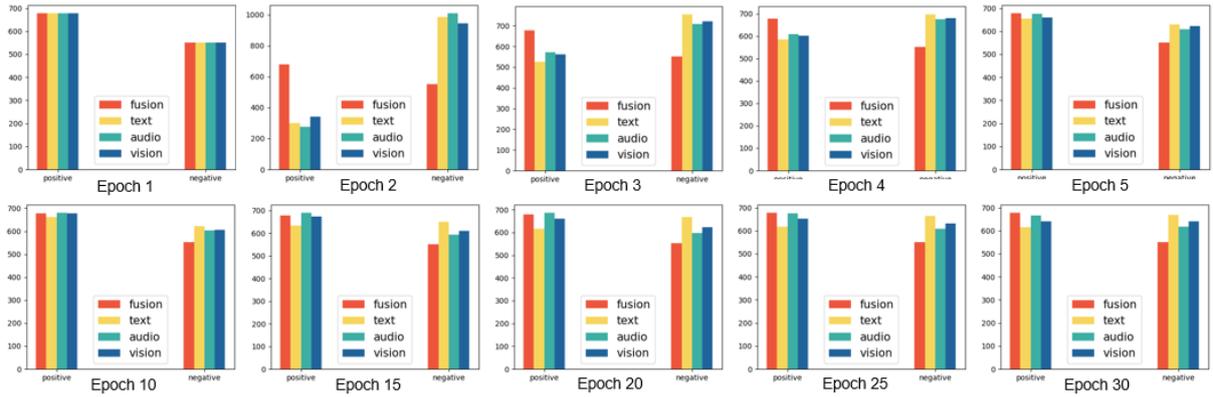

Figure 4: Visualization of the generated unimodal labels update process throughout epochs on CMU-MOSI dataset

step and data to have its inherent trait of unalignment, which could further facilitate real-time sentiment analysis.

5.2 Ablation Study

To explore the contributions of the unimodal tasks in our model, we conducted experiments using combinations of different unimodal tasks as shown in Table 3. The general trend of the results shows that incorporating the unimodal tasks leads to improvement in the model performance, which proves the effectiveness of our model. Particularly, using all three unimodal tasks along with the multimodal task resulted in substantial performance gain on all metrics compared to using the multimodal task alone on the MOSI dataset. An interesting trend on the MOSI dataset is that the performance rather decreased when only one of the unimodal tasks was added. However, we can observe that the addition of more than one unimodal task helps the model to achieve better results. On the other hand, introducing all the unimodal tasks (M,T,A,V) on the MOSEI dataset did not show as apparent performance gain as the MOSI dataset. However, we can easily observe a generally increasing trend in performance with the addition of unimodal tasks on the MOSEI dataset.

To compare our ULGM as well as the effectiveness of our architecture against that of Self-MM (Yu et al., 2021), we conducted an ablation study as shown in Table 4. Our model surpassed the performance of Self-MM via the combination of MRM, SPT, and ULGM_{ours} modules. To study the effectiveness of each module, we added MRM to Self-MM, replaced LSTM in Self-MM with SPT for learning sequence representation, and replaced ULGM_{Self-MM} with ULGM_{ours}. The addition of

MRM and the replacement of SPT on the MOSI dataset certainly led to improved performance but on a limited range of metrics. However, the replacement of ULGM_{ours} significantly increased the performance on all metrics. Results on the MOSEI dataset show a notable performance boost in all tasks across a wide range of metrics. Particularly, the replacement of SPT, which showed trivial results on the MOSI dataset, played an important role in improving the performance on the MOSEI dataset.

Similarly, we removed or replaced MRM, SPT, and ULGM_{ours} to evaluate their contribution to our model. First, we removed MRM, replaced SPT with the vanilla Transformer encoder (TE) (Tsai et al., 2019) and LSTM, and replaced ULGM_{ours} with ULGM_{Self-MM}. The results in Table 4 predominantly show that the inclusion of all modules results in the best performance. Replacing SPT with the vanilla Transformer encoder and ULGM_{ours} with ULGM_{Self-MM} led to an increase in certain metrics. However, not only the improvement is minuscule for both replacements, but the opportunity cost for exchanging computational efficiency with such minuscule improvement is rather counterproductive particularly for the SPT → TE replacement.

5.3 Qualitative Results

To evaluate the quality of the generated labels of each modality, we display four samples from the CMU-MOSI dataset in Table 5. We observe that the generated unimodal annotations are generally in line with the descriptions from the text, acoustic, and visual information. This further confirms the efficacy of our ULGM.

Table 1: Results on the aligned CMU-MOSI and CMU-MOSEI datasets. In Acc₂ and F1-Score, the left side of the “/” is the “negative/non-negative” method and the right side is the “negative/positive” method.

Model	MOSI				MOSEI

6 Conclusion and Future Work

In this paper, we proposed SUGRM, a novel framework for multimodal sentiment analysis (MSA) which incorporates unimodal subtasks to aid the learning process of the multimodal task. To enable this, we first designed Modality Recalibration Module (MRM) so that features of each modality are recalibrated based on the features of other modalities. Then, we designed a unimodal label generation module (ULGM) based on the notion that the distance between two features in a common semantic feature space is proportional to the distance between the corresponding labels in a label space. From this, ULGM was able to generate unimodal annotations from the multimodal label in a self-supervised manner, which saved a tremendous amount of human labor. The experiment results validated our notion as well as the reliability of the unimodal labels generated from our ULGM.

For future work, expanding the framework to jointly train sentiment and emotion tasks could be worthwhile. Recently (Akhtar et al., 2019) proposed that MSA and Multimodal Emotion Recognition are closely correlated; therefore their tasks can be carried out jointly. Applying contrastive learning for different emotion classes and exploiting correlation between sentiment and emotion could help achieve better results in both tasks.

Limitations

A limitation of our work is that the initial features for audio and video are extracted using off-the-shelf frameworks: COVAREP and FACET. Therefore these features are fixed and cannot be further fine-tuned unlike the text features which are fine-tuned during training. Working with fixed features, compared to dynamic features which can be adjusted via learning, inevitably results in subpar

performance. We expect this limitation can be alleviated by making our framework completely end-to-end by using raw audio and video data and introducing learning-based audio and video feature extraction modules. However, using raw data can exponentially increase memory usage which is another challenge that needs to be considered. Further, by introducing additional MRM and SPT modules, our method took approximately twice the time as the (Yu et al., 2021) during inference using the unaligned MOSI dataset.⁵ Double in inference time hinders the community's strive to build faster and more compact models.

Huber loss	78.1/79.2	78.2/79.2	0.818	0.744

Fighting FIRE with FIRE: Assessing the Validity of Text-to-Video Retrieval Benchmarks

Abstract

Searching troves of videos with textual descriptions is a core multimodal retrieval task. Owing to the lack of a purpose-built dataset for text-to-video retrieval, video captioning datasets have been re-purposed to evaluate models by (1) treating captions as positive matches to their respective videos and (2) assuming all other videos to be negatives. However, this methodology leads to a fundamental flaw during evaluation: since captions are marked as relevant *only* to their original video, many alternate videos *also* match the caption, which introduces false-negative caption-video pairs. We show that when these false negatives are corrected, a recent state-of-the-art model gains 25% recall points—a difference that threatens the validity of the benchmark itself. To diagnose and mitigate this issue, we annotate and release 683K additional caption-video pairs. Using these, we recompute effectiveness scores for three models on two standard benchmarks (MSR-VTT and MSVD). We find that (1) the recomputed metrics are up to 25% recall points higher for the best models, (2) these benchmarks are nearing saturation for Recall@10, (3) caption length (generality) is related to the number of positives, and (4) annotation costs can be mitigated through sampling. We recommend retiring these benchmarks in their current form, and we make recommendations for future text-to-video retrieval benchmarks.

1 Introduction

Text-to-video retrieval (TVR) is a challenging multimodal retrieval task (Hu et al., 2011) with practical applications ranging from web search to organizing media collections (Lew et al., 2006). To measure TVR model improvement—despite a dearth of purpose-built TVR benchmarks—researchers created benchmarks by re-purposing video captioning datasets such as MSR-VTT (Xu et al.,

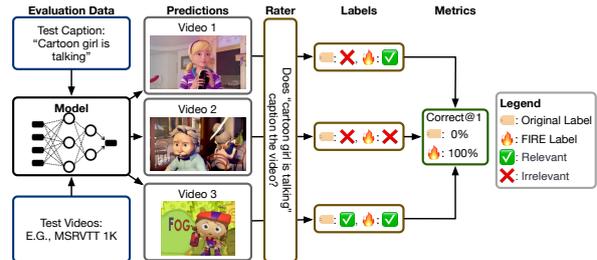

Figure 1: MSR-VTT and MSVD have one positive video per caption (each video’s caption). Captions often match multiple videos, leading to false negatives. When models rank false negatives highly, model quality is understated (full example in Appendix Figure 5). This leads to evaluations where reported metrics do not reflect their true value and are therefore not internally valid (§2.2.1).

2016), MSVD (Chen and Dolan, 2011), and ActivityNet (Heilbron et al., 2015; Krishna et al., 2017). Early work established an evaluation paradigm that treated captions as search queries over the collection of captioned videos (Zhang et al., 2018; Yu et al., 2018; Gabeur et al., 2020); each caption and their corresponding video are positives (relevant) during retrieval, and all other caption-video pairs are negatives (irrelevant).

However, even a cursory inspection of videos and captions reveals many additional positive caption-video pairs (§2). In current benchmarks, *true positives* that are not the video’s original caption are falsely assumed to be *negatives*. Wray et al. (2021) first identified this fundamental, false-negative problem in TVR evaluation; our work builds on this by quantifying the absolute metric differences that false negatives induce (see discussion in §6). Accurate absolute metrics are crucial in industrial settings where deployment criteria are often defined by minimum quality targets. These **False Implicit Relevance** labels introduce measurement error—e.g., CLIP4CLIP’s (Luo et al., 2021) Recall@1 is underestimated by 25% points (§2.2). We estimate measurement error by

*Correspondence to me@pedro.ai

annotating 683K additional caption-video pairs, which we call the FIRE 🔥 dataset (§3).¹

A core measurement principle is that operationalized metrics should strongly correlate to the quantity they intend to measure (Mathison, 2004; Liao et al., 2021). For example, Recall@K operationalizes the intent to measure retrieval quality. Label errors are a common way that measurements are invalidated (Bowman and Dahl, 2021; Northcutt et al., 2021). Our work shows that since TVR metrics are computed with false negative label errors, Recall@K does not accurately reflect retrieval quality, which negates the measurement’s validity. In the remainder of this paper, we posit rationales of why models gain different score boosts (§4.1) and estimate how useful the FIRE dataset is for evaluating future models (§4.2 and §4.3).

To conclude, we review the implications of our findings. Looking to the past, retrieval effectiveness has been understated for some models, which gives an overly pessimistic view of recent advances (Bowman, 2022). Critically, our results also suggest that the MSR-VTT benchmark is nearing saturation and should be retired soon in favor of a purpose-made benchmark. Looking outward, we identify structurally similar benchmarks—such as photo retrieval—that likely also have the same **False Implicit Relevance** problem. A successful benchmark should avoid the pitfalls we identify in this paper, be faithful to the real-world user task it targets (Rowe and Jain, 2005; de Vries et al., 2020), improve reproducibility, and evolve (§7).

2 Text-to-Video Retrieval Evaluation

This section reviews current TVR evaluation practices using two concepts: *internal validity* (Campbell, 1957, §2.2.1) and *construct validity* (Tague-Sutcliffe, 1992, §2.2.2). *Internal validity* refers to whether an evaluation reliably establishes a cause-effect relationship between the measured dependent variable and the independent variable to be estimated (Brewer and Crano, 2014; Liao et al., 2021). In TVR evaluations, false negatives confound model quality and label errors (i.e., is the model wrong or is the label wrong?) which makes *reliably* establishing cause (model quality) and effect (retrieval score) difficult. *Construct validity* “pertains to the degree to which the measure of a construct sufficiently measures the intended concept” (O’Leary-Kelly and J. Vokurka, 1998)—in

¹Data and Code: pedro.ai/multimodal-retrieval-evaluation.

TVR evaluations, an important intended concept is real-world search quality. *Construct validity* asks: can we expect that measuring retrieval quality with the benchmarks at hand generalizes to real-world search quality? This section argues that TVR evaluations are not internally valid or construct valid.

2.1 Model Evaluation

Multimodal retrieval evaluations typically focus on two tasks: text-to-video and video-to-text retrieval. The first task’s goal is—given a text query—to retrieve videos that match; the second task’s goal is—given a video—to retrieve the matching queries. The applications of text-to-video search are straightforward: it is useful for searching the web and personal media.² Since the applications of TVR are clear, and the false-negative problem is present in both tasks, here we focus on TVR.

The MSR-VTT and MSVD Datasets: It is standard for TVR evaluations (Zhang et al., 2018; Yu et al., 2018; Gabeur et al., 2020) to report on MSR-VTT and MSVD, so in the interest of comparability, we use these benchmarks too. Although these datasets were originally meant for evaluating video captioning models, they have been repurposed for TVR (Zhang et al., 2018; Gabeur et al., 2020). In this paper, we focus our investigation on MSR-VTT and MSVD since they are the most prevalent in prior work. MSR-VTT consists of 10K videos, 1K of which are in the test split. Each video has twenty captions, but for evaluation, only one (arbitrarily chosen) caption is used. MSVD contains 1,970 videos, 960 of which are in the test split. Videos have about forty captions; unlike with MSR-VTT, retrieval quality for each caption is evaluated.

Fundamentally, both MSR-VTT and MSVD are video captioning datasets—not retrieval datasets. MSVD addressed the lack of standard benchmarks for paraphrasing (Chen and Dolan, 2011). In the original task, annotators selected short clips from YouTube, watched the clip, and wrote a sentence describing its contents. The process was repeated for each video, with each sentence being written by a new annotator. This conditional independence—given the video—resulted in a diverse set of captions. MSR-VTT captions were collected similarly: independent annotators captioned the same video. Videos were sourced from the output of a commercial video search engine (Xu et al., 2016). In both

²The applications of video-to-text retrieval—that are not simply captioning—are not clear to us.

datasets, video captions are used as search queries and labeled relevant to the original video.

Metrics: Previous TVR work (Zhang et al., 2018; Yu et al., 2018; Gabeur et al., 2020; Luo et al., 2020; Zhu and Yang, 2020; Li et al., 2020; Xu et al., 2021; Park et al., 2022) reports Recall@K (R@K)³ and sometimes supplemental metrics such as median or mean rank of the first correct result. However, R@K in TVR work differs from the textbook information retrieval definition (Manning et al., 2008, p. 155) where

$$\text{R@K} = \frac{\# \text{ retrieved positives in top K}}{\# \text{ total positives in collection}}. \quad (1)$$

In TVR work, query retrieval results are scored one if a relevant video is in the top K and zero otherwise. The traditional definition of Recall@K *only* reduces to this when there is *exactly* one positive in the collection but is not comparable when there are multiple positives per caption—as in this case.

With the difference now salient, we avoid confusion by defining a new quantity Correct@K (C@K) which is 1 if at least one positive is in the top K and 0 otherwise. Correct@K naturally reduces to Recall@K—as defined in prior work—when there is exactly one positive, but handles the additional positives in our work. We recommend reporting Correct@K as well as mean average precision (Su et al., 2015; Mitra and Craswell, 2018, MAP), a metric widely used in Information Retrieval.

The drawback of Correct@K—shared by median (or mean) rank to first positive—is that it does not directly factor in rank order when there are multiple positives in retrieved results, only coarsely factoring in rank via K value. MAP (Mitra and Craswell, 2018, p. 19) is calculated by taking the mean of

$$\text{AvgPrec}_q = \frac{\sum_{\langle i,v \rangle \in R_q} \text{Prec}_{q,i} \times \text{rel}_q(v)}{\sum_{v \in V} \text{rel}_q(v)} \quad (2)$$

for each test query q where i is a video’s position in the ranked list R_q of videos, v is a video in collection V , and $\text{rel}_q(v)$ denotes whether query q is relevant to video v . Intuitively, this translates to calculating the mean of Precision@K for every K where a positive occurs in ranked predictions R_q . In all experiments, we report Correct@K and MAP.

2.2 Questioning the Validity of Evaluations

In this section, we experimentally argue that current TVR evaluations are not *internally valid*. Then

³Typical K values include 1, 5, 10, and 50.

we argue that they are not *construct valid* by considering actual use-cases for video search.

2.2.1 Internal Validity

If an evaluation metric is internally valid (Liao et al., 2021), then model effectiveness (cause) should be *accurately and reliably* reflected in metrics (effect) (Brewer and Crano, 2014). A central hypothesis of this paper is that the prevalence of false negatives invalidates the cause-effect relationship between measured model effectiveness and actual effectiveness—i.e., that correcting false negatives will significantly change metrics.⁴

To test this hypothesis, we build the FIRE dataset, which Fixes Implicit Relevance Errors. We detail the dataset later (§3), but in short, we take strong retrieval models from the past few years and annotate their top ten predictions on both MSR-VTT and MSVD. This process—called system pooling—has been used for decades in information retrieval (Spark-Jones, 1975) and, by construction, eliminates implicit false negatives.⁵ For MSR-VTT, we collect annotations from TeachText (Croitoru et al., 2021), Support-Set Bottlenecks (Patrick et al., 2021, SSB), and CLIP4CLIP (Luo et al., 2021) models; for MSVD, we collect annotations from TeachText and CLIP4CLIP models.^{6,7} Next, we compute model scores using the original positives and compare them to scores calculated with *both* the original positives *and* the new positives in FIRE.

Table 1 clearly demonstrates that FIRE annotations reveal large metric differences in both MSR-VTT and MSVD. For example, the C@1 score of CLIP4CLIP is understated by 25% points, and its C@10 score arguably saturates the benchmark at 95.7%. Even “small” differences such as those for TeachText and SSB are on par with the differences used to claim state-of-the-art results. False negatives directly cause high measurement error, which invalidates the internal validity of the benchmark.

⁴We do not see rank changes in our three models, but score differences suggest that ranks may change with more models.

⁵By implicit, we mean false negative from the lack of labeling and presuming non-positives are (implicitly) negative. There may still be false negatives arising from human error during annotation.

⁶We prioritize models that are (1) publicly available and (2) have sufficient documentation to reproduce.

⁷Annotating MSR-VTT predictions translates to $1,000 * 10 = 10\text{K}$ annotations since only one caption per video is used. This is easy compared to MSVD annotation, which uses tens of captions per video.

Dataset	Metric	TeachText	SSB	CLIP4CLIP
MSR-VTT	C@1	24.1 (23.3 + 0.800)%	27.3 (26.8 + 0.500)%	67.4 (42.4 + 25.0)%
MSR-VTT	C@5	53.2 (50.9 + 2.30)%	55.9 (54.5 + 1.40)%	90.7 (70.4 + 20.3)%
MSR-VTT	C@10	67.0 (64.8 + 2.20)%	68.9 (66.3 + 2.60)%	95.7 (80.2 + 15.5)%
MSR-VTT	AP	36.1 (35.8 + 0.296)%	39.3 (39.2 + 0.0374)%	69.5 (54.9 + 14.7)%
MSVD	C@1	34.7 (19.6 + 15.2)%	Not Annotated	65.3 (46.6 + 18.8)%
MSVD	C@5	64.7 (48.9 + 15.8)%	Not Annotated	89.6 (76.8 + 12.8)%
MSVD	C@10	76.1 (63.9 + 12.2)%	Not Annotated	94.0 (85.4 + 8.61)%
MSVD	AP	44.3 (33.1 + 11.2)%	Not Annotated	71.3 (59.7 + 11.6)%

Table 1: The table shows the impact of FIRE annotations on MSR-VTT and MSVD text-to-video retrieval metrics. “A (B + C)” has metrics computed with FIRE positives (A), only original positives (B), and the delta (C). The deltas emphasize the deleterious effects of false negatives: CLIP4CLIP’s C@1 on MSR-VTT is understated by 25% points.

2.2.2 Construct Validity

In addition to problems with internal validity, we posit that TVR evaluations are also not *construct valid* (Cronbach and Meehl, 1955; O’Leary-Kelly and J. Vokurka, 1998). Construct validity is related to “how closely our evaluations hit the mark in appropriately characterizing the actual anticipated behaviour of the system in the real world or progress on stated motivations and goals for the field” (Raji et al., 2021). What is the real-world use of text-to-video retrieval (or alternatively, the field’s motivations)? Consider the most straightforward answer: that such systems will be used by users to search through video collections, whether on the web or in personal collections. First, search queries issued by real users are very likely not similar to captions written by crowd annotators; this is easily observed by inspecting captions in Table 5 and Appendix Table 6. Second, the video distribution is unlikely to reflect real use-cases as they were selected by annotators or are search results from seed queries. Due to these problems, it seems unlikely that the evaluations are construct valid, and future benchmarks should improve this by building evaluations that match the intended use of models—i.e., be ecologically valid (de Vries et al., 2020).

3 FIRE Dataset Collection and Validation

Next, we describe and analyze the FIRE dataset.

3.1 Annotation Task and Dataset Collection

In the FIRE annotation task, annotators mark whether the displayed caption is relevant to the displayed video. Implicitly, the caption’s video is relevant to it, but how do we judge whether another arbitrary video is relevant? In other words, how should annotators mark whether a caption is relevant to a video? In both datasets (§2.1), the caption

must be completely consistent with the video; otherwise, it would not be an accurate caption. Therefore, we enforce the same condition in our task to preserve the original relevance semantics.⁸

Annotators are instructed to mark a caption as relevant to a video only if every element mentioned in the query could be reasonably considered present. Elements included persons, objects, locations, and activities, as well as quantifiers, qualifiers, and adjectives. Raters are given some leeway to use interpretation and inference but instructed to err in favor of not relevant if the caption is ambiguous or vague. For example, for the caption “a boy playing the violin,” the video must show a boy who is playing the violin, not a video of only violins or a video with only a boy. Screenshots of the annotation interfaces and details of sensitive category handling are in Appendix B. Complete annotation guidelines are included in supplemental materials.

To select caption-video pairs to annotate, we obtain the top ten MSR-VTT and MSVD test set predictions from three models: CLIP4CLIP (Luo et al., 2021), SSB (Patrick et al., 2021), and TeachText (Croitoru et al., 2021). For TeachText, we use model checkpoints available on their webpage. For CLIP4CLIP and SSB, checkpoints are not available, so we train new models and verify that retrieval quality is on par with the literature (see Table 1).

Table 2 summarizes the resulting FIRE dataset. During data collection, 683K labels were collected across a set of 579K unique caption-video pairs. Some duplication was intentional: we obtained a second label for 10% of annotations, and if the labels disagreed, we collected a third label to resolve the disagreement. Elsewhere, duplication was unintentional: for MSVD we did not deduplicate caption-video pairs between two models, so where the pre-

⁸Requiring complete matches makes the annotation task easier by eliminating ambiguous partial match cases.

Dataset	# Pairs	Percent	# Labels
MSR-VTT	24,183	100%	24,507
└ Agreement	24,167	99.9%	-
└ Relevant	2,855	11.8%	-
└ Irrelevant	21,312	88.2%	-
└ Disagreement	16	0.0662%	-
MSVD	555,391	100%	659,126
└ Agreement	553,832	99.7%	-
└ Relevant	39,909	7.21%	-
└ Irrelevant	513,923	92.8%	-
└ Disagreement	1,559	0.281%	-

Table 2: The FIRE dataset is composed of labels for MSR-VTT and MSVD text-video pairs. The positive-to-negative ratio is skewed, reflecting that queries do not match most videos. We multiply annotate a subset to compute annotator agreement rates and Krippendorff’s α . Agreement on MSR-VTT was .931 with $\alpha = .691$ and on MSVD was .958 with $\alpha = .798$. Appendix C disaggregates agreement rates which are consistent.

dictions overlapped, we obtained additional labels. Fortunately, this provided an unexpected opportunity to further validate dataset quality.

3.2 Dataset Quality Validation

Before, throughout, and after the collection, we took steps to collect high-quality data and validate its quality. The annotation task was completed by a team of one hundred raters specifically trained to review caption-video pairs and assess relevance. These annotators completed a 1,000 job training queue, which was reviewed by data quality leads and this paper’s authors. This allowed annotators to learn to annotate according to our guidelines, request clarification to the guidelines, and request tooling improvements. Annotators could also escalate tasks for being too ambiguous or confusing, which occurred less than 0.0001% of the time.

After the dataset was collected, we computed three measures of quality in Table 2: (1) the rate that judgments resolved to a label (Percent), (2) the degree to which examples with multiples labels agreed (Agreement), and (3) the Krippendorff alpha score amongst examples with multiple labels (Krippendorff, 2004). Caption-video pairs resolved to a label 99.9% of the time in MSR-VTT and 99.6% of the time in MSVD. Agreement in both datasets exceeded 90%, and the Krippendorff score suggests reasonable agreement as well. Based on this analysis, we see no evidence of data quality issues. The next section digs deeper into FIRE and suggests explanations for the observed phenomena.

Dataset	Models	Overlap	RBO
MSR-VTT	C4C & SSB	0.0638	0.0568
MSR-VTT	C4C & TT	0.0610	0.0509
MSR-VTT	TT & SSB	0.440	0.231
MSVD	C4C & TT	0.411	0.211

Table 3: Annotated predictions of one model boost the score of another model when predictions overlap. In MSR-VTT, there is little overlap between CLIP4CLIP and other models; there is far more overlap in MSVD.

Model	Data	C@1	C@5	C@10
CLIP4CLIP	All	0.674	0.907	0.957
CLIP4CLIP	New	0.430	0.713	0.812
TeachText	All	0.241	0.532	0.670
TeachText	New	0.239	0.527	0.663
SSB	All	0.273	0.559	0.689
SSB	New	0.271	0.553	0.679

Table 4: We compare C@K of a MSR-VTT model: (1) with all annotations (All) and (2) without the model’s annotated predictions to emulate model development (New). CLIP4CLIP exhibits large differences.

4 Analysis Experiments

The difference FIRE makes on metrics (Table 1) is striking, which begs the question: *why* are there such *large* differences? We suggest explanations for these differences (§4.1) while investigating how these metrics vary under commonplace evaluation settings such as new model development (§4.2).

4.1 Why Are Score Boosts Not Uniform?

FIRE-based metrics are interesting for at least two reasons: (1) the magnitude of difference and (2) the non-uniformity of boosts. Specifically, CLIP4CLIP has a larger boost than TeachText and SSB on MSR-VTT. First, we investigate the degree of prediction overlap between models. When predictions overlap, the models share the boost. Likewise, when they do not overlap, there is an opportunity for differing boosts. Table 3 shows this: on MSR-VTT, CLIP4CLIP and the other two models have little overlap; in contrast, TeachText and SSB have substantial overlap and their boosts are of roughly the same magnitude. Overlap is computed between the top ten predictions of each model using simple overlap and rank-biased overlap (Webber et al., 2010, RBO).⁹ As we might expect based on CLIP4CLIP

⁹If the ordering of predictions amongst the top ten did not matter, the overlap would be acceptable. However, as in most IR settings, we *do* care about the order so use a rank-aware metric like RBO.

and TeachText having large boosts on MSVD, their predictions also overlap. This mechanically explains the difference but fails to explain “why?”

We test the hypothesis that shorter queries have more positives because they are less specific (i.e., general) and speculate that differences in CLIP4CLIP and TeachText pre-training could make CLIP4CLIP fare better on general queries. Intuitively, shorter captions should be less specific and therefore match more videos, so models that handle general captions well should benefit the most. Table 5 and Appendix Table 6 validate this intuition by showing MSVD and MSR-VTT captions. The captions are sampled from the shortest 100 captions, median length captions, and longest 100 captions.

First, we empirically validate that short captions have more positive videos. Figure 2 shows that longer captions have fewer positive videos while shorter captions have more. By construction, since we find only positives if a model predicts them, these are where models make gains.

Figure 3 takes the next step and compares model accuracy as a function of caption length. For each bin of caption lengths (e.g., captions of length zero to twenty characters), we show the proportion of whether both CLIP4CLIP and TeachText are correct, neither are correct, or only one is correct. Empirically, we observe that CLIP4CLIP makes the largest gains from accounting for false negatives with FIRE when queries are short—whether this is due to short queries containing more positives or CLIP4CLIP handling these better is difficult to discern. Although it is difficult to validate, our best, educated guess at a causal reason for CLIP4CLIP finding more positives in MSR-VTT is that its image-text backbone, CLIP (Radford et al., 2021), was trained with text that contains many general captions.

4.2 Does System Pooling Generalize?

Although system pooling eliminates (implicit) false negatives, it comes with the substantial drawback that every new model must have its predictions annotated—otherwise, the results are potentially biased against the new model due to the possibility of false negatives in novel predictions (Yilmaz et al., 2020).¹⁰ System pooling has traditionally been used in synchronized shared tasks where all models are submitted by a deadline and evaluated

¹⁰If a model predicts a video that no prior model does and it is a false negative, then the model’s effectiveness will be underestimated. Yilmaz et al. (2020) study this when comparing traditional and deep learning IR systems.

at the same time, as in the Text REtrieval Conferences (TREC) in IR.¹¹ However, the trend in machine learning and NLP is for continuously running or even dynamic benchmarks (Kiela et al., 2021). Beyond benchmarking, even the development of new models is affected since gains from improved modeling may be understated. The question then is: how large is this bias, and how fast does it decrease with the number of pooled models?

The magnitude of the bias is affected by two factors: (1) the percent of model predictions that do not exist in pooled annotations and (2) the prevalence of false negatives in this subset.¹² While Table 3 captures prediction overlap between pairs of models, it does not capture the setting where some number of models have annotated predictions, and we wish to test a new model. Table 4 calculates (1) model scores when using all annotated predictions versus (2) model scores using only annotated predictions from the other two models. In this small three-model experiment, the bias is unfortunately still significant (24.4% for C@1) for the best model (CLIP4CLIP). Thus, the degree to which the FIRE dataset will mitigate the false negative problem in new model development is dependent on the similarity of new models to current ones. The generalizability also depends on the number of unknown positives, which we indirectly study by plotting the ranks of positive videos (Appendix G).

4.3 Mitigating Annotation Costs by Sampling

A limitation of our method is that until existing annotations include most positives, our method either disadvantages new models or introduces non-trivial annotation costs. Indeed, the costs of exhaustive annotation in our work are substantial, but exhaustive annotation is also excessive if the goal is only to (robustly) estimate model scores. Instead, we propose that future work need only annotate the top 10 predictions from N examples in the evaluation data. But how large should N be so that we can be confident that the difference between model scores is statistically significant? In our next experiment, we use bootstrap sampling to characterize the relationship between N and the effect size corresponding to a statistically significant difference at the 95% confidence level.

In our bootstrap sampling experiment, we treat the 27,763 MSVD test examples as a sample from

¹¹<https://trec.nist.gov>

¹²See Appendix F for analysis of the number of known positive videos per query.

MSVD Short Length Captions	MSVD Median Length Captions
playing panda	a gymnast falls off a balance beam
some work	a person is riding a horse
a man	a girl is riding a bicycle
a baby	two men are pushing an airplane
jumping dachhund	the turtle is playing with the cat
naah	piano is played by an artist
amanplaysaguitar	the girl put stickers on her face
a woman	a boy is reading a card
camp	a little boy is playing golf
plying music	a man is slicing a tomato
MSVD Long Length Captions	
a man holding an open umbrella jumps across a wooden stand in a park and then does a summersault after kicking a wall	
a man in a jail cell motions to a man in another cell who shows the first man his middle finger	
a bowling man picks up a spare in his lane and manages to knock over the one remaining pin in the lane to his right	
a woman is exercising by stepping from right to left and then from left to right while swinging her arms back and forth	
a man wearing a black cape is walking toward a group of people and a man in the group is shooting at him with a pistol	

Table 5: This table shows three sets of MSVD captions sampled from: (1) the 100 shortest captions, (2) median length captions, and (3) the 100 longest captions. As also observed in MSR-VTT captions (Table 6), short captions are general (e.g., “a man”) compared to the longest captions.

a population.¹³ We characterize the population distribution through bootstrap re-sampling of the original sample. Specifically, we estimate the absolute difference in model scores that correspond to a statistically significant effect size (i.e., score difference) at the 95% confidence level. For each sample size $N \in [500, 1000, 3000]$, we (1) re-sample N examples from MSVD evaluation data, (2) calculate scores on the re-sample, (3) repeat this 10,000 times, (4) average the scores then calculate the absolute value of the difference between the average score and score calculated with the full dataset, and finally (5) plot the distribution and score corresponding to the 95% percentile. The experimental results (Figure 4) demonstrate that annotation volumes of 1,000 detect statistically significant differences when C@1 differs by 0.029. The results demonstrate that (1) annotating a subset of test examples detects absolute differences of one absolute point, and (2) the number of annotated test predictions varies based on the metric of interest.

5 Recommendations for Benchmarks

Towards improving TVR evaluations, we make recommendations for both current and future benchmarks. This paper only investigated the effects of false negatives in MSR-VTT and MSVD. However, it is likely that other similarly constructed benchmarks exhibit the same problem, and testing this is important. Second, we show that for MSR-VTT

¹³MSR-VTT is small. To avoid convergence to the sample mean, bootstrap sizes need to stay low.

and MSVD, certain metrics such as Correct@10 are potentially saturated since improvements above CLIP4CLIP’s 95.7% and 94% are plausibly noisy. Consequently, since the remaining gains reside in re-ranking the top K, the community should consider retiring these evaluations. Third, the introduction of multiple positives and use of various K values makes mean average precision attractive since: (1) it factors in preference for correctness at higher ranks and (2) it handles multiple positives.

It is difficult to recommend that model developers exhaustively annotate model predictions. This suggests a future where query or video set size is a trade-off between annotation load and evaluation quality. For example, one might choose to trade-off annotation load with statistical power to differentiate between models (Card et al., 2020). TREC-style, annual shared tasks are one model for this (Voorhees, 2019; Church and Hestness, 2019); instead of building a monolithic benchmark that becomes overfit over time (Blum and Hardt, 2015; Anderson-Cook et al., 2019), stakeholders develop evaluations that evolve with research objectives.

Looking forward, TVR evaluation would benefit from: (1) a purpose-built benchmark that is grounded in an actual use case so as to be ecologically valid (de Vries et al., 2020) and (2) centralized evaluation by submitting runnable models to shared infrastructure such as Dynabench (Kiela et al., 2021). This would improve reproducibility, which was a limiting factor in selecting which model predictions to reproduce in this paper. This

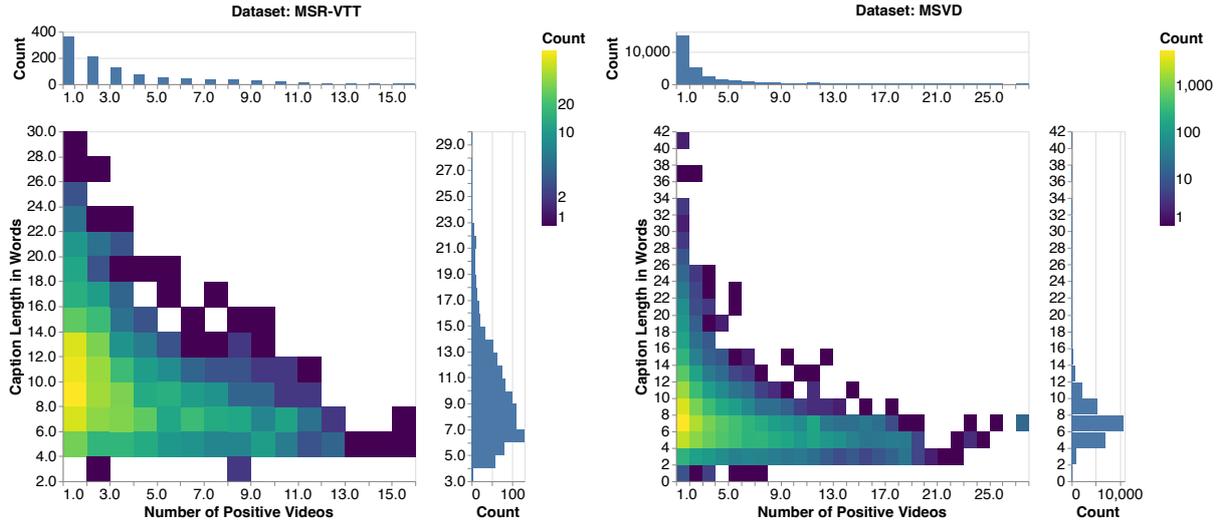

Figure 2: This figure shows the relationship between the number of positive videos and the length of captions in words for MSR-VTT and MSVD. We show a log-scale density heatmap binned by the number of positive videos and caption length; on the margins, are histograms. From this figure, we can infer that: (1) if a caption is long, it is less likely to have many positive videos, and (2) if a caption is short, then the number of positive videos can vary widely.

also makes calculating statistical tests easy (Ethayarajh and Jurafsky, 2020), which are often not reported (Dror et al., 2018; Dodge et al., 2019). TVR modeling has advanced enough to demand better benchmarks for measuring future progress.

6 Related Work

The paper draws on ideas in multimodal retrieval, information retrieval, and evaluation methodology.

Improving Benchmark Quality: Wray et al. (2021) is directly relevant to our work, and we share their motivation: to study the effects of false negatives in TVR evaluations. While we share motivation and our works are complementary, our work differs substantially in methods, contributions, and conclusions. The primary difference is this: our goal is to quantify the difference in absolute metrics that false negatives cause, even if there is no promise the data can be effectively reused in the future; Wray et al. (2021) develop automatically runnable proxy measures that improve the reliability of model rankings, but do not precisely quantify the impact of false negatives on existing metrics since automatic labeling is not equivalent to human annotation. Both these works are valuable: our work conclusively quantifies that false negatives create differences of 25% absolute points and demonstrate that new measures like those by Wray et al. (2021) are necessary for current benchmarks.

Wang et al. (2022) argue that video captioning datasets used in TVR evaluation are noisy due to

low-quality captions but differ by identifying single query tasks as the root problem (as opposed to false negatives) and recommend multi-query evaluation where users make followup refinement queries. While the multi-query problem is important, we do not agree with the assessment that single-query problems should be abandoned for multi-query problems: for example, users often have a low tolerance for voice assistant errors and abandon their query entirely after an error. Both problems are important. Fortunately, the approaches are complementary and should be combined: the multi-query setting still has false negatives, whose effects on measurement can be mitigated with our methods (§4.3). Just as we use predictions to improve datasets, Beyer et al. (2020) improve ImageNet labels by using predictions to reduce the label space which makes the annotation task easier.

Benchmarking: Across machine learning, computer vision, and natural language processing (Eger et al., 2020; Bowman and Dahl, 2021; Rogers, 2021) there is a broad effort to critically examine the benchmarks (Schlangen, 2021), data (Linzen, 2020; Thrush et al., 2022), evaluation methods (Rodriguez et al., 2021), and evaluation paradigms (Rodriguez and Boyd-Graber, 2021; Kiela et al., 2021) used in research studies. This effort goes beyond particular methodologies and extends to identifying the values prized by the community (Sculley et al., 2018; Dotan and Milli, 2020) which are subsequently operationalized in computer vision

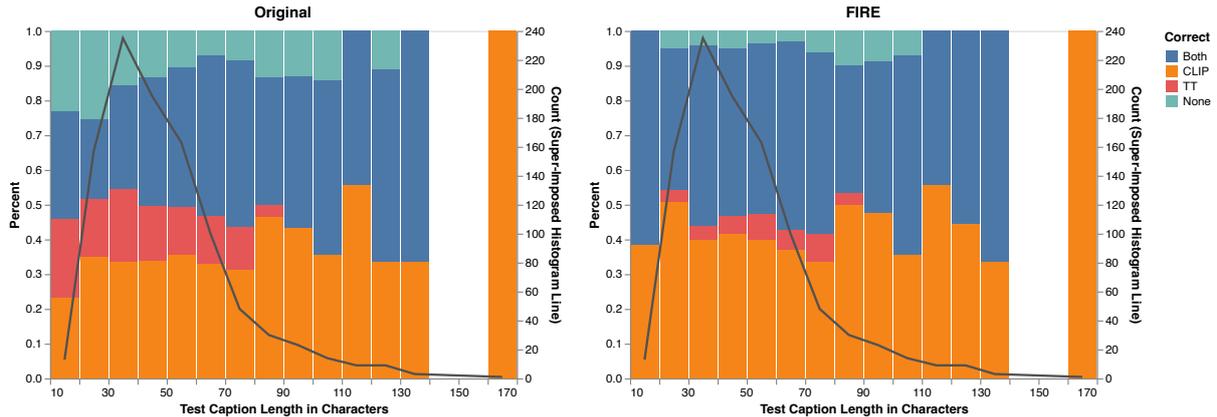

Figure 3: On MSR-VTT, we show relative model effectiveness differences (y-axis and color bars) broken down by test caption length (x-axis); we super-impose the caption length distribution (black line). Short captions tend to be more general, so they should match more videos and produce more false negatives. The gains for both models and especially CLIP4CLIP occur predominantly on this subset (reduction of “None”) as we would expect.

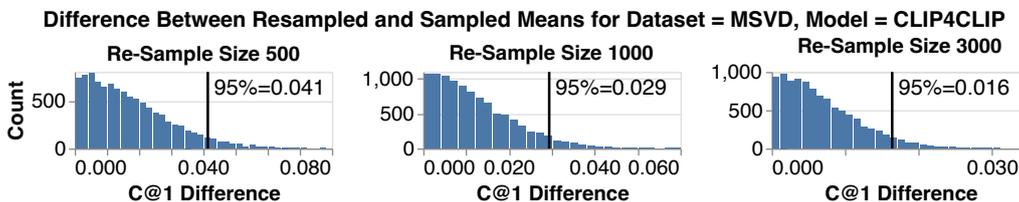

Figure 4: The distribution of absolute differences between bootstrap re-sample estimates of CLIP4CLIP C@1 and the true sample mean, by re-sample size. This estimates the number of annotations to detect an effect size at 95% confidence. Appendix E expands on this experiment by showing results for C@5, C@10, and TeachText.

datasets and benchmarks (Wu et al., 2017; Scheuerman et al., 2021). Our work is in line with this broader initiative and critically examines text-to-video retrieval evaluation methodology.

We examine internal validity (§2.2.1) and find a broken yardstick (Hernandez-Orallo, 2020). By examining construct validity (§2.2.2), we also argue that TVR evaluations should prize usefulness to ecologically valid use cases such as real-world text-to-video search (de Vries et al., 2020). Lastly, our experimental results suggest we may not be far off from retiring MSR-VTT and MSVD for TVR evaluation, something we should not be afraid to do in general (Boyd-Graber and Börschinger, 2020). An alternate approach is smaller, periodic evaluations as in TREC (Smeaton et al., 2002; Voorhees and Tice, 2000; Smeaton et al., 2009). Part of the solution is to create purpose-built datasets with clear goals (Gebru et al., 2021; Bender and Friedman, 2018) as opposed to continually re-using datasets intended for different uses (Koch et al., 2021).

Structurally Similar Tasks: TVR is not the only evaluation with the implicit false negative problem. Our critique is applicable to image retrieval bench-

marks that use caption-media pairs from image captioning datasets (Lin et al., 2014; Plummer et al., 2015) as the only positives (Karpathy and Fei-Fei, 2015; Kim et al., 2021; Singh et al., 2022).

7 Conclusion

In this work, we show that label errors (false negatives) in text-to-video retrieval benchmarks invalidate their *internal validity*—the measured metrics do not accurately reflect reality (§2). Following this, we critique the applicability of benchmarks to real-world use cases (*construct validity*). To estimate the impact of false negatives on benchmark metrics, we collect the FIRE dataset (§3) which contains 683K relevance judgements. Analysis experiments (§4) suggest explanations for why CLIP4CLIP scores higher and estimate system pooling generalization. Based on our findings, we highlight properties that future TVR benchmarks should have and outline approaches to addressing inherent challenges in retrieval evaluation (§5). Finally, we position our work in the broader effort to improve benchmarking by better aligning tasks with the intended use and improving measurement (§6).

8 Limitations

Our work has several notable limitations. First, our experiments use two representative and commonly used TVR datasets (MSR-VTT and MSVD). While we expect that our results will generalize, it is still possible that these results do not generalize. For example, both datasets are based on YouTube videos and annotator-written captions: perhaps videos and captions from alternate sources differ by too much. Similarly, our experiments use three well-known models, so while we expect our results to generalize to similar models, future models may differ substantially in ways that cause the empirical results not to hold. This said, system pooling has long been used in TREC (Voorhees et al., 2005), so we expect this to work for future models as well.

Beyond limitations in generalizability, the in-principle critiques in our work apply only to benchmarks where implicit false positives are likely to be prevalent; it does not apply to benchmarks in general. From the methods perspective, while our computational experiments are coded to be easily reproduced, the scale of our annotations is difficult to reproduce (hence limited reproducibility in this sense), but we do study sampling-based alternatives to mitigate this limitation.

9 Ethics

This section discusses potential ethical issues related to our dataset-centric work. First, we discuss data-related ethics. The FIRE dataset is built on MSR-VTT and MSVD. We distribute the minimal amount of data related to these datasets necessary to reproduce our experiments: triplets of caption identifiers, video identifiers, and annotated labels. Section 3 and Appendix B describe how the data was collected. All annotators were compensated, and the data collection was reviewed before starting. Potential risks due to the use of our dataset are limited by the additional labels we provide for an existing dataset. We thoroughly discuss the risks associated with negatively influencing benchmark reliability (i.e., prediction overlap with future models), and these risks are mitigated by our recommendation that more appropriate datasets be developed.

Our work does not directly have negative societal impacts, but it is feasible that the improved model scores we report could be used to misrepresent the capability of retrieval systems. For example, while we only claim that a model achieves a

particular measure of effectiveness on a particular benchmark, the media often inflates the importance of these metrics (Cuthbertson, 2018). In our work, we intentionally do not connect these higher metrics to more general capability and emphasize the importance of establishing construct validity.

Acknowledgements

We thank Yookoon Park, Prahal Arora, and Bernie Huang for providing code and data that were helpful to kickstart this project. We thank Daniel Haziza for infrastructure support in hosting live demos. We thank Nathan Tokala for their support with annotation infrastructure. For insightful discussion and ideas, we thank Simran Motwani, Patrick Lewis, Thomas Hayes, Joe Barrow, Xilun Chen, Chenglei Si, Ronghang Hu, Max Bain, and Jacob Kahn. For feedback on prior versions of this paper, we thank Rich James, Florian Metze, Peter Rankel, Weijia Xu, Yoo Yeon Sung, Yuandong Tian, John P. Lalor, and Kirmani Ahmed.

A Model Prediction Comparison

As part of this paper, we develop several web apps to make exploring the data more accessible. For example, Figure 5 compares the predictions of three models along with the labels in the original MSR-VTT dataset compared to augmenting them with FIRE’s labels. The source code repository provides instructions to run these web app demos.

B Annotation Interfaces

The FIRE dataset (§3) was collected using the annotation interface in Figure 6.

In addition to the previously described annotation instruction (§3.1), raters were also instructed on how to handle sensitive categories. The raters were instructed to accept the caption as accurate unless they had compelling, concrete reasons to believe otherwise (e.g., a little baby should be not considered old, and octogenarians with white hair and wrinkled skin should not be considered young); raters should not attempt to make more fine-grained distinctions. In particular, they were instructed not to make any assumptions about gender and accept the gender described by the caption.

C FIRE Data Quality

This section provides additional evidence to validate the quality of the FIRE dataset. Specifically, Figure 7 complements the agreement metrics computed in §3.2 and Table 2 by un-aggregating agreement rates.

D Shorter Captions, Their Generality, and Correlation to Model Behavior

Experiments in §4.1 establish that shorter captions have more positives and longer captions have fewer. We intuitively explain this by stating that shorter captions by nature are less specific, so will, in principle, match more videos. For example, one of the shortest captions in MSVD is “a man” (Table 5) which is less specific than one of the longest captions like “a man holding an open umbrella jumps across a wooden stand in a park and then does a summersault after kicking a wall.” Inspecting these captions also validates our construct validity critique (§2.2.2): they do seem like search queries.

In previous experiments (§4.1), we discussed how caption length is related to which models gain higher boosts. This section breaks down which models gain the most on MSR-VTT by train-test

overlap. We take inspiration from question answering and language modeling, where unintentional textual overlap between train and test sets degrades evaluation and model quality (Lewis et al., 2021; Borgeaud et al., 2021; Lee et al., 2022). Our objective is to measure the degree to which test captions in MSR-VTT are present in the training captions—be it word-for-word or approximate. To measure this, we use Scikit-Learn (Pedregosa et al., 2011) to fit a 5-gram character TF-IDF encoder to the test captions and compute the cosine similarity of each test caption to each train caption. For each test caption, we compute the mean similarity of the top train ten captions and combine this information with Correct@5 scores (Figure 8). The results suggest that TeachText overfits the train set, which may explain its comparatively better scores on the original positives—were it not overfit, train-test overlap should not matter.

Lastly, these factors are not unrelated. Since shorter captions tend to be less specific, these are also the captions that we would expect are more prevalent in the training set, whether in exact form or approximate (e.g., the phrase “a man” is likely in the train set). To test whether these factors are related, we compute the Kendall Tau correlation and Spearman Rank correlation between the train-test textual similarity score and caption length (in both words and characters). As we expect, there is a non-trivial negative correlation between caption length and similarity score (Table 7): the lower the caption length, the higher the train-test overlap score.

E Can Annotation Costs be Mitigated Through Sampling?

In our experiments, we use bootstrap sampling to estimate the number of example annotations needed to detect given effect sizes at the 95% confidence level (§4.3). Figure 4 reports these results for CLIP4CLIP since it was the best model; in practice, it represents the type of model we would test after models like TeachText. Figure 9 extends the results from C@1 to C@5 and C@10. Figure 10 replicates these results, but using the TeachText model.

F Number of Positive Videos per Text Query

The generalization of the FIRE dataset to newer models is reliant on two factors: (1) the number of positive videos per query and (2) whether the

Model Comparison Viewer for MSRVT/MSVD

 <p>Label: <input checked="" type="checkbox"/> Relevant Label: <input checked="" type="checkbox"/> Relevant</p>	 <p>Label: <input type="checkbox"/> Irrelevant Label: <input checked="" type="checkbox"/> Relevant</p>	 <p>Label: <input type="checkbox"/> Irrelevant Label: <input type="checkbox"/> Irrelevant</p>

Figure 5: The web application shows the ranked predictions of three models: CLIP4CLIP, TeachText, and SSB. Qualitatively, CLIP4CLIP predictions better match the query by showing only cartoon videos. This is reflected quantitatively when FIRE labels are incorporated. Lastly, the ranked predictions also show some of the overlap that TeachText and SSB shared.

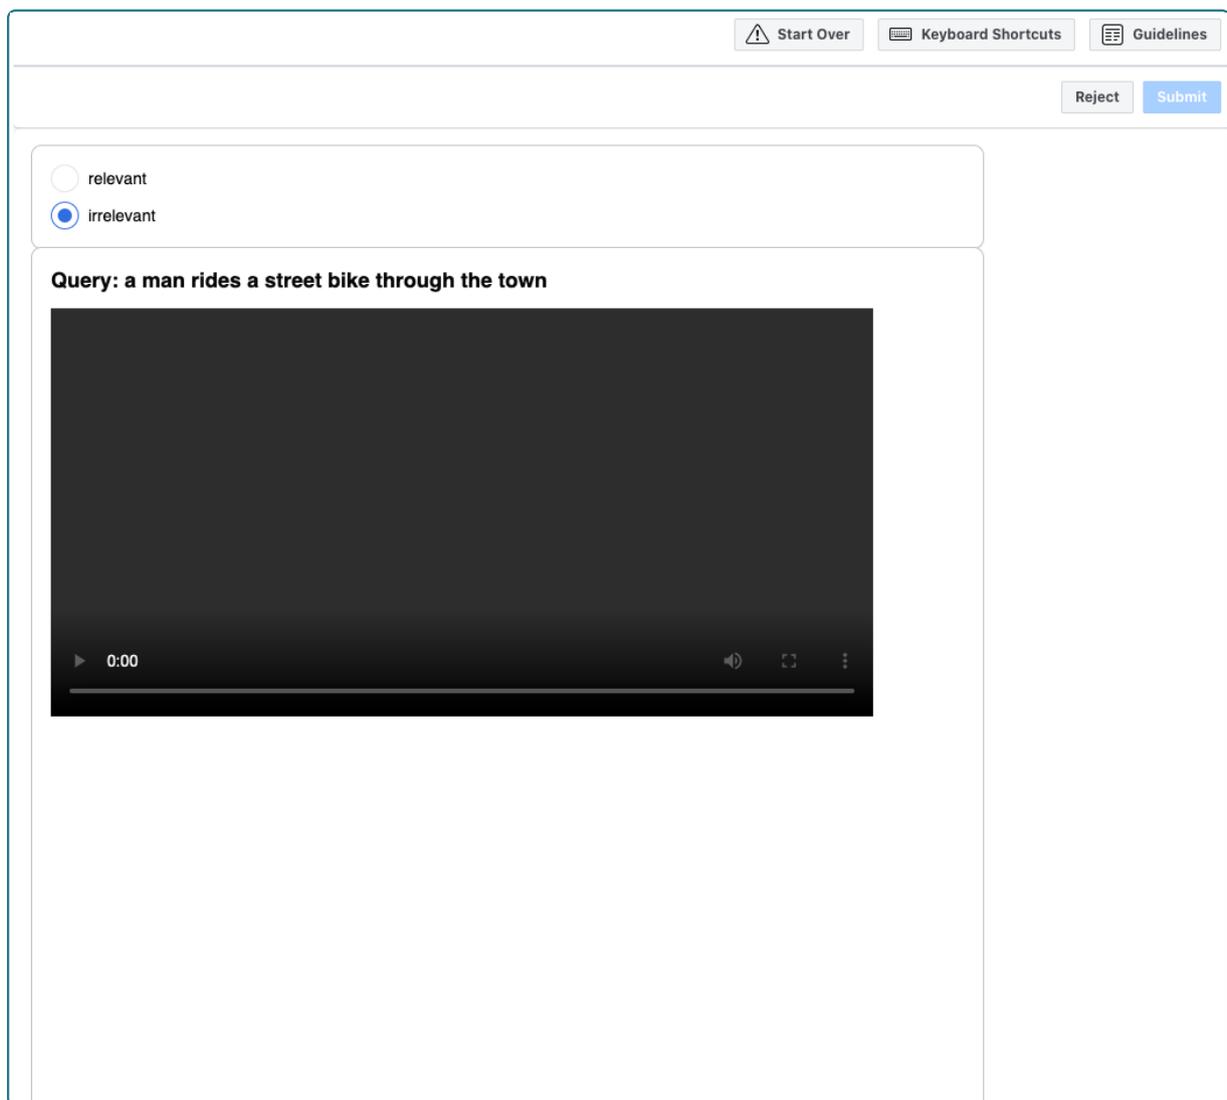

Figure 6: To annotate the FIRE dataset, raters used this annotation interface. The interface shows the candidate query (caption) and video; raters are trained to select “relevant” or “irrelevant” based on whether every component of the query matches the video.

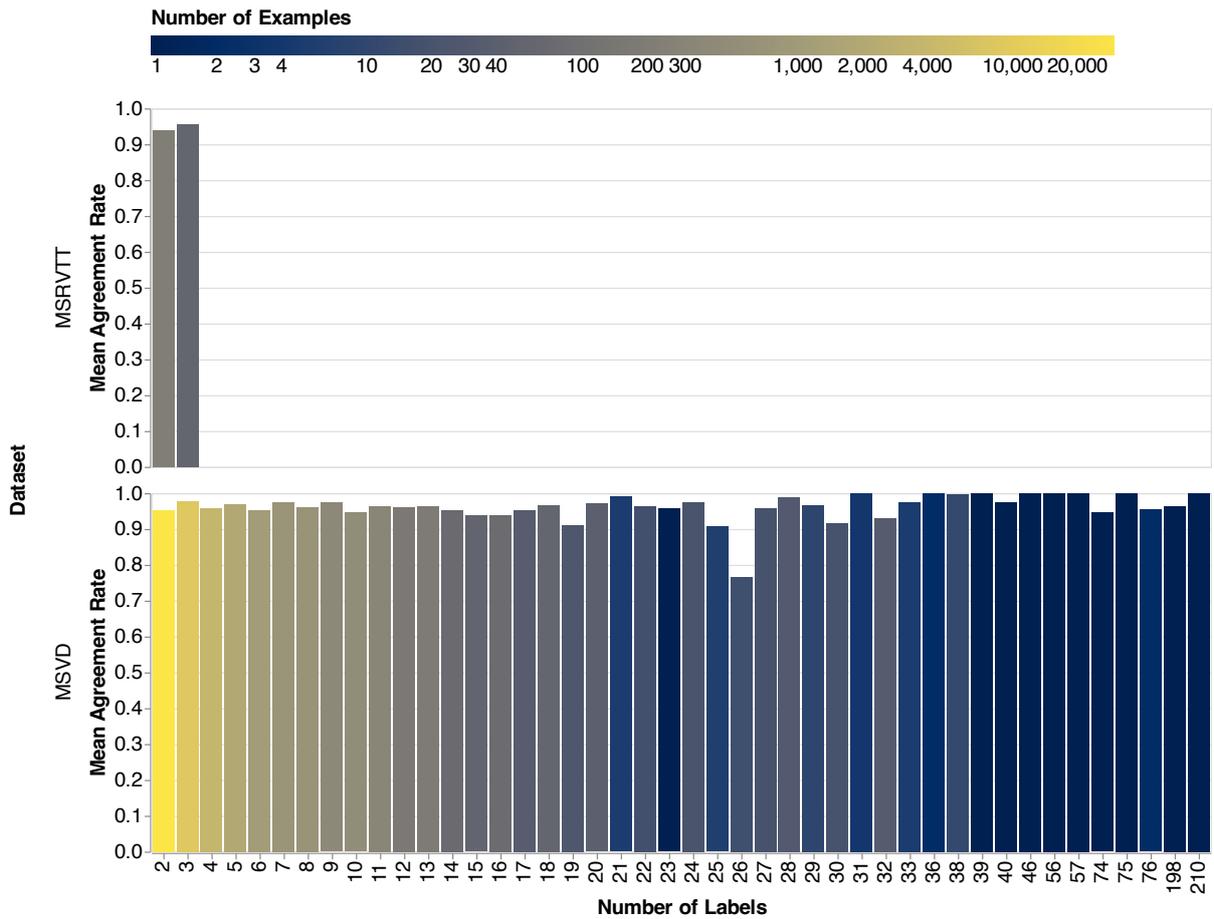

Figure 7: The agreement rate of annotators is broken down by the number of labels. For example, about 10,000 MSVD examples (text-video pairs) were annotated twice; of those, the two labels agreed on about 95% of examples. As we did with the MSR-VTT collection, our intent for the data collection was to de-duplicate text-video pairs and only annotate about 10% of the data multiple times to estimate reliability. However, we accidentally omitted this step for the MSVD collection which resulted in some examples being annotated many times. Fortunately, this provides an unplanned opportunity to further validate inter-annotator agreement.

MSR-VTT Short Length Captions

a man playing video games
anchor talking about a shows
a woman is stirring food
sports are being played
a woman holding a ribbon
a diver goes underwater
baseball player hits ball
cartoon show for kids
two women are embracing
advertisement of seat basket

MSR-VTT Median Length Captions

a man runs into the crowd when trying to catch a basketball
in a music video a man is laying with women while singing
some people video conferencing as they watch a movie
a boy is trying out for a part on the voice kids
basketball players making a shot in the last seven seconds
views of two persons working on the super computer with the head phones on
a character is jumping and floating in the air in a video game
two people playing basketball and the one with a hat makes every shot
batman is beating up bane in a scene from a batman movie
a girl being surprised with a stuffed animal by male friend

MSR-VTT Long Length Captions

a man and a woman are sitting in front of a television and addressing and audience
a woman stirs up some soup sprinkles a spice in and drops a shot of liquid into it
a man is filming as he and a woman watch the news where it shows an area filled with smoke
flight is shaken and the pilots trying to land the flight while they opened the air
the chef adds fish sauce and fish paste to a large stainless steel cooking pot
a girl wearing a dress stands to the side of the screen while lyrics to a song playing in the background appear on the other side
the man is giving an informational speech to a group of people about telling someone something
a girl in blue color dress wearing sitting speaking and television screen with black shirt man beside still image displaying on screen
a man plays a video game where the player has a first person perspective and shoots other characters
a man playing a video game character that is carrying a sword and killing animals with it

Table 6: This table shows three sets of captions from MSR-VTT sampled from: (1) the 100 shortest captions, (2) the median length captions, and (3) the 100 longest captions. As we argued by intuition (§4.1), inspecting these samples validates that the shorter captions are more general (e.g., “sports are being played”) and longer captions are very specific (e.g., “a woman stirs up some soup sprinkles a spice in and drops a shot of liquid into it”).

models we studied in this work predict all the true positives. Estimating the number of true positives per query without exhaustive annotation is difficult at best. However, we can at least characterize how many positives there are when including FIRE annotations. Figure 11 shows a histogram of the number of positive videos per query across MSR-VTT and MSVD. For example, about 350 MSR-VTT queries have only one known positive, which implies that the other 650 have more than one known positive. Unfortunately, even estimating the upper bound would require annotating all the videos for each query in a representative sample (e.g., for a sample of MSR-VTT 200 queries, exhaustive annotation would include $200 * 1,000 = 200,000$ query-video annotations).

G Rank of Positive Videos

While we follow prior work in measuring models based on metrics computed from their top ten predictions, this still leaves open the question: ignoring prior work, is ten predictions the right choice? If ten is the correct choice, then we should see a clear trend that positives are primarily distributed below ten. Figure 12 plots the rank of positive videos in CLIP4CLIP predictions (i.e., 1 is top-ranked) versus their count. As expected, the number of positives drops dramatically before rank 10 (especially for MSVD), although not to zero; the ranks of the original positives suggest there is a long tail of undiscovered positives. Note that the steep dropoff at 10 is due to annotating only the top 10; positives beyond this are either from the original dataset or predicted by other models. From

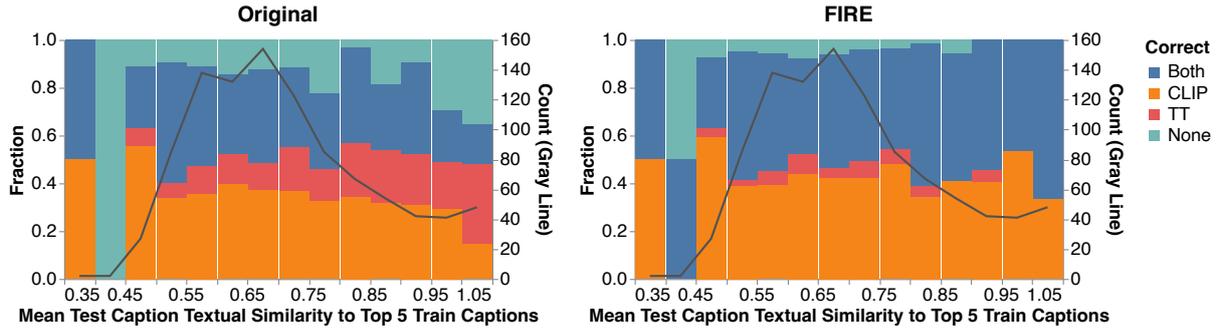

Figure 8: Why are the MSR-VTT score differences between CLIP4CLIP and TeachText when using FIRE large? We test the hypothesis that TeachText (comparatively) overfits textual training data. We compute the textual similarity of each test caption to each train caption with a 5-gram character model; for each test caption, we calculate the mean similarity of the ten most similar captions. The plot shows whether both models score a point on Correct@5, binned by train-test similarity (the overall histogram is shown as the super-imposed line) when using original versus FIRE annotations. On the original annotations, CLIP4CLIP fares much better compared to TeachText when similarity is not nearly 1.0 (i.e., not overfitting).

Length	Spearman	Kendall
Word	-0.419	-0.296
Character	-0.479	0.334

Table 7: This table shows the Spearman and Kendall rank correlations between the train-test textual similarity score used to measure train-test overlap (Figure 8) and the length of captions in both words and characters. The results support our hypothesis that caption length and train-test overlap are correlated.

this, we conclude that although most positives have likely been collected, there likely remain more past rank 10, especially in MSR-VTT.

H Computational Resources

This paper was developed using two types of computational resources. To rerun text-to-video retrieval models, we trained and evaluated on a single AWS p4d compute node which has 96 vCPUs, 1152GB of RAM, and eight Nvidia A100 GPUs.¹⁴ All other experiments were run locally on a 16 inch, 2019 Macbook Pro with a 2.4GHz 8-core Intel Core i9 CPU and 32GB of RAM.

¹⁴<https://aws.amazon.com/ec2/instance-types/p4/>

Absolute Difference Between Resampled and Sampled Metric Means for Dataset = MSVD, Model = CLIP4CLIP

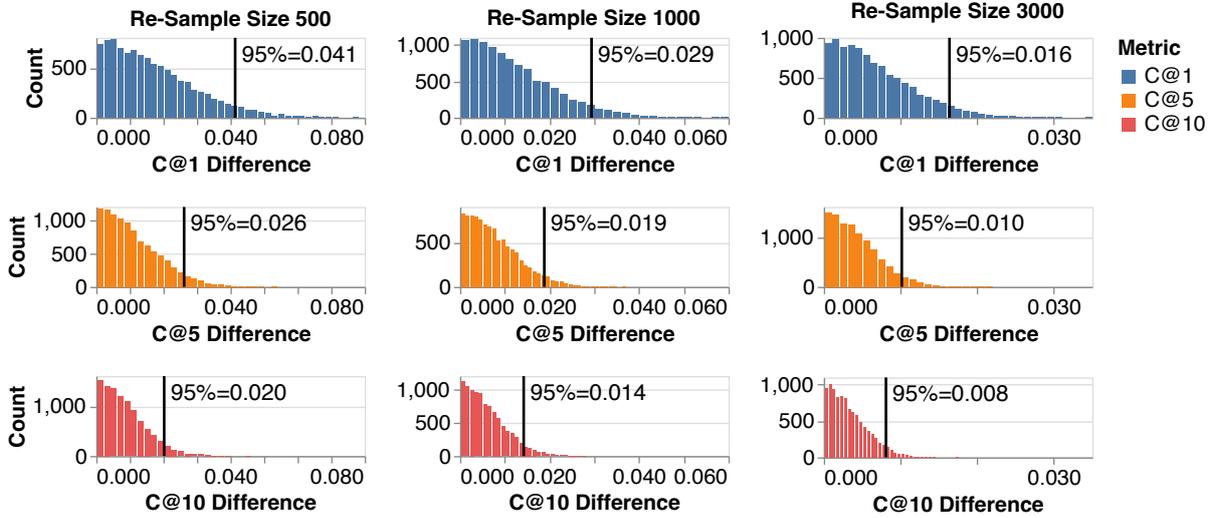

Figure 9: This figure replicates the C@1 results from Figure 4 but adds results for C@5 and C@10. The additional results are consistent in showing that differences of about 1 point are already detectable with 1,000 annotations.

Absolute Difference Between Resampled and Sampled Metric Means for Dataset = MSVD, Model = TeachText

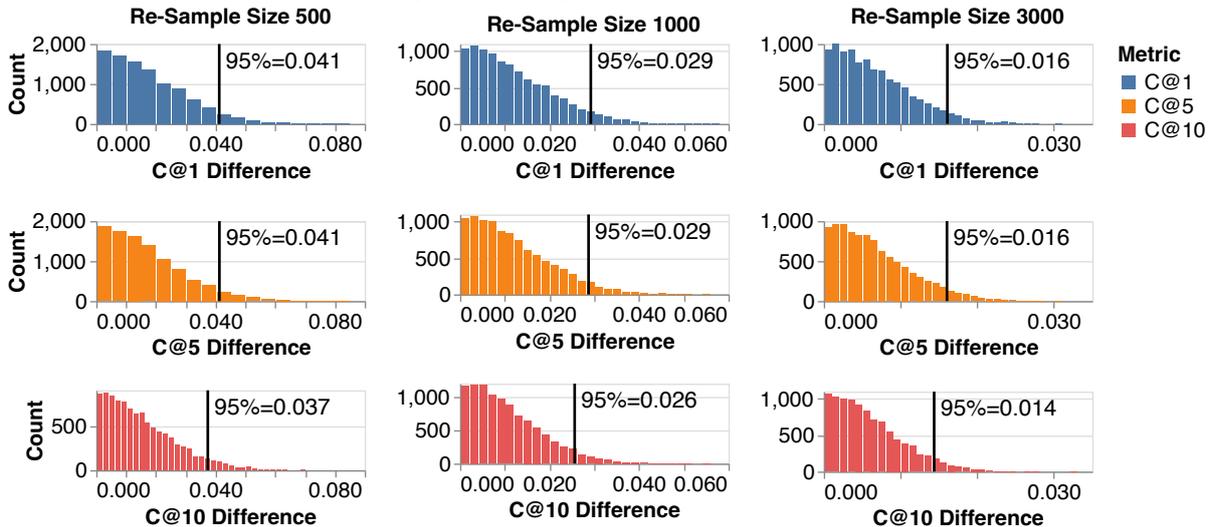

Figure 10: Similar to Figure 4, this figure shows the distribution of absolute differences between bootstrap re-sample estimates of TeachText C@1, C@5, and C@10 scores and their true sample mean (i.e., scores on the full test set). Compared to CLIP4CLIP, statistically significant differences are marginally harder to detect.

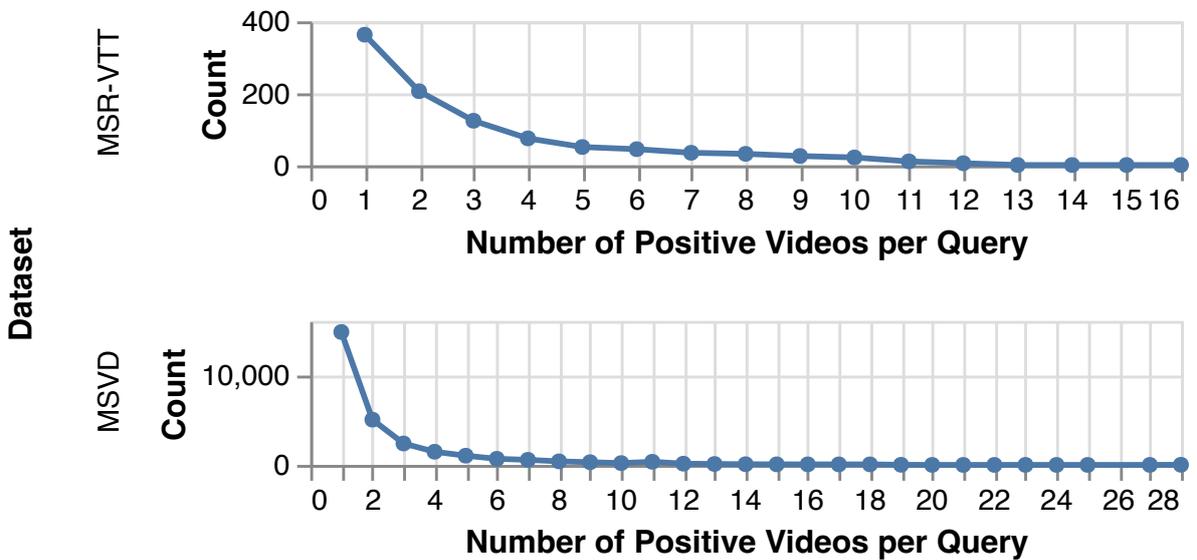

Figure 11: For MSR-VTT and MSVD, we plot the number of positive videos per test set query. While many queries across both datasets have only one known positive, many others have more than that.

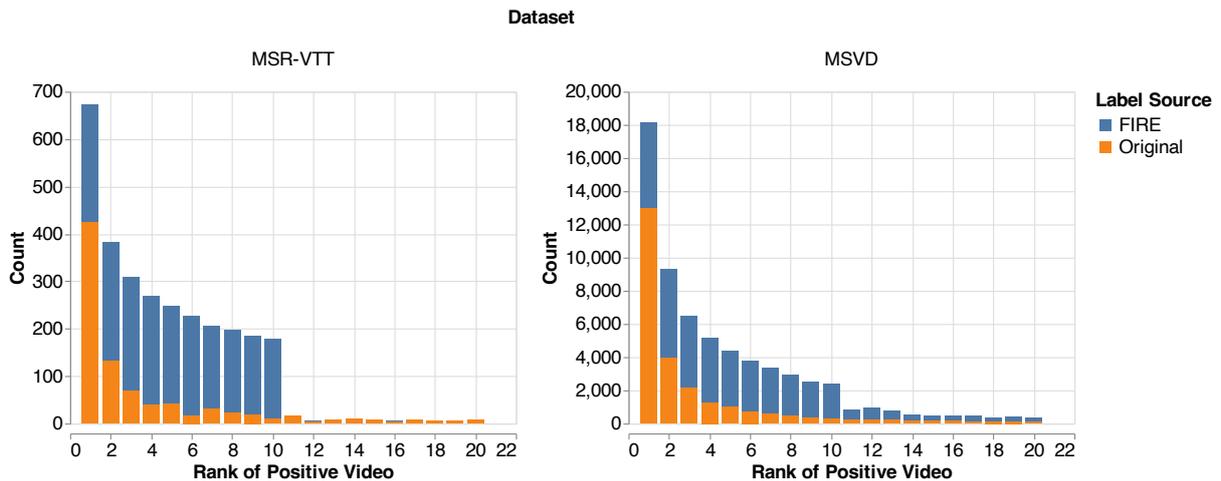

Figure 12: The figure plots the rank of positive video predictions from CLIP4CLIP versus their count. The plot displays MSR-VTT and MSVD separately, and it breaks down the source of each positive (from the original dataset versus from FIRE). While the distribution suggests most positives are found within the top 10, the long tail suggests that there are still unknown positives.

Improving Numeracy by Input Reframing and Quantitative Pre-Finetuning Task

Abstract

Numbers have unique characteristics to words. Teaching models to understand numbers in text is an open-ended research question. Instead of discussing the required calculation skills, this paper focuses on a more fundamental topic: understanding numerals. We point out that innumeracy—the inability to handle basic numeral concepts—exists in most pretrained language models (LMs), and we propose a method to solve this issue by exploring the notation of numbers. Further, we discuss whether changing notation and pre-finetuning along with the comparing-number task can improve performance in three benchmark datasets containing quantitative-related tasks. The results of this study indicate that input reframing and the proposed pre-finetuning task is useful for RoBERTa.

1 Introduction

Numerals are an indispensable part of narratives and provide much fine-grained information.¹ How models learn the number system has intrigued many researchers (Spithourakis and Riedel, 2018; Naik et al., 2019; Chen et al., 2019; Wallace et al., 2019; Zhang et al., 2020). Researchers have long discussed some numeracy-related properties of pretrained language models (LMs). In this study, we propose a new concept — *innumeracy*. The problem of innumeracy becomes most evident when models are faced with numerals that do not appear in training data, e.g., when the range of numerals in training data is different from that in the test data. Moreover, LMs often face difficulties understanding numbers even though the numbers are present in the training data. One possible cause of this problem is that numerals can have various notations, some of which are difficult to understand from their subwords. Another possible cause is

¹In this paper, we focus on the numerals represented by digits (0 to 9 and decimal point) and do not discuss those written in words such as “one” and “two”.

Model	Notation	Tokenized Example
BERT	<i>Org.</i>	"147", "##70", "##2"
	<i>Digit</i>	"1", "4", "7", "7", "0", "2"
	<i>SN</i>	"1", ".", "47", "##70", "##200", "##00", "##0", "##e", "+", "05"
RoBERTa	<i>Org.</i>	"147", "702"
	<i>Digit</i>	"1", "4", "7", "7", "0", "2"
	<i>SN</i>	"1", ".", "47", "70", "200000", "E", "+", "05"

Table 1: Tokenized example. *Org.* and *SN* denote original and scientific notation, respectively.

that LMs are not pretrained to deal with numbers. Therefore, in this study, we address the problem of innumeracy via input reframing and quantitative pre-finetuning tasks.

Input reframing refers to changing the notations of numbers, which can be one of the crucial clues for understanding numerals (Zhang et al., 2020; Chen et al., 2021). In addition to the original notation, we consider the digit-based and scientific notations. Table 1 lists examples of using different representations for numerals. Our experiments indicate that RoBERTa (Liu et al., 2019) performs poorly than BERT-based models (Devlin et al., 2019; Yasunaga et al., 2022) in understanding numerals. However, its performance is at par with vanilla BERT-based models with a proper input reframing method. Furthermore, in previous studies, pretraining with the self-supervised learning approach been determined to be a compelling method (Devlin et al., 2019; Yasunaga et al., 2022). However, it is costly to pretrain a new LM from scratch. Thus, an alternative way is to design pre-finetuning tasks to enhance the ability of LMs (Aghajanyan et al., 2021). Inspired by this idea, we propose a novel pre-finetuning task to enhance the ability of the models to deal with quantitative questions and improve the numeracy of the models. Specifically, the proposed method automatically generates a simple dataset for the comparing-numbers task (ComNum), and uses it to pre-finetune LMs. This study experiments with representative pretrained LMs, includ-

ing BERT, RoBERTa, and LinkBERT (Yasunaga et al., 2022), and the experimental results show that pre-finetuning with the proposed ComNum improves the performance in the Quantitative Natural Language Inference (QNLI) task regardless of the LMs used.

To evaluate the influence of the input re-framing and the quantitative pre-finetuning task, we constructed the Quantitative 101 dataset, which is a combination of three benchmark datasets: Numeracy-600K (Chen et al., 2019), EQUATE (Ravichander et al., 2019), and NumGLUE Task 3 (Mishra et al., 2022). The tasks in Quantitative 101 include Quantitative Prediction (QP), QNLI, and Quantitative Question Answering (QQA). In the future, Quantitative 101 can be used as a new collection by researchers studying the quantitative skills of LMs.²

2 Related Work

Numeracy, one of the recent hot topics in NLP, incorporates many skills such as calculation, algebra, and geometry. Some previous studies (Spithourakis and Riedel, 2018; Chen et al., 2019) have discussed the prediction of the masked number tasks, while others (Wallace et al., 2019; Naik et al., 2019; Zhang et al., 2020) have explored numeracy from the perspective of embedding properties. The math word problem (Chen et al., 2021; Mishra et al., 2022) is a high-level task requiring several numeracy skills. The textual representation of numerals, such as digit-based or scientific notations-based, is one of the possible directions for improving numeracy. Chen et al. (2021) suggested to use a digit-based encoder to encode numerals. Meanwhile, Zhang et al. (2020) used scientific notation to represent numerals and explored scale understanding tasks. In this paper, we explore the role of these notations of numbers in quantitative skill tasks.

A recent trend is to design pretraining tasks to enhance the capability of models to understand natural language. Devlin et al. (2019) proposed two pretraining tasks: masked language model (MLM) and next sentence prediction (NSP), and broadened the horizons of the transformer-based natural language processing research direction. Yasunaga et al. (2022) designed a new cross-document pretraining task, called document relation prediction (DRP), to improve the performance of LMs in sev-

²We release this dataset for academic use and follow the license of the sources (Appendix C).

eral benchmark datasets, especially those requiring multi-hop reasoning and multi-document understanding skills. To the best of our knowledge, this is one of the earliest works proposing a tailor-made pre-finetuning task to understanding numerals. Our experimental results also support the usefulness of the proposed task, specifically in the QNLI task.

3 Datasets and Tasks

This section introduces two datasets: the Comparing Numbers Dataset (CND) and Quantitative 101, with the corresponding quantitative tasks, including ComNum, QP, QNLI, and QQA.

3.1 Comparing Numbers Dataset (CND)

Comparing numbers (ComNum) is one of the basic quantitative skills. We propose the Comparing Numbers dataset (CND) to test the ability of different pretrained LMs to perform the ComNum task. CND is an automatically created dataset, and the ComNum task is designed as a binary classification task. In essence, the models need to determine whether a given statement of comparing numbers is true or false. In the CND, there are only three templates as shown in Table 2. There is one training set and two test sets in CND. Specifically, we randomly select two numbers from 0 to 199,999 and insert them into the template. The selected numbers are deleted from the pool of numbers to avoid duplication. Finally, 100,000 instances are obtained, and the numbers in all instances are unique. Note that the distributions of each template and answers are balanced. 80% of the dataset is considered as the training set and the remaining 20% is taken as the CND-T1 test set. Next, two numbers from 4,000,000 to 5,000,000 are randomly selected for 10,000 times to construct the CND-T2 test set. Thus, the order of magnitude of the training set and the first test set (CND-T1) is from 0 to 5, and that of the other test set (CND-T2) is 6. In this study, we focused on natural numbers, and fu-

Table 4: Experimental results of the BERT-based models. The results in bold are the ones that are better than the *Original*. The score indicates Quantitative-101 Score.

ture studies can extend our results to decimals and fractions. Since natural numbers are in the infinite set, and it is impossible to let models learn with a dataset containing all magnitudes and numbers, we designed the task in the way following the human learning process because human beings do not need to learn to count from zero to trillion to get the ability to compare all numbers.

3.2 Quantitative 101

Quantitative 101 collects recent benchmark datasets and focuses on quantitative tasks. There are three tasks in Quantitative 101, including Quantitative Prediction (QP), Quantitative Natural Language Inference (QNLI), and Quantitative Question Answering (QQA). This section briefly introduces the tasks, and we further provide details in Appendix C.

QP is the task of predicting the correct magnitude of the masked numeral. Although a possible choice would be to predict the exact number given a context, doing so is often very difficult, even for a human. For example, the QP listed in Table 2, in which the correct answer is 2.2. However, making an accurate rough estimate for the magnitude would often be feasible only for seasoned experts. We attempt to test whether models can also learn such a numeracy skill after being trained with a large amount of data. Thus, we adopt Numeracy-600K (Chen et al., 2019) as the dataset for this task. Chen et al. (2019) designed this task as an eight-class classification task, which includes the magnitude from 1 to 6, decimal, and a magnitude

larger than 6. Numeracy-600K contains two subsets: market comments and blog headlines.

QNLI is the task of making natural language inferences based on quantitative clues. It is a complex version of ComNum, because the given sentences could be varied. The example of QNLI presented in Table 2 shows that models need to compare numbers based on more complex semantics. We selected EQUATE (Ravichander et al., 2019) to experiment on real-world scenarios for QNLI. EQUATE has five subsets, including RTE-QUANT, AWP-NLI, NEWSNLI, REDDITNLI, and Stress Test.

QQA is the other format for testing whether models can understand numerals and semantics. We selected the Task 3 subset of NumGLUE (Mishra et al., 2022) for the QQA experiments. Table 2 provides an example of this dataset. It is under a binary-classification setting, and each instance has two options.

We chose these three datasets to test the basic quantitative skills of models. We noticed that several instances in these datasets can be solved using only the basic ability to understand numbers. However, the other subtasks in NumGLUE required reasoning skills including the generation of equations. These tasks are not the target of this paper.

4 Methods

4.1 Notation of Numbers

The findings of previous studies (Chen et al., 2021; Zhang et al., 2020) suggest two methods that are worth trying: digit-based notation and scientific no-

Model	Notation	QP		QNLI					QQA	Score
		Comment	Headline	RTE-QUANT	AWP-NLI	NEWSNLI	REDDITNLI	Stress Test		
RoBERTa	<i>Original</i>	60.46%	58.03%	60.15%	57.64%	79.58%	58.77%	98.93%	51.96%	65.69
	<i>Digit-based</i>	69.25%	57.65%	59.40%	56.69%	78.90%	62.38%	99.91%	54.34%	67.31
	<i>Scientific Notation</i>	64.32%	55.49%	60.08%	57.41%	78.68%	60.81%	100.00%	53.67%	66.31
CN-RoBERTa	<i>Digit-based</i>	64.25%	55.92%	68.96%	58.80%	77.99%	60.99%	99.73%	50.88%	67.19
	<i>Scientific Notation</i>	60.28%	54.85%	62.15%	58.74%	65.92%	59.59%	99.47%	52.27%	64.16

Table 5: Experimental results of the RoBERTa-based models.

tation. Table 1 shows an example for each method. *Original* signifies that we did not perform any pre-processing on the input data, and the results are tokenized based on WordPiece (Schuster and Nakajima, 2012; Wu et al., 2016) and Byte-Pair Encoding (BPE) (Sennrich et al., 2016). In the *Digit-based* method, we separated a numeral into digits. In the *Scientific Notation* method, we converted numerals into scientific notation according to the method described in Zhang et al. (2020), and Table 1 provides examples to show that tokenizers provide different results in this case. Note that we pad the mantissa to 10 significant figures to retain the information of most numerals.

4.2 Pre-Finetuning Task

We pre-finetune LMs with the CND for learning the numeracy of comparing numbers. We believe that this learning process can make models aware of the numerals and may help answer the questions listed in Table 2. We further test whether the proposed pre-finetuned method is helpful in the QP, QNLI, and QQA tasks. We primarily use BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and LinkBERT (Yasunaga et al., 2022) for the experiments. Since the market comment subset for the QP task is in the financial domain, we also experiment with FinBERT (Araci, 2019) in this subset. The pre-finetuned LMs using BERT, RoBERTa, LinkBERT, and FinBERT as initial models are named CN-BERT, CN-RoBERTa, CN-LinkBERT, and CN-FinBERT, respectively. During the pre-finetuning process, we use the *Digit-based* or *Scientific Notation* reframing methods to transform the numerals in the input data. Thus, each proposed pre-finetuned LM has two versions depending on the notation of numbers.

5 Experiment

5.1 Innumeracy

Innumeracy can be tested via various experiments. In this section, we observe the innumeracy phenomenon with the empirical results of the Com-

Model	Reframing	QP-Comment
FinBERT	<i>Original</i>	65.26%
	<i>Digit-based</i>	69.89%
	<i>Scientific Notation</i>	70.03%
CN-FinBERT	<i>Digit-based</i>	68.84%
	<i>Scientific Notation</i>	69.76%

Table 6: Results of the FinBERT-based models.

Num task. We aim to answer whether LMs have different performances between CND-T1 and CND-T2. We use the micro-average of the F1 score to evaluate the results of the ComNum task. Table 3 shows the results. It is not surprising that models perform well in CND-T1. However, model performances drop when we test using CND-T2. In CND-T2, the order of magnitude of the numerals is different from that in the training set. We call this phenomenon “innumeracy”, and find that both *Digit-based* and *Scientific Notation* perform well for most pretrained LMs. In particular, using *Scientific Notation* method leads to the least performance drops with all LMs.³

5.2 Experimental Results

We follow the setting of previous studies to use the macro-average of F1 score for the QP task and the micro-average of F1 score for the QNLI and QQA tasks. Table 4 presents the results of the BERT-based models, and Table 5 presents the results of the RoBERTa-based models.⁴ To evaluate the aggregate performance, we average all results as in previous studies (Dua et al., 2019; Mishra et al., 2022), and named this score the Quantitative-101 Score. First, it can be observed that all notation methods and the pre-finetuning task improved the overall performance of RoBERTa, and lead RoBERTa to perform at par with the BERT-based LMs. Second, we observed that the proposed pre-finetuning task helped improve the QNLI task performance. Third, using a proper reframing method improved the QQA task performance. Fourth, the

³We provide more analysis on this point in Appendix B.

⁴We provide a fine-grained analysis in Appendix A for the QNLI-Stress Test.

Model	Preprocessing	QP		RTE-QUANT	QNLI			Stress Test	QQA	Score
		Comment	Headline		AWP-NLI	NEWSNLI	REDDITNLI			
RoBERTa		60.46%	58.03%	60.15%	57.64%	79.58%	58.77%	98.93%	51.96%	65.69
CN-RoBERTa	<i>Original</i>	86.86%	77.29%	62.52%	56.70%	78.82%	64.29%	99.94%	50.71%	72.14

Table 7: Results of CN-RoBERTa without input reframing.

reframing methods and the pre-finetuning task were not helpful for the BERT-based LMs in the QP task as well as the overall performance.

Table 6 shows the results of the FinBERT-based models in QP-comment. The results indicate that the performances of FinBERT can be improved with a proper reframing method. Additionally, the proposed CN-FinBERT performs better than the *Original* FinBERT.

To sum up our findings, the input reframing methods can improve the performance of RoBERTa and FinBERT. However, it does not work for BERT-based models. The proposed pre-finetuning task can improve the performance in the QNLI task regardless of the LM used.

5.3 Ablation Analysis

In this section, we train CN-RoBERTa without input reframing for ablation analysis. Table 7 shows the results. The results indicate that the performances of QP tasks were improved significantly, and the performance of QNLI tasks was also improved. These results indicate the proposed pre-finetuning task is important for the QP tasks, but input reframing is not. However, the performance of the QQA did not improve without input reframing. This result implies that, for QQA, input reframing provides some hints to the models to make predictions. Overall, this study does not find a silver bullet for solving quantitative problems, but shows that input reframing and basic quantitative pre-finetuning design are promising directions.

6 Conclusion

This study deals with the innumeracy of LMs and shows that the notation of numbers matters, especially for RoBERTa. We also propose a novel pre-finetuning task for improving the quantitative skills, and find that the performance in the QNLI task can be improved after pre-finetuning. We hope our results in Quantitative 101 lead to a more in-depth discussion on the ability of LMs to understand numerals.

Limitations

The first limitation of the paper is that we focus on the numerals represented by digits (0 to 9 and decimal point) and do not discuss those written in words such as “one” and “two”. Future work can extend the findings of this work and transfer the numeral words to digits. The second limitation of this paper is that we do not discuss long text scenarios because the length of the instances in the datasets is within 512. Future work can design quantitative-related tasks with longer documents and examine whether the proposed methods still work. The third limitation of this paper is that we do not train the model from scratch with the proposed input reframing methods. We leave it as one of the open questions for future studies. The fourth limitation of this work is that we do not experiment with all cases, including using data in several ranges and experimenting with all kinds of pretrained LMs, to prove that the innumeracy phenomenon is a general phenomenon. Instead, we present a pilot exploration of the phenomenon and further pay attention to improving the performances of other quantitative-related tasks.

Ethical Note

All datasets used in our experiment are available online, and we provide the details and the license information in Appendix C. We release the pre-finetuned LMs (CN-BERT, CN-RoBERTa, CN-LinkBERT, and CN-FinBERT) on the Hugging Face models platform.⁵ Future work can reproduce our results easily and use our pre-finetuned LMs for further research issues. Please refer to Appendix B for details.

A Analysis of QNLI-Stress Test

QNLI-Stress Test uses the data collected from AQUA-RAT, and was annotated by an automatic method (Ravichander et al., 2019). We follow the splitting method in NumGLUE Task 7 (Mishra et al., 2022) to separate it into training, development, and test sets. First, we find 316 repeated instances in both training and evaluation sets (development and test sets). We already removed these repeated instances from the training set in our experiment. Second, we check the instances by removing all numerals in each instance and find that 2,229 instances appear in both training and evaluation sets, with 1,639 appearing in the same training and test sets, and 80.17% have the same answer. That could be the reason that the models perform well in this dataset, since most instances do not need to understand numerals.

B Implementation Detail

We used the Hugging Face transformers package (Wolf et al., 2019) for the experiment.⁶ Intel Xeon Gold CPU and Nvidia Tesla V100 w/32GB are the CPU and GPU used in our experiment. Table 8 provides the links to the LMs used in our experiment. All pre-finetuned LMs (CN-BERT, CN-RoBERTa, CN-LinkBERT, and CN-FinBERT) are released on the Hugging Face platform.

Figure 1 to 4 present the tracing results of the drop between CND-T1 and CND-T2 during the training process. It can be observed that when using Scientific Notation, the performances of LMs stabilizes more quickly. In contrast, the change of the performances with the *Digit-based* method varies, and we did not obtain stable results in some cases.

C Dataset

CND is our own generated dataset; therefore, we did not have to obtain license permissions to use it. There are three subsets in the proposed Quantitative 101. Numeracy-600K (Chen et al., 2019) for

QP task could be downloaded from GitHub⁷, and it is under the Creative Commons Attribution-Non-Commercial-ShareAlike 4.0 International (CC BY-NC-SA 4.0) license. EQUATE (Ravichander et al., 2019) for QNLI task can also be downloaded from GitHub⁸, and it is under the MIT License. NumGLUE (Mishra et al., 2022) for QQA task can be downloaded from the page of Allen Institute for AI (AI2)⁹, and it is under the ODC Attribution License (ODC-By).¹⁰ In the following subsections, we provide details of each subset. The README document of the dataset provides all details about the separation. Please download the dataset from <https://huggingface.co/datasets/NLPFin/Quantitative101>.

C.1 Quantitative Prediction

Quantitative prediction (QP) is a task to predict the correct magnitude of the masked numeral. For example, even for a human, it is difficult to predict the exact numeral (2.2) of the QP’s instance in Table 2; however, some seasoned experts can make a correct rough estimate of the magnitude. We attempt to test whether models also learn to make such predictions after being trained with a large amount of data. Thus, we adopt Numeracy-600K (Chen et al., 2019) as the dataset for this task. Chen et al.

⁷<https://github.com/aistairc/Numeracy-600K>

⁸<https://github.com/AbhilashaRavichander/EQUATE/blob/master/LICENSE>

⁹<https://allenai.org/data/numglue>

¹⁰<https://github.com/allenai/numglue/blob/main/license.txt>

(2019) designed this task as an eight-class classification task, which includes the magnitude from 1 to 6, decimal, and the magnitude larger than 6. We follow their setting in this paper. There are two subsets, including 600K market comments and 600K news headlines. We use 80%, 10%, and 10% of instances as training, development, and test sets in each subset, respectively.

C.2 Quantitative Natural Language Inference

Quantitative Natural Language Inference (QNLI) is a complex version of ComNum because the given sentences can be varied. The example of QNLI provided in Table 2 shows that models need to compare numbers based on more complex semantics. We select EQUATE (Ravichander et al., 2019) to experiment on real-world scenarios for QNLI. EQUATE has five subsets collected from different sources, including RTE-QUANT, AWP-NLI, NEWSNLI, REDDITNLI, and Stress Test. Since four of these subsets are less than 1,000 instances, we perform the 10-fold cross-validation in the experiments. For the Stress Test, which contains 7,500 instances, we follow the splitting method in NumGLUE Task 7 (Mishra et al., 2022) to separate it into training, development, and test sets. Ravichander et al. (2019) designed the QNLI task as a two or three-class classification task depending on the subset. We follow their settings for each subset.

C.3 Quantitative Question Answering

Quantitative Question Answering (QQA) is the other format for testing whether models can un-

derstand numerals and semantics. We selected the Task 3 subset of NumGLUE (Mishra et al., 2022) for the QQA experiments. Table 2 provides an example of this dataset. It is under a binary-classification setting, and each instance has two options. We follow Mishra et al. (2022) to separate the dataset into training, development, and test sets.

Visualize Before You Write: Imagination-Guided Open-Ended Text Generation

Abstract

Recent advances in text-to-image synthesis make it possible to visualize machine imaginations for a given context. On the other hand, when generating text, human writers are gifted at creative visualization, which enhances their writings by forming imaginations as blueprints before putting down the stories in words. Inspired by such a cognitive process, we ask the natural question of whether we can endow machines with the same ability to utilize visual information and construct a general picture of the context to guide text generation. In this work, we propose iNLG that uses machine-generated images to guide language models (LM) in open-ended text generation. The experiments and analyses demonstrate the effectiveness of iNLG on open-ended text generation tasks, including text completion, story generation, and concept-to-text generation in both few-shot and full-data scenarios. Both automatic metrics and human evaluations verify that the text snippets generated by our iNLG are coherent and informative while displaying minor degeneration.¹

1 Introduction

One great resource human writers cherish is the ability of imagination, with which they render mental images about an actual or vicarious experience and link knowledge that would later make the writing more concrete, sensible, and intriguing. Cognitive studies show that visual imagery improves comprehension during language processing (Gambrell and Bales, 1986; Joffe et al., 2007; Sadoski and Paivio, 2000), and that mental imagery facilitates humans’ written language expression at young ages (Gambrell and Koskinen, 2002).

When it comes to the study of Artificial Intelligence (AI), one classic challenge for AI systems is to generate informative and coherent text snippets. Open-ended text generation is such a task that provides an input context, and asks the model to

¹Our code & data: <https://github.com/VegB/iNLG>.

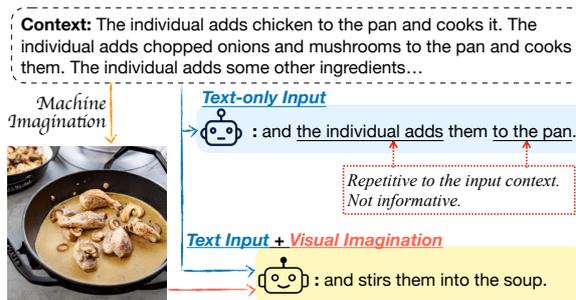

Figure 1: When performing open-ended text generation, the language models prompted with text-only input may generate repetitive or unilluminating contents, which is also known as degeneration. Hereby, we propose to use machine-generated images as additional visual supervision to guide the language models in generating more informative and coherent text with the given context.

generate a piece of text that is consistent with the context. This is the cornerstone of a wide range of downstream tasks such as text completion (Guan et al., 2019; Radford et al., 2019), story generation (Fan et al., 2018; Goldfarb-Tarrant et al., 2020; Swanson et al., 2021; Su et al., 2022b), and dialogue systems (Schatzmann et al., 2007; Wen et al., 2015, 2017; Wei et al., 2018; Wu et al., 2021), and has received much attention throughout the years. Inspired by human writers’ common practice of creative visualization, we ask the following question: Can we endow machines with the same ability to construct a general picture of the context and use it as a blueprint to guide text generation?

Recent advances in text-to-image generation make it possible to visualize machine imaginations for a given context (Ramesh et al., 2021; Rombach et al., 2022; Crowson et al., 2022; Wang et al., 2022b; Saharia et al., 2022). Moreover, this line of work shows great potential in utilizing textual information to guide image synthesis. It comes naturally that one may attempt to complete the loop by using visual supervision to guide text generation.

In this work, we propose using machine-

generated images to guide the language model (LM) in open-ended text generation. More specifically, we visualize machine imagination for the input context by rendering images with StableDiffusion (Rombach et al., 2022), a state-of-the-art text-to-image generator. The machine imagination acts as additional visual supervision to guide LMs in generating informative and coherent text in two ways. Firstly, the machine-generated images are introduced as the input to the LM in the form of the visual prefix. Secondly, we designed a contrastive training objective that enforces the generated text to be semantically similar to the visual supervision.

We conduct experiments on three open-ended text generation tasks, namely text completion, story generation, and concept-to-text generation. Extensive experiments in the few-shot settings show better or competitive performance to state-of-the-art baselines on both automatic metrics and human evaluation. Experiments with full-data settings show that introducing machine-generated visual supervision with our iNLG yields consistent improvements on various LM models including GPT-2 (Radford et al., 2019), BART (Lewis et al., 2020), and T5 (Raffel et al., 2020).

Our main contributions are as follows:

- We introduce a novel paradigm that leverages machine-generated images to guide open-ended text generation. This endows the machines with the ability of creative visualization that human writers often demonstrate.
- We distill the vision information from the pre-trained multimodal models and further construct visual prefixes to guide language models performing text generation with teacher forcing and contrastive objectives.
- Extensive experiments show the effectiveness of iNLG as a model-agnostic framework in open-ended text generation tasks, including text completion, story generation, and concept-to-text in both few-shot and full-data settings.

2 Related Work

Open-ended Conditional Text Generation is the task of generating a coherent portion of the text based on the given context. Recent advances in pre-trained models have pushed frontier in the open-ended conditional text generation, such as text completion (See et al., 2019; Ippolito et al., 2020), story generation (Guan et al., 2020; Fan

et al., 2018; Yao et al., 2019) and concept-to-text generation (Zhou et al., 2021; Liu et al., 2021). Despite the success of large language models, text degeneration and semantic coverage still remain as two core technical challenges in few-shot open-ended text generation. To improve the text coverage, StoryEndGen (Guan et al., 2019) leverages the knowledge graph to encode context sequentially. Fan et al. (2018) and Yao et al. (2019) plan the content (premise or keywords) first and then encourage the generation based on planned content. To mitigate the text degeneration, SimCTG (Su et al., 2022b) uses a contrastive training strategy to encourage the model to learn isotropic token embeddings. Similar to our approach, Wang et al. (2022a) generates a scene graph for each concept and combines them with text for the model input. Previous work has proposed to add visual information to LM by retrieving images from the Internet or large-scale image sets (Yang et al., 2020; Cho et al., 2021; Su et al., 2022a). However, the retrieved images may fail to fully incorporate the context, which will misguide the LM from yielding contextually consistent predictions.² Unlike prior work, our approach leverages images generated conditioning on the context to assist the text generation process.

Visually-aided NLP Recent work show the power of visual guidance in natural language processing, spanning from the language representation learning (Lu et al., 2019; Li et al., 2019; Sun et al., 2019; Luo et al., 2020; Chen et al., 2020; Li et al., 2020; Tan and Bansal, 2020; Lu et al., 2022), the downstream tasks (Grubinger et al., 2006; Elliott et al., 2016; Xie et al., 2019; Christie et al., 2016; Shi et al., 2019; Lu et al., 2022) and evaluation (Zhu et al., 2021). They either leverage visual information from an external vision-and-language corpus or obtain such visual knowledge from the large pre-trained model. In this line of work, imagination achieves promising performance in various NLP domains (Long et al., 2021; Zhu et al., 2021; Wang et al., 2022a; Lu et al., 2022). Previous imagination-based work in NLP either study non-generation problems (Zhu et al., 2021; Lu et al., 2022) or utilize non-visual information (Long et al., 2021; Wang et al., 2022a). Our work explores the potential of generating visual imagination to improve open-ended text generation tasks.

²Figure 8 shows examples where the image retrieved from the search engine is irrelevant with the input context.

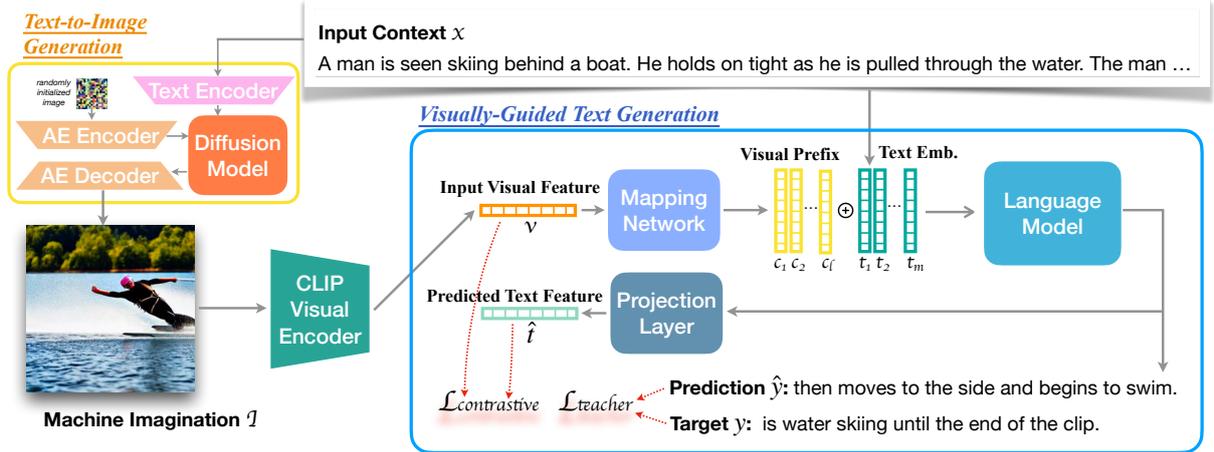

Figure 2: An overview of our iNLG. Given an input context x , we first visualize the context with the text-to-image generation model. Then we use the machine-generated image I as the additional visual supervision to guide the language model in open-ended text generation. The visual feature is provided as a source of input to the LM in the form of the visual prefix. Aside from the teacher forcing objective $\mathcal{L}_{\text{teacher}}$, we also enforce the LM to generate text that is semantically similar to the machine imagination with a contrastive training objective $\mathcal{L}_{\text{contrastive}}$.

3 Method

3.1 Overview

Open-ended text generation is a task that provides an input context, and asks the model to generate a piece of text that is consistent with the context.

This work mainly focused on introducing machine-rendered images to assist LM in performing open-ended text generation. More specifically, given the context x^i , we first use a text-to-image generator to illustrate an image I^i that depicts the input context. The LM is prompted with image I^i as the visual prefix along with the text context x^i , and will incorporate the multimodal input to generate the output text \hat{y}^i .

Figure 2 provides an overview of our iNLG framework, which mainly involves two modules. The first module is a text-to-image generator that takes in the input context and illustrates a descriptive image, which we also refer to as the machine imagination. The second module is a visually-guided language model that utilizes the machine imagination as a source of input and also a supervision that encourages the LM to generate text that is semantically similar to the visual information.

3.2 Text-to-Image Rendering

In this work, we propose to use images generated conditioning on the context by the machines as additional visual information to the LM. The text-to-image generation backbone is StableDiffusion (Rombach et al., 2022), which mainly consists

of a text encoder, a diffusion model, and an auto-encoder. The text encoder is from the frozen CLIP ViT-L/14 (Radford et al., 2021) and encodes the input text to textual embeddings. The diffusion model uses UNet (Ronneberger et al., 2015) to provide noise estimation. The UNet is modified so as to attend to the input textual embeddings. The encoder of the pretrained autoencoder encodes images into the lower-resolution latent maps z_T . At each step t , the diffusion model provides the noise estimation ϵ and modifies z_t correspondingly. The decoder of the pretrained autoencoder takes the final noise-free latent map z and generates the image prediction. StableDiffusion is trained with LAION-5B (Schuhmann et al., 2022).

3.3 Visually Guided Text Generation

Visual Prefix Construction One can encode the visual information with the pre-trained visual models. However, such visual embedding may lie in a representation space different from the LM due to the discrepancy between models. One way of introducing features extracted by another network to the current model is through feature mapping (Mokady et al., 2021). With a dataset of image-text pairs (I', x') , we can pre-train a mapping network \mathcal{F} for a given LM in an image captioning formulation. More specifically, we encode I' with the visual encoder $\text{Enc}_{\text{visual}}$ and receive its visual features v' . Then we apply the mapping network \mathcal{F} over v' , and receive a sequence of l visual prefixes:

$$c'_1, c'_2, \dots, c'_l = \mathcal{F}(v') = \mathcal{F}(\text{Enc}_{\text{visual}}(I')) \quad (1)$$

We provide the list of visual prefix as input to the LM with the corresponding text x' as the target output. Such a pre-training process enables \mathcal{F} to project visual features into the visual prefix that lies within the same embedding distributions as the LM. The mapping network is agnostic of the downstream task, and only depends on the visual source and the LM.

After generating a descriptive image I^i for the input context x^i , we use CLIP to encode I^i and receive its visual features v^i . We apply the pre-trained mapping network \mathcal{F} over v^i , and receive the visual prefix c^i of length l :

$$c^i = \{c_1^i, c_2^i, \dots, c_l^i\} = \mathcal{F}(\text{CLIP}(I^i)) \quad (2)$$

Visually-guided Language Modeling We use the visual information to guide text generation in two ways, reflected in the following two training objectives. Firstly, we directly introduce the machine-generated visual information as input to the LM. We concatenate the visual prefix c^i and the text embeddings t^i for the input context x^i with m tokens. LM input can be denoted as $[c^i; t^i] = \{c_1^i, \dots, c_l^i, t_1^i, \dots, t_m^i\}$. With $y^i = \{y_1^i, y_2^i, \dots, y_n^i\}$ denoting the target output of n tokens, and θ denoting the trainable parameters, we can list out the teacher forcing training objective as follows:

$$\mathcal{L}_{\text{teacher}} = - \sum_{j=1}^n \log p_{\theta}(y_j^i | c^i; t^i; \mathbf{y}_{<j}^i) \quad (3)$$

In addition, we design a contrastive objective to enforce the generated text to be semantically similar to the input visual supervision with the InfoNCE loss (van den Oord et al., 2018; Yan et al., 2021):

$$\mathcal{L}_{\text{contrastive}} = - \log \frac{\exp(\text{sim}(\mathbf{v}^i, \hat{\mathbf{t}}^i)/\tau)}{\sum_{j \neq i} \exp(\text{sim}(\mathbf{v}^i, \hat{\mathbf{t}}^j)/\tau)} \quad (4)$$

in which $\hat{\mathbf{t}}$ is the projected representation of the decoder’s last layer’s output, and can be viewed as the sentence-level representation of the generated text. Here $\text{sim}(\cdot, \cdot)$ first normalizes the two vectors, then compute their cosine similarity, and τ is the temperature.

3.4 Training & Inference

We first pre-train the mapping network on the pre-training dataset with the teacher-forcing objective. Such pre-training is agnostic of the downstream task, and only depends on the type of base LM.

When applying our iNLG on downstream tasks, we train the base LM with the teacher forcing objective for the first $N_{\text{no_contra}}$ epochs. Then, we introduce the contrastive objective and tune the base LM together with the mapping network and projection layer by minimizing the following loss \mathcal{L} . Here ep denotes the epoch and λ is the factor:

$$\mathcal{L} = \begin{cases} \mathcal{L}_{\text{teacher}}, & ep < N_{\text{no_contra}}, \\ \mathcal{L}_{\text{teacher}} + \lambda \mathcal{L}_{\text{contrastive}}, & ep > N_{\text{no_contra}}, \end{cases} \quad (5)$$

During inference, we provide the context and machine-generated image to the LM. We use beam search during decoding with a beam width of 10.

4 Experimental Setup

4.1 Tasks, Datasets, and Baselines

We apply our iNLG on three open-ended text generation setups: sentence completion, story generation, and concept-to-text generation. Table 1 shows examples for each task.

Sentence Completion is a task of finishing the sentence in a commonsense inference scenario. We conduct experiments on the ActivityNet (Heilbron et al., 2015) subset³ of HellaSwag (Zellers et al., 2019), which is a benchmark for commonsense natural language inference that ask the model to predict the most likely follow-up among several choices given a specific context. We compare with StoryEndGen (Guan et al., 2019) which encodes the given context incrementally and attends to the one-hop knowledge graph retrieved from ConceptNet for the context tokens. We implement our iNLG on top of the GPT-2 (Radford et al., 2019), which by nature, can generate the follow-up for an arbitrary input in a zero-shot manner.

Story Generation requires the model to compose a story based on the given title or context. We conduct experiments on the widely used story generation benchmark ROCStories (Mostafazadeh et al., 2016). Each data item consists of a story title and a human-written five-sentence everyday life story that incorporates commonsense related to the title.⁴ We provide the story title and the story’s first sentence as the input context, and ask the LM to predict the following four sentences. We consider the

³14740/982/2261 samples for train/validation/test.

⁴We use the split provided by Su et al. (2022a), which is based on the ROCStories Winter 2017 release and contains 49666/1500/1500 items for the train/validation/test sets.

Task	Input Context	Target Output
Text Completion	Different people are interviewed on camera while several others are shown raking up the leaves. A man is seen sitting in his car and another puts his gloves on. The camera	pans over the raked up leaves while several others discuss their hard work.
Story Generation	Live Show. Tim was in his school’s play.	He was nervous about their first show. He almost dropped out. The show went smoothly. Tim was excited for his second show.
Concept-to-Text	grow, flower, pavement	Wild flower growing through crack in the tiled pavement.

Table 1: Exemplars of the input context and corresponding target output for three open-ended text generation task covered in this study, namely story generation, text completion, and concept-to-text generation.

following methods as baselines: Action-Plan (Fan et al., 2018) first predicts the premise of a story with the convolutional LM (Dauphin et al., 2017), then use the fusion mechanism (Sriram et al., 2018) to encourage a convolutional seq2seq model (Gehring et al., 2017) to generate the story from the premise. Plan-and-Write (Yao et al., 2019) first plans a storyline that consists of keywords, then generate the story conditioned on the storyline. Its model structure is built upon GRU (Cho et al., 2014). SimCTG (Su et al., 2022b) proposes a contrastive training objective that encourages the LM to learn discriminative and isotropic token representations, and is implemented on GPT-2 (Radford et al., 2019).

Concept-to-Text is a relatively more constrained conditional text generation task involving common-sense reasoning. This task provides a set of concepts as input, and requires the model to generate a piece of text that incorporates the concepts and describes an everyday scenario. We conduct experiments on the CommonGen (Lin et al., 2020) benchmark.⁵ We compare against the following models: KG-BART (Liu et al., 2021) encompasses the relations of concepts with the knowledge graph and augments the BART (Lewis et al., 2020) encoder and decoder with graph representations. ModelAdapt (Ma et al., 2021) is built upon BART and removes the positional embedding in the encoder. Imagine-and-Verbalize (I&V) (Wang et al., 2022a) predicts a scene graph for each set of concepts, and uses it as an additional input to the LM. In contrast to I&V, we directly visualize the concepts and use the machine-generated images as the auxiliary information to assist the concept-to-text generation.

4.2 Evaluation

Automatic For sentence completion and story generation, we follow previous work and eval-

⁵We use the in-house split provided by Wang et al. (2022a), which contains 65323/2066/4018 samples for train/validation/test.

uate the quality of the generated text from the aspect of model degeneration level (rep- n , diversity, distinct- n), text distribution divergence (MAUVE), and semantic similarity (BERTScore): (1) rep- $n = 1.0 - \frac{|\text{unique } n\text{-grams}|}{|\text{total } n\text{-grams}|}$ measures sequence level repetition by computing the portion of duplicate n -grams (Welleck et al., 2020). (2) diversity = $\prod_{n=2}^4 (1 - \text{rep-}n)$ measures the diversity of n -grams (Su et al., 2022a). (3) distinct- $n = \frac{|\text{unique } n\text{-grams}|}{|\text{length of text}|}$ measures the portion of distinct n -grams in the text (Li et al., 2016). (4) MAUVE measures the learned distributions divergence between the generated text and human-written text (Pillutla et al., 2021),⁶ a low MAUVE indicates a great difference between the distributions of generated text and human text. (5) BERTScore assesses contextual text similarity between two pieces of texts by computing the cosine similarities between their tokens’ embeddings (Zhang* et al., 2020),⁷ a low BERTScore means the generated text is contextually different from the ground-truth.

For concept-to-text, following prior work, we report the metrics scores on BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016), and BERTScore (Zhang* et al., 2020).

Human We also set up a human evaluation as a complementary evaluation beyond the automatic metrics. We select 100 samples from the test set for sentence completion and story generation and perform the head-to-head comparison between the text snippets generated by our iNLG and the baseline models. We invite human annotators to compare the text quality from the following three independent aspects: (1) *Coherence*: Which snippet is more semantically consistent with the context, and follows the logic of the context more naturally. (2) *Fluency*: Which snippet is more fluent in English. (3) *Informativeness*: Which snippet contains more

⁶We report MAUVE with gpt2-large as the base model.

⁷We report BERTScore with roberta-large as base model.

Task	*	Setting	rep-2 ↓	rep-3 ↓	rep-4 ↓	diversity ↑	distinct-2 ↑	MAUVE ↑	BERTScore ↑
Sentence Completion	0	Human	0.45	0.05	0.01	99.50	77.32	-	-

Table 2: Generation quality scores for few-shot text completion on the ActivityNet and few-shot story generation on ROCStories. “Human” shows the human performance and “GPT2 *no finetune*” denotes the vanilla GPT2 model without tuning. All the other listed models are trained with 1% of the training data. “+iNLG” denotes introducing machine-generated images on top of the base LM.

interesting content, and describes the scenes that are more likely to happen in real life. Three human judges rate each comparison.

4.3 Implementation Details

We use StableDiffusion-v1-1 (Rombach et al., 2022) to render a 512x512 image from the context, and use CLIP ViT/B-32 to extract features offline. The mapping network is an 8-layer Transformer, and the visual prefix length is 20. For the sentence completion and story generation tasks, the mapping network is pre-trained on the MSCOCO (Lin et al., 2014) dataset. For the concept-to-text task, the mapping network is pre-trained on VIST (Huang et al., 2016).⁸ We pre-train the mapping network for 5 epochs with a batch size of 128. Results are reported on three repeat runs. Detailed hyperparameters are listed in the Appendix.

5 Result and Analysis

5.1 Few-Shot Learning Results

Open-ended text generation is a broad topic with flexible and inexhaustible setups, many of which have low resources. Collecting annotations is often extremely expensive and time-consuming. Therefore, we first report few-shot results to check if our iNLG can rapidly adapt to new task setups with a few examples, which is more practical in real-life.

More specifically, we report few-shot open-ended text generation results with 1% of the training data. For sentence completion and story gen-

eration tasks, the base LM is GPT2-base (Radford et al., 2019). For concept-to-text, we test it with BART-base (Lewis et al., 2020) as the base LM.

Sentence Completion As shown in Table 2, StoryEndGen (#2) suffers from degeneration with the highest rep- n and the lowest diversity. Training with only 1% of the training data improves GPT2’s performance on all metrics (#3 vs. #1). Under the same few-shot setting, adding additional machine-generated images with our iNLG (#4) further alleviate model degeneration. The improvement on MAUVE also indicates that introducing visual input can aid GPT2 in generating text that is more similar to the human-written ones.

Story Generation As shown in Table 2, for the story generation task that requires the LM to compose longer text, we see the vanilla GPT2 without tuning suffering from more severe degeneration compared to rendering a sentence ending (#6 vs. #1). The high rep- n scores indicate that the two non-Transformer-based baselines Action-Plan (#7) and Plan-and-Write (#8) stammer with repetitive tokens, which greatly differs from the human-written text (leads to low MAUVE) and does not have concrete meanings (leads to low BERTScore). The models based on GPT-2 (#9-#10) yield more complete sentences with concrete meanings (BERTScore gets higher). However, they keep repeating the same sentence, which is still quite different from human language (MAUVE remains low). Applying iNLG to GPT-2 leads to minor degeneration and has the best performance on all metrics (#11). Examples of generated text snippets can be found in Figure 6 and in Appendix.

⁸CommonGen is built upon image and video captioning datasets including MSCOCO. To avoid data leakage, we choose to pre-train the mapping network on VIST, which is not revealed to CommonGen.

Task	Models	Coherence			Fluency			Informativeness		
		Win(%)	Tie(%)	Lose(%)	Win(%)	Tie(%)	Lose(%)	Win(%)	Tie(%)	Lose(%)
Sentence Completion	Ours vs. StoryEndGen	51.67	20.33	28.00	44.67	19.33	36.00	41.33	18.33	40.33
	Ours vs. GPT2 <i>no finetune</i>	51.00	22.67	26.33	45.00	22.33	32.67	41.00	21.00	38.00
	Ours vs. GPT2 <i>text-only finetune</i>	58.00	24.33	17.67	43.33	18.67	38.00	42.33	21.67	36.00
Story Generation	Ours vs. Action-Plan	51.00	24.67	24.33	54.67	16.33	29.00	52.00	15.00	33.00
	Ours vs. Plan-and-Write	45.33	25.67	29.00	53.00	16.67	30.33	54.67	17.00	28.33
	Ours vs. SimCTG	42.00	27.67	30.33	40.33	25.67	34.00	43.33	18.33	38.33
	Ours vs. GPT2 <i>no finetune</i>	43.33	24.33	32.33	43.67	20.33	36.00	44.67	19.00	36.33
	Ours vs. GPT2 <i>text-only finetune</i>	39.33	26.67	34.00	38.67	26.67	34.67	44.33	22.67	33.00

Table 3: Human evaluation results for the sentence completion task and the story generation task. The scores indicate the percentage of win, tie or lose when comparing our iNLG with the baseline models.

* Setting	B-4	M.	CIDEr	SPICE	BertS.
1 BART-base <i>text-only finetune</i>	20.72	25.47	114.49	24.58	59.76
2 +KG (Liu et al., 2021)	15.26	24.44	98.53	23.13	52.76
3 +Adapt (Ma et al., 2021)	23.11	25.96	123.44	25.14	61.53
4 +I&V (Wang et al., 2022a)	24.50	25.89	119.61	25.59	57.29
5 +iNLG	25.07	26.48	127.93	26.32	63.37

Table 4: Automatic metrics scores for few-shot concept-to-text generation on CommonGen with 1% of the training data. All listed models are implemented on BART-base. “+KG” adds knowledge graph, “+Adapt” applies model adaption, “+I&V” adds scene graph, and “+iNLG” introduces machine-generated images as input. B-4: BLEU-4; M.: METEOR; BertS.: BERTScore.

Concept-to-Text Table 4 shows that knowledge graph information may not be fully exploited under the few-shot setting (#2), while removing the information of relative positions between input concepts helps the LM write better sentences (#3). Introducing machine-generated images can improve the base LM’s performance on concept-to-text generation (#5 vs. #1). While both I&V and our iNLG involve machine “imagination”, we provide such information in different forms (scene graphs vs. images). Comparing #4 and #5, our iNLG outperforms I&V with BART-base as the base LM. This suggests that the additional information introduced by I&V and iNLG is complementary.

Human Evaluation Table 3 lists out human evaluation results on text completion and story generation. Our iNLG outperforms the compared baselines on all three criteria in the model-level head-to-head comparisons. This further verifies the effectiveness of our iNLG in generating fluent and informative text snippets that better align with the given context.

5.2 Model-Agnostic Improvement

We further report open-ended text generation results with various base LM when trained with the full set of data. For concept-to-text, we experiment

Base LM	Setting	Metrics				
<i>Concept-to-Text</i>		B-4↑	MET↑	CIDEr↑	SPICE↑	BertS.↑
BART-base	text-only	30.32	31.35	158.92	31.22	68.50
	+iNLG	30.60	31.44	160.63	31.42	69.02
BART-large	text-only	32.38	33.06	169.69	33.01	70.33
	+iNLG	32.76	33.17	171.47	33.35	70.79
T5-base	text-only	30.39	30.87	163.67	32.77	70.03
	+iNLG	31.09	31.18	165.52	32.81	70.35
T5-large	text-only	34.13	32.91	175.67	34.30	72.44
	+iNLG	34.50	33.87	177.65	35.48	72.70
<i>Sentence Completion</i>		rep-4↓	div.↑	dist-2↑	MAUVE↑	BertS.↑
GPT2-base	text-only	4.20	87.46	72.87	61.42	29.84
	+iNLG	3.95	89.33	74.09	64.01	30.10
GPT2-large	text-only	1.77	96.54	76.74	87.81	31.66
	+iNLG	2.05	95.90	76.80	89.11	32.15
<i>Story Generation</i>		rep-4↓	div.↑	dist-2↑	MAUVE↑	BertS.↑
GPT2-base	text-only	7.83	68.42	49.53	33.13	28.81
	+iNLG	6.80	71.17	49.92	38.86	29.13
GPT2-large	text-only	1.02	91.91	54.17	82.81	31.86
	+iNLG	0.85	92.51	54.54	87.83	32.03

Table 5: Automatic metric scores when trained with the full set of data with ablations of the base LM. Introducing our iNLG leads to model-agnostic improvements across the board. B-4: BLEU-4; MET.: METEOR; BertS.: BERTScore; div.: diversity; dist-2: distinct-2.

with BART-base/large (Lewis et al., 2020) and T5-base/large (Raffel et al., 2020). For sentence completion and story generation, we record results on GPT2-base/large (Radford et al., 2019). As shown in Table 5, introducing machine-generated visual supervision with our iNLG leads to model-agnostic improvements over text-only finetuning. This holds true for all the listed base LM with different architectures and verifies that our iNLG is a model-agnostic framework.

5.3 Performance Analysis

Source of Image We first perform an ablation study to understand how the source of visual information affects our iNLG framework. We compare retrieved/generated images from four sources: (1) the first returned result by Yahoo Image Search;⁹

⁹<https://images.search.yahoo.com/>

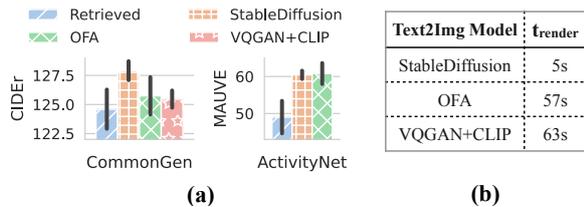

Figure 3: (a) iNLG’s performance on CommonGen and ActivityNet with visual supervisions retrieved from the web or generated by machines. Scores are reported with error bars. (b) Average time to render an image on TITAN RTX with each text-to-image generator.

(2) images rendered by VQGAN+CLIP (Crowson et al., 2022);¹⁰ (3) images rendered by OFA (Wang et al., 2022b),¹¹ and (4) images rendered by StableDiffusion (Rombach et al., 2022), with which we report the main results.

As shown in Figure 3(a), the images generated by machines act as a more effective supervision than the retrieved images. This validates our motivation of introducing machine-generated images over retrieved ones to guide LM in performing text generation. Among the three text-to-image generators, VQGAN+CLIP is slightly inferior to the other two, while StableDiffusion and OFA have mixed performance. Images generated by StableDiffusion rank first on CommonGen, while images rendered with OFA score slightly higher on ActivityNet. Figure 3(b) reports the average image rendering time, where StableDiffusion is 10× faster when rendering images than the other two.

Contrastive Training We examine the effect of the contrastive training objective on CommonGen, and the results are presented in Figure 4. We notice that introducing $\mathcal{L}_{\text{contrastive}}$ improves iNLG’s performance on 4 out of 5 listed few-shot setups, which suggests that our contrastive training objective generally can assist the LM in composing open-ended text snippets. One exception is in the extreme few-shot setting with only 0.1% of training data, where the amount of data is insufficient to let the LM form a decent representation. In this case, enforcing the sentence representation to be similar to the visual supervision with $\mathcal{L}_{\text{contrastive}}$ might misguide the LM.

Mapping Network & Visual Prefix We discuss the effects of different types of mapping networks and various visual prefix lengths. Aside from the 8-layer Transformer we used in the main experi-

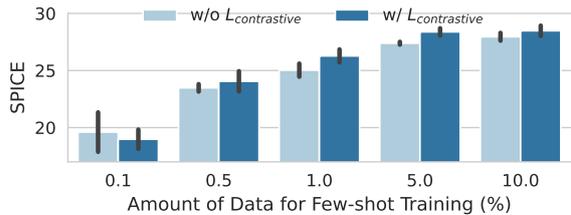

Figure 4: Performance of applying our iNLG on BART-base for few-shot concept-to-text with ablated training objective $\mathcal{L}_{\text{contrastive}}$ on various few-shot settings. Scores are reported with error bars.

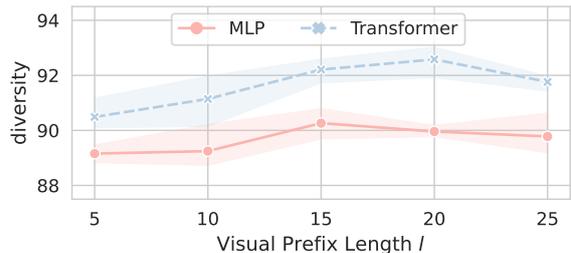

Figure 5: Performance of our iNLG on few-shot sentence completion with various visual prefix lengths and with MLP and Transformer as mapping network. Scores are reported with error bands.

ments, we also tried a simple Multi-Layer Perceptron (MLP) with two fully-connected layers. As shown in Figure 5, the Transformer-based mapping network outperforms MLP on all listed l . MLP has the best performance when visual prefix length $l = 15$, while the Transformer-based mapping network scores highest when $l = 20$.

Model Weight Tuning Table 6 compares the influence of pre-training/tuning the weights of different modules of our iNLG. Generally speaking, tuning the weights during training outperforms freezing the weights, which applies to both the base LM and the mapping network. In addition, considering our few-shot setup, pre-training the mapping network also helps our iNLG gain better performances. The best combination is applying the pre-trained mapping network, and tuning it together with the base LM on the few-shot downstream task.

Showcase Figure 6 provides two showcases on few-shot sentence completion and story generation to compare our iNLG with the GPT2-based baselines. SimCTG and GPT2 tuned with text-only corpus rendering repeated segments, either copying from the input context, or simply repeating themselves. In comparison, our iNLG has minor degeneration and writes coherent sentence endings or stories with more creative details in both tasks.

Tune LM	Pretrain Map.	Tune Map.	diversity \uparrow	MAUVE \uparrow
X	X	X	15.52	0.47
X	X	✓	78.20	33.79
X	✓	X	27.06	1.83
X	✓	✓	76.36	25.15
✓	X	X	87.45	48.06
✓	X	✓	88.68	51.81
✓	✓	X	89.05	55.61
✓	✓	✓	92.68	60.62

Table 6: Performance of our iNLG on few-shot sentence completion with ablated settings on whether to tune the LM, pretrain the mapping network (Pretrain Map.) and tune the mapping network (Tune Map.).

Context: Two girls are standing in a yard wearing cheerleading outfits. A girl...	
Generated Image:	
	GPT2 (text-only) is <u>standing in a yard</u> with a group of girls.
	GPT2 +iNLG is wearing a white bikini and blue shorts.
(a) Sentence Completion	
Context: Barry at the Mall. Barry and his friends spent a day at the mall.	
Generated Image:	
	SimCTG Barry was at the mall with his friends. They were all very excited to see him at the mall. <u>They all had a great time at the mall. They all had a great time at work. They all had a great time at school</u>
	GPT2 (text-only) <u>They went to the local mall and bought a new car. They drove to the mall and bought a new car. They drove to the mall and bought a new car.</u> Barry's friends were very happy they <u>bought a new car.</u>
	GPT2 +iNLG They were swamped by the crowds. Barry was scared to go home. They tried to avoid the mall, but they were stopped by the people at the mall.
(b) Story Generation	

Figure 6: Sentence ending and stories generated by GPT2-based methods tuned with 1% of the training data. *Repetitive contents* are underlined. The sentence ending and story written by our iNLG is coherent with the context, related to the machine-generated image, and has minor degeneration. More demonstrative examples can be found in the Appendix.

6 Conclusion

In this work, we propose iNLG, a framework that introduces machine-generated images to guide open-ended text generation. This endows the machines with the ability of creative visualization that human writers often demonstrate. We distill the vision information from the pre-trained multimodal models and further construct visual prefixes to guide language models to perform text generation with the teacher forcing and the contrastive objective. Extensive experiments show the effectiveness of iNLG in open-ended text generation tasks, including text completion, story generation, and concept-to-text generation in few-shot settings.

Limitations

This work mainly focuses on open-ended text generation, where the search space for the target output is infinite, and the language model would benefit from additional visual imagination distilled from large text-to-image generation models to produce coherent and meaningful content. However, we should note here that despite the commendable performance of text-to-image generation models, there are certain terms and concepts that are inherently challenging to visualize, such as numerical values and abstract philosophical terms. This problem itself is an interesting open research question for all tasks involving text-and-vision.

In our current approach, the images are generated offline. In future work, one may explore the integration of text-to-image and image-to-text modules in an end-to-end manner, which may be more suitable for longer text generation that is not covered in this work.

Text-to-image generation models currently have a length limit on the input text prompt, which may impede their ability to visualize long text inputs in a single image. Furthermore, as previously discussed, text-to-image models may also encounter difficulties in generating images of complex scenes or situations that are challenging to depict through a single image. Future research could explore the use of multiple images or supplementary videos as visual input in order to provide a more comprehensive representation of the scene or situation in question. The iNLG framework can be easily extended to take video representation by taking longer visual prefixes or iteratively applying visual prefixes at each step.

Ethics Statement

In this work, we use pre-trained multimodal models to visualize machine imagination. The machine-generated images may contain uncontrolled bias if any inductive bias exists from the pre-training data. Even though we do not witness such an issue in our study, this may be a potential factor that affects the quality of the generated text. We do not anticipate any major ethical concerns given that all the datasets and models used in this study have already been released to the public. We reproduce baselines with the released code repository. For human evaluation, our study is approved for IRB exempt. The estimated hourly wage paid to MTurk annotators is \$10.

A Appendix

A.1 Experiment Details

Pretraining We pre-train the mapping network for GPT-2-base (Radford et al., 2019) on the MSCOCO (Lin et al., 2014) dataset with 414,113 (image, text) pairs for training. We pre-train the mapping network for BART-base (Lewis et al., 2020) on VIST (Huang et al., 2016) story-in-sequence subset, with 141,593 (image, text) pairs for training after excluding the images that the users have removed. For each setting, we pre-train the mapping network for 5 epochs with a batch size of 128, learning rate of 2e-5, weight decay of 0.01, and warmup steps of 5,000.

Few-Shot Training for Downstream Tasks Table 7 lists out the hyperparameters we used during few-shot experiments on the three open-ended text generation tasks.

Hyperparameters	Concept-to-Text	Text Completion	Story Generation
Base LM	BART-base	GPT2-base	GPT2-base
Batch Size	8	8	8
Training Epoch	20	20	20
$N_{\text{no_contra}}$	4	10	15
λ	1.5	1	0.2
Learning Rate	2e-5	2e-5	2e-5
Weight Decay	0.01	0.01	0.01
Warmup Steps	400	400	400
Max Output Length	64	100	150
Num of Beam	10	10	10

Table 7: Hyperparameter settings for few-shot open-ended text generation.

Parameter Search We tried the learning rate in the following setting: {1e-5, 2e-5, 5e-5, 1e-4}, and tried the batch size in {4, 8, 16, 32}.

Parameter Size Table 8 lists out the parameter size for the network modules used in our study.

Environment & Run Time Table 9 lists out the execution time for the three open-ended text generation tasks with 1% of the training data. Experiments are conducted on NVIDIA A100.

A.2 Human Evaluation

We invite Amazon Mechanical Turk¹² annotators to judge the quality of the generated text. Figure 7 shows an example template we use for head-to-head comparison.

Abstract

Automatic evaluations for natural language generation (NLG) conventionally rely on token-level or embedding-level comparisons with the text references. This is different from human language processing, for which visual imagination often improves comprehension. In this work, we propose IMAGINE, an imagination-based automatic evaluation metric for natural language generation. With the help of StableDiffusion (Rombach et al., 2022), a state-of-the-art text-to-image generator, we automatically generate an image as the embodied imagination for the text snippet and compute the imagination similarity using contextual embeddings. Experiments spanning several text generation tasks demonstrate that adding machine-generated images with our IMAGINE displays great potential in introducing multi-modal information into NLG evaluation, and improves existing automatic metrics’ correlations with human similarity judgments in both reference-based and reference-free evaluation scenarios.

1 Introduction

A major challenge for natural language generation (NLG) is to design an automatic evaluation metric that can align well with human judgments. To this end, many approaches have been investigated. Metrics that base on matching mechanisms such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), have been widely adopted in the field. Edit-distance based metrics, such as CharacTER (Wang et al., 2016), WMD (Kusner et al., 2015), SMD (Clark et al., 2019), have also been explored. Recently, BERTScore (Zhang* et al., 2020) and BLEURT (Sellam et al., 2020) attempt to leverage BERT (Devlin et al., 2019) to compare text embedding similarities, which correlates better with human judgments than previous methods. These automatic evaluation metrics make use of textual information from various angles extensively.

But what happens in our minds when we read, comprehend, and evaluate text? Research (Just et al., 2004; Eviatar and Just, 2006) has found that, unlike commonly designed automatic evaluation methods that compare the generated candidates with the references on the text domain only, humans, in contrast, leverage visual imagination and trigger neural activation in vision-related brain areas when reading text. Cognitive studies show that visual imagery improves comprehension during language processing (Gambrell and Bales, 1986; Joffe et al., 2007; Sadoski and Paivio, 2013). Inspired by this imagination-based multi-modal mechanism in human text comprehension, we ask a critical research question: *can machines create a visual picture of any underlying sentence, and use their imaginations to improve natural language understanding?* The advances of recent pre-trained vision-language models such as CLIP (Radford et al., 2021) provide an excellent opportunity for us to utilize the learned image-text representations. This enables us to explore the possibility of incorporating multi-modal information into NLG evaluation.

In this work, we propose IMAGINE, an imagination-based automatic evaluation metric for text generation. Specifically, we first use the state-of-the-art text-to-image generator StableDiffusion (Rombach et al., 2022) to visualize machine imagination from sentences, which is to generate descriptive images for the candidate text and the references. Then we receive the IMAGINE scores by computing two sets of similarity scores with the pre-trained CLIP model (Radford et al., 2021): the visual similarity of the generated images, and the cross-modal similarity between the text and the generated image. Figure 1 shows an example.

To understand the role the machine-generated images play in NLG evaluation, we conduct a series of experiments with IMAGINE on multiple NLG tasks and datasets, including machine translation, text summarization, and sentence completion for

Text for Summarization:

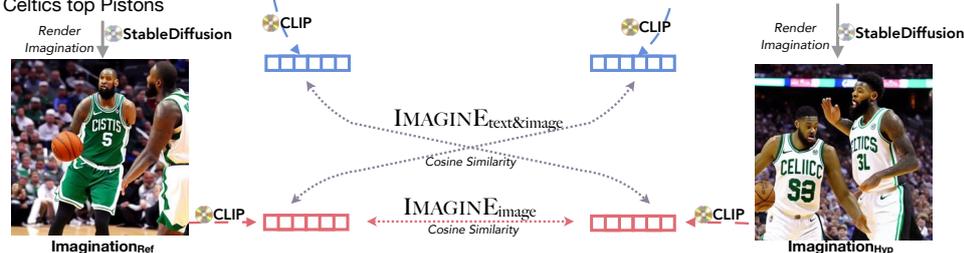

Kevin Garnett scored ## points in his return after a one-game suspension and the Boston Celtics ripped Detroit ##-## here Thursday in a rematch of last season's NBA semi-finals.

Basketball: Garnett makes triumphant return as Celtics top Pistons

Hypothesis:

Celtics sink Detroit ##-## in NBA semi-final rematch

Metric	Score	
BLEU-4	0.0	✗
ROUGE-1	12.5	✗
ROUGE-2	0.0	✗
ROUGE-L	10.9	✗
BERTScore	5.7	✗
ImaginE _{image}	91.2	✓
ImaginE _{text&image}	63.7	✓
Human	4.2/5.0	✓

Figure 1: An evaluation example on GigaWord for text summarization. IMAGINE visualizes machine imagination with StableDiffusion (Rombach et al., 2022) and extracts textual and visual representations with CLIP (Radford et al., 2021). While traditional evaluation metrics for natural language generation rely on n -grams matching or textual embeddings comparison, IMAGINE incorporates machine-generated images into the evaluation process and enhances the understanding of the text snippet as a whole through the integration of multi-modal information.

open-ended text generation, aiming to answer the following questions:

1. *How influential is IMAGINE in NLG evaluation in terms of correlations with human judgments? Can it provide additional reference information on top of existing metrics?*
2. *What are the applicable scenarios of introducing IMAGINE to NLG evaluation? When and why do machine-generated images help?*
3. *What are the potentials and limitations of introducing machine-generated images with IMAGINE to NLG evaluation?*

Experimental results show that IMAGINE can serve as a complementary evaluation metric to text-based ones, and adding IMAGINE scores to existing metrics surprisingly improves most of the popular metrics' correlations with human performance on various text generation tasks. This holds for both reference-based evaluation and reference-free evaluation. We further conduct comprehensive quantitative analyses with case studies to verify its effectiveness. Overall, IMAGINE displays great potential in introducing multi-modal information into NLG evaluation.

2 Related Work

Automatic Metrics for Natural Language Generation Common practices for NLG evaluation compare the generated hypothesis text with the annotated references. Metric performance is conventionally evaluated by its correlation with human judgments. Existing automatic evaluation metric calculations are mainly based on three mechanisms: n -grams overlap, edit distance, and em-

bedding matching. BLEU (Papineni et al., 2002), ROUGE- n (Lin, 2004), METEOR (Banerjee and Lavie, 2005) and CIDEr (Vedantam et al., 2015) are a few widely used n -gram based metrics for text generation tasks. Another direction is based on edit distance (Tomás et al., 2003; Snover et al., 2006; Panja and Naskar, 2018; Tillmann et al., 1997; Wang et al., 2016), where they calculate the edit distance between the two text snippets with different optimizations. Embedding-based metrics (Kusner et al., 2015; Rubner et al., 1998; Clark et al., 2019; Lo, 2017, 2019) evaluate text quality using word and sentence embeddings, and more recently, with the help of BERT (Zhang* et al., 2020; Sellam et al., 2020).

Multi-Modal Automatic Metrics Aside from previous text-only metrics, some metrics utilize pre-trained multi-modal models and introduce visual features on top of text references for NLG evaluation. TIGER (Jiang et al., 2019) computes the text-image grounding scores with pre-trained SCAN (Lee et al., 2018). ViLBERTScore-F (Lee et al., 2020) relies on pre-trained ViLBERT (Lu et al., 2019) to extract image-conditioned embeddings for the text. The CLIPScore (Hessel et al., 2021) proposes a metric for image captioning by directly comparing images with captions using CLIP (Radford et al., 2021). Our method differs in that we use visual picture generation as embodied imagination and apply our metric to various text-to-text generation tasks.

Mental Imagery The debate between pictorialists and propositionalists about how imagery infor-

mation is stored in the human brain is still an open question in the neuroscience and psychology community (Troscianko, 2013). We follow the views from pictorialists that information can be stored in a depictive and pictorial format in addition to language-like forms (Kosslyn et al., 2001; Pearson and Kosslyn, 2015). In pictorialists’ model, mental imagery is constructed in the “visual buffer” either from the retinal image in seeing or from a long-term memory store of “deep representations” in the brain. Our image generation method is to mimic the generation of deep representations in machines, with the help of recent powerful text-to-image models. Inspired by empirical studies from cognitive science that visual imagination improves human text comprehension (Gambrell and Bales, 1986; Sadoski and Paivio, 1994; Nippold and Duthie, 2003; Just et al., 2004; Joffe et al., 2007; Sadoski and Paivio, 2013), we are interested in exploring if one can draw similar conclusions from automatic text evaluations by machines.

3 IMAGINE

This section describes how our IMAGINE metric evaluates the similarity between two pieces of text with the help of machine imagination. Figure 2 provides an overview of our method.

3.1 Model Details

CLIP We use the cross-modal retrieval model, CLIP (Radford et al., 2021), for our evaluation purposes. CLIP jointly trains an image encoder and a text encoder to predict the correct pairing of image-text pairs with InfoNCE (van den Oord et al., 2018) on 400M image-text pairs gathered from the web. We utilize the CLIP-ViT-B/32 variant, which consists of a 12-layer, 8-head Transformer text encoder with a hidden size of 512, and a Vision Transformer (ViT) (Dosovitskiy et al., 2021; Vaswani et al., 2017) image encoder adopting the BERT-base configuration and using a 32×32 input patch size. Both the text and image representations are normalized and projected into the multi-modal space before computing pairing likelihood through cosine similarity.

StableDiffusion We perform text-to-image generation with StableDiffusion (Rombach et al., 2022), which is a denoising diffusion probabilistic model (Ho et al., 2020). The model comprises three key components: a text encoder, a diffusion model, and an autoencoder. The text encoder,

adopted from the frozen CLIP-ViT-L/14 (Radford et al., 2021), is utilized to encode the input text into textual embeddings. The diffusion model, which leverages UNet (Ronneberger et al., 2015) for noise estimation, is modified to attend to the input textual embeddings. We conduct experiments with StableDiffusion-v1-1, which was trained with LAION (Schuhmann et al., 2022), using 256×256 images for pre-training, followed by 512×512 images for fine-tuning.

3.2 IMAGINE Similarity Score

In our proposed approach, as depicted in Figure 2, the computation of IMAGINE consists of three sequential steps. Firstly, the StableDiffusion model (Rombach et al., 2022) is utilized to generate descriptive images, referred to as machine imagination, from the two text snippets being compared. Secondly, both the text snippets and the generated images are encoded using the CLIP model (Radford et al., 2021). Finally, IMAGINE is calculated by computing the cosine similarities of the resulting text and visual features, both in a mono-modal and cross-modal manner.

Step 1: Render Imagination For each image, StableDiffusion randomly initializes a latent matrix H from the standard normal distribution and uses the encoder of the pre-trained autoencoder to encode H into the lower-resolution latent map z_T (T is the total inference steps). At each step t , the diffusion model estimates the noise, ϵ , and subtracts it from z_t . The decoder of the pretrained autoencoder takes the final noise-free latent map z and generates the image prediction I of size 512×512 .

Step 2: Extract Feature In the previous step, we generate the corresponding images I_1 and I_2 for the pair of text x_1 and x_2 for comparison with the text-to-image synthesis backbone. Then we pass the machine-generated images I_1 and I_2 and the input text x_1 and x_2 through corresponding CLIP encoders to receive the visual representations v_1 , v_2 , and the textual representation t_1 , t_2 .

Step 3: Measure Similarity With $\text{sim}(\cdot, \cdot)$ denoting the process of first normalizing the two vectors, then computing their cosine similarity, we compute two types of similarity scores for IMAGINE with the extracted textual and visual features:

(1) IMAGINE_{image} computes the visual representation similarity between v_1 and v_2 :

$$\text{IMAGINE}_{image} = \mathcal{F}(\text{sim}(v_1, v_2)) \quad (1)$$

Figure 2: Illustration of the computation process of the IMAGINE metric. Given the two pieces of text for comparison, x_1 and x_2 , we render the machine imagination by generating two images I_1 and I_2 with the pre-trained StableDiffusion (Rombach et al., 2022). We extract features of the input text and corresponding generated images with CLIP (Radford et al., 2021). We receive two variants of IMAGINE by computing the cosine similarity of the extracted features, in which IMAGINE_{image} measures mono-modal similarities on the visual side, while $\text{IMAGINE}_{text\&image}$ conducts cross-modal matching.

(2) $\text{IMAGINE}_{text\&image}$ ($\text{IMAGINE}_{t\&i}$) takes both the text and the generated image into consideration, and conducts cross-modal comparisons between (t_1, v_2) , as well as (t_2, v_1) :

$$\text{IMAGINE}_{t\&i} = \mathcal{F} \left(\frac{\text{sim}(t_1, v_2) + \text{sim}(t_2, v_1)}{2} \right) \quad (2)$$

The cosine similarity between the text and image representations theoretically has a range of $[-1, 1]$. However, in practice, the IMAGINE similarity scores tend to cluster within a more narrow interval $[l, h]$. Following Hessel et al. (2021), we use a linear function \mathcal{F} to stretch the similarity score distribution to the range of $[0, 1]$, which is also the score range for most of the automatic metrics covered in this study. Eq. (3) shows how we re-scale the similarity score s into s' . Appendix Figure 6 plots the two IMAGINE variants' distributions before and after rescaling.

$$s' = \frac{s - l}{h - l},$$

$$[l, h] = \begin{cases} [0.1, 1.0], & \text{for } \text{IMAGINE}_{image}, \\ [0.1, 0.4], & \text{for } \text{IMAGINE}_{text\&image}. \end{cases} \quad (3)$$

3.3 Integration with Existing Metrics

The IMAGINE similarity scores can serve as standalone automatic metrics. Additionally, IMAGINE can be incorporated as an extension to existing metrics, as it offers multimodal references and addresses the limitations of current text-only evaluations that only compare tokens or text embeddings. This mimics the human process of comprehending

text, where both text and visual imagination are utilized. The integration of IMAGINE with other automatic metrics is straightforward, achieved by summing the IMAGINE similarity score with the other automatic metric's score for each example:

$$metric_score' += \text{IMAGINE}_{similarity_score} \quad (4)$$

4 Experimental Setup

4.1 Tasks, Datasets, and Models

We evaluate our approach on three popular natural language generation tasks: machine translation, abstractive text summarization, and open-ended text generation.

Machine Translation We use Fairseq (Ott et al., 2019) to generate English translation from German on IWSLT'14 (Cettolo et al., 2014) and WMT'19 (Barrault et al., 2019) datasets.

Abstractive Text Summarization We use the implementation of Li et al. (2017) to generate summarization on DUC2004¹ and use ProphetNet (Qi et al., 2020b) for generation on Gigaword.² Both datasets are built upon news articles.

Open-ended Text Generation We perform experiments on the ActivityNet (Heilbron et al., 2015) subset of HellaSwag (Zellers et al., 2019), which is a benchmark for commonsense natural language inference that ask the model to predict the most likely follow-up among several choices given a specific

context. The dataset is derived from ActivityNet video captions and we use it for the task of sentence completion, where the model is given a context and asked to complete the sentence. The predicted sentence endings generated by StoryEndGen (Guan et al., 2019) and GPT-2 (Radford et al., 2019) are collected and used in the following evaluation.

4.2 Automatic Metrics

Machine Translation & Summarization In the evaluation of machine translation and text summarization tasks, it is a common practice to compare the predicted text with the reference. Adhering to previous studies, we present results using reference-based metrics. For machine translation, we present scores using BLEU- n ($n=1,2,3,4$) (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and CIDEr (Vedantam et al., 2015). Meanwhile, for text summarization, we present ROUGE- n ($n=1,2$) (Lin, 2004) precision scores. Additionally, we report the scores of ROUGE-L (Lin, 2004), BERTScore (Zhang* et al., 2020), and BLEURT (Sellam et al., 2020) for both tasks.

Open-ended Text Generation In the context of open-ended text generation, where the number of possible answers for a given scenario can be inexhaustible, evaluating the quality of generated text through a comparison with a fixed set of references is challenging. To address this issue, previous studies have proposed to utilize reference-free metrics to evaluate the quality of the generated text. In this work, we experiment with the following reference-free metrics which assess model degeneration: (1) $\text{div-}n = \frac{|\text{unique } n\text{-grams}|}{|\text{total } n\text{-grams}|}$ measures sequence level repetition by computing the portion of duplicate n -grams ($n=2,3,4$) (Welleck et al., 2020). (2) $\text{diversity} = \prod_{n=2}^4 \text{rep-}n$ measures the diversity of

n -grams (Su et al., 2022), and assesses the model degeneration. (3) $\text{distinct-}n = \frac{|\text{unique } n\text{-grams}|}{|\text{length of text}|}$ measures the portion of distinct n -grams (here $n=2$) in the text (Li et al., 2016). In addition, we report results on BERTScore (Zhang* et al., 2020) and BLEURT (Sellam et al., 2020) for comparison of contextual similarity.

4.3 Human Evaluation

We invite Amazon Mechanical Turk³ annotators to evaluate the quality of the generated text. Due to cost constraints, when conducting human evaluation, we randomly sample 1,000 test examples for each dataset, except for DUC2004 which has 500 examples in the test set. Each example is evaluated by three human judges using a 5-point Likert scale, which assessed the fluency, grammar correctness, and factual consistency of the generated text with the reference text. The overall human assessment score is calculated as the mean of the scores obtained from the three aspects. We compute the Pearson correlation (Freedman et al., 2007) between the human scores and the scores obtained from the automatic metrics, and the results are reported as a multiple of 100 for clarity.

5 Results and Analysis

5.1 Main Results

Machine Translation Table 1 presents the results of the system-level Pearson correlation with human judges when extending the IMAGINE similarity metric to various existing automatic natural language generation (NLG) metrics on the IWSLT'14 and WMT'19 German-to-English datasets. The results demonstrate that the addition of both IMAGINE_{image} and IMAGINE_{text&image}

Table 3: The effect of applying our IMAGINE similarities on ActivityNet for open-ended text generation, reflected in the Pearson correlation with human judgments. In the “Reference-based” setting, we compare the predictions with the references, while in the “Reference-free” setting, we compare the predictions with the input contexts. The image generation process is conducted over five different random seeds for each piece of text. We report the mean and standard deviation of the repeated runs. IE: IMAGINE.

improves the Pearson correlation for all metrics listed. Among the two variants, the mean of $\text{IMAGINE}_{\text{text}\&\text{image}}$ consistently performs better on both datasets. It is observed that there is a more substantial variance in $\text{IMAGINE}_{\text{image}}$, which is attributed to the difference in the images generated by the StableDiffusion model (Rombach et al., 2022) due to varying random seed and initialization values. As a result, $\text{IMAGINE}_{\text{image}}$, which compares two machine-generated images, has a higher standard deviation compared to $\text{IMAGINE}_{\text{text}\&\text{image}}$.

Abstractive Text Summarization The results in Table 2 demonstrate the system-level Pearson correlation with human judges when incorporating our IMAGINE similarity into existing automatic NLG metrics on the DUC2004 and GigaWord datasets. In alignment with the observations made in the machine translation task, the addition of both $\text{IMAGINE}_{\text{image}}$ and $\text{IMAGINE}_{\text{text}\&\text{image}}$ results in an improvement in Pearson correlation across all metrics. On the two summarization datasets, we notice that the correlation after incorporating $\text{IMAGINE}_{\text{image}}$ exhibits higher mean values along with larger variances compared to the correlation with $\text{IMAGINE}_{\text{text}\&\text{image}}$.

Open-ended Text Generation For the sentence completion task, we conduct evaluations in two setups. In the reference-based evaluation, we com-

pare the predicted sentence ending with the ground-truth ending provided in the dataset. In reference-free evaluation, we compare the predicted sentence ending with the input context. This setup is designed to assess the coherence of the prediction with the input context, as it is hypothesized that a high-quality prediction for open-ended text generation should be consistent with the input context.

The results of extending our IMAGINE similarity metric to existing automatic NLG metrics for the sentence completion task on the ActivityNet dataset are shown in Table 3. In the reference-based setting, both IMAGINE variants demonstrate improvement over the listed metrics and exhibit comparable performances. In the reference-free setting, the introduction of $\text{IMAGINE}_{\text{text}\&\text{image}}$ continues to enhance the Pearson correlation, while the implementation of $\text{IMAGINE}_{\text{image}}$ results in a decrease in correlation. One possible reason for the decline in correlation when $\text{IMAGINE}_{\text{image}}$ is used in the reference-free setting of the sentence completion task on ActivityNet (which is comprised of video captions) is that, despite the requirement for the predicted continuation to be coherent with the given context, the visual representation of the context and continued text may differ greatly in this scenario (e.g., due to a plot twist in the video). Consequently, direct comparison of images through $\text{IMAGINE}_{\text{image}}$ may result in a decrease in correla-

tion. However, the inherent coherence between the input text and the continued text may be captured through cross-modal comparison, which may explain why $\text{IMAGINE}_{\text{text}\&\text{image}}$ still improves the correlation for the listed metrics.

5.2 Performance Analysis

Why is ImagineE helpful? As shown in Tables 1 to 3, the incorporation of certain variants of IMAGINE improves the correlation between the reference-based and reference-free metrics and human scores in the majority of cases. This indicates the usefulness of extending text-only metrics with multi-modal knowledge. However, how do these machine imaginations actually help text understanding and evaluation? In this section, we further explore how and why IMAGINE works. We first provide a case study to show the uniqueness of IMAGINE over text-based metrics, then systematically analyze the effectiveness of our method from different perspectives.

Case Study Figure 3 shows an example in which IMAGINE effectively detects the dissimilarity in keywords between two text snippets. Despite the similarity in sentence structure between the reference and hypothesis, the crucial distinction lies in the inclusion of the terms “manager” and “ladder”. While traditional automatic metrics that rely on n -grams matching (BLEU, ROUGE) or textual embedding comparison (BERTScore, BLEURT) may exhibit high scores, the quality of the generated text remains questionable. In contrast, IMAGINE generates distinctive images and exhibits a relatively low cross-modal similarity score, which aligns with human perception.

Metric	Original	+IE _i (dVAE)	+IE _i (BigGAN)	+IE _i (VQ-GAN)	+IE _i (SD)
ROUGE-1	13.7	15.9 ± 0.9	15.7 ± 1.0	15.9 ± 0.8	16.8 ± 1.3
ROUGE-2	9.7	14.9 ± 1.2	14.6 ± 1.3	14.9 ± 1.0	15.7 ± 1.7
ROUGE-L	13.1	16.0 ± 1.0	15.8 ± 1.1	16.0 ± 0.9	16.4 ± 1.5

Table 4: The Pearson correlations with human judges when using $\text{IMAGINE}_{\text{image}}$ (IE_i) to augment ROUGE-1/2 and ROUGE-L on DUC2004. We compute four sets of $\text{IMAGINE}_{\text{image}}$ similarity scores (mean±std) with dVAE, BigGAN, VQGAN, and StableDiffusion (SD).

	dVAE	BigGAN	VQGAN	StableDiffusion
Entity Recall	88.8%	41.2%	87.2%	94.1%

Figure 4: An example caption from Flickr30k Entities, and images rendered by dVAE, BigGAN, VQGAN and StableDiffusion. The bounding boxes point to the visualizations of the entities marked in the same color.

Sensitivity to Different Image Generation Backbones

In previous sections, we utilize StableDiffusion (Rombach et al., 2022) as the image generation backbone for IMAGINE. Here, we examine the influence of the image generation backbone on the evaluation performance of IMAGINE by conducting experiments on the DUC2004 dataset for summarization and comparing StableDiffusion with three alternative models: dVAE (Ramesh et al., 2021), BigGAN (Brock et al., 2019), and VQGAN (Esser et al., 2021). The results, as shown in Table 4, indicate comparable performance of $\text{IMAGINE}_{\text{image}}$ with dVAE and VQGAN, both of which outperform BigGAN across all metrics. StableDiffusion achieves the highest mean value, but also displays the largest variance among the models. These findings highlight the significance of considering the image generation architecture when evaluating text, as it can result in varying machine-generated images and affect the final evaluation outcomes.

Reliability of Machine-Generated Images

The reliability of IMAGINE’s visualization capability is further evaluated on the Flickr30k Entities dataset (Plummer et al., 2015), which consists of annotated image captions. We randomly sample

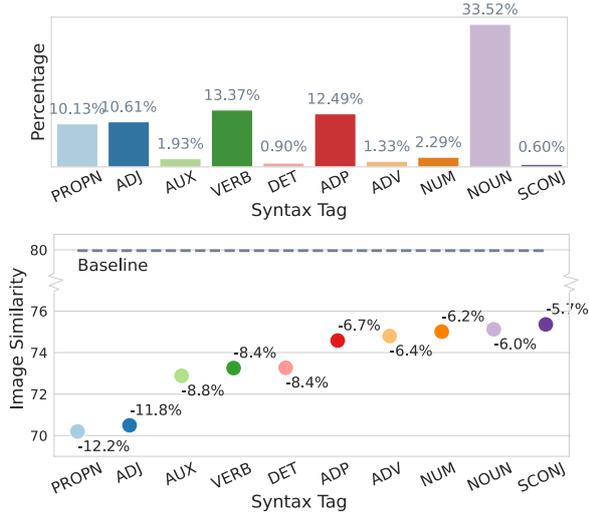

Figure 5: The influence on visualization when masking tokens of different syntax tags. Upper: The occurrence frequency of each syntax tag in DUC2004. The top-10 syntax tags that have the most significant impact on visualization are listed here.

100 captions and use the four generative backbones to render images. We present the captions and generated images to human annotators, and ask them to indicate if the entities mentioned in the captions are visually represented. The results, in terms of entity recall rates, are presented in Table 5. A higher recall rate indicates that the text-to-image generator is more capable of visualizing the content described in the text. The results show that StableDiffusion has the highest entity recall rate of approximately 94%, followed closely by dVAE and VQGAN. In contrast, BigGAN has the lowest recall rate of around 41%. An example of entity recall for a set of images generated by the four generative backbones is shown in Figure 4.

Syntax Importance to Machine-Generated Images

We evaluate the significance of different syntax tokens in the image generation process using the DUC2004 summarization dataset. We utilized the Stanza (Qi et al., 2020a) part-of-speech (POS) tagger to parse the text and created ablated examples by masking out a token of a specific syntax tag.⁴ The visual similarity of the images generated from the ablated examples is then compared to the visualization of the original text. The results, as reported in Table 5, indicated that the re-

⁴We report Universal POS tags in this study: <https://universaldependencies.org/u/pos/>

POS Tag	10 Most Frequent Tokens
NOUN	president, minister, government, space, party, station, budget, game, right, arrest
PROPN	U.S., Clinton, China, Korea, Gaza, Microsoft, Congo, Israel, Livingston, Lebanon
ADJ	new, prime, Russian, international, Asian, possible, Cambodian, first, human, economic

Table 6: The most frequent NOUN, PROPN, and ADJ tokens in DUC2004.

moval of PROPN and ADJ tags has a significant impact on the visualization results, resulting in a 12% decrease in visual similarity. Conversely, removing NOUN tokens has a comparatively smaller effect. The most frequent NOUN, PROPN, and ADJ tokens in the DUC2004 dataset were listed in Table 6. For DUC2004 built upon new clusters, PROPN and ADJ tokens cover concrete concepts such as nations, corporations, and celebrities, while NOUN tokens involve more abstract concepts such as government, party, and right. For this particular dataset, our IMAGINE approach pays more attention to PROPN and ADJ tokens that are easier to visualize by nature. Further analysis for other dataset domains can be found in the Appendix.

Which IMAGINE Variant to Report? From Tables 1 to 3, we can see a mixed trend of performance between the two IMAGINE variants. In general, $IMAGINE_{text\&image}$ has smaller variances among repeated runs. Nevertheless, we would still suggest reporting both IMAGINE variants since they conduct comparisons from different aspects, with $IMAGINE_{image}$ comparing similarity within the visual modality, while $IMAGINE_{text\&image}$ compares cross-modal similarity.

IMAGINE as a Standalone Metric Table 7 presents the Pearson correlation with human evaluations on each dataset when utilizing the two IMAGINE variants as standalone metrics. The results reveal that both IMAGINE variants demonstrate a lower correlation compared to other metrics as reported in Tables 1 to 3. Additionally, the scores produced by IMAGINE are not determinate, given the probabilistic nature of text-to-image models that generate various images with different random seeds. Hence, IMAGINE may not be an optimal choice as a standalone metric. Nonetheless, it is important to emphasize the capability of IMAGINE in introducing multimodal aspects to traditional text-only metrics. In this study, integrating IMAG-

	IWSLT'14	WMT'19	DUC2004	GigaWord	AN(w/ ref)	AN(w/o ref)

Table 7: The Pearson correlation between IMAGINE variants and human assessments on each dataset. Here we use $IMAGINE_{image}$ (IE_i) and $IMAGINE_{text\&image}$ (IE_{t&zi}) as two individual metrics. AN: ActivityNet, “w/ ref”: reference-based, “w/o ref”: reference-free.

INE with text-only metrics leads to an improvement in the Pearson correlation with human evaluations. Future work may explore alternative methods of integrating multimodal information in text evaluation.

6 Conclusion

We present IMAGINE, a novel automatic evaluation metric for NLG that is based on machine imagination. Our experiments on five datasets across three different NLG tasks demonstrate the potential of incorporating IMAGINE similarity scores as a supplement to existing automatic NLG metrics, which can lead to improvement in their correlation with human evaluations in various scenarios. In the future, it is interesting to explore effective ways of visualizing abstract concepts, and how to incorporate machine imagination efficiently. We hope our work can contribute to the discussion and advancement of multi-modal studies.

Limitations

The current limitations of IMAGINE include the length constraint of the CLIP text encoder, which is limited to 77 BPE tokens (including [BOS] and [EOS]), thus limiting its applicability to longer text generation tasks such as story generation or document summarization. As a metric that relies on “machine imagination”, IMAGINE is limited by the inherent limitations of the generative models for images. The non-determined nature of machine-generated images can lead to non-determined IMAGINE scores. Possible solutions to mitigate this issue includes but are not limited to fixing the random seeds or repeating the evaluation process several times to reduce the variance effect. Additionally, it remains a challenge for machines to properly visualize certain abstract concepts or numerical values, which could limit the scope of IMAGINE’s applicability.

Ethical Statement

Our study has received IRB exempt status and the estimated hourly wage paid to MTurk annotators is \$12. It is important to note that our “imagination” approach may raise questions of fairness if the training dataset for CLIP or StableDiffusion contains any biases. This could result in a tendency for IMAGINE to generate certain types of images based on what it has seen in the training data. While we did not observe such issues in our study, it is important to consider that such unfair behavior would undermine the effectiveness of IMAGINE as an evaluation tool.

All of the datasets used in our study on machine translation, abstractive text summarization and open-ended text generation tasks are publicly available. We use the public repositories to implement IMAGINE. The implementations of image generators used in our study are DALL-E(dVAE+CLIP),⁵ Big-Sleep(BigGAN+CLIP),⁶ VQGAN+CLIP,⁷ and StableDiffusion.⁸

A Appendix

A.1 Score Distributions

In this study, we use cosine similarity to evaluate the similarity between features, which yields a score distribution in the range of $[-1, 1]$. However, our results indicate that negative scores were not observed when computing the similarities between the features generated by CLIP. The score distributions of the two IMAGINE variants are depicted in Figure 6. Prior to re-scaling, the scores generated by $\text{IMAGINE}_{\text{image}}$ typically fall within the range of $[0.1, 0.4]$, while those generated by $\text{IMAGINE}_{\text{text}\&\text{image}}$ are within $[0.1, 1.0]$. Following re-scaling, both IMAGINE metrics are linearly transformed to lie within the range $[0, 1]$.

(a) Before re-scaling

(b) After re-scaling

Figure 6: The score distributions of $\text{IMAGINE}_{\text{image}}$ and $\text{IMAGINE}_{\text{text}\&\text{image}}$ before and after re-scaling.

A.2 Syntax Importance to Imaginations

In Section 5.2, we discussed the impact of DUC2004 Part-of-Speech (POS) tags on the quality of generated images. In this section, we extend our examination to another dataset domain, the Flickr30k Entities dataset (Plummer et al., 2015), which is an image captioning corpus. While the domain of the Flickr30k Entities dataset is distinct from that of the DUC2004 (based on news articles), similar trends are observed. The results displayed in Figure 7 also suggest that concrete concepts are easier to be visualized and play a more significant role in the visualization process, similar to the results observed in Figure 5.

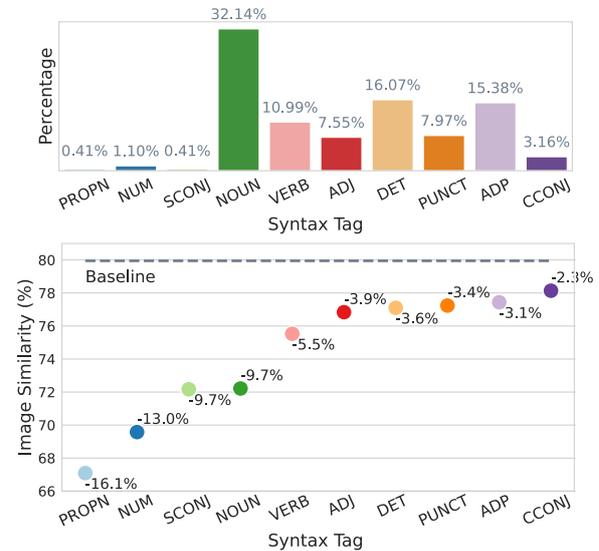

Figure 7: The influence on visualization when masking tokens of different syntax tags. Upper: The occurrence frequency of each syntax tag in Flickr30k. Lower: The relative image similarity decrease after masking each syntax tag. Baseline: The average intra-group pairwise image similarity. The top-10 syntax tags that have the most significant impact on visualization are listed here.

Entity-Aware Dual Co-Attention Network for Fake News Detection

Abstract

Fake news and misinformation spread rapidly on the Internet. How to identify it and how to interpret the identification results have become important issues. In this paper, we propose a Dual Co-Attention Network (Dual-CAN) for fake news detection, which takes news content, social media replies, and external knowledge into consideration. Our experimental results support that the proposed Dual-CAN outperforms current representative models in two benchmark datasets. We further make in-depth discussions by comparing how models work in both datasets with empirical analysis of attention weights.¹

1 Introduction

The development of the Web and social media platforms helps us obtain news quickly, but also provides a gateway for spreading false information. The impact of false information is wide, and the spread speed might be even faster than the actual one (Vosoughi et al., 2018). For example, fake news is proven empirically to influence the 2016 U.S. presidential election (Bovet and Makse, 2019; Grinberg et al., 2019; Budak, 2019). Given the impact of false information, previous studies paid a lot of effort to detect it from different aspects, including (1) news content only (Santos et al., 2020; Kim and Ko, 2021), (2) the combination of news articles and social media replies (Li et al., 2020; Lu and Li, 2020), and (3) additional publisher/user information (Long et al., 2017; Yuan et al., 2020; Del Tredici and Fernández, 2020). In this work, we focus on using both news contents and social media replies, and further add external knowledge to enhance the model’s ability to capture critical entities.

Named entities play an important role in document understanding and influence text generation

¹Code repository: <https://github.com/SinHanYang/Dual-CAN>

performances (Narayan et al., 2021, 2022). Inspired by this notion, we design a novel model, named Dual Co-Attention Network (Dual-CAN), which takes entities’ descriptions into consideration to enhance the background knowledge of the model. The proposed Dual-CAN is modified based on one of the representative fake news detection models, dDEFEND (Shu et al., 2019a). There are three major improvements in the proposed Dual-CAN: (1) Inspired by Hu et al. (2021), we add entities’ descriptions for enhancing the performance. (2) Instead of using LSTM-based architectures (Shu et al., 2019a; Lu and Li, 2020), we adopt attention architecture (Vaswani et al., 2017) as the backbone. (3) We further tailor-made a co-attention layer for comparing the given news article with entity descriptions. In sum, in addition to adopting entity descriptions from Wikipedia, we design a new architecture to fusion all information. Our main contribution is providing a novel model for fake news detection and pointing out a new direction for enhancing performance.

2 Related Works

Previous works in fake news detection mainly focused on two aspects: news content based and social context based. Rashkin et al. (2017) focus on the linguistic characteristics of the news content to detect fake news, and find that fake news often contain specific kinds of words. Ma et al. (2016) use recurrent neural networks (RNN) to learn the hidden representations from the contextual information of relevant posts over time. Monti et al. (2019) analyze social graph and user profile to predict fake news. Shu et al. (2019b) find that user profile features are useful in fake news detection. Shu et al. (2019a) and Lu and Li (2020) use co-attention model to leverage news content and social context. Their models not only have better performance but also provide interpretability to their models. Several works also use external

knowledge to improve model’s predictions. Wang et al. (2020) and Hu et al. (2021) use entity linking method to capture entity descriptions and leverage them in their models. Inspired by these works, we use external knowledge for entities to enhance performance, and use both news content and social media context in the proposed model.

3 Method

Figure 1 shows the architecture of the proposed Dual-CAN. This section describes the details of the proposed Dual-CAN model, which is composed of five components.² The first one is *news content encoder*, which employs word-level attention network and sentence-level encoder to generate features for the corresponding news contents. The second is *entity description encoder*. For each entity in news content, entity description encoder grabs its descriptions from the external knowledge base and creates features to represent them. The third is *user engagement encoder*, which employs the same method as *news content encoder* to create features to represent user comments. The fourth is *dual co-attention component*, which captures the relation between (news content, entity description) and (news content, user engagement) pairs. The last is *prediction component*, which combines all information from the previous components to make the final predictions.

3.1 News Content Encoder

A news story is composed of a sequence of sentences $\mathbf{S} = [s_1, s_2, \dots, s_N]$, and a sentence is composed of up to M words $s_i = [w_{i1}, w_{i2}, \dots, w_{iM}]$. Here, N is the maximum number of sentences in a piece of news, and M is the maximum number of words in a sentence. We perform padding to control the maximum number of sentences and words in news content. To create features to represent a news story, we use *word-level attention network* to encode each sentence, and use *sentence-level encoder* to encode all sentences in news content.

3.1.1 Word-Level Attention Network

We use Glove (Pennington et al., 2014) to create word embedding of d dimensions during the pre-processing stage for each word in sentences. For a sentence $s \in \mathbb{R}^{d \times M}$, we utilize bi-directional Gating Recurrent Units (GRU) (Chung et al., 2014) to learn the word-level representation. The output

²The hyperparameters are reported in Appendix B.

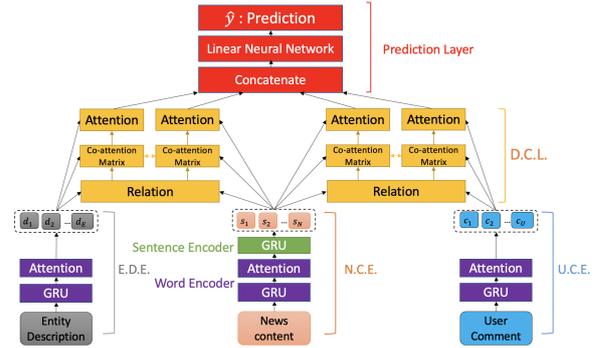

Figure 1: Architecture of Dual-CAN. D.C.L., E.D.E., N.C.E., and U.C.E. stand for dual co-attention layer, entity description encoder, news content encoder, and user comment encoder, respectively.

of the BiGRU is $\mathbf{v}_i = BiGRU(w_i) \in \mathbb{R}^{2h}, i \in \{1, 2, \dots, M\}$, where h is the dimension of the GRU. Next, we perform the basic attention mechanism to increase performance and interpretability (Lu and Li, 2020) of the word encoder. Attention weight α_i shows the importance of the i th word. The word-level attention network generates the representation of a sentence vector $\mathbf{v}' \in \mathbb{R}^{2h \times 1}$ calculated as follows:

$$\mathbf{v}' = \sum_{i=1}^M \alpha_i \mathbf{v}_i \quad (1)$$

where α_i is:

$$\mathbf{k}_i = \tanh(\mathbf{P}_n \mathbf{v}_i + \mathbf{b}_n) \\ \alpha_i = \frac{\exp(\mathbf{u}_n \mathbf{k}_i)}{\sum_{j=1}^M \exp(\mathbf{u}_n \mathbf{k}_j)} \quad (2)$$

$\mathbf{P}_n \in \mathbb{R}^{2h \times h}$, $\mathbf{u}_n \in \mathbb{R}^{h \times 1}$ are learnable parameter. We perform a linear layer on \mathbf{v}_i , and use a parameter \mathbf{k}_j to calculate the attention weight.

3.1.2 Sentence-Level Encoder

We use BiGRU again to encode sentences in a news story. A sentence vector $s_i \in \mathbb{R}^{2h \times 1}$ is calculated from the output of *word-level attention network*:

$$s_i = BiGRU(\mathbf{v}'_i), i \in \{1, 2, \dots, N\} \quad (3)$$

Finally, single news content is represented by a list of sentence vectors $\mathbf{S} = [s_1, s_2, \dots, s_N] \in \mathbb{R}^{2h \times N}$.

3.2 Entity Description Encoder

For each news content, we identify entities in it and grab their descriptions from Wikipedia using tools TAGME (Ferragina and Scaiella, 2010). For each entity description, we only use the first E

sentences. With the word-level attention network in Section 3.1.1, we create features that describe entity descriptions $\mathbf{D} = [\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_E]$. Finally, entity descriptions for a piece of news is represented by a list of sentence vectors $\mathbf{D} = [\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_E] \in \mathbb{R}^{2h \times E}$.

3.3 User Comment Encoder

For all user comments related to a news story, we only use the first U sentences. We extract features to describe user comments $\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_U]$ with the word-level attention network in Section 3.1.1. Finally, user comments for a news story are represented by a list of sentence vectors $\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_U] \in \mathbb{R}^{2h \times U}$.

3.4 Dual Co-Attention Component

Because we want to know whether the entity description confirms/refutes the news content and whether user comments reflect the character of the news content, we adopt co-attention network for capturing the relationship between news content and entity descriptions, and another co-attention network for linking the relationship between news content and user comments. Given news content feature vectors $\mathbf{S} = [\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_N] \in \mathbb{R}^{2h \times N}$, entity description feature vectors $\mathbf{D} = [\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_E] \in \mathbb{R}^{2h \times E}$, and user comments feature vectors $\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_U] \in \mathbb{R}^{2h \times U}$, we use *dual co-attention mechanism* for interpreting model predictions.

3.4.1 Entity Description Co-attention

First, we compute a relation matrix \mathbf{F}

$$\mathbf{F} = \tanh(\mathbf{D}\mathbf{W}_r\mathbf{S}) \in \mathbb{R}^{E \times N} \quad (4)$$

to capture the relationship between news content and entity descriptions, where $\mathbf{W}_r \in \mathbb{R}^{2h \times 2h}$ is a learnable parameter. Second, we calculate interaction maps for news content H_s and entity description H_c ,

$$\begin{aligned} \mathbf{H}_s &= \tanh(\mathbf{W}_s\mathbf{S} + \mathbf{W}_d\mathbf{D}\mathbf{F}^T) \\ \mathbf{H}_d &= \tanh(\mathbf{W}_d\mathbf{D} + \mathbf{W}_s\mathbf{S}\mathbf{F}) \end{aligned} \quad (5)$$

where $\mathbf{W}_s, \mathbf{W}_d \in \mathbb{R}^{2h \times 2h}$ are learnable parameters. Third, we calculate attention weights on each sentence in news content and entity descriptions.

$$\begin{aligned} \mathbf{a}_{s_1} &= \text{softmax}(\mathbf{w}_{hs}\mathbf{H}_s) \\ \mathbf{a}_d &= \text{softmax}(\mathbf{w}_{hd}\mathbf{H}_d) \end{aligned} \quad (6)$$

where \mathbf{w}_{hs} and $\mathbf{w}_{hd} \in \mathbb{R}^{1 \times 2h}$ are learnable parameters. After we get attention weights $\mathbf{a}_{s_1} \in \mathbb{R}^{1 \times N}$, $\mathbf{a}_d \in \mathbb{R}^{1 \times E}$, we generate new feature vectors for news contents and entity descriptions:

$$\begin{aligned} \hat{\mathbf{s}}_1 &= \mathbf{a}_{s_1}\mathbf{S}^T \\ \hat{\mathbf{d}} &= \mathbf{a}_d\mathbf{D}^T \end{aligned} \quad (7)$$

Finally, we represent news content in a feature vector $\hat{\mathbf{s}}_1 \in \mathbb{R}^{1 \times 2h}$, and entity descriptions in a feature vector $\hat{\mathbf{d}} \in \mathbb{R}^{1 \times 2h}$.

3.4.2 User Comment Co-attention

We apply co-attention model as shown in Section 3.4.1 to news content and user comments. We represent news content in a feature vector $\hat{\mathbf{s}}_2 \in \mathbb{R}^{1 \times 2h}$, and user comments in a feature vector $\hat{\mathbf{c}} \in \mathbb{R}^{1 \times 2h}$. The attention weights vector for news content and user comments are $\mathbf{a}_{s_2} \in \mathbb{R}^{1 \times N}$ and $\mathbf{a}_c \in \mathbb{R}^{1 \times U}$.

3.5 Prediction Component

Our task is a binary classification task with real/fake labels. First, we concatenate all feature vectors $\mathbf{f} = [\hat{\mathbf{s}}_1, \hat{\mathbf{d}}, \hat{\mathbf{s}}_2, \hat{\mathbf{c}}]$, and feed the result into a 2-layer linear neural network. It is calculated by:

$$\hat{y} = \mathbf{W}_2(\mathbf{W}_1\mathbf{f} + \mathbf{b}_1) + \mathbf{b}_2 \quad (8)$$

where \mathbf{W}_1 and \mathbf{W}_2 are learnable parameters and $\mathbf{b}_1, \mathbf{b}_2$ are bias terms. The prediction result $\hat{y} = [y_0, y_1]$ indicates the probabilities of label 0 is y_0 , and label 1 is y_1 . We choose cross entropy as our loss function:

$$\mathcal{L}(\theta) = -y \log(\hat{y}_1) - (1 - y) \log(1 - \hat{y}_0) \quad (9)$$

where θ is all parameters in our model. We choose Adam optimizer (Kingma and Ba, 2014) to optimize all parameters θ .

4 Experiments

4.1 Datasets

We adopt two datasets in our experiment. The first dataset is GossipCop (Shu et al., 2018), which collects both news content and social context from fact-checking website. The second dataset is CoAID (Cui and Lee, 2020), which is a benchmark dataset for COVID-19 misinformation. Please refer to Appendix A for the statistics of the datasets. We follow the evaluation settings as previous studies (Shu et al., 2018; Cui and Lee, 2020) to use (Accuracy, F1, Precision, Recall) for *GossipCop* and use (PR-AUC, F1, Precision, Recall) for *CoAID*.

Model (Input) (# of Parameters)	Accuracy	GossipCop			CoAID			
		F1	Precision	Recall	PR-AUC	F1	Precision	Recall
BiGRU (N+C+E) (28M)	0.580	0.367	0.290	0.500	0.876	0.782	0.769	0.804
BERT (N+C+E) (339M / 110M)	0.787	0.776	0.787	0.771	0.940	0.877	0.901	0.859
RoBERTa (N+C+E) (384M / 125M)	0.894	0.890	0.896	0.887	0.918	0.877	0.901	0.859
LinkBERT (N+C+E) (330M / 110M)	0.824	0.811	0.841	0.802	0.927	0.880	0.903	0.863
dEFEND (N+C) (5M)	0.771	0.758	0.771	0.754	0.749	0.799	0.792	0.808
Dual-CAN (N+E) (33M)	0.895	0.891	0.901	0.885	0.853	0.884	0.905	0.868
Dual-CAN (N+C) (33M)	0.914	0.912	0.913	0.911	0.937	0.887	0.907	0.872
Dual-CAN (N+C+E) (33M)	0.949	0.947	0.946	0.949	0.954	0.884	0.905	0.868

Table 1: Experimental results. N, C, and E denote news content, user comments, and entity description, respectively. BERT-based models are implemented in two methods (details in Appendix B) with different number of parameters.

4.2 Results

We compare the results with the following representative models: BiGRU (Chung et al., 2014), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), LinkBERT (Yasunaga et al., 2022), and dEFEND (Shu et al., 2019a).³ Table 1 shows our experimental results. Our Dual-CAN outperforms all baselines in both datasets. In addition, our Dual-CAN uses fewer parameters than BERT-based models. Our approach also performs better than dEFEND (Shu et al., 2019a) when no entity descriptions are provided. This is because we use different preprocessing methods, and the differences between two model architectures. The bottom half of Table 1 shows ablation analysis of the proposed model. The results indicate the importance of adding entity information to the proposed model, especially in *GossipCop*. However, only a few improvements in PR-AUC when experimenting with *CoAID*. *CoAID* usually are short posts that contain few entities, which results in the limitation of the proposed entity-aware concept. The main source to predict whether a piece of news is fake is the news content itself. Therefore, N+E, N+C, and N+C+E results only have small differences because they both contain N. The roles of C and E are to improve the predictions.

5 Interpretability

We examine attention weights $[a_{s_1}, a_d, a_{s_2}, a_{s_c}]$ to find those sentences that the proposed model is focusing on when making predictions. Figure 2 illustrates the results. We find that our model pays a certain degree of attention to the first sentence in the entity descriptions of both datasets (Figure 2a,2c).

³Because Shu et al. (2019a) did not release the information for dataset separation, we use the same hyperparameter reported in their work to reproduce the results. All implemental details are provide in Appendix B

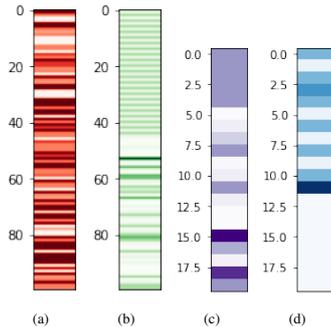

Figure 2: Attention weights of: (a) *GossipCop* entity description, (b) *GossipCop* user comments, (c) *CoAID* entity description, and (d) *CoAID* user comments. Dark colors means higher attention weights. The vertical axis means the index of the sentence.

Our intuition about this phenomenon is that the first sentence always provides a brief definition of the entity, and it would be helpful for models to understand the given entity. On the other hand, model’s attention weights on user comments of both datasets are in the middle replies, as shown in Figure 2b and Figure 2d. It follows our intuition because the sentences like “FYI. It’s a fake news.” for clarifying the given news/post is fake news always appears later than some discussions. Based on Figure 2d, we also find that models give little attention weight to the twelfth or later sentences. Besides weight distributions studies, we also did some case studies in Appendix C. The results show that attention weights do reflect the important parts of the input, which help us interpret the model better. For example, we understood the importance and usage of entity descriptions from attention weights.

6 Conclusion

We propose a dual co-attention network for fake news detection, which improves the previous representative model, dEFEND, by (1) adding entity

description as external knowledge and (2) redesigning co-attention architecture for using all input information. Our results support the usefulness of the proposed Dual-CAN model. The interpretability based on the attention weight is also discussed.

Limitations

The major limitation of the proposed model is that when the given text (news article or social media post) is short, and the performance of adding entity description may not be significantly improved. It is because such text provides few entities in the narrative, and it will limit the proposed entity-aware concept.

Ethical Statement

We will follow the licenses of GossipCop (Shu et al., 2018) and CoAID (Cui and Lee, 2020) to share the training, development, and test datasets in our experiments.

and CoAID. Due to the size limits, we cannot upload the dataset via the submission system. Please download it via the following anonymous link: <https://drive.google.com/file/d/1QuZeINFHqy80F1Av5627zTyyVVg7g2HD/view?usp=sharing>.

B Implementation Detail

Below are the implementation details of the baseline models:

- **BiGRU** (Chung et al., 2014): We use Glove 300d for word embedding of news content, entity descriptions and user comments. The word embedding of three resources are feed into BiGRU and concatenate their results $\mathbf{T} = [v_n, v_d, v_c]$. Second, we feed \mathbf{T} into linear neural network described in Section 3.5 to get final result.
- Pretrained language models (**BERT** (Devlin et al., 2019), **RoBERTa** (Liu et al., 2019), **LinkBERT** (Yasunaga et al., 2022)): We adopt three representative pretrained language models for comparison, and implemented in two different ways.

– Method 1

For each experiment, we feed news content, entity descriptions, and user comments into three tokenizers respectively. Afterwards, we feed input id and attention masks of each resource into three pretrained language models respectively. Each pretrained model handles one resource. Finally, we concatenate the outputs of three pretrained models, and pass a linear layer to output probability of two labels \hat{y} . This method is used for *GossipCop* dataset in Table 1.

– Method 2

The number of parameters in **Method 1** is huge, but it’s necessary for *GossipCop* dataset. We tried another method

to reduce the number of parameters. We concatenate all three resources and feed into one tokenizer. Second, we feed input id and attention masks into one pretrained models. The final procedure is same as the previous method. The experiment results for *CoAID* dataset are in Table 1, and the results are better than **Method 1**’s. The experiment results for *GossipCop* dataset is in Table 4. The performances are worse than **Method 1**’s. We believe it’s because *GossipCop* dataset’s data are too long for a single pretrained model. Therefore, we tried **Longformer** (Beltagy et al., 2020) which accept longer input. The performance becomes better, but this methods uses more parameters.

- **dEFEND** (Shu et al., 2019a): dEFEND is one of the representative fake news detection methods. It is based on co-attention model to increase explainability.⁴

Table 2 reports the hyperparameters used in the proposed Dual-CAN. In the ablation study, we remove the original data of entity description E or user comments C, and replace them with padding token <PAD>. Therefore, the model architecture remains the same as Section 3 stated. We have submitted the code for review, and it will be released on GitHub.

C Case Study of Interpretability

We analyzed individual sentences and words which have higher attention weight, in order to figure out the explainability of the attention weight.

For sentence-level analysis, entity descriptions that define an entity would have higher attention weights. Here are two example entity descriptions that have higher attention weights:

1. **{Dataset: GossipCop, id: 587, attention weight: 0.036 >average 0.01}**: “*IMDb (an abbreviation of Internet Movie Database) is an online database of information related to films, television series, home videos,...*”

⁴Because Shu et al. (2019a) did not release the information for dataset separation, we use the same hyperparameter reported in their work to reproduce the results. We will release the datasets for reproduction.

Model (Input) (# of Parameters)	Accuracy	GossipCop		
		F1	Precision	Recall
BERT (N+C+E) (110M)	0.643	0.587	0.645	0.599
RoBERTa (N+C+E) (125M)	0.698	0.631	0.774	0.646
LinkBERT (N+C+E) (110M)	0.702	0.694	0.694	0.693
Longformer (N+C+E) (148M)	0.752	0.742	0.758	0.723

Table 4: **Method 2** experiment results of GossipCop dataset. N, C, and E denote news content, user comments, and entity description, respectively.

2. **{Dataset: CoAID, id: 48, attention weight: 0.182 > average 0.05}**: *“The Centers for Disease Control and Prevention (CDC) is the national public health agency of the United States.”*
3. **{Dataset: CoAID, id: 1304, attention weight: 0.119 > average 0.05}**: *“Getty Images, Inc. is a British-American visual media company and is a supplier of stock images, editorial photography, video and music for business and consumers, with a library of over 477 million assets.”*

Moreover, we can see some correlation between highlighted entity descriptions and news content that contain them. For example, the news sentence which contains entity (2,3), both have higher attention weight than average.

1. **{Dataset: CoAID, id: 48, attention weight: 0.33 > average 0.25}**: *“enters for disease control and prevention, **cdc** twenty four seven, saving lives protecting people centers for disease control and prevention”*
2. **{Dataset: CoAID, id: 1304, attention weight: 0.33 > average 0.25}**: *“**getty images** the antimalarial drug hydroxychloroquine is being widely promoted as a cure for covid-19 but we still lack good data on its true benefits.”*

Case studies indicate that our model performs like it is doing “fact-checking”, which is an useful and important strategy for fake news detection. Meanwhile, entity descriptions are essential for fact-checking. Therefore, with the good usage of entity descriptions, fake news detection can achieve better performance, same as the ablation studies in Section 4.2 shown.

For word-level analysis, we discovered similar results as (Lu and Li, 2020) did. Some fake news contains emotional words or words that catch people’s attention like “Breaking” or “warn”.

CIKQA: Learning Commonsense Inference with a Unified Knowledge-in-the-loop QA Paradigm

Abstract

We propose a new commonsense reasoning benchmark to motivate commonsense reasoning progress from two perspectives: (1) Evaluating whether models can distinguish knowledge quality by predicting if the knowledge is enough to answer the question; (2) Evaluating whether models can develop commonsense inference capabilities that generalize across tasks. We first extract supporting knowledge for each question and ask humans to annotate whether the auto-extracted knowledge is enough to answer the question or not. After that, we convert different tasks into a unified question-answering format to evaluate the models' generalization capabilities. We name the benchmark Commonsense Inference with Knowledge-in-the-loop Question Answering (CIKQA). Experiments show that with our learning paradigm, models demonstrate encouraging generalization capabilities. At the same time, we also notice that distinguishing knowledge quality remains challenging for current commonsense reasoning models.

1 Introduction

Understanding human language requires both language knowledge (e.g., grammar and semantics) and world knowledge, which can be further divided into factual and commonsense knowledge (Katz and Fodor, 1963). Recently, the community has made great progress in helping machines acquire and apply language and factual knowledge. However, how to help machines acquire and infer over commonsense is still unclear. To answer this question, many commonsense reasoning datasets (Roemmele et al., 2011; Sakaguchi et al., 2020; Talmor et al., 2019; Zellers et al., 2019; Lin et al., 2020) have been proposed. Even though they target different knowledge types, modalities, and formats, they often

* This work was done when the second author was visiting HKUST.

follow a standard supervised learning setting that aims at helping machines solve a specific task with training data. However, two limitations of this learning paradigm have restricted the development of commonsense reasoning systems.

First, there is no clear separation between knowledge and inference. As discussed in Elazar et al. (2021), a common phenomenon is that larger training data will lead to better performance, mainly because richer knowledge is covered. However, due to the large scale of commonsense knowledge, it is infeasible to annotate a large enough training set for each task, and the responsibility of the training data should be teaching models how to make inferences rather than acquire commonsense knowledge. Several recent works have explored using structured knowledge for commonsense reasoning tasks (Lin et al., 2019; Lv et al., 2020; Paul and Frank, 2020). However, as these works did not clearly analyze the coverage of the structured knowledge (i.e., knowledge graphs (KGs)), it is still unclear what the performance means, better knowledge coverage, or better inference capability. To investigate what is behind this learning process, we propose to equip each question with auto-extracted knowledge and ask humans to annotate whether the knowledge is sufficient to answer the question. By doing so, we could evaluate whether models can know if the provided knowledge is good or not and how well they can conduct inference over the provided knowledge to solve the task.

Second, supervised learning may force the model to learn the distribution of the training data rather than a universal inference model. As a result, the model may perform well on the test set that follows the same distribution but fail to generalize (Kejriwal and Shen, 2020). Previously, as different tasks have different formats, it is hard to evaluate the generalization ability of commonsense reasoning models. Following the trend of

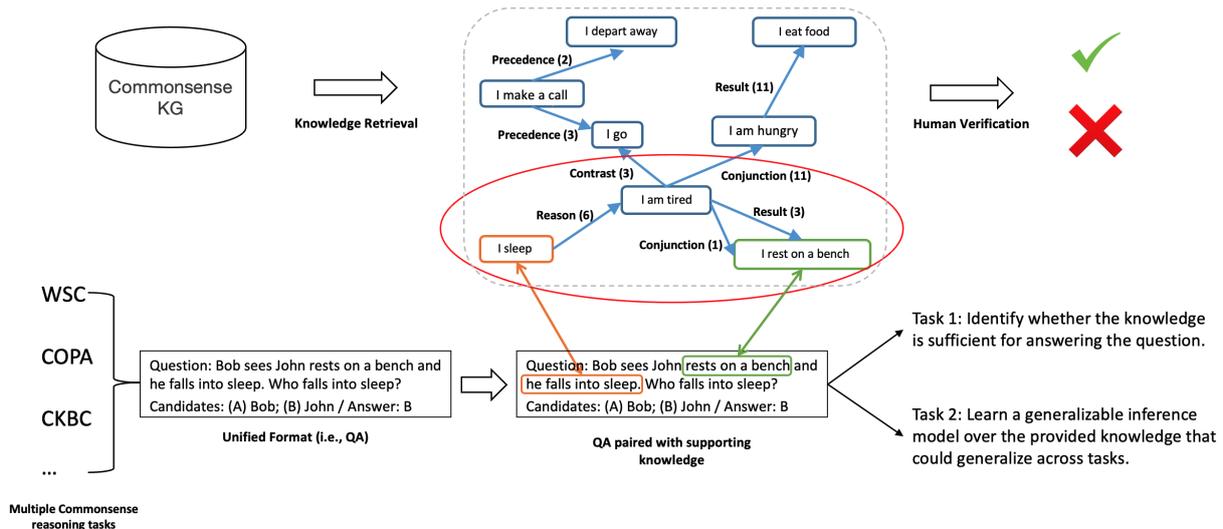

Figure 1: **CIKQA** demonstration. All tasks are converted into a unified format such that we can easily evaluate the generalization capability of all models. We also equip all questions with auto-extracted knowledge graphs from existing KGs and ask humans to annotate whether the knowledge is gold or not. In this example, we expect models to first identify the quality of the knowledge and then conduct inference over the knowledge to solve the question.

using a unified format (i.e., question answering) for different tasks (Khashabi et al., 2020), we propose to convert various commonsense reasoning tasks into a unified QA format such that we can easily and fairly evaluate the generalization ability of learned commonsense reasoning models.

Combining these two lines of effort, we propose a new commonsense inference benchmark Commonsense Inference with Knowledge-in-the-loop QA (**CIKQA**). An example is shown in Figure 1. We first convert several popular commonsense reasoning tasks into a unified QA format and equip them with the relevant knowledge from existing commonsense knowledge graphs. We leverage human annotation to label whether the provided knowledge is correct and enough¹ to answer the question. The **CIKQA** benchmark can motivate us to answer two questions: (1) Whether current models can distinguish the knowledge is gold or not; (2) Can current commonsense inference models generalize across different commonsense reasoning tasks?

Experiments with several recent knowledge-based commonsense reasoning models show that even though current deep models could learn to conduct simple inferences after training with a few examples when gold knowledge is provided, they still cannot learn to distinguish gold knowledge very well. Moreover, although current mod-

¹In the rest of the paper, we denote such knowledge as the gold knowledge.

els demonstrate encouraging generalization ability across the three tasks we consider, they still struggle with complex inference (e.g., abductive reasoning). We hope that our benchmark² can motivate more advanced commonsense inference methods in the future.

2 Dataset Construction

In **CIKQA**, to encourage a generalizable commonsense inference model, we follow previous work (Khashabi et al., 2020; Cohen et al., 2020; Wu et al., 2020; Du and Cardie, 2020) to unify all selected tasks as a binary question answering problem, and equip each question with a supporting knowledge graph G retrieved from existing commonsense KGs. We leverage crowd-sourcing workers to annotate whether the knowledge is gold (i.e., accurate and enough) for answering the question. With that, we can evaluate whether models know how to distinguish gold and knowledge and whether they can learn the generalizable inference with the help of the knowledge. In total, **CIKQA** contains 15 thousand instances from four kinds of commonsense reasoning tasks. Details about task selection, format unification, knowledge extraction, and annotation are as follows.

2.1 Task Selection

In **CIKQA**, we select the following four popular commonsense reasoning tasks:

²Available at <https://github.com/CogComp/CIKQA>.

Task Name	Original Assertion	Transformed Question	Answer
HardPCR	The fish ate the worm. It was hungry.	The fish ate the worm. It was hungry. What was hungry?	(A) Fish ; (B) Worm
CommonsenseQA	What is a place that someone can go buy a teddy bear?	What is a place where someone can go buy a teddy bear?	(A) Toy store ; (B) Shelf
COPA	I drank from the water fountain.	I drank from the water fountain. What was the cause of this?	(A) I was thirsty. ; (B) I felt nauseous.
ATOMIC	PersonX buys the bike.	Before PersonX buys the bike, what did PersonX want?	(A) To be social. ; (B) To have transportation.

Table 1: Demonstration of the original assertion, transformed questions, and answers. Correct and wrong answers are indicated in blue and red, respectively.

1. HardPCR (Zhang et al., 2021): The hard pronoun coreference resolution (HardPCR) task is one of the most famous commonsense reasoning tasks. For each question, a target pronoun and two candidate mentions are provided, and the task is to select the correct mention that the pronoun refers to. Careful expert annotations are conducted to get rid of the influence of all simple linguistic rules, and the models are required to solve the problem with commonsense reasoning. We include instances from WSC (Levesque et al., 2012), DPR (Rahman and Ng, 2012), and WinoGrande (Sakaguchi et al., 2020). To create a question regarding the target pronoun, we first find the sentence that contains the target pronoun and then determine whether the participating pronoun refers to a person or an object.
2. CommonsenseQA (Talmor et al., 2019) is a multiple-choice question answering dataset. For each question-answer pair, four relevant but wrong concepts are used as the other candidates, and the models are required to select the correct one out of five candidates. In **CIKQA**, we randomly sample a negative answer to make it a binary choice task, which is consistent with other datasets.
3. COPA (Roemmele et al., 2011) focuses on evaluating the understanding of event causality. Two follow-up events are provided for a target event, and models are asked to predict the one caused by or the reason for the target event.
4. ATOMIC (Sap et al., 2019): is a commonsense knowledge graph, which we convert into a completion problem. Given a head concept (e.g., “eat food”) and a relation (e.g., “cause”), we want to predict the tail concept, focusing on predicting the edges of ATOMIC.

In COPA and ATOMIC, where the task is to predict the relations between two events or states (e.g., “PersonX eats”-*Causes*-“PersonX is full”), for each triplet, we randomly sample another event or state as the negative tail and ask the model to select the correct one. To make the task challenging and avoid sampling irrelevant events or states, we restrict the sampled negative event or state to be connected with the head of a different triplet (e.g., “PersonX is hungry” from the triplet “PersonX eats”-*CausedBy*-“PersonX is hungry”). For each relation, we write a pattern to generate the question. For example, for the “Causes” relation, we will ask “What can be caused by the event ‘PersonX eats’?”. Examples of instances in the original datasets and their transformed questions and candidate answers are presented in Table 1.

2.2 Supporting Knowledge Extraction

As discussed in Section 1, a limitation of existing commonsense reasoning benchmarks is that there is no clear boundary between knowledge and inference. As such, it is unclear what is learned from the training data, the knowledge, how to perform inference, or a combination of both. We propose to equip each question with supporting knowledge to address this issue and encourage models to learn inference rather than knowledge from the training data. The question is selected as part of the dataset only if we find supporting knowledge to answer the question. Note that this procedure serves as an improved evaluation setup than purely supervised learning and not as a solution to commonsense reasoning. This section introduces the selected commonsense knowledge graphs and then introduces how we extract the corresponding commonsense knowledge for each question.

2.2.1 Commonsense KG Selection

Many commonsense knowledge graphs were developed to enhance machines’ commonsense reasoning abilities, including ConceptNet (Liu and Singh, 2004), ATOMIC (Sap et al., 2019), GLUCOSE (Mostafazadeh et al., 2020), and ASER (Zhang et al., 2020a). Among these four, ConceptNet, ATOMIC, and GLUCOSE were constructed via crowd-sourcing, while ASER was constructed automatically with information extraction techniques. Besides ATOMIC, which is used as one of the tasks, we use the other KBs as supporting knowledge resources.

2.2.2 Supporting Graph Extraction

Here we introduce how to extract the supporting knowledge from external commonsense knowledge bases. For each question, we need to obtain a sub-graph from supporting knowledge graphs to contain the relevant commonsense knowledge about the question. The sub-graph extraction process includes the following three steps: (1) Pre-processing: Convert each question into several key sentences; (2) Matching: Match the sentences into nodes in the KG; (3) Extraction: Retrieve the relevant sub-graphs from the entire KG. In what follows, we give some more details on each of the steps.

Data Pre-processing: For each question and the associated candidate answers, we first replace the question words (e.g., “What”) with the two candidate answers such that they become two declarative sentences. For instance, if the question is “The fish ate the worm. It was hungry. Who is hungry?” and the candidates are “Fish” and “Worm,” we will convert the question into the declarative sentence: “The fish is hungry” and “The worm is hungry.” As a result, we will get three sentences for this question: “The fish ate the worm,” “The fish is hungry,” and “The worm is hungry.”

KG Matching: After getting the declarative sentences containing the question and key answers, we map them to nodes in knowledge graphs to extract the relevant knowledge. Considering that each sentence may have multiple words and it is often hard to find an exact match, we adopt an embedding-based fuzzy matching technique. For each sentence and node in the KG, we treat them as a sentence and get the corresponding representations with SimCSE (Gao et al., 2021). For each input sentence, SimCSE encodes the sentence into a vector. A close distance between two

vectors indicates that the two sentences are similar to each other. We use cosine similarity on the obtained representations to measure the similarity between two sentences.³ Since there are 287 thousand nodes in GLUCOSE and 194 million nodes in ASER, it is computationally infeasible to compute the cosine similarity between sentences pair by pair. Thus we use an approximation. For each extracted sentence, we first apply Faiss (Johnson et al., 2017), a large-scale similarity-based matching algorithm that first clusters all KG nodes in the vector space to increase the matching efficiency when finding the top N nodes in the KG. We encode all the nodes of the graph and index them using Faiss (Johnson et al., 2017). Then, we can perform fast and quick retrieval of the most-similar nodes with each query sentence. After that, we sort the N nodes based on the cosine similarity to find the top K similar nodes. We set N and K to be 60 and 1, respectively. On average, it takes 25 seconds to retrieve the relevant nodes for each question.

Graph Extraction: Next, we extract the sub-graph that contains all the relevant nodes. We denote the extracted m nodes as n_1, n_2, \dots, n_m , and for each of them, we find K similar nodes from the KG. The resulting matched node sets are denoted as $\mathcal{N}_1, \mathcal{N}_2, \dots, \mathcal{N}_m$. For any pair of nodes $n \in \mathcal{N}_i$ and $n' \in \mathcal{N}_j$ ($i \neq j$), if there exists a path in the KG between n and n' , we will keep that path. After adding all paths together, we will get the final sub-graph. On average, constructing a graph for each question takes less than two seconds.

Knowledge Quality Annotation: Since our extraction method is automatic, some of the sub-graphs may be irrelevant or insufficient for answering the questions. We use crowdsourcing to annotate whether the extracted knowledge is gold (i.e., accurate and enough), five per example. The average Inter-annotator agreement (Cohen’s kappa statistic) is 0.83, indicating our annotation’s high quality. In the end, we apply a strict standard (at least four of five annotators need to vote for gold) to select the gold knowledge.

2.3 CIKQA Statistics

We report the dataset statistics in Table 2. In total, CIKQA contains 14,599 instances, among which Hard PCR and ATOMIC provide the most

³We also tried other techniques such as string match, ROUGE (Lin, 2004), and BLEURT (Sellam et al., 2020), but found them to be either inaccurate or too slow for our scale.

Task Name	# Instance by Knowledge Resource			# Total Instance	Avg Sub-graph Size	# Gold Instance
	ASER	ConceptNet	GLUCOSE			
HardPCR	2,030	202	2,143	4,375	2.85	670
CommonsenseQA	530	31	37	598	3.19	59
COPA	103	41	149	293	3.03	78
ATOMIC	5,655	212	3,466	9,333	2.67	2,200
Total	8,318	486	5,795	14,599	2.75	3,007

Table 2: **CIKQA** statistics. “Avg Sub-graph Size” is the average graph size measured by the number of edges. “# Gold Instance” means the number of instances supported by different knowledge resources and annotated gold (i.e., Accurate and Enough) knowledge.

questions because their original datasets are much larger than others. According to the annotation, 20.59% of the instances contain gold knowledge. Based on our analysis, annotators hold a very strict standard for selecting the gold knowledge. We randomly split the dataset into training, development, and testing sets for each task with a standard 8:1:1 splitting. As a result, we get 11,678 training, 1,459 development, and 1,462 testing instances.

3 Experiment Setup

We present the performance of the following commonsense inference models on **CIKQA**:

(1) Vanilla LM: We use the language model (LM) based multiple-choice (MC) model as the basic baseline. For each candidate answer, we concatenate it with the question and feed it to the model. After getting the sentence representation, a linear layer is used to obtain a score and trained with a cross-entropy loss.

(2) KagNet: As one of the pioneering works that utilized structured knowledge for solving commonsense reasoning tasks, KagNet (Lin et al., 2019) first uses a graph convolution network to encode the knowledge graph and then apply an LSTM based hierarchical attention mechanism to encode the knowledge paths that start with the nodes corresponding to the question and end with nodes corresponding to the answer. At the same time, KagNet encodes the question and answers with pre-trained LMs. In the end, it concatenates all representations for the final prediction.

(3) Graph-Based Reasoning (GBR): Instead of only encoding paths starting with the question nodes and ending with answer nodes, in GBR (Lv et al., 2020), they propose to run a depth-first algorithm over the knowledge graph to generate a sequence of paths as the supporting knowledge paths.

(4) Multi-Head Knowledge Attention (MHKA):

To further utilize the knowledge, MHKA (Paul and Frank, 2020) uses a transformer network to model the paths from the question nodes and answer nodes, then concatenates the knowledge and context representation for the final prediction.

(5) Graph-to-Text (G2T): In the end, we also evaluate a simple yet effective approach of combining structured knowledge and language models: Graph-to-Text (Bian et al., 2021), which first verbalizes knowledge into a sentence and then concatenates the knowledge sentence and target question together. On top of that, a transformer-based model is used to encode the input sentence and make the final prediction.

Implementation Details We implement all experiments with Huggingface (Wolf et al., 2019). We select BERT-base (Devlin et al., 2019) as the base language model for all models. The batch size is set to 16. All models are trained for 10,000 steps⁴, and the best-performing checkpoints on the dev set are evaluated. For our model, we set both the number of random walk paths and the walk length to five. Considering that the auto-extracted knowledge could contain noise or miss certain knowledge, we add a “gold knowledge” setting, where only examples with the gold knowledge are used for training and testing, for all models as the upper bound of their model. All other hyper-parameters are the same as the base language model. All models are trained with GTX 2080, and the average running time is 12 hours.

4 Result Analysis

We first conduct analysis experiments to evaluate to what extent the provided knowledge could help existing models. For each model, we train it with different numbers of training instances and report the average performance and standard de-

⁴All models converge at 10,000 steps.

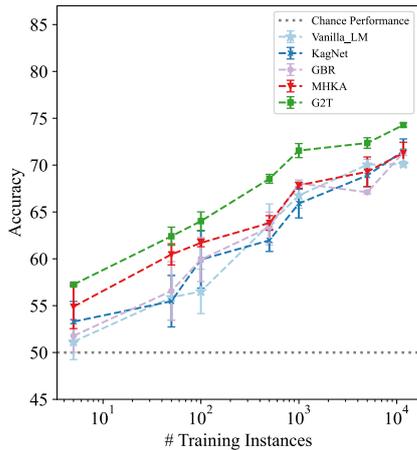

Figure 2: Learning curves of all evaluated models on all instances of **CIKQA**. We evaluate all models with the full dataset.

violation of five trials. Experiment results with all instances and the gold subset of **CIKQA**, where only instances with gold knowledge are used for training and testing, are presented in Figure 2 and 3, respectively. From the results, we can make the following observations. First, when explicitly including the knowledge, all inference models outperform the baseline model with no supporting knowledge, especially G2T. When the auto-extracted and gold knowledge is provided, G2T outperforms the baseline Vanilla LM model by 4.17 and 15.34 accuracy, respectively. It supports our assumption that learning all knowledge from the limited training data is hard, and external structured knowledge could help. At the same time, we also notice a significant gap between auto-extracted knowledge and gold knowledge. For example, if gold knowledge is available, models could learn to answer the questions with only a few examples. This indicates that the knowledge quality can significantly impact models’ performance, which further shows the importance of distinguishing whether the knowledge is gold or not automatically. Last but not least, we can see that G2T outperforms other inference models in most settings, which shows that with the help of current large-scale LMs, jointly encoding questions and knowledge is more efficient and a more effective strategy than acquiring them separately. Due to the simplicity and efficiency of G2T, we will conduct the rest analysis experiments with G2T.

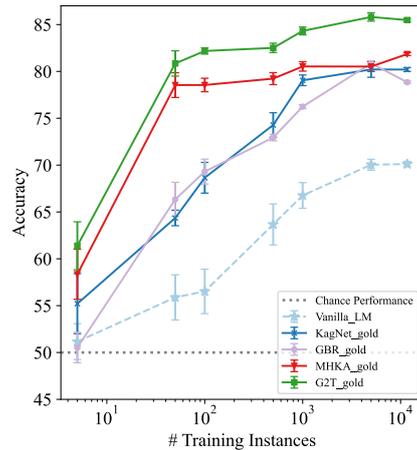

Figure 3: Learning curves of all evaluated models on the gold subset of **CIKQA**, where only instances with gold knowledge are used for training and testing.

4.1 Distinguishing the Gold Knowledge

Humans can say “I do not know” when they find out that they cannot answer a question with their knowledge. To investigate whether current deep models have a similar capability, we use G2T as an example to test whether these deep models can distinguish the gold knowledge. For each (question, answer, and knowledge) triplet, we train and test G2T with annotated knowledge quality labels. To address the imbalanced distribution problem, we randomly select the same number of “Not Gold” examples as the “Gold” ones to make the dataset balanced. From the results in Figure 4, we can see that the performance of G2T can be improved slightly with the increase of training data. However, after seeing thousands of examples, it still can only achieve 0.65 accuracy on a binary classification problem. It shows that knowing when to say “I do not know” is still a challenging task for current deep models, which is consistent with the observations in previous literature that deep models cannot understand the reasons and knowledge they used to answer questions (Zhang et al., 2020b; Sanh et al., 2022). We hope that **CIKQA** could motivate more future work on this important research problem.

4.2 Generalization Ability

An important assumption and motivation behind the unified problem design of **CIKQA** is that even though the commonsense could be enormous, the inference rules over commonsense knowledge can

Training Task	Testing Task			
	Hard PCR	CommonsenseQA	COPA	ATOMIC
Hard PCR	-	37.50 → 52.30	75.00 → 53.24	44.13 → 53.32
CommonsenseQA	50.00 → 50.14	-	62.50 → 56.67	56.34 → 70.56
COPA	45.95 → 51.26	62.50 → 58.33	-	49.77 → 62.96
ATOMIC	39.19 → 50.76	50.00 → 76.67	62.50 → 73.33	-

(a) Full Dataset (Vanilla LM (without knowledge) → G2T (with knowledge))

Training Task	Testing Task			
	Hard PCR	CommonsenseQA	COPA	ATOMIC
Hard PCR	-	46.67 → 51.67	63.33 → 56.67	51.85 → 55.78
CommonsenseQA	49.32 → 50.32	-	50.00 → 75.00	60.39 → 91.08
COPA	52.51 → 54.79	56.67 → 87.50	-	53.01 → 76.06
ATOMIC	50.46 → 51.35	68.33 → 93.75	56.67 → 87.50	-

(b) Gold Subset (Vanilla LM (without knowledge) → G2T (with knowledge))

Table 3: Generalization ability demonstration. We report the performance on both the full dataset and the gold dataset (i.e., only questions with gold knowledge are selected for training and testing) to show the generalization ability. Strong and moderate generalization settings are indicated with the **green** and **orange** background, respectively.

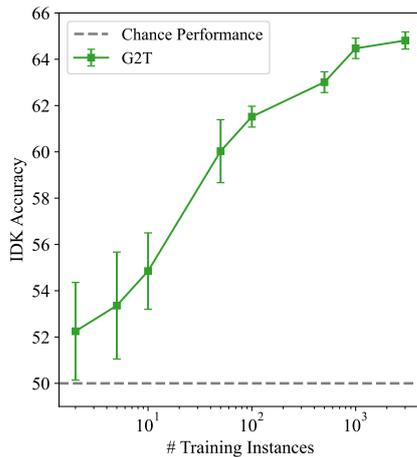

Figure 4: The learning curve of G2T on the gold knowledge identification task.

be limited. As a result, even though we could not learn all the commonsense from limited training data, we can learn how to conduct inference with several tasks and then generalize to others. In this section, we conduct experiments with both the “Without Knowledge” and “With Knowledge” models to show that we can gain such generalization ability across different tasks with our unified formulation. We conduct experiments on two settings: (1) Full Set: We train and test the model with the whole dataset; (2) Gold Subset: We only train and test the model on questions where the supporting graph is annotated as gold. We train the model with questions from a specific task and

test it on all tasks. The results are in Table 3.

From the results, we can see that the knowledge can help models to generalize well among CommonsenseQA, COPA, and ATOMIC. The only exception is HardPCR. This is mainly because the inference needed for solving HardPCR is more complex than the other tasks, where we not only need to find the relevant knowledge but also need to replace the target pronouns with the entity in the provided knowledge. As shown in Figure 5, two paths can be found relevant to question: (1) “I am drunk” → *Co_Occurrence* → “I hit someone”; (2) “I am drunk” → *Co_Occurrence* → “That is not fair” → *Co_Occurrence* → “You kick me”. For the correct inference, we need to know when there is a conflict, we should trust the one-hop inference more because the additional node in the two-hop path may introduce extra noise. As a comparison, for other tasks, the main inference we need is to find the relevant paths, which is relatively easy. How to train a model that can learn to conduct such complex reasoning is a problem worth exploring in the future.

In general, the observed generalization ability is encouraging because if we can learn a good model on **CIKQA**, based on the assumption that there are limited types of inference, we can potentially solve any commonsense reasoning task as long as the needed inference types are covered by **CIKQA**. At the same time, we also notice that models typically generate better when gold knowledge is provided, further proving the importance

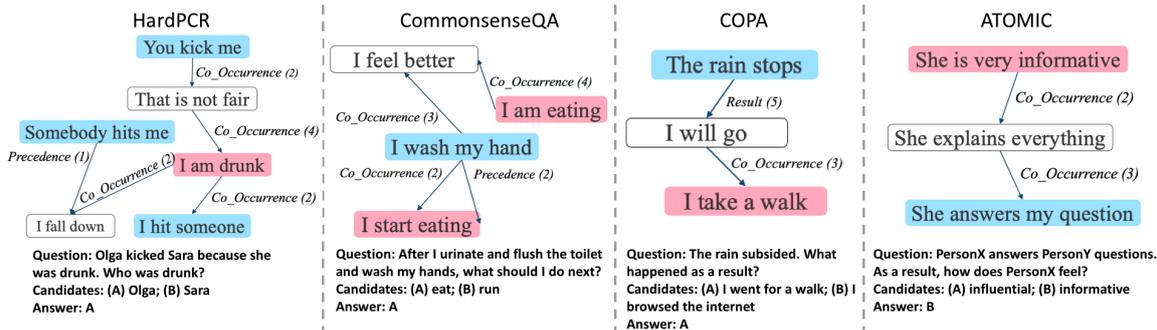

Figure 5: **CIKQA** Case Study. Mapped nodes for the question/answers are in blue/pink. Other nodes are white. Edge weights are in brackets. We only show the relevant parts of the graphs for clear representation.

of the gold knowledge identification task.

5 Related Work

To help machines understand commonsense, the community has devoted great efforts to constructing commonsense knowledge bases with either crowdsourcing (e.g., ConceptNet (Liu and Singh, 2004) and ATOMIC (Sap et al., 2019)) or information extraction techniques (e.g., ASER (Zhang et al., 2020a)). Typically, crowd-sourced knowledge bases are of higher quality, and the auto-constructed ones have broader coverage. Besides acquiring commonsense knowledge, the community also developed many commonsense reasoning datasets to train and test models’ commonsense reasoning abilities. Even though these datasets may have different *formats* (e.g., slot fitting in Winogrande (Sakaguchi et al., 2020) and question answering in CommonsenseQA (Talmor et al., 2019)), *knowledge types* (e.g., causal commonsense in COPA (Roemmele et al., 2011) and numerical commonsense in NumerSense (Lin et al., 2020)), or *modalities* (e.g., visual commonsense in VCR (Zellers et al., 2019) and textual commonsense in many others), they follow a standard supervised learning setting, and aim at helping machines to solve a specific commonsense task in an end-to-end manner. Given this setting, it is often difficult to tell what has been learned during the training. Was it used to acquire commonsense knowledge, learn to conduct commonsense inference, or both? Such ambiguity limits our progress in solving these commonsense reasoning tasks. In this work, we connect the efforts on commonsense acquisition and inference by creating a commonsense inference benchmark **CIKQA**, where models can focus on learning to identify the gold knowledge and perform inference over the sup-

porting commonsense knowledge.

Answering questions in natural language based on a knowledge base (KB) is a mature research topic in the NLP community, which is also known as the KBQA problem (Clark et al., 1999; Yih et al., 2015, 2016; Usbeck et al., 2017; Cui et al., 2017). Previous work mainly focuses on factual knowledge, which is stored in the triplets format. The main challenge is to parse the question and then precisely and effectively identify the correct path over a large-scale KB to make the inference. Compared with inference over factual knowledge, inference over commonsense knowledge brings the following unique challenges: (1) Commonsense is a kind of preference rather than fixed knowledge. As a result, the ideal commonsense reasoning process could involve the comparison of multiple candidates. For example, both “drink coffee” and “drink bear” could happen in the morning, but a normal person will prefer “drink coffee;” (2) Beyond named entities, commonsense knowledge also covers daily entities and events, and thus it is difficult to find an exact node from the commonsense KB that matches the question, and we may need to conduct inference based on the partial match (i.e., the extracted nodes are relevant but not identical).

6 Conclusion

In this paper, we present **CIKQA**, a unified commonsense inference benchmark. Specifically, we first convert several popular commonsense tasks into a unified QA format and then equip each question with a supporting commonsense knowledge graph. We also leverage humans to annotate the quality of auto-extracted knowledge. Experiments show that even though models can better learn how to perform commonsense inference with a few ex-

amples and significantly outperform the baseline method that does not use structured knowledge in the data-scarce setting, identifying the gold knowledge is still a challenging problem. More interestingly, with our unified formulation, models demonstrate the encouraging generalization ability across tasks. As both the format unification and supporting graph extraction are automatic, we can easily extend to other commonsense reasoning tasks in the future.

Limitations

A common limitation of existing semi-parametric models is the coverage of knowledge resources. **CIKQA** also faces this limitation. Based on our analysis, the largest commonsense knowledge bases can still cover part of the questions in existing commonsense benchmarks. How to populate these commonsense knowledge graphs is an important research question in the future.

Data-Efficient Methods For Improving Hate Speech Detection

Abstract

Scarcity of large-scale datasets, especially for resource-impooverished languages encouraged exploration of data-efficient methods for hate speech detection. In this work, we progress *implicit* and *explicit* hate speech detection using an input-level data augmentation technique, task reformulation using entailment and cross-learning across five languages. Our proposed data augmentation technique `EasyMixup`, improves the F1 performance across languages by **0.5-9%**. We also observe substantial F1 gains of **1-8%** by reformulating hate speech detection as `Entailment-style` problem. We further probe the contextual models and observe that higher layers encode *implicit* hate while lower layers focus on *explicit hate*, highlighting the importance of token-level understanding for *explicit* and context-level for *implicit* hate speech detection.¹

1 Introduction

Deep learning based methods (Badjatiya et al., 2017; Zhang et al., 2018; Kshirsagar et al., 2018) have shown impressive results in detecting hate speech. Transformer based models (Caselli et al., 2021; Tekiroğlu et al., 2020; Aluru et al., 2020; Mozafari et al., 2019; Dutta et al., 2022) have further pushed the state-of-the-art by leveraging large amount of unlabeled data in a self-supervised manner. Various hate speech detection datasets have been contributed in textual (Gibert et al., 2018; Davidson et al., 2017; Founta et al., 2018), audio (Gupta et al., 2022) and visual (Gomez et al., 2020) domains. However, these algorithms are data-hungry and motivate development of algorithms which are data-efficient.

To tackle this, we introduce an input-level data augmentation technique `EasyMixup` and improve hate speech detection in monolingual and

multilingual settings. `EasyMixup` is inspired by *mixup* based augmentation techniques which are broadly categorized into input-level mixup (Yun et al., 2019; Kim et al., 2020; Uddin et al., 2021; Walawalkar et al., 2020) and hidden-level mixup (Verma et al., 2019). `EasyMixup` follows the input-level paradigm and leverages a simple observation that the label of a hateful instance is preserved on concatenation with a hateful or non-hateful instance. Similarly, label of a non-hateful instance does not change on concatenation with another non-hateful instance.

We also study the efficacy of reformulating hate speech detection as `Entailment-style` problem. We extend the work by (Wang et al., 2021) and perform detailed experiments under *implicit*, *explicit* and *multilingual* settings. We observe that monolingual entailment performs better than English based entailment. This observation is intuitive because the models are pretrained using pair of sentences from same language and monolingual entailment reflects the same settings.

Majority of the existing textual datasets focus on *explicit* hate speech where *swear*, *cuss*, *abusive* words are used to express the hateful intent. In contrast, *implicit* hate speech employs subtle, indirect and contextual ways for expressing hate speech making it extremely harmful and difficult, as shown in (ElSherief et al., 2021). Acknowledging this difference of expression, we explore the relationship between *explicit* and *implicit* hate speech using cross-learning and observe strong correlations. We also perform probing experiments and observe that lower layers focus on *explicit* hate speech while higher layers are responsible for encoding *implicit* hate speech. This alludes to the hypothesis that *implicit* hate speech is more contextual in nature and requires more understanding, while *explicit* hate speech can be detected by leveraging lower-level information.

In summary, our main contributions are:

*Work done during internship at ShareChat

¹Code and Dataset splits - https://github.com/Sumegh-git/data_efficient_hatedetect

- We propose input-level data augmentation technique `EasyMixup` which outperforms previous methods for our task.
- We show performance gains by reformulating hate speech detection as monolingual `Entailment-style` problem.
- We probe contextual models and observe that higher layers encode *implicit* hate speech while lower layers focus on *explicit hate* speech.
- We show that correlations exist between *explicit* and *implicit* hate speech and leverage that for improving hate speech detection.

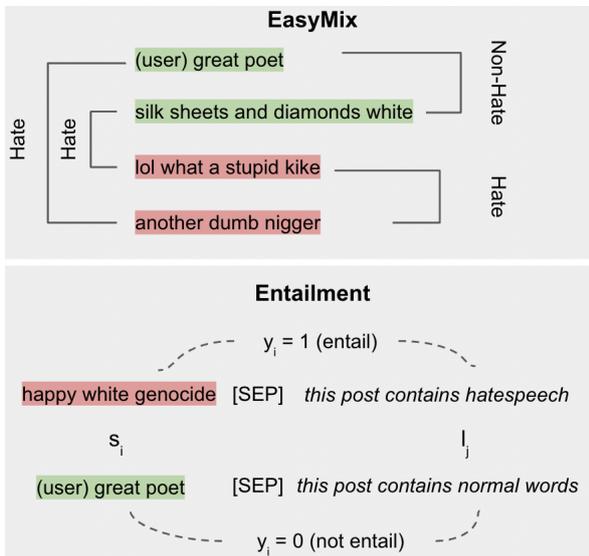

Figure 1: (top) Mixing hateful (red) samples with either hate (red) or non-hate (green) samples doesn't change the final label. Similarly mixing two non-hate (green) samples preserve the final label. (bottom) Posing hatespeech classification as entailment task. [Best viewed in color]

2 Methodology

2.1 EasyMixup

`EasyMixup` is an input-level data augmentation technique where we leverage the observation that ground truth label of a hateful sample does not change on concatenation with another hateful or non-hateful samples. Similarly, concatenation of a non-hate sample with another non-hate sample results in a novel non-hate sample as shown in Figure 1(top). More formally, let's say (s_i, y_i) is the sentence and it's corresponding label $y \in \{hate, non-hate\}$ in a minibatch S and D is the entire

dataset,

$$S = \{(s_0, y_0), (s_1, y_1), \dots, (s_n, y_n) | (s_i, y_i) \in D\}$$

For every sample in the batch, $s_i \in S$, we randomly select $(\bar{s}_i, \bar{y}_i) \in D$ with $\bar{s}_i \neq s_i$ and augmentation probability p_{aug} to create new augmented sample:

$$s_{i_{aug}} = \phi(s_i, \bar{s}_i), y_{i_{aug}} = y_i \vee \bar{y}_i$$

where ϕ is defined as :

$$\phi(s_i, \bar{s}_i) = \begin{cases} \text{concat}(s_i; \bar{s}_i) & \bar{p} > p_{flip} \\ \text{concat}(\bar{s}_i; s_i) & , \text{otherwise} \end{cases}$$

where, p_{flip} is the sentence flipping probability and $\text{concat}()$ refers to concatenation. Flipping introduces more augmentation and prevents the model from learning positional bias. Finally, we get the updated minibatch \bar{S} by replacing original with augmented samples $(s_{i_{aug}}, y_{i_{aug}})$.

2.2 Entailment-style

We reformulate hate speech classification task as an entailment-style task (Wang et al., 2021). The (input, target) for the contextual model is: $(s_i[\text{sep}]l_j, y_i)$, where, s_i is the original sentence, l_j is the label-prompt, $[\text{sep}]$ is the separator and $y_i \in \{0, 1\}$ as shown in Figure 1 (bottom). Label-prompt represents the ground-truth label of the sentence in textual format. For example, *this post contains hatespeech* / *this post contains normal words* can be used as label-prompt for *hate* and *non-hate* sentences respectively (Table B). The target to the model, $y_i = 0$ indicates that the sentence, s_i and label-prompt, l_j do not entail each other. $y_i = 1$ indicates entailment. We extend analysis of `Entailment-style` for multiple languages using monolingual and multilingual label-prompts.

2.3 Explicit and Implicit Hate Speech

In this section, we study the correlation between *explicit* and *implicit*. As discussed previously, *explicit* hate speech comprises of *cuss*, *swear*, *abusive*, *profane* words but *implicit* hate speech is more contextual and indirect. While the manner of expression is different, the intent behind both these modes is similar. To leverage this, we pretrain on the task of *explicit* hate speech detection and finetune it on *implicit* hate speech dataset and vice-versa and observe consistent gains. We probe the

layers of contextual models by extracting the features from each layer and training a classifier over these representations to understand how contextual models encode the information about hate speech and observe that *explicit* and *implicit* hate speech is encoded differently.

3 Dataset and Models

Explicit: We experiment with HateXplain (HX)(Mathew et al., 2021) dataset for *explicit* hate speech study. HateXplain (HX) captures explicit lexicon based hate speech posts collected from popular social media sites like Twitter and Gab.

Implicit: For *implicit* hate speech, we use LatentHatred (LH)(ElSherief et al., 2021), which comprises of *implicit* hate speech containing indirect/coded language.

Multilingual: We also experiment with *explicit* hate speech datasets in French (FR), Spanish (ES), Arabic (AR) and Portuguese (PT)² for evaluating our methodology for different languages. Since the taxonomy was different for each label, we focus on the datapoints annotated with *hate* and *non-hate* labels only (Poletto et al., 2021). In Appendix Section A, we summarize the details and statistics

Table 5: F1 score on entailment task for all datasets using english prompts (prompt-en) and language-specific prompts (prompt). Baseline corresponds to BERT-base for HX, LH and mBERT for rest. For English datasets, prompt is equivalent to prompt-en.

of all the datasets.

Models: We consider RoBERTa-base (Liu et al., 2019) and XLM-R (Conneau et al., 2020) as the baseline model for English and other languages respectively. For exploring the impact of domain adaptive models, we experiment with RoBERTa-Tw and XLM-Tw models. For the multilingual experiments, we use XLM-TwS, which is the XLM-Tw model finetuned on the UMSAB dataset (Barbieri et al., 2021). More details in Appendix Section C.

4 Results

Explicit: In Table 1, we report the results on HateXplain dataset. We observe that RoBERTa-Tw improves upon the results of RoBERTa-base model. This shows that the pre-training over similar domain (social media) helps in achieving better performance. RoBERTa-TwS which has been trained for sentiment detection demonstrates further improvement highlighting the correlation between sentiments and hate-speech detection. On adding our augmentation (RoBERTa-TwS-EasyMixup), we notice further performance gains demonstrating the benefits of EasyMixup augmentation. Overall, our results improve upon the previously reported baseline (Mathew et al., 2021).

Implicit: We conduct similar experiments on LatentHatred dataset. We notice gains by using the domain adapted RoBERTa-Tw model.

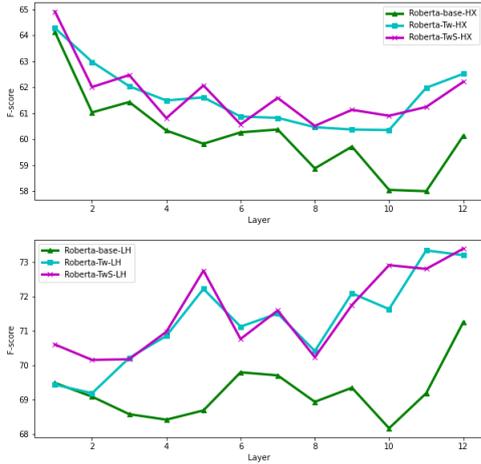

Figure 2: Layer-wise probing results on HateXplain (top) and LatentHatred (bottom) datasets for RoBERTa-base, RoBERTa-Tw and RoBERTa-TwS [Best viewed in color].

RoBERTa-TwS does not improve the accuracy but improves upon the F1 score which is a better metrics due to data imbalance. Addition of EasyMixup (RoBERTa-TwS-EasyMixup) further improves the performance. Our results improve upon the previously reported state-of-the-art results 2.

Explicit-Multilingual: We evaluate our method on 4 more languages in Table 4 and observe similar trends. For all the languages, multilingual domain (XLM-Tw) and task adapted (XLM-TwS) models perform better than the base model (XLM-R). On integration of EasyMixup, we further note improvements. We also experiment with sampling augmented samples from other languages (EM-mu) and notice further gains highlighting the cross learning between languages by 1-3%. We compare EasyMixup with state-of-the-art method SSMixup in Table 6 and observe that EasyMixup improves the performance by 1-2% for both implicit and explicit hate-speech detection. **Entailment-style:** In Table 5, we report the results using monolingual³ and English prompts and observe that monolingual prompts outperform English prompts. This is not surprising considering that models are trained on pairs of sentences from same language only. We use mBERT/BERT-base for this study as it has been trained with NSP task which aligns with Entailment-style. Check Appendix B for more details.

Implicit-Explicit Correlation: We finetune the RoBERTa-Tw model on *implicit* hate speech

³We used Google Translate to obtain monolingual prompt

Model	Acc	F1
LatentHatred		
BERT-base	76.51	73.70
+SSMixup (Yoon et al., 2021)	77.30	74.76
+EasyMixup	77.52	75.28
HateXplain		
BERT-base (Mathew et al., 2021)	69.00	67.40
+SSMixup	69.59	67.72
+EasyMixup	69.70	68.66

Table 6: Comparing EasyMixup with SSMixup (Yoon et al., 2021)

(RoBERTa-Tw-IH) before training it for implicit hate speech and observe the F1 improvement from 67.64 to 68.88 in Table 3. This shows that *implicit* hate speech detection benefits the task of *explicit* hate speech. Similarly, F1 score of *implicit* hate speech detection improves from 75.77 to 75.95 by finetuning using *explicit* hate speech dataset.

Probing: In Figure 2, we plot the F1 score of RoBERTa-base and RoBERTa-Tw for *explicit* and *implicit* hate speech across different layers of the contextual model. We note that lower layers show higher F1 for *explicit* hate speech detection (expected layer = 0.98), while higher layers demonstrate better *implicit* hate detection performance (expected layer = 5.12). This alludes to the hypothesis that *implicit* hate speech is contextual in nature while *explicit* hate speech can be detected by using token-level information also. Training details are described in Appendix Section D.

5 Conclusion

In this work, we introduced a novel input-level data-augmentation technique, EasyMixup which shows performance gains over monolingual and multilingual settings. We also explored reformulation of hate speech classification as Entailment-style problem and achieved substantial performance gains using monolingual entailment. We also performed layer probing to find that higher layers encode *implicit* hate information, while lower layers are more focused on *explicit* hate speech highlighting the contextual nature of *implicit* and token-level dependence of *explicit* hate speech. In future work, we would like to explore how EasyMixup and Entailment-style perform when ensembled together in both mono, multi-lingual settings.

6 Limitations

One limitation would be that EasyMixup won't be applicable in tasks like sentiment analysis where the final mixed label might not be binary.

A Dataset

In Table 7, we note the dataset size and source of the datasets used in our study. Majority of the datasets are source from Twitter and have data imbalance.

Explicit Hate (HX): HateXplain dataset has been sourced from Twitter and Gab. The lexicon set from (Davidson et al., 2017), (Ousidhoum et al., 2019a) & (Mathew et al., 2019) is combined to sample 1% tweets in the period Jan-2019 to Jun-2020. For Gab, they use the dataset provided by (Mathew et al., 2019). All posts containing embedded links, pictures, videos were removed and usernames were anonymized by replacing with *user* token. Each post in the dataset is labelled into 3 categories: *Normal*, *Offensive* or *Hateful*. For the annotation task, Amazon Mechanical Turk (MTurk) workers are used where each post is labelled by 3 annotators and the ground truth class is chosen by majority voting. Finally, 19,229 posts were annotated of which 5,935 were hateful, 5,480 were offensive and 7,814 were normal. For the rest 919 posts the annotators provided 3 different classes and hence these were discarded.

Implicit Hate (LH): LatentHatred introduces a theoretically-justified taxonomy of implicit hate-speech with fine-grained labels on eight ideological clusters of US hate groups as given by the SPCL report - *Black Separatist*, *White Nationalist*, *Neo-Nazi*, *Anti-Muslim*, *Racist Skinhead*, *Ku Klux Klan*, *Anti-LGBT* and *Anti-Immigrant*. For high-level categorization, the tweets were categorized into *explicit hate*, *implicit hate* & *non-hateful*. Overall, the dataset contains 21,480 tweets, where 7,100 were implicit hate, 1,089 explicit hate and 13,291 non-hateful. Using majority vote, labels were obtained for 19,112 tweets of which 4,909 were implicit hate, 13,291 non-hateful and rest 933 explicit hate were discarded. For a finer categorization, 6 labels were chosen representing principal axes of implicit hate - *White Grievance*, *Incitement*, *Inferiority*, *Irony*, *Stereotypes & Threatening*. The 4,909 implicit hate tweets labeled in the high-level stage were further annotated using the above mentioned fine-grained labels.

Multilingual: We collected 6 publicly available datasets in 4 different languages - French, Spanish, Arabic and Portuguese and combined them individually. Each dataset had a variety of labels - *hate*, *abusive*, *profanity*, *offensive* etc. Since the taxonomy is different for each label, we focus on the

Dataset	Source	#datapoints	%hate
HateXplain	Twitter, Gab	19,229	30.86
LatentHatred	Twitter	20,391	34.82
Arabic	Twitter	5,418	17.07
Portuguese	Twitter	5,670	31.53
Spanish	Twitter	11,150	33.29
French	Twitter	1,028	20.14

Table 7: Dataset Statistics

datapoints annotated with *hate* and *non-hate* labels. We describe each dataset in following section.

- **Arabic (AR):** Mulki et al. (2019) contains Syrian/Lebanese political tweets labeled as abusive, normal or hate. (Ousidhoum et al., 2019b) consists of multi-labeled tweets based on attributes like hostility, target, directness, etc.
- **Spanish (ES):** Basile et al. (2019) provided a multilingual hatespeech dataset against women & immigrants. Quijano-Sanchez et al. (2019) collected a small hatespeech dataset in spanish with hate/non-hate labels.
- **Portuguese (PT):** Fortuna et al. (2019) provided a hierarchically labeled hatespeech dataset of which we use only the binary labels for our task.
- **French (FR):** Ousidhoum et al. (2019b) consists of multi-labeled tweets based on attributes like hostility, target, directness, etc.

B Prompts used for Entailment-style task

Refer to Table 8.

C Model Details

ROBERTa-Tw is based on ROBERTa-base model trained on 60M English tweets. XLM-Tw (Barbieri et al., 2021) is a XLM-R model trained on 200M tweets retrieved from 30+ languages. For task-adaptive models, we take ROBERTa-TwS and ROBERTa-Tw-EH which are initialized with the ROBERTa-Tw model and further finetuned using Sentiment and Hatespeech classification data from the TweetEval (Barbieri et al., 2020) benchmark.

D Implementation Details

We perform all experiments with 3 different seeds on a single NVIDIA V100 GPU and report the

Language	Label Description
HateXplain	<i>this post contains hate speech / this post contains {offensive,normal} words</i>
LatentHatred	<i>this is implicit hate / this is normal</i>
French	<i>c'est odieux / c'est normal</i>
Spanish	<i>esto es odioso / esto es normal</i>
Arabic	<small>هذا المنشور يحتوي على كلمات / هذا المنشور يحتوي على كلام جارح عابث / غير الكراهة</small>
Portuguese	<i>este post contém discurso de ódio / este post contém palavras normais</i>

Table 8: Prompts used across various datasets for Entailment-style task.

average score. We use a batch size of 16 and maximum sequence length of 128. We choose initial learning rate from $\{3e-5, 4e-5, 5e-5\}$ and perform linear decay after 10% warmup steps. We use the AdamW optimizer and train our models for 5 epochs. The classifier head consists of a 2-layer MLP with ReLU activation. We choose the best checkpoint using validation metrics every epoch. From our experiments, we found best reported results were obtained by combining *offensive+normal* & *hate+normal* classes for HateXplain and *hate+normal* classes for LatentHatred and keeping $p_{aug} = 0.2$ and $p_{flip} = 0.5$.

For the probing experiments, we train the 2-layer MLP probe classifier for 50 epochs with batch size 64 and learning rate $1e-3$.

For the entailment experiments, we use a batch size 128 (required for entailment method to get good gains) consistently for all methods and learning rate $3e-5$.

E Effect of Length

We used the max sequence length of 128 in our experiments. $< 1\%$ of samples exceed this limit across all datasets - HateXplain, LatentHatred, MultilingualHate. Thus, length of 128 tokens does not degrade Entailment-style performance. However, in case of EasyMixup, length of concatenated sentences could exceed 128 tokens. To evaluate the impact, we repeat experiments using best performing model - RoBERTa-TwS-EasyMixup (averaged over 3 random seeds) keeping maximum sequence length as 512. For HateXplain, Δ Accuracy / F1 $\sim 0.00 / -0.03 \%$ and for LatentHatred Δ Accuracy / F1 $\sim +0.21 / -0.05 \%$. As we can see there is no significant impact from the reported results. This can be attributed to the fact that we do probabilistic mixup in EasyMixup ($p_{aug} = 0.2$ and $p_{flip} = 0.5$). Thus the model sees all type of examples during the training phase.

F Ethical Considerations

All the datasets that we use are publicly available. We report only aggregated results in the main paper. We have not or do not intend to share any Personally Identifiable Data with this paper. We release the code and data associated with this paper as well - https://anonymous.4open.science/r/data_efficient_hatedetect/

Learning the Effects of Physical Actions in a Multi-modal Environment

Gautier Dagan, Frank Keller, Alex Lascarides

gautier.dagan@ed.ac.uk, {keller, alex}@inf.ed.ac.uk

Abstract

Large Language Models (LLMs) handle physical commonsense information inadequately. As a result of being trained in a disembodied setting, LLMs often fail to predict an action’s outcome in a given environment. However, predicting the effects of an action before it is executed is crucial in planning, where coherent sequences of actions are often needed to achieve a goal. Therefore, we introduce the multi-modal task of predicting the outcomes of actions solely from realistic sensory inputs (images and text). Next, we extend an LLM to model latent representations of objects to better predict action outcomes in an environment. We show that multi-modal models can capture physical commonsense when augmented with visual information. Finally, we evaluate our model’s performance on novel actions and objects and find that combining modalities help models to generalize and learn physical commonsense reasoning better.

1 Introduction

Large Language Models (LLMs) are trained on large corpora of disembodied texts. They are typically pre-trained on a masked language modeling task: the model must predict a masked word in a text given its context. LLMs have achieved state-of-the-art performance on many NLP tasks (Devlin et al., 2019; Brown et al., 2020), but they can also fail on seemingly easy and obvious tasks and in unpredictable ways (McCoy et al., 2020; Bommasani et al., 2021). Commonsense knowledge is shared knowledge and is often so obvious that it is absent from the LLMs’ training data: people don’t mention what is already known to their interlocutors. This includes physical commonsense information, including how executed actions affect the physical attributes of objects; e.g., shape and weight (Forbes et al., 2019). Humans may learn such knowledge from their embodied environment. But LLMs, being trained on disembodied text, can make incorrect

predictions about physical attributes and how these change when actions occur. For instance, when asked what the weight of a 150 grams potato after it is sliced, GPT-3 (Brown et al., 2020) incorrectly answers 75 grams (see Appendix A for the exact prompt). GPT-3 is an LLM with 175 billion parameters, and nonetheless its disembodied existence limits its physical commonsense estimates.

Zellers et al. (2021) inject physical commonsense information into LLMs via their model PIGLeT—a modified LLM that is trained on their PIGPeN simulated 3D environment dataset. PIGLeT estimates how an environment changes as a result of specific actions. In training and testing, the model uses ground-truth symbolic representations of the environment but not the images: it ignores visual sensory observations. These symbolic representations of objects in an environment are chosen to capture the possible effects of actions, and include attributes like weight, size and temperature. However, in an embodied situation, an agent needs to use visual perception to estimate its interpretation of the scene. Therefore, the symbolic representations should be treated as latent rather than observed.

We propose an alternative to the PIGLeT model, PIGLeT-Vis, which uses images directly as input into a multi-modal LLM to ground the model to its physical environment. We compare our approach to the original PIGLeT model and evaluate the generalization capabilities gained from using image inputs. At test time, our model foregoes symbolic labels: only the images and the name of the action are observed. Thus our model tackles a more challenging task than the original PIGLeT model in that it must not only predict the effect of actions but also (indirectly) estimate the symbolic representations of objects in the images. We also evaluate a model for predicting the effects of actions that trains on PIGPeN’s images and their associated natural language (NL) descriptions, eliminating the need for

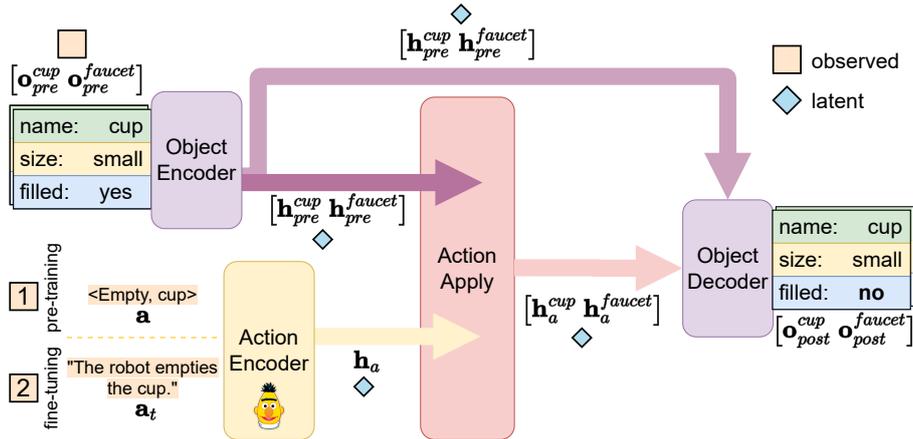

Figure 1: **Original PIGLeT Physical Dynamics Model (Zellers et al., 2021)**. During pre-training the model receives as input the full symbolic representation of two objects (\mathbf{o}_{pre}^0 and \mathbf{o}_{pre}^1) before the action is taken and the symbolic representation of the action itself (\mathbf{a}) and is tasked with predicting the attributes of the objects after the action (\mathbf{o}_{post}^0 and \mathbf{o}_{post}^1). During fine-tuning, the action encoder is replaced by an LLM to process a natural language description of the action being taken and with what objects.

formal symbolic representations.

Our contributions are three-fold. First, we show that it is possible to predict the physical effects of actions from visual data. Second, we show that it is possible to learn the task on training data where formal symbolic representations, which are unobservable in real-world settings, are replaced with NL descriptions (which can be observed through natural interaction). Third, we evaluate all our models in a stricter zero-shot setup to promote ways to train agents that generalize. Overall our work paves the way for multi-modal models that learn the effects of actions in realistic environments.

2 Related Work

Commonsense reasoning has been highlighted as a potential weak point of LLMs in recent years (Shen and Kejriwal, 2021; Forbes et al., 2019; Bisk et al., 2020). Datasets such as PIGPeN (Zellers et al., 2021), commonsenseQA (Talmor et al., 2019), VCR (Zellers et al., 2019) and GD-VCR (Yin et al., 2021) help evaluate different aspects of commonsense reasoning in modern LLMs. In this paper, we focus on physical commonsense reasoning, which involves understanding the (often) unexpressed rules of the physical world.

Forbes et al. (2019) reported that neural representations found it challenging to infer the link between actions and what they imply about the attributes of objects. Accordingly, Zellers et al. (2019) introduced the Visual Commonsense Reasoning (VCR) task to test how images can inform

question answering models that tackle commonsense information. Bisk et al. (2020) designed the PIQA benchmark to evaluate physical commonsense reasoning in LLMs through question answering. Sampat et al. (2021) proposed an extension to the CLEVR dataset, where an agent must reason and answer questions about a scene after a hypothetical action is taken.

Multiple approaches can improve the capabilities of LLMs in commonsense reasoning, such as using handcrafted knowledge graphs (Hwang et al., 2021) or leveraging simulated environments (Zellers et al., 2021). PIGLeT, in particular, combines a traditional LLM and a “Physical Dynamics” model to ground an LLM (Zellers et al., 2021). The Physical Dynamics model enhances the commonsense knowledge of an LLM by fine-tuning it, using trajectories sampled from a realistic environment (see Figure 1). Trajectories are an action and a pair of environment states (before and after the action) expressed in a formal symbolic representation. Zellers et al. (2021) found that fine-tuning LLMs with symbolic data from the simulated environment helped them outperform other models in physical commonsense reasoning tasks: in particular, predicting the effects of an action when executed in a particular state.

Image inputs offer a way to ground an LLM, as they only require general alignment with a text or symbolic input and do not require the comprehensive environment ground-truth labels that PIGLeT uses. Gao et al. (2018) used multi-modal web data to learn actions and their effects from images

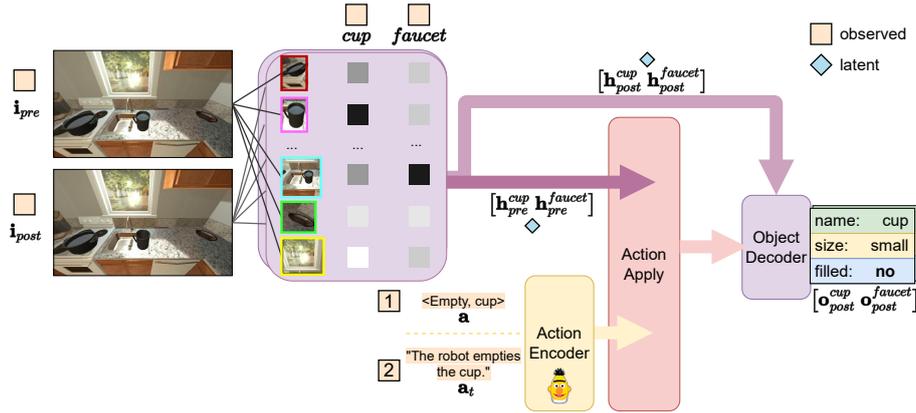

Figure 2: **PIGLeT-Vis**. We introduce PIGLeT-Vis, where we modify the PIGLeT architecture to replace its Symbolic Object Encoder with a vision component that makes use of images of the environment before and after an action is taken to predict the symbolic representation of objects post-action. We use an attention mechanism over the extracted bounding boxes to obtain a visual hidden representation of an object given its name. The only remaining symbolic inputs during pre-training are the action description and object names.

and corresponding text descriptions. Zellers et al. (2019) used an off-the-shelf ResNet50 model (He et al., 2016) to augment an existing BERT language model (Devlin et al., 2019) with vision capabilities. Transformer models such as UNITER (Chen et al., 2020), ERNIE-ViL (Yu et al., 2021), VisualBERT (Li et al., 2020), and ViLBert (Lu et al., 2019) have been applied to visual commonsense reasoning. These models use a joint transformer backbone for images and text and vary their pre-training objectives. However, most of these models are trained on static text-image pairs: they aren’t designed to capture the dynamics of an environment, particularly how object attributes change with actions. Notably, recent work by Hanna et al. (2022) uses CLIP (Radford et al., 2021) and MOCA (Singh et al., 2021) embeddings to predict a post-action image given a set of possible images. In contrast, we focus on adapting an LLM with a vision-based component to predict the consequences of actions on the environment.

3 Method

We propose PIGLeT-Vis (Figure 2) for learning the effects of actions on objects from images. We use a pre-trained vision backbone, DETR (Carion et al., 2020), as a Vision Object Encoder and combine it with a RoBERTa LLM (Liu et al., 2019) as an Action Encoder. We experiment with different configurations of inputs to measure the impact of the various components of our architecture. In particular, we test a variation in which we remove the formal symbolic labels even in training, replacing

them with NL text labels. To evaluate our models, we use the PIGPeN dataset (Zellers et al., 2021), which consists of a symbolic and visual representation of an environment before and after an action is taken. However, we filter PIGPeN to create a viable testing ground for visual grounding of physical actions and more accurately measure generalization capabilities of models.

3.1 Architecture

PIGLeT-Vis (shown in Figure 2) consists of separate components, which can combine multi-modal inputs in different ways. Through this modular approach, we can turn off specific components to evaluate how different inputs and model structures affect performance on the task. We test models with and without symbolic inputs and image inputs. For all components, we use a dropout of $p = 0.1$ in between layers and a default hidden layer size of $h = 64$.

3.1.1 Object Encoder

We reproduce Zellers et al. (2021), where all actions are assumed to involve two objects, \mathbf{o}^0 and \mathbf{o}^1 , and the symbolic representation of objects are encoded in an Object Encoder model. The symbolic representation of an object before the action is represented by \mathbf{o}_{pre} . Both objects (\mathbf{o}_{pre}^0 and \mathbf{o}_{pre}^1) in the environment are described by a vector of 38 attributes, chosen on the basis that they are the kinds of physical attributes that are influenced by actions. They describe an object as small/large, cold/hot, empty/full, etc.

We first embed these symbolic object attributes

using an embedding layer $\mathbf{E}^{e \times h}$, where $e = 329$ is the total number of unique attributes and h is our hidden size. For an object k :

$$\hat{\mathbf{o}}_{pre}^k = \mathbf{E}(\mathbf{o}_{pre}^k) \quad (1)$$

The Object Encoder $\mathbf{O}_{encoder}$ takes in the embedded object attributes through a set of multi-head attention layers to encode the symbolic representation of each object. We use the default Pytorch implementation of the Transformer Encoder (Paszke et al., 2019) with three layers and 4 heads. The first encoded output of each object sequence is used for representing the entire object.

$$\mathbf{h}_{pre}^k = \mathbf{O}_{encoder}(\hat{\mathbf{o}}_{pre}^k) \quad (2)$$

3.1.2 Action Encoder

Actions are encoded either as a symbolic triplet (action, action object, action receptacle) or as an annotated text describing an action being taken (e.g., “robot empties the cup”).

During pre-training, the Action Encoder $\mathbf{A}_{pretrain}$ uses an action embedding layer \mathbf{E}' to embed the first dimension of the action, and re-uses the object embedding layer \mathbf{E} to embed the action object name a_o and action receptacle name a_r . The action embedding layer \mathbf{E}' has dimensionality $10 \times h$ for the 10 distinct actions. The three embedded representations are summed and passed to the Action Encoder’s linear layers to produce \mathbf{h}_a (see equation 3). Similarly to Zellers et al. (2021), a tanh activation is applied after each linear layer.

$$\mathbf{h}_a = \mathbf{A}_{pretrain}(\mathbf{E}'(\mathbf{a}) + \mathbf{E}(a_o) + \mathbf{E}(a_r)) \quad (3)$$

When fine-tuning on the annotated dataset, the action input is text and therefore we switch out the Action Encoder $\mathbf{A}_{pretrain}$ for $\mathbf{A}_{finetune}$ —our text-based Action Encoder. $\mathbf{A}_{finetune}$ uses a RoBERTa-base¹ model (Liu et al., 2019) to process a tokenized version of the text input \mathbf{a}_t . The first token ([CLS]) of the RoBERTa output layer is used to represent the action sequence and then passed through a linear layer to map the dimensionality of the hidden states from 256 to h .

$$\mathbf{h}_a = \mathbf{A}_{finetune}(\mathbf{a}_t) \quad (4)$$

¹Implementation and pre-trained model weights are taken from the Huggingface library (Wolf et al., 2019).

3.1.3 Vision Object Encoder

The Vision Object Encoder takes in images (\mathbf{i}_{pre} and \mathbf{i}_{post}) to provide a visual representation of each object k before and after (\mathbf{h}_{pre}^k and \mathbf{h}_{post}^k). We use the DETR¹ (Carion et al., 2020) model as a backbone to predict N bounding boxes in a pair of images (pre- and post-action). As DETR is pre-trained on the COCO object detection dataset (Lin et al., 2014), its predicted object labels do not align with those in PIGPeN. Therefore, we instead learn a mapping between the predicted bounding box representations and the PIGPeN objects. For each image, we obtain a hidden representation \mathbf{h}_b of dimensionality $N \times 256$ where $N = 100$.

We use an attention mechanism over the bounding boxes’ hidden representation, conditioned on the object names. For a given object o^k , its conditional representation \mathbf{h}_c^k is the encoded name of the object: $\mathbf{E}(o_{name}^k)$. We can therefore obtain the attention score of a given object o^k and image \mathbf{i}_m by calculating the alignment between the conditional representation \mathbf{h}_c^k and the hidden representations of bounding boxes \mathbf{h}_{b_m} :

$$\mathbf{h}_{b_m} = \text{DETR}(\mathbf{i}_m) \quad (5)$$

$$\alpha_m^k = \text{Softmax} \left(\sum_{i=1}^h (\mathbf{h}_c^k \mathbf{h}_{b_m})_i \right) \quad (6)$$

We obtain the final representation for a given object and image by multiplying our attention scores α with the extracted output representation from DETR and summing along the bounding box axis:

$$\mathbf{h}_{o_m}^k = \mathbf{W} \left(\sum_{j=1}^b (\alpha_m^k \mathbf{h}_{b_m})_j \right) \quad (7)$$

We use a final output layer \mathbf{W} to decrease the dimensionality of \mathbf{h}_o from the DETR dimensionality of 256 to h .

Through the Vision Object Encoder, we replace the previously symbolic inputs with images and can extract $[\mathbf{h}_{pre}^0 \mathbf{h}_{pre}^1]$ and $[\mathbf{h}_{post}^0 \mathbf{h}_{post}^1]$ from \mathbf{i}_{pre} and \mathbf{i}_{post} respectively. Note that we make the implicit assumption that \mathbf{i}_{pre} and \mathbf{i}_{post} contain the information necessary to predict object attributes of the objects post-action.

3.1.4 Action Apply

The Action Apply Model β is a simple fuse operation (concatenation in the hidden dimension) followed by three linear layers, which combine

the action representation \mathbf{h}_a and an object representation of the scene pre-action \mathbf{h}_{pre}^k . The model outputs an object’s representation \mathbf{h}_a^k , containing information conditioned all inputs:

$$\mathbf{h}_a^k = \beta(\mathbf{h}_a, \mathbf{h}_{pre}^k) \quad (8)$$

3.2 Object Decoder

Finally, the Object Decoder is a transformer module that maps the object representations h_o from the pre-action state back to 38 symbolic attributes. It uses a default three layer Transformer Decoder (Paszke et al., 2019) that takes the hidden representation from the Action Apply \mathbf{h}_a^k as an encoded memory state and \mathbf{h}_{pre}^k as the source sequence to predicts a label for each attribute.

$$\dot{\mathbf{o}}_{post}^k = \mathbf{O}_{decoder}(\mathbf{h}_a^k, \mathbf{h}_{pre}^k) \quad (9)$$

When we use image inputs, we also have access to the post-action visual representation and can therefore use $\mathbf{h}_{pre}^k + \mathbf{h}_{post}^k$ instead of \mathbf{h}_{pre}^k .

The output has post-action object states $\dot{\mathbf{o}}_{post}^k$ which are compared to the ground truth \mathbf{o}_{post}^k to calculate cross-entropy. As an additional loss, we also use the cross-entropy between $\dot{\mathbf{o}}_{pre}^k$ and \mathbf{o}_{pre}^k by passing an empty \mathbf{h}_a^k to force the Object Decoder to recreate the attributes in the pre-action state. We weight both losses equally.

3.3 Evaluation Metrics

Since our task involves predicting 38 attributes for two different objects per example, we follow Zellers et al. (2021) and report different types of accuracy metrics on the test set (after fine-tuning). We measure the overall accuracy by scoring how many objects have all attributes correctly predicted (exact match). Note that this is a high bar for a model where the symbolic representations are latent: to predict an object correctly, our model must first estimate its attributes before the action and then estimate whether and how these change given an action. So we also measure the attribute-level and action-level accuracies of each model, so as to explore which attributes and actions are more difficult to predict than others.

3.4 PIGPeN-Vis Dataset Split

To evaluate physical commonsense reasoning using PIGLeT-Vis, we filter PIGPeN (Zellers et al., 2021) to create a subset (PIGPeN-Vis) which we use for all our experiments. We motivate PIGPeN-Vis as

a way to isolate the effects of adding our vision component, because while PIGPeN already has images, these images were not used in PIGLeT.

The PIGPeN dataset consists of trajectories of an environment before (*pre*) and after (*post*) an action is taken. Each trajectory contains representations of two distinct objects before and after. One of the objects is usually targeted by the action, while the other acts as a distractor. In addition, image pairs $(\mathbf{i}_{pre}, \mathbf{i}_{post})$ for each trajectory are provided, where each image is snapshot of the simulated photo-realistic 3D environment which contains the objects in view (see Appendix B for an example). Each image is an RGB image of dimensions 640×385 .

The original dataset is separated into two distinct sets:

1. A *pre-training* set of 278,009 trajectories, which includes the symbolic representations of objects \mathbf{o} before and after a symbolic action \mathbf{a} is taken. A separate validation set of 33,042 examples is also included.
2. A *fine-tuning* set of 1,000 trajectories which has been annotated to replace the symbolic action \mathbf{a} with a textual representation \mathbf{a}_t describing the action. Separate validation and test sets of 500 examples each are also included. All metrics are reported on the test set.

In PIGPeN, the object states \mathbf{o}_{pre} and \mathbf{o}_{post} contained 40 different attributes and 13 different actions \mathbf{a} . Attributes range from intrinsic such as name or moveable to stateful such as distance or isCooked. In forming PIGPeN-Vis, we remove two attributes and three actions from the dataset to obtain 38 attributes and 10 possible actions (see Appendix B for more details).

3.4.1 Viewpoint and Action Filtering

Since the PIGPeN images were not generated with the goal of being used as input data, we identified several issues with the quality of certain scenes. A notable difficulty is that in some cases, the before and after images are not captured from the same camera angle or they have different lighting conditions. Changing orientations and lighting conditions makes it difficult to use an image pair $(\mathbf{i}_{pre}, \mathbf{i}_{post})$ to isolate the outcome of an action. Conversely, image pairs with too few perceivable differences also break our assumption that the changes in

the environment are perceivable. Therefore, we filter the dataset using pixel statistics to remove image pairs that have either large perceivable differences (likely due to changes in viewpoint) or small perceivable differences (where the action’s results are not visually salient enough) (see Appendix B.2). We exclude 15.4% of the total dataset through visual filtering of the original dataset.

3.4.2 Zero-Shot Filtering

To evaluate the generalization capabilities gained from a vision component, we further filter the dataset to exclude a subset of training examples. Unlike the original PIGPeN dataset which only tested for zero-shot generalization at the level of the fine-tuning data, we remove all instances with selected specific objects or action-object pairs from all training and validation sets. To minimize the effect of removing examples from the dataset, we pick objects and action-object pairs with an already low number of samples in the training sets. In total, we exclude 14 objects and 27 action-object pairs, which amounts to less than 3% (6,816 samples) of the remaining training sets (see Appendix B.3). These zero-shot examples comprise around 10% of the test set.

After both filtering stages, PIGPeN-Vis contains a pre-training dataset of 232,625 trajectories with a validation set of 26,823, and a fine-tuning training set of 750 examples with a validation set of 367 examples and a test set of 398 examples.

3.5 Training Configurations

We evaluate the impact of the vision component on PIGPeN-Vis through five different setups:

- **base:** We implement a baseline model without symbolic object inputs. Our implementation removes the Object Encoder entirely, such that the model must predict the attributes of objects solely from knowing the action and the object names that it relates to. This model acts as a lower bound on the capabilities of the vision model: its performance would match the vision model if images are irrelevant to solving the task.
- **base+symbolic:** This is our implementation of the original Zellers et al. (2021) PIGLeT model, shown in Figure 1. This model acts as an upper bound on the capabilities of the vision model since it observes the true symbolic

representations of objects before the action (which the vision model must estimate).

- **base+images:** This is our proposed PIGLeT-Vis, shown in Figure 2, where the Vision Object Encoder replaces the previously symbolic Object Encoder. This model leverages the before and after images of the environment as well as the name of the objects to extract representations of the object attributes.
- **base+symbolic+images:** We sum the hidden symbolic representations of objects with their visual representations in a unified model. Through this setup, we evaluate whether images can provide additional information to the already comprehensive symbolic representations.
- **base+images+text-labels:** We convert the symbolic representations of the labels for the object names and actions to their text label and encode them using a frozen LLM during pre-training. We use the same LLM to encode the text labels that we later use in the fine-tuning stage. This setup replaces all symbolic inputs from the pre-training stage to only language and image inputs.

Note that there are a few differences between the original Zellers et al. (2021) model and our implementation of base+symbolic. For instance, for simplicity, we opted to use an off-the-shelf RoBERTa-base (Liu et al., 2019) model instead of training our own custom GPT2 (Radford et al., 2019). Additionally, we also reduce the dimensionality of the PIGLeT layers from $h = 256$ to $h = 64$. We found that not only does this allow faster training times as it shrinks the Physical Dynamics model from 11.9 million parameters to 2 million parameters, it also improves the overall accuracy by a small margin (+1.51%).

We train each model for 80 epochs with a batch size of 256 using the Pytorch implementation of the Adam optimizer (Kingma and Ba, 2014) and a learning rate of 10^{-3} during pre-training and 10^{-5} during fine-tuning. We run each setup over 10 different seeds and report the average and standard deviation for each metric (see Appendix C.1 for more details).

	Accuracy (% \pm σ)	
	Overall	Zero-Shot
base	21.23 \pm 0.72	5.34 \pm 2.77
base+symbolic (PIGLeT)	85.03 \pm 0.45	39.04 \pm 3.37
base+symbolic+images	86.01 \pm 0.89	35.89 \pm 3.47
base+images (PIGLeT-Vis)	45.47 \pm 1.50	7.53 \pm 2.60
base+images+text-labels	47.55 \pm 2.10	8.90 \pm 3.24

Table 1: Overall and zero-shot accuracies (PIGPeN-Vis)

4 Results and Discussion

We evaluate all models on our PIGPeN-Vis split and report the overall (exact match), zero-shot, action-level, and attribute-level accuracy results for all setups in Tables 1 and 2. For completeness, we also evaluate models on the original PIGPeN to contrast the effects of our filtering operations (see §3.4 and Appendix D) and find PIGPeN-Vis is a more challenging subset for all models.

The base model provides a low bar estimate of what is achievable using only the action encoder inputs. Unsurprisingly, the base model performs worst on overall accuracy, which demands an exact match of all attributes. It does relatively well on (individual) attribute-level accuracy, primarily because it predicts the most common attribute for each object. Some actions are also easier than others—for instance, the model reaches 27.38% accuracy on ToggleOn from only knowing the action and object names. This is likely because ToggleOn is constrained to a small set of objects and effects.

Our base+symbolic model obtains similar results to the original implementation by Zellers et al. (2021), with an overall accuracy of 85.03%. However, it performs much worse on the zero-shot split (39.04%) than the original PIGLeT model reported (80.2%) (Zellers et al., 2021). This disparity can be explained by the fact that the original zero-shot PIGPeN dataset was not a true zero-shot dataset, because the Physical Dynamics model was exposed to the “unseen” objects in its pre-training. The base+symbolic model provides a high bar estimate of what could be achievable if: (i) i_{pre} and i_{post} capture the symbolic environment; and (ii) the Vision Object Encoder can subsequently extract these features. However, as we will argue in Section 6, both (i) and (ii) are unrealistic given the constraints of both the dataset and the model.

Our base+images (PIGLeT-Vis) model scores 45.28% in overall accuracy but only 7.53% on the zero-shot set. Nevertheless, it outperforms the base model in overall accuracy ($p < 0.0001$) and in zero-shot accuracy ($p = 0.08$), which demon-

strates that the images improve the prediction of the effects of actions. The base+images model also performs significantly better than base on difficult attribute-level accuracies such as distance ($p < 0.0001$). However, as before, accuracy on individual attributes benefits from the skewed distributions of their values and does not necessarily translate to high scores on predicting all 38 attributes correctly.

Utilizing both images and symbolic representations as inputs helps the base+symbolic+images model outperform purely symbolic inputs in overall accuracy, from 85.03% to 86.01% ($p < 0.01$). However, image inputs also decrease the model’s zero-shot performance from 39.04% to 35.89%, although this isn’t statistically significant ($p = 0.05$) due to high variance. We suspect that this high variance is caused by an increase in noise in the model resulting from adding images to the symbolic model. However, the overall picture is more complicated, as images can also provide gains on certain actions (e.g., PickUp accuracy increases from 80.48% to 86.14%) even though it causes a decrease in many other cases (e.g., ToggleOn).

Finally, when we utilize NL descriptions to replace the formal symbolic inputs (action name and object names), base+images+text-labels improves overall accuracy when compared to base+images from 45.47% to 47.55% ($p = 0.02$). Text inputs appear to improve zero-shot accuracy, but not by a statistically significant margin ($p = 0.31$). Accuracy also improves in most actions, for instance the Slice accuracy improves from 41.64% to 45.57% ($p = 0.03$). So the NL descriptions inform the task in a beneficial way, over and above the raw images. But encoding the labels as text rather than formal symbolic representations also adds noise.

Nevertheless, text labels improve accuracy on actions where the semantic information contained in the label provides a richer context to help generalize to similar objects. For instance, a “cup” and a “mug” are semantically close, and thus learning the effects of actions on a “cup” might help the model predict the same effects on a “mug” even if the word forms are different. In contrast, the formal symbolic representations treat the predicate symbols cup and mug as unrelated, and so don’t benefit from the lexical relationships that the LLM captures. Fully removing the symbolic representations allows us to adapt our model

	Action Accuracy (%)				Attribute Accuracy (%)		
	Open	Pickup	ToggleOn	Slice	size	distance	temperature
base	8.33	10.96	27.38	22.13	73.78	51.01	95.91
base+symbolic (PIGLeT)	85.73	80.48	96.90	75.41	94.98	95.13	99.85
base+symbolic+images	88.75	86.14	92.86	81.31	96.35	96.13	99.59
base+images (PIGLeT-Vis)	20.83	33.49	70.24	41.64	87.03	76.62	96.10
base+images+text-labels	22.92	40.12	67.14	45.57	87.89	78.06	96.72

Table 2: Action and attribute specific accuracies for a subset of actions and attributes; for a comprehensive table with standard deviations see Appendix D. size and distance each have eight possible classes while temperature has three.

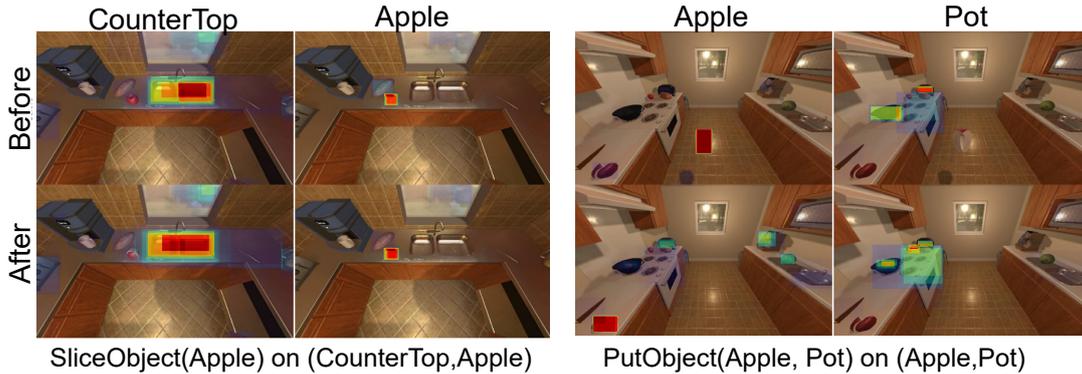

Figure 3: We visualize the attention of the Vision Object Encoder from a trained base+images model on two different actions and environments. The left grid focuses on the effect of Slice(Apple) on CounterTop and Apple, while the right grid focuses on the effects of Slice(Apple) on Apple and Pot objects.

to any possible unseen object during test time. base+images+text-labels is adaptable to general settings without knowing the symbolic mapping of objects and actions in the environment.

The results of both base+symbolic+images and base+images+text-labels make the case multi-modal modeling of commonsense reasoning, as both language and images are complementary to generalize to unseen settings.

4.1 Qualitative Attention Maps

Visualizing attention is another benefit of a vision component, as we can see what the model focuses on and partially explain its predictions. Figure 3 shows two separate examples and corresponding attention maps. In the left example, base+images is tasked with predicting the attributes of CounterTop and Apple after the Slice action is applied on the Apple. In the right example, the Put action is applied on the Apple, and the model must predict the attributes of the Apple and the distractor object Pot. The two rows are the before and after images (i_{pre} and i_{post}), and the two columns are the two objects used to condition the attention. The attention maps display the strength of the attention for each bounding box given an object name.

Both examples in Figure 3 show that the Vision

Object Encoder can map known objects to relevant bounding boxes. The model successfully tracks the Apple in both cases by placing the most weight on the bounding box targeting the Apple. However, these examples also show the difficulty of this task—the environments are realistic and can be filled with more than one instance of an object.

5 Conclusion

In this paper, we tackle the task of predicting the effects of actions on objects’ physical attributes. In contrast to (Zellers et al., 2021), our model does not treat the formal symbolic representation of the images as observed. Instead, PIGLeT-Vis supports inference when the inputs are images alone or images plus NL descriptions and a phrase denoting the action (e.g., “the robot empties the cup”). While PIGPeN offers challenges for applying a multi-modal approach, our model can extract useful information from images, opening the door for generalizing learning physical commonsense to real-world data. Importantly, our PIGPeN-Vis split can be used to evaluate the zero-shot capabilities of different model configurations. Moreover, while base+symbolic still outperforms base+images, it does so without estimating the attributes of ob-

jects and thus solves a much easier but unrealistic task. Through `base+images+text-labels`, we show that, when replacing symbolic inputs, the best solution is to complement image inputs with NL descriptions to leverage information from both modalities. Finally, our results show the need to improve the generalization capabilities of multimodal models such that they can learn and adapt to unseen situations.

6 Limitations

There are several limitations to our approach that result directly from the inherent limitations of PIGPeN and our proposed Vision Object Encoder respectively.

PIGPeN was not originally designed for testing commonsense reasoning using images and contains numerous inconsistencies which cannot all be solved with the PIGPeN-Vis split obtained from filtering (Section 3.4.1). Given the presence of non-physically salient attributes such as temperature, images are not guaranteed to fully capture their symbolic representations. PIGPeN includes certain attributes which are not discernible from images, e.g., even humans would be unable to tell a hot plate from a cold plate from vision alone. The images in PIGPeN can also contain more than one object (e.g., more than one cup) without ever specifying which one the symbolic representation refers to. This causes difficulty for our approach because judging specific attributes such as distance is impossible if there are two cups at different distances from the viewpoint. Additionally, PIGPeN also discretizes continuous variables such as distance into categories which can be hard to disambiguate.

To approach the accuracy of `base+symbolic` with our vision component, we also need a vision representation from which to correctly estimate all latent attributes. Even if images are assumed to be perfect representations of the symbolic environment, the model still has to extract each of the 38 attributes correctly for both objects using only two images. It is possible (and likely) for the vision detection backbone to miss the target object entirely because it is not trained to detect the specific object in question. We see this effect in Figure 3, where the model falls back to using a bounding box around the sink area to describe the CounterTop object. The DETR vision model used to extract bounding boxes was pre-trained on the COCO dataset (Lin et al., 2014) which does not

contain CounterTop as an object. PIGLeT-Vis is therefore ultimately limited by the capabilities of its vision backbone.

Ethics Statement

While this work does not introduce new data or involve human participants, we use the PIGPeN dataset which contains human-labelled data. The fine-tuning portion of the dataset was annotated through MTurk by Zellers et al. (2021) and they report following best practices (paying decent wages, providing feedback and using a qualification test) in their data collection. We filter and use a subset of PIGPeN and introduce methods to learn the effects of actions in a multimodal setting. We, therefore, believe that our work does not raise any ethical concerns.

A GPT-3 Example of Physical Reasoning

The weight of the potato is 150 grams.
 The robot then slices the potato into thin slices.
 The weight of the potato is now 75 grams.

Figure 4: Example of incorrect physical commonsense by an LLM. When predicting what comes after the **input text**, the large 175 billion parameter GPT-3 (Brown et al., 2020) predicts that the weight of the potato halves after a slicing action is taken.

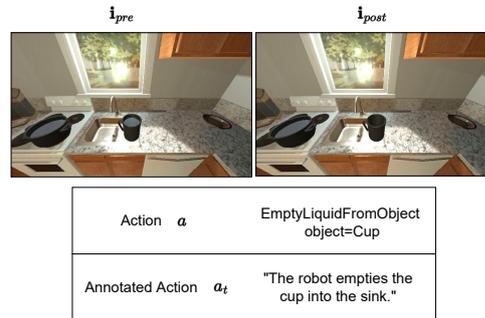

Figure 5: Image pair and actions for a selected PIGPeN example.

Table 3: Attributes for a selected PIGPeN example. The total number of attributes is 38 as the Materials attribute is a multi-hot encoding.

B PIGPeN-Vis

We select an example from PIGPeN to display in Figure 5 and Table 3.

From the original dataset, we remove two attributes (`isUsedUp` and `salientMaterials_Organic`) because they are unchanged in all examples. We also remove 3 actions (`ThrowObject10`, `ThrowObject100` and `ThrowObject1000`) which are all related to throwing an object across a certain distance. These actions account for only a small subset of the dataset and create inconsistent image pairs due to the agent’s momentum being captured in the images. The angle of the camera changes as a result of `ThrowObject` and this breaks our assumption that the difference between \mathbf{i}_{pre} and \mathbf{i}_{post} solely reflects the effects of the action on the environment (and not on the viewer). We therefore reduce the total number of symbolic attributes per object to 38 and the number of possible actions to 10.

B.1 Attributes

The following 38 symbolic attributes are used to describe an object in PIGPeN:

ObjectName,	parentReceptacles,
receptacleObjectIds,	distance, mass, size,
ObjectTemperature,	breakable, cookable,
dirtyable, isBroken,	isCooked, isDirty,
isFilledWithLiquid,	isOpen, isPickedUp,
isSliced, isToggled,	moveable, openable,
pickupable, receptacle,	salientMaterials_Ceramic,
salientMaterials_Fabric,	salientMaterials_Food,
salientMaterials_Glass,	salientMaterials_Leather,
salientMaterials_Metal,	salientMaterials_Paper,
salientMaterials_Plastic,	
salientMaterials_Rubber,	salientMaterials_Soap,
salientMaterials_Sponge,	salientMaterials_Stone,
salientMaterials_Wax,	salientMaterials_Wood,
sliceable, toggleable	

B.2 Filtering Statistics

We initially filter the PIGPeN dataset using two main strategies to remove images with too much or too little change between the pre and post images. In both cases, the goal is to remove pairs of images in which it would be impossible for a vision model to predict what has changed.

Images with too many changes are often images taken from different viewpoints or with different lighting conditions. We filter these images by look-

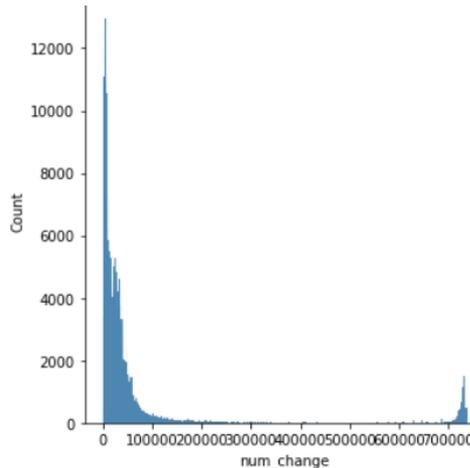

Figure 6: Distribution of the number of pixels changed per image in the PIGPeN dataset.

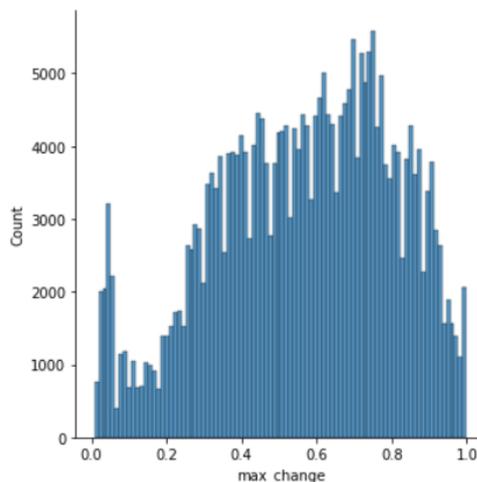

Figure 7: Distribution of the maximum pixel value changed per image in the PIGPeN dataset.

ing at the number of pixels changed between \mathbf{i}_{pre} and \mathbf{i}_{post} . We show the distribution of the number of pixels changed per image over the training dataset in Figure 6. Using this visualization we can clearly see a small peak at the extreme - where almost all the pixels in \mathbf{i}_{post} are different from \mathbf{i}_{pre} . Note that since each image is an RGB image of dimensions 640×385 , the max number of change is $640 \times 385 \times 3 = 739,200$ (we also compare pixels across color channels). We opt to remove all images with more than 400,000 changes, which corresponds to around 6.2% of the training dataset.

Images with too little change could be examples of where the action has no visual outcome and \mathbf{i}_{pre} and \mathbf{i}_{post} are indistinguishable. To filter these images we measure the maximum magnitude of change in each pixel and each color channel be-

tween the pairs of images. We visualize the max change across the training dataset in Figure 7. Here a low values implies almost no salient change, and as max change approaches zero - it becomes unlikely that a human would be able to perceive the difference between the pair of images. We opt for to keep images with a max change greater than 0.2 which corresponds to excluding 7.8% of the training dataset.

Filtering on the number of changed pixels lead to the exclusion of around 13.89% of the training dataset.

B.3 Zero-shot Filtering

We remove the following 14 objects from both the train and validation (3, 401 examples total):

HandTowel, Towel, Plunger, Watch, CD, SoapBottle, Pen, RemoteControl, SoapBar, Box, Bottle, CreditCard, Statue, KeyChain

We remove the following 27 action-object pairs from both the train and validation (3, 278 examples total):

(CloseObject, Toilet),
 (DirtyObject, Pan), (DirtyObject, Pot),
 (EmptyLiquidFromObject, Bottle),
 (EmptyLiquidFromObject, Pot), (OpenObject, Toilet),
 (PickupObject, Box), (PickupObject, CellPhone),
 (PickupObject, CreditCard),
 (PickupObject, KeyChain), (PutObject, CD),
 (PutObject, CreditCard), (PutObject, HandTowel),
 (PutObject, Laptop), (PutObject, Lettuce),
 (PutObject, Pen), (PutObject, Plunger),
 (PutObject, Pot), (PutObject, RemoteControl),
 (PutObject, SoapBar), (PutObject, SoapBottle),
 (PutObject, Statue), (PutObject, ToiletPaper),
 (PutObject, Towel), (PutObject, Watch),
 (ToggleOff, CellPhone), (ToggleOff, Television)

C Code Release and Training

Our full code, models, and PIGPeN-Vis split can be found at github.com/gautierdag/piglet-vis.

C.1 Additional Training Details

As previously mentioned, there are a few differences between the original Zellers et al. (2021) model and our implementation of base+symbolic. We use an off-the-shelf RoBERTa-base (Liu et al., 2019) model instead of a custom GPT2 (Radford et al., 2019). Additionally, we also reduce the dimensionality of the PIGLeT layers from $h = 256$ to $h = 64$. This shrinks the overall model (ex-

cluding the LLM) from 11.9 million parameters to less than 2 million parameters during pre-training and improves the overall accuracy by a small margin (+1.51%). We do not run any other hyperparameter search throughout our experiments and wherever possible use the same hyper-parameters as PIGLeT. We also reduce the batch size from 1024 to 256 because we use a mix of NVIDIA GTX 1080 and NVIDIA A100 GPUs and wish to keep batch size constant.

The +images models use the extracted representations from a frozen off-the-shelf DETR model (41.3 million parameters), however it is ran only once over all images as we cache its predictions. We do not use the “NO OBJECT” predictions from DETR, and simply pass all 100 bounding boxes representations to the attention mechanism. Since we do not have access to the true bounding boxes in PIGPeN, we do not fine-tune DETR and therefore ignore its prediction heads which have also been trained on COCO and mismatch our possible objects.

The +symbolic models use the Symbolic Object Encoder which is an additional 800, 000 parameters on its own. During fine-tuning all models use a RoBERTA-base model (+120 million parameters) in the Action Encoder. The +text-label model also uses the RoBERTA-base model during pre-training, but again this is frozen and its outputs are cached for the full dataset.

We pre-train each model for 80 epochs and fine-tune for 60 epochs. For all setups, pre-training takes between 1 to 2 hours and fine-tuning takes less than 1 hour on an NVIDIA A100 GPU. We use the Pytorch implementation of the Adam optimizer (Kingma and Ba, 2014) and a learning rate of 10^{-3} during pre-training and 10^{-5} during fine-tuning. We use early stopping on the validation loss with a patience of 10 epochs. We run each setup over 10 different seeds ($s \in [1, 2, \dots, 10]$) and report the average and standard deviation for each metric.

D Accuracy Results

D.1 Comparing PIGPeN and PIGPeN-Vis

Table 4 compares the overall accuracy on the original PIGPeN dataset with our proposed PIGPeN-Vis split. We find that our PIGPeN-Vis split is consistently harder to solve than the original PIGPeN dataset. We explain the increased accuracy in the original dataset with the fact that some of the filtered out actions (see Appendix B) are easy to

	Overall Accuracy ($\% \pm \sigma$)		
	PIGPeN	PIGPeN-Vis	Δ
base	29.18 \pm 0.34	21.23 \pm 0.72	-7.95%
base+symbolic (PIGLeT)	86.39 \pm 0.79	85.03 \pm 0.45	-1.36%
base+symbolic+images	87.45 \pm 0.66	86.01 \pm 0.89	-1.44%
base+images (PIGLet-Vis)	49.13 \pm 1.53	45.47 \pm 1.50	-3.66%
base+images+text-labels	51.28 \pm 1.68	47.55 \pm 2.10	-3.73%

Table 4: Overall Accuracies comparing full PIGPeN with the PIGPeN-Vis split across 10 seeds.

	Overall Accuracy ($\% \pm \sigma$)	
	validation	test
base	23.85 \pm 0.95	21.23 \pm 0.72
base+symbolic (PIGLeT)	88.08 \pm 0.50	85.03 \pm 0.45
base+symbolic+images	89.49 \pm 0.82	86.01 \pm 0.89
base+images	50.73 \pm 2.97	45.47 \pm 1.50
base+images+text-labels	53.33 \pm 3.15	47.55 \pm 2.10

Table 5: Validation and test overall accuracies. Note the zero-shot accuracy is not calculated on the validation set since there are no unseen examples in the validation set to prevent leakage.

solve from knowing the object name and action: e.g., most of the images we exclude due to little salient changes are appliances like stoves being turned on or off. However, it is easy for a model to predict the post-condition attributes of a stove, which are mostly static, across all examples given an action such as ToggleOn, which always has the same effect.

D.2 Complete Accuracy Results on PIGPeN-Vis

Table 5 shows the overall accuracies for both the test and validation sets. The full accuracy results for all actions in Table 6 and for all attributes in Table 7.

E Additional Attention Maps

We plot additional attention visualizations for all three image models base+images, base+symbolic+images, and base+images+text-labels in Figures 8, Figures 9, and Figures 11. Since the DETR object detector remains frozen, all models have access to the same bounding boxes and bounding box representations. Qualitatively, we find that the attention weights of base+images and base+images+text-labels both learn to map to globally relevant bounding boxes given an objects. We also find the attention maps in base+images+text-labels to be less confident overall than base+images, likely due to the noise introduced by the semantic text inputs. As a result, base+images+text-labels makes less mistakes

by not focusing too much attention to the wrong bounding box.

On the other hand, base+symbolic+images focuses on seemingly random bounding boxes. Since base+symbolic+images already receives the full representation of each objects, it does not learn to complement the object’s representation with accurate visual information. While base+symbolic+images extracts 1% of additional overall accuracy from image inputs when compared to base+symbolic, it does so by falling back to vision for visually salient actions such as Pickup. base+symbolic+images focuses only a narrow set bounding boxes with overconfidence with no regard for whether or not the bounding box relates to the object. We posit that the model might use vision to better estimate more difficult attributes to predict such as distance in some contexts. Note Pickup is a salient action because when the agent in the environment picks an object up, the object is placed directly in the middle of its field of vision (as if the agent were holding the object in front of it).

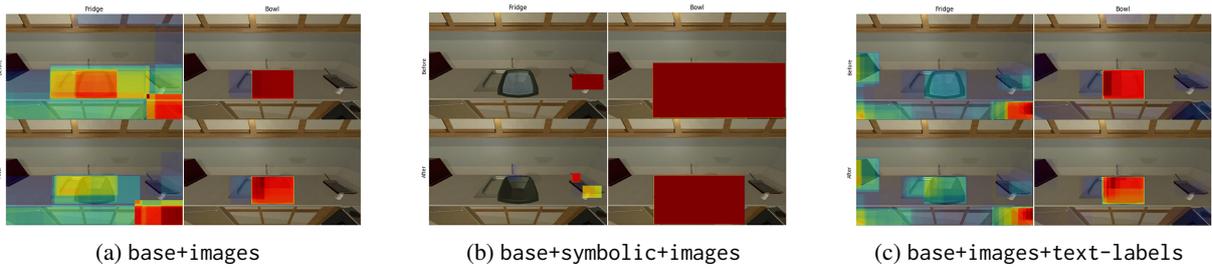

Figure 8: Attention maps for the effects of the EmptyLiquid action on Bowl with objects Fridge and Bowl. The top row of each grid maps to the before environment and the bottom row maps to the after environment. The columns map to each respective object. The Fridge object appears in the lower left of the image, and is only correctly identified by base+images+text-labels, even though the model does place more weight to the bounding box of the stove (lower right).

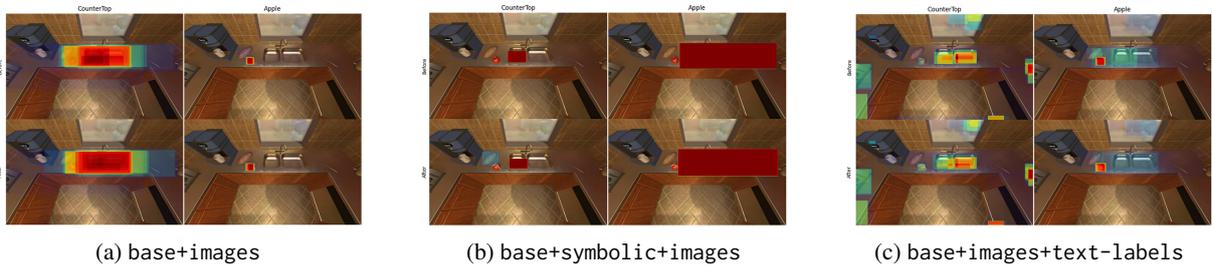

Figure 9: Attention maps for the effects of the Slice action on Apple with objects CounterTop and Apple. The top row of each grid maps to the before environment and the bottom row maps to the after environment. The columns map to each respective object.

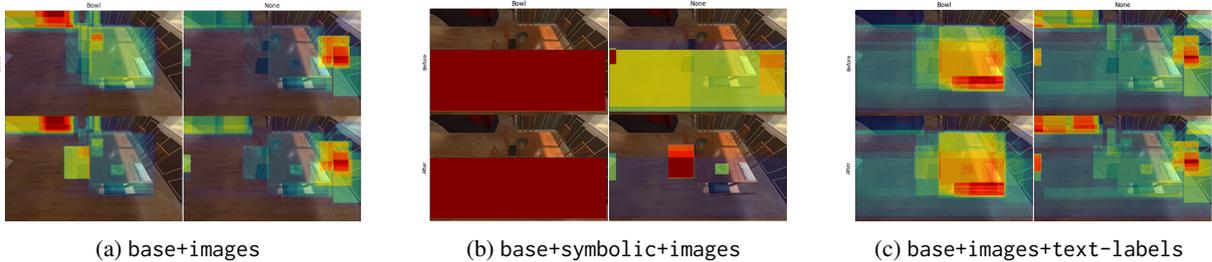

Figure 10: Attention maps for the effects of the Dirty action on Bowl with objects Bowl and None. The top row of each grid maps to the before environment and the bottom row maps to the after environment. The columns map to each respective object. None can be an object in PIGPeN, but we do not predict its attributes and exclude it in all model predictions.

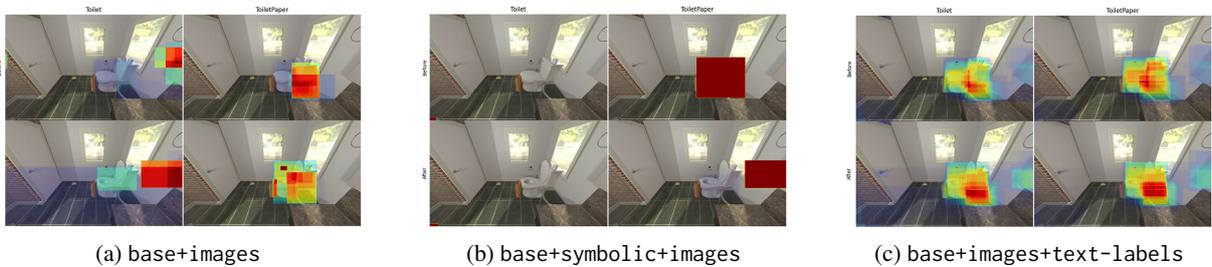

Figure 11: Attention maps for the effects of the Open action on Toilet with objects Toilet and ToiletPaper. The top row of each grid maps to the before environment and the bottom row maps to the after environment. The columns map to each respective object. This particular set example is an unseen combination of action and object that has been excluded from the training and validation set.

Abstract

The widely used Fact-based Visual Question Answering (FVQA) dataset contains visually-grounded questions that require information retrieval using common sense knowledge graphs to answer. It has been observed that the original dataset is highly imbalanced and concentrated on a small portion of its associated knowledge graph. We introduce FVQA 2.0 which contains adversarial variants of test questions to address this imbalance. We show that systems trained with the original FVQA train sets can be vulnerable to adversarial samples and we demonstrate an augmentation scheme to reduce this vulnerability without human annotations.

1 Introduction

Knowledge-based Visual Question Answering (KB-VQA) lies at the intersection of Computer Vision, Natural Language Processing, and Information Retrieval. A KB-VQA system must access external knowledge sources to find a correct and complete answer, a task that is sometimes hard for humans.

Fact-based Visual Question Answering (FVQA) (Wang et al., 2017) is a VQA task in which visually-grounded questions and answers about images are grounded by knowledge-graph (KG) triplets taken from several ‘common sense’ knowledge bases, such as ConceptNet (Speer et al., 2017), Webchild (Tandon et al., 2017), and DBpedia (Auer et al., 2007). For instance, “Question: Which thing in the image can be used for scooping food? Answer: spoon” is associated with the KG triplet “spoon - UsedFor - scooping food”. These questions are challenging in that retrieving information from external KGs is necessary.

The original FVQA dataset (Wang et al., 2017) has several readily observed limitations. First, the dataset is small (5486 samples) and the annotations are limited to a single answer per question, ignoring other correct answers. This limitation arises

from the FVQA creation process in which annotators were first asked to select a KG triplet on which they would ask a question about an image. This approach prevented the annotators from labeling other valid KG triplets. Secondly, the dataset is highly imbalanced. Some triplets and answers are frequently used, but other KG triplets and answers are severely underrepresented in training. For example, there are 1,129 possible answers in total, but over 90% of questions focus on only a half of them; 792 (70%) answers appear less than 3 times; only 4,216 out of ~220k triplets are used.

These limitations lead to a potential problem: KB-VQA systems trained on this dataset overfit on these frequently used triplets and perform poorly on variants that contain other valid triplets or other images. Also, extensive overlap between training and test can lead to an unrealistically high question answering baseline performance. We noted that a question with a triplet unseen in training is often answered with ‘person’, since it is the most frequent answer in the original data distribution.

To overcome these limitations, we introduce an enlarged test set that contains two types of adversarial samples (as shown in Fig. 1): (1) *FixQ*: the question remains the same, but is associated with a different image and a different correct answer. This ensures that a system is less able to achieve high performance if it is biased by language patterns in questions; (2) *FixA*: the answer remains the same, but the question is asked in a different way. This favours systems that do more than make straightforward associations between questions and answers based on the training data. In contrast to the original test set, this new set further challenges KB-VQA system to retrieve knowledge from KBs and answer questions without being biased towards frequent answers in the original dataset. We show that models trained on the original FVQA training sets are significantly less robust on these adversarial test samples.

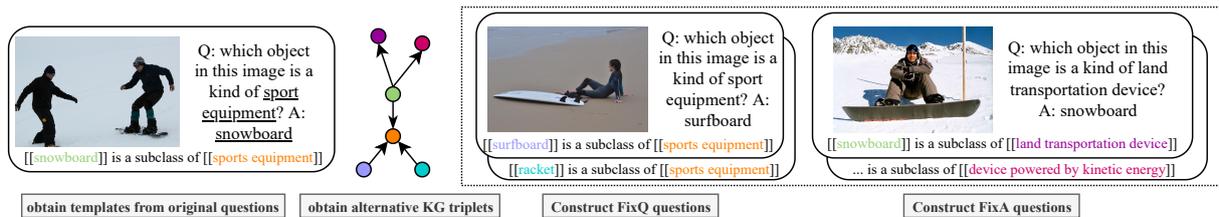

Figure 1: The workflow of constructing adversarial samples (FixQ and FixA questions) from the original test set questions.

Given that it is hard to guarantee a good triplet coverage during annotation, we explore an augmentation scheme to address this problem without costly human annotation of large-scale adversarial training samples. Our scheme generates slightly noisy adversarial samples that improve the coverage of valid KG triplets to enhance model training.

Our contributions are:

(1) We introduce FVQA 2.0, which adds an adversarial test set that challenges KB-VQA system robustness to adversarial variants of questions.

(2) We demonstrate the performance gap between the original test set and the adversarial test set, showing that considering adversarial samples is important for better realistic KB-VQA performance.

(3) To further demonstrate the importance of adversarial samples, we leverage a semi-automated augmentation scheme to improve system robustness on the adversarial test through the creation of large-scale noisy adversarial examples.

2 Related Work

KB-VQA questions can focus on facts and concepts, as in FVQA (Wang et al., 2017) and OK-VQA (Marino et al., 2019). Such questions challenge the information retrieval ability of systems. KB-VQA questions can also require common-sense reasoning, as in parts of OK-VQA and A-OKVQA (Schwenk et al., 2022). In particular, S3VQA (Jain et al., 2021) is an augmented version of OKVQA, improving both the quantity and quality of some question types. A-OKVQA has shifted its core task to “reasoning questions”. Only 18% of questions in A-OKVQA require answers from an external knowledge base.

VQA 2.0 (Goyal et al., 2017) collects ‘complementary images’ such that each question is associated with a pair of images that result in different answers. Jain et al. (2021) derive new S3VQA questions from manually defined question templates. They annotated spans of objects that could be replaced, and then substituted them with a com-

plicated substitute-and-search system. In contrast to their labour-intensive annotation work, our adversarial samples are collected through a semi-automatic approach that fully leverages the structural information in KGs to significantly reduce the human work required.

More broadly, in Knowledge-Graph Question Answering (KG-QA), work has exploited KG to generate synthetic data in unseen domains (Linjordet, 2020; Trivedi et al., 2017; Linjordet and Balog, 2020). Our work extends visually-grounded questions with valid common sense KG triplets.

3 Method

Extracting Question Templates. We extract question templates that can be used to reconstruct new questions using other valid KG triplets. We apply a rule-based system to replace KG entities that appear in the questions. For example, ‘what is used for storing liquid in this image?’ is transformed to ‘what is used for <t> in this image?’ given that the associated KG triplet is “bottle (<h>) - /r/UsedFor (<r>) - store liquid (<t>)”.

For each template, we construct new question-answer pairs by exploring the node structure of the KG. For example, “bottle - /r/UsedFor - hold water” is also a valid triplet from ConceptNet, whose head and relation are the same as the original triplet. A new question “Q: what is used for holding water in this image? A: bottle” can now be constructed.

Template Filtering. We focus on questions about object concepts that are transferable to other images, ignoring a small portion (<10%) of FVQA questions to which the answers are based on particular scenes (e.g. ‘what can you often find in the place shown in this picture?’).

Human annotators are employed to filter out non-transferable templates, such as questions that contain specific object positioning (“what is the object in the lower right of this image used for?”). This process takes around 1 hour with two annotators to obtain 440 valid templates after removing highly similar templates.

Matching Suitable Images. We use 619 of FVQA images¹ that are also present in the Visual Genome dataset (Krishna et al., 2017). Using the object annotations of the VG dataset to determine if an image contains the object being asked, we employ a rule-based system to assign a suitable image to each generated adversarial sample, within which process all images are assigned to approximately the same number adversarial samples by a simple approach described in Appendix B. We limit the number of FixQ and FixA questions generated by each template to 5, which guarantees a reasonable dataset size. 3,805 questions are generated.

Manual Verification. We conduct manual verification to rule out samples that are incorrectly generated. 432 counter-intuitive KG triplets are removed in this step. Finally, we obtain 2,820 adversarial samples, offering 1,671 new valid triplets from the KG. Around 75% samples are verified as correct, showing that the rule-based generation works well. The remainder are discarded.

The official FVQA evaluation performs 5-fold validation: each split preserves around half its samples for testing. As a naming convention, under each split, the templates extracted from the original training samples are called ‘train templates’ while the rest are ‘test templates’. Since the train templates may contain language patterns that have been learned in training, we ensure that only questions derived from test templates are used in the adversarial testing. As a result, we have 1,376 adversarial test samples per split on average, with 1,129 FixQ and 246 FixA questions.

Augmentation with Adversarial Data. We explore an augmentation scheme to augment the training data with slightly noisy but auto-generated adversarial samples, which avoids heavy annotation work. In each split, **only the train templates** (defined in the above paragraph) are used to generate adversarial samples for training such that no information of test samples is leaked to training. This avoids biasing the training to the test sets, which would make the test sets less indicative of true system performance. We obtain an augmentation set with 2,262 questions per split on average semi-automatically, which would otherwise cost hundreds of hours to build from scratch. The origins of these adversarial samples are referred to as ‘*Originating Questions*’. There are 435 such

questions per split. In training, these questions are randomly replaced by their adversarial variants.

4 FVQA 2.0 Statistics

Set Name	#Samples	std
Standard Train Set	2,927	69
Standard Test Set	2,899	69
Originating Questions Set	435	52
Adversarial Test Set	1,376	193
- FixA Questions	1,129	157
- FixQ Questions	246	38
Augmentation data	2,262	267

Table 1: Dataset Statistics. #Samples: average number of samples across 5 folds; std: the standard deviation over 5 folds.

The numbers of samples in each set are provided in Table 1. The official FVQA dataset creates 5 folds by splitting the images being used. Half of these images are used in training while the other half are reserved for testing. In all our new sets, under each split, questions for training are not leaked to testing. The ‘Originating Question Set’ is a subset of Standard Test Set by its definition (Sec. 3). The Adversarial Test Set is formed by FixA questions and FixQ questions; it is created by automatically generating adversarial question variants from the questions in the ‘Originating Question Set’. It covers relationships such as */r/RelatedTo*, */r/IsA*, */r/PartOf*, */r/HasA*, */r/UsedFor*, */r/CapableOf*, */r/AtLocation*, */r/Desires*, */r/MadeOf*. The augmentation data consists of adversarial variants that are derived from the questions in the Standard Train Set.

5 Experiments

Baseline Systems We use several FVQA systems for comparison²: FVQA (Wang et al., 2017), the baseline system provided in the official FVQA dataset paper; GCN (Narasimhan et al., 2018), a model that leverages graph convolutional networks (GCNs) to aggregate features from visual/language/fact modalities; Mucko (Zhu et al., 2020), the current state-of-the-art system that uses GCNs to combine visual, fact, and semantic graphs.

We test our augmentation scheme on several systems that have code available: **RAVQA-NoDPR**

¹FVQA images are from Microsoft COCO (Lin et al., 2014) and ILSVRC (Russakovsky et al., 2015).

²Since many recent FVQA systems are not open-sourced, we additionally include KB-VQA systems from OKVQA.

and **RAVQA-DPR** (Lin and Byrne, 2022), T5 (Rafel et al., 2020)-based models that transform images into texts (e.g. objects, attributes, and image captions) and the DPR version additionally uses Dense Passage Retrieval (Karpukhin et al., 2020) to retrieve documents from knowledge bases³; **TRiG** (Gao et al., 2022), a model that is similar to RAVQA-DPR but different in embedding fusion; **ZS-F-VQA** (Chen et al., 2021), an FVQA system that obtains the final prediction by fusing the individual predictions in answer/fact/relation graphs.

Metrics. We report accuracy and standard deviation over 5 splits (Sec. 4). In calculating accuracy for open-ended generation systems (RAVQA/TRiG), a question is considered successfully answered if the generated answer string is an exact match to the ground-truth answer node, which is the closest KG node to the ground-truth answer string (shortest in Levenshtein distance computed from node names).

Performance and Discussion. Table 2 shows that the systems used for evaluating the new adversarial set are sufficiently strong (e.g. 69.56% accuracy by RAVQA-DPR) in comparison with the three models that do not have code available, which achieve 58.76% (FVQA), 69.35% (GCN), and 73.06% (Mucko, current state-of-the-art) respectively. RAVQA-NoDPR achieves 84.59% accuracy on the originating questions but obtains only 71.48% accuracy on the adversarial samples derived from them. Such performance gaps are readily observed on all systems. Systems trained on the original training sets fail to perform equally well on the two sets, showing that the original FVQA training data does not contain adversarial variants and the resulting systems are vulnerable to them.

By incorporating adversarial variants in training, all systems achieve much better performance on the challenging adversarial set, e.g. RAVQA-NoDPR is improved from 71.48% to 82.38% (+10.9%). The performance on the standard and adversarial test sets now match well, with the gap reduced from more than 10% to \sim 3%, showing that the augmentation scheme significantly improves systems’ reliability and robustness. The relative improvement is slightly less (+8.1%) for RAVQA-DPR, which is expected given that it is a retrieval-based system designed to answer both seen and unseen questions with its strong retrieval ability. ZS-F-VQA benefits

³In our experiments, the knowledge base consists of surface texts of triplets (e.g. “[car] has [4 wheels]”).

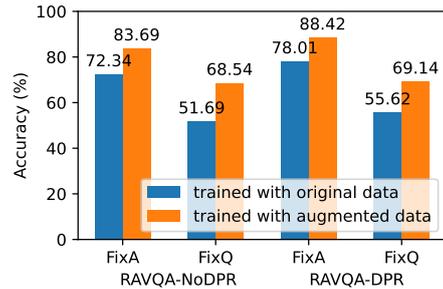

Figure 2: Performance on FixQ and FixA questions.

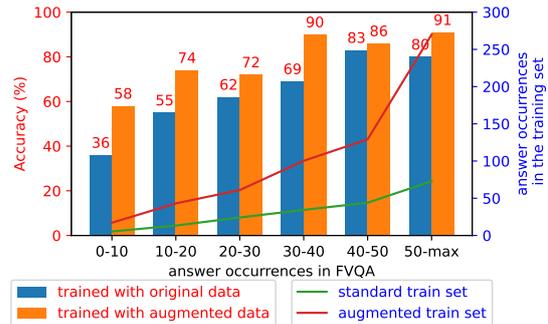

Figure 3: RAVQA-DPR accuracy on adversarial questions and answer occurrences in the standard/augmented training sets. They are grouped by the number of answer occurrences in the original FVQA dataset. For example, a question is counted towards the ‘0-10’ group if its answer appears less than 10 times in the original dataset.

greatly from augmentation: its adversarial performance is improved by 24.09%. This is because its model size is much smaller and it can easily be biased by language patterns, images, and frequent answers seen in training.

In summary, systems trained on the original training sets are vulnerable to adversarial variants of the test questions. We show that through generating adversarial samples for data augmentation, systems become much more robust to these variants.

Analysis of Model Vulnerability. As shown in Fig. 2, RAVQA systems trained with original training sets perform better on FixA questions (\sim 88%) than on FixQ questions (\sim 69%). This suggests that systems perform worse when asked the same questions on different images. This is potentially because the language patterns seen in training bias the models to frequent choices, lowering the FixQ generalizability. In contrast, systems are less distracted by different ways of asking for the same answer, potentially due to the strong language modelling capability of T5 used by them. The augmentation scheme improves systems on both types of questions significantly (by \sim 10% on each), showing the value of adversarial samples in training.

Test on:	Standard Test Set		Originating Question Set		Adversarial Test Set	
Trained on:	Original	Augmented	Original	Augmented	Original*	Augmented (improv. over *)
ZS-F-VQA	48.16 \pm 1.03	48.57 \pm 1.00	63.67 \pm 0.88	64.63 \pm 0.81	49.97 \pm 2.37	74.06 \pm 1.92 +24.09
TRiG	64.94 \pm 0.93	65.73 \pm 0.33	81.67 \pm 1.12	83.48 \pm 1.89	68.86 \pm 3.26	79.79 \pm 1.34 +10.93
RAVQA-NoDPR	66.19 \pm 1.15	66.70 \pm 1.00	84.59 \pm 1.24	85.75 \pm 0.90	71.48 \pm 2.08	82.38 \pm 1.65 +10.90
RAVQA-DPR	69.56 \pm 0.78	69.90 \pm 0.56	87.52 \pm 1.68	88.33 \pm 1.40	76.91 \pm 1.93	85.05 \pm 1.15 +8.14

Table 2: Model performance on the standard test set, originating questions (from which the adversarial questions are derived), and adversarial test set. Results are reported as the average of 5 folds with standard deviations.

Fig. 3 plots the RAVQA-DPR performance on the adversarial test set questions that are grouped by their answer occurrences in the original FVQA dataset. The answer distribution of the original dataset affects adversarial performance greatly: systems perform much worse on questions whose answers appear less frequently in FVQA. In contrast, the performance deterioration that arises from answer rarity is mitigated significantly after augmentation. The augmentation scheme (red v.s. green curve in Fig. 3) compensates for the imbalanced answer distribution by providing more question variants so that systems are trained on both popular and rare answers.

6 Conclusion

We show that the FVQA test sets are not sufficiently indicative of true system performance through providing a new human-verified adversarial test set that contains adversarial variants of the original test set questions. We show the value of adversarial samples in KB-VQA datasets by showing an augmentation scheme that leverages structural information in KGs to create augmentation questions for training, which improves models’ robustness to adversarial variants.

We release the dataset and the codes in Github (<https://github.com/LinWeizheDragon/Retrieval-Augmented-Visual-Question-Answering>).

7 Limitations

The adversarial test set was firstly generated from the original FVQA dataset by a rule-based system and then filtered by human annotators. As a result, the new set is limited with respect to the question types, language patterns, and knowledge triplets used in FVQA. One potential solution to overcome this limitation is to invest more human effort to generate adversarial questions from scratch, which is, however, much more expensive than the semi-automatic approach presented here.

The proposed augmentation approach also relies on the relationships encoded in the knowledge base (e.g. ConceptNet (Speer et al., 2017)). These will influence the quality and diversity of the augmented data, with the expectation that improvements in KG scope and quality will improve data augmentation.

The number of adversarial examples introduced in this work is sufficiently large for investigating the performance discrepancies (on the original and adversarial test sets) and demonstrating the necessity of KB-VQA adversarial samples. However, it is considered beneficial to introduce adversarial samples on a larger scale by considering them in the design of future KB-VQA datasets.

8 Ethics Statement

Our dataset was created semi-automatically from the FVQA dataset and ConceptNet, a crowd sourced common sense knowledge graph. Though we have included human annotators in the loop to remove sexual, offensive, and other inappropriate data samples that were automatically generated (we removed \sim 200 inappropriate knowledge graph triplets during annotation), we recognize that the dataset may still contain a small number of inappropriate samples. Any developers who replicate the semi-automatic methodology described in the paper to extend the datasets should include a similar review step in the manual work flow. We also recognize that the systems trained on this dataset may convey such inappropriate information to users in real-life applications. Therefore, extra care must be taken when using this dataset in applications that interact directly with real users.

9 Acknowledgement

A Training Details

ZS-F-VQA: The experiments were performed on $1 \times$ Nvidia RTX 3090. We used the code from the official repository⁴. The original paper dropped questions that have rare answers. For fair comparison with other models, we added these rare answers back and performed training and testing. We chose to report the performance of the system which uses ‘SAN’ as the base model (details are in the paper and the repository), since this setting has achieved the best performance. The hyperparameters for training are kept the same as the original paper. In testing, we selected $k_e = 10$; $k_r = 1$; $score = 10$ by grid search (search range: $0 \leq k_e \leq 20$; $0 \leq k_r \leq 20$; $0 \leq score \leq 20$).

⁴<https://github.com/China-UK-ZSL/ZS-F-VQA>

RA-VQA-NoDPR/RAVQA-DPR/TRiG: All experiments were performed on $1 \times$ Nvidia A-100 GPU. We chose Adam (Kingma and Ba, 2015) as the optimizer. When the model has a DPR component, we trained the DPR component for 4 epochs with a constant learning rate 10^{-5} . In training the answer generator, the learning rate linearly decays from 6×10^{-5} to 0 after 10 epochs, as suggested in the original paper. For each split, the checkpoints at global step 2k (around 3.5 epochs) were used in testing. We retrieve 5 best documents when predicting the answer ($K_{train} = 5$), since this number was reported to best balance the computation and performance (Lin and Byrne, 2022).

We obtained the pre-trained model parameters (T5-large and BERT-base) from Huggingface (Wolf et al., 2020). These systems are implemented with Huggingface Python libraries (under Apache License 2.0). The FAISS (Johnson et al., 2019) system is under MIT License.

B Balancing Images in Adversarial Variants

In assigning suitable images to question templates, it is necessary to ensure the diversity of images being used. We achieve this by controlling the number of assignments per image with a simple approach so that the numbers are approximately the same for all images.

In the process, for each new question-answer pair that needs an image, we rank all the images that contain the object being asked in the the question by their current total number of assignment. We select the image that satisfies the conditions as well as having the fewest number of assignment as the associated image of the new sample. We found that by applying this simple yet effective strategy, the assigned images present a good diversity.

C Annotation Details

Two annotators (volunteers in the research group) worked independently to rule out incorrectly generated examples. An example was accepted only if the two annotators achieved consensus. The annotators attempted to fix grammar errors that caused severe misunderstanding, while mild errors were kept (for example, ‘is used for carry people’ does not prevent models/people from understanding the question, and thus the annotators are not required to fix them).

In particular, questions that might contain information of individuals / private information were dropped, though it is a very rare case.

Questions with multiple answers: when a question can be answered with multiple instances in an image, all possible answers are included. During annotation, incorrect answers were dropped from the list. In evaluation, answering any correct answer is considered successful. There are around 11% multiple-answer questions at the end.

D Additional Results

We include some additional baseline performance in Table 3. It can be easily seen that the performance on originating questions (the original FVQA questions that are used to derive the adversarial samples) is very high even when images are excluded. This further supports our argument that the original dataset is heavily biased to frequent answers. The performance on the adversarial set is lower, showing that this new test set is more challenging and less biased toward language patterns.

E More Examples of FVQA 2.0

We demonstrate some more examples from the new Adversarial Test Set in Fig. 4.

Models	Standard Test Set	Originating Question Set	Adversarial Test Set
RAVQA-DPR	69.56 \pm 0.78	87.52 \pm 1.68	76.91 \pm 1.93
(without triplets)	66.19 \pm 1.15	84.59 \pm 1.24	71.48 \pm 2.08
(without images)	43.83 \pm 0.68	57.53 \pm 2.93	50.02 \pm 1.00
(without triplets and images)	40.29 \pm 1.60	51.41 \pm 3.25	42.55 \pm 0.90

Table 3: The performance of some additional baseline systems on the standard test set, originating questions (from which the adversarial questions are derived), and adversarial test set. Results are reported as the average of 5 folds with standard deviations.

Originating Question Set	Adversarial Test Set (FixA)
 <p>Question: which object in this image can hold liquid? Triplet: [[A glass]] can [[hold liquid]] Answer: glass</p>	 <p>Question: which object in this image can break easily? Triplet: [[glass]] can [[break easily]] Answer: glass</p>
 <p>Question: which object in this image is used for travel around town? Triplet: You can use [[a bus]] to [[travel around town]] Answer: bus</p>	 <p>Question: which object in this image is used for carry person? Triplet: [[A bus]] is used to [[carry people]] Answer: bus</p>
Originating Question Set	Adversarial Test Set (FixQ)
 <p>Question: which object in this image is hollow? Triplet: [[Tennis balls]] are [[hollow]] Answer: tennis ball</p>	 <p>Question: which object in this image is hollow? Triplet: [[a bowl]] is [[hollow]] Answer: bowl</p>
 <p>Question: which object in this image has a frame? Triplet: [[bicycle]] has [[frame]] Answer: bicycle</p>	 <p>Question: which object in this image has a frame? Triplet: [[A frame]] is part of [[a bed]] Answer: bed</p>

Figure 4: More examples taken from the FVQA 2.0 adversarial test set. The questions in the left column are from the official FVQA test set. They are used to derive the adversarial questions in the right column. FixA: the answer remains the same while the way of asking for the answer is different; FixQ: the question remains the same, but the answer changes in a different image. More details are presented in Sec. 1.

Revisiting Intermediate Layer Distillation for Compressing Language Models: An Overfitting Perspective

Abstract

Knowledge distillation (KD) is a highly promising method for mitigating the computational problems of pre-trained language models (PLMs). Among various KD approaches, Intermediate Layer Distillation (ILD) has been a *de facto standard* KD method with its performance efficacy in the NLP field. In this paper, we find that existing ILD methods are prone to overfitting to training datasets, although these methods transfer more information than the original KD. Next, we present the simple observations to mitigate the overfitting of ILD: distilling only the last Transformer layer and conducting ILD on supplementary tasks. Based on our two findings, we propose a simple yet effective consistency-regularized ILD (CR-ILD), which prevents the student model from overfitting the training dataset. Substantial experiments on distilling BERT on the GLUE benchmark and several synthetic datasets demonstrate that our proposed ILD method outperforms other KD techniques. Our code is available at <https://github.com/jongwooko/CR-ILD>.

1 Introduction

Recent advances in NLP have shown that using PLMs such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) on downstream tasks is effective. Although these models achieve state-of-the-art performances in various domains, the promising results of PLMs require numerous computation and memory costs. Deploying such large models on resource-constrained devices such as mobile and wearable devices is impractical. It is thus crucial to train computationally efficient small-sized networks with similar performance to that of large models.

KD is promising model compression technique where knowledge is transferred from a large and high-performing model (teacher) to a smaller model (student). KD has been shown to be reliable in reducing the number of parameters and

computations while achieving competitive results on downstream tasks. Recently, KD has attracted more attention in the NLP field, especially due to large PLMs. However, it is clear that the original KD (Hinton et al., 2015) is not performing well in terms of maintaining the performance of compressed PLMs and that it needs to have additional auxiliary training objectives (Sun et al., 2019; Jiao et al., 2020).

ILD methods (Jiao et al., 2020; Wang et al., 2020), which encourage the student model to extract knowledge from the Transformer layers of the teacher network, have demonstrated efficacy in improving student model performance and have become a *de facto standard* in KD. Despite of success of ILD methods, many research have been proposed to design layer mapping functions (Li et al., 2020; Wu et al., 2020) or new training objective (Park et al., 2021) to transfer the teacher’s knowledge better. These ILD methods transfer more knowledge to the student model from the intermediate Transformer layers of the teacher model. However, we find that the use of ILD in fine-tuning may induce performance degradation in some cases. As shown in Figure 1, while existing ILD methods such as TinyBERT (Jiao et al., 2020) and BERT-EMD (Li et al., 2020) work well on standard GLUE benchmark (Wang et al., 2019), we observe that these methods have performance degradation compared to original KD on ill-conditioned datasets such as those with few-samples and label noise. Because few-sample (Zhang et al., 2021) or heterogeneous datasets (Jin et al., 2021; Liu et al., 2022) can be easily found in real-world datasets, the existing ILD methods, which show performance reduction in Figure 1, are hard to use in real-world applications.

To mitigate such performance degradation, we identify the main problem as that intermediate Transformer knowledge can incur overfitting on the training dataset of the student model. We further

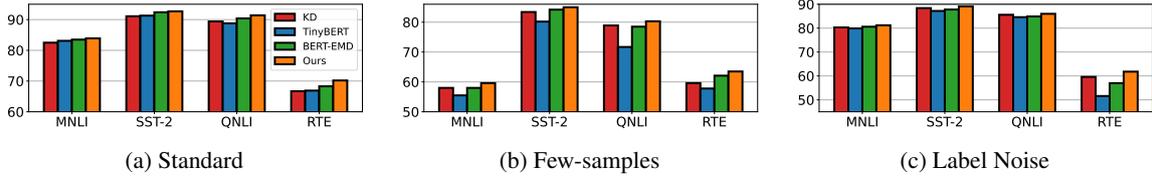

Figure 1: The motivation of our work. While existing ILD methods (Jiao et al., 2020; Li et al., 2020) work well on the standard GLUE benchmark (Wang et al., 2019), we observe that the existing ILD methods are problematic under few-samples training datasets or the presence of label noise. However, our proposed method shows robustly higher performance than the original KD for all datasets. We use BERT_{Small} (Turc et al., 2019) as the student model and BERT_{BASE} (Devlin et al., 2019) as the teacher model. The detailed descriptions for dataset are in Appendix B.

discover that distilling only the last Transformer layer knowledge and using supplementary tasks can alleviate the overfitting. Through our observations, we finally propose a simple yet effective method, consistency-regularized ILD (CR-ILD) with several analyses. Our main contributions are:

- We design and conduct comprehensive experiments to identify that overfitting is one of the main problems for performance degradation of ILD in fine-tuning. To the best of our knowledge, this is the first study to find that existing ILD methods have overfitting issues.
- Based on our findings, we propose the consistency regularized ILD (CR-ILD) that a student self-regularized itself from risk of overfitting from ILD. We further provide empirical (and theoretical) analyses for our proposed method.
- We experimentally demonstrate that our proposed method achieves state-of-the-art performance on both standard GLUE and ill-conditioned GLUE (few samples and label noise), despite its simplicity.

2 Related Works

Model Compression of LMs. Transformer encodes contextual information for input tokens (Vaswani et al., 2017). In recent years, from the success of Transformer, Transformer-based models such as GPT (Radford et al., 2018), BERT (Devlin et al., 2019), and T5 (Raffel et al., 2020) have become a new state of the arts, driving out recurrent or convolutional networks on various language tasks. However, the promising results of these models are accompanied by numerous parameters, which necessitate a high computation and memory cost for inference. Existing compression techniques can be categorized as low-rank matrix factorization (Mao et al., 2020), quantization (Bai et al., 2021), and KD (Sun et al., 2019).

Knowledge Distillation for LMs. KD is one of the most well-known neural model compression techniques. The goal of KD is to enable the student model with fewer parameters to achieve similar performance to that of the teacher model with a large number of parameters. In the recent few years, a wide range of different methods have been developed that apply data augmentation (Jiao et al., 2020; Liang et al., 2021), adversarial training (Rashid et al., 2021), and loss terms re-weighting (Jafari et al., 2021) to reduce the performance gap between the teacher and the student. In another line in the NLP field, ILD-based methods have exhibited higher effectiveness over original KD (Hinton et al., 2015) methods for compression PLMs. Sun et al. (2019) proposed the BERT-PKD to transfer representations of the [CLS] token of the teacher model. Jiao et al. (2020) proposed TinyBERT, which performed Transformer distillation in both pre-training and fine-tuning. Wang et al. (2020) distilled the self-attention module of the last Transformer layer of the teacher. Li et al. (2020) leveraged earth mover’s distance (EMD) to determine the optimal layer mapping between the teacher and student networks. Park et al. (2021) presented new KD objectives that transfer contextual knowledge via two types of relationships.

3 Observations: Two Things Everyone Should Know to Mitigate Overfitting

In this section, we identify that overfitting is the main problem for performance degradation while conducting ILD in fine-tuning. This overfitting problem can occur even in the standard GLUE benchmark. Moreover, the ill-conditioned dataset, where overfitting problems can occur more easily, induces a larger performance reduction. Furthermore, we investigate that this overfitting problem is able to be reduced by (1) distilling the last Transformer layer and (2) conducting ILD on supplement-

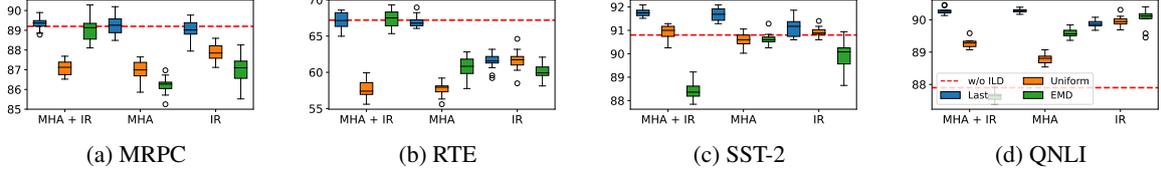

Figure 2: Performance distribution box plot across 20 random trials and the four datasets with different distillation methods. As the student model, we apply Truncated BERT (Sun et al., 2019) which initialized as the bottom 6 layers from BERT_{BASE}. Distilling knowledge of the last Transformer layer enhances generalization and reduces the variance of fine-tuning. The red-dotted lines are baseline performances that only use prediction layer KD.

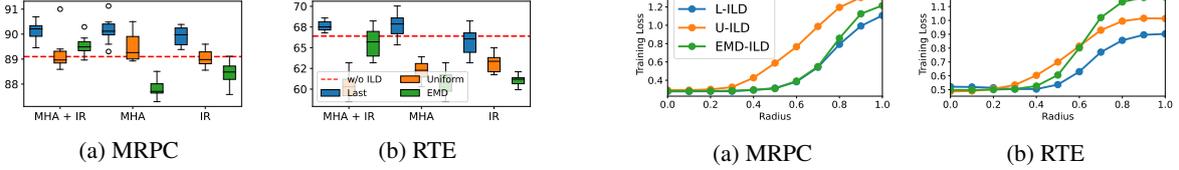

Figure 3: Performance distribution box plot across 20 random trials for MRPC and RTE when BERT_{Small} (Turc et al., 2019) is used as the student model. Well-pretrained student models have more consistent performance to the choice of layer mappings.

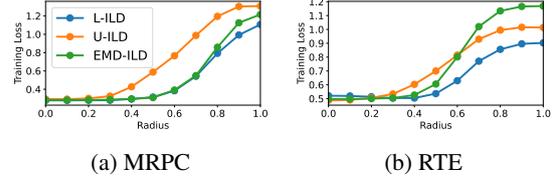

Figure 4: Training loss of different distillation approaches (L-ILD, U-ILD, EMD-ILD) with increasing Gaussian noise: models trained with L-ILD are more tolerant of noise, which proves that our L-ILD leads models to be more general.

tary tasks. While our suggested findings already have worked well in various domains (Wang et al., 2020; Phang et al., 2018), these previous works under-explored the effects of the techniques. However, this is the first work to use such techniques with empirical justification for mitigating overfitting problems.

Among the various ILD objectives, we focus on the two most commonly used distillation objectives: multi-head attention (MHA) and intermediate representations (IR). Formally, for the student’s layer $\ell^S \in [1, M]$, the loss function of MHA and IR are as follows:

$$\mathcal{L}_{\text{MHA}}^{\ell^S} = \frac{1}{A_h} \sum_{a=1}^{A_h} \text{KLD}(\mathbf{A}_{m(\ell^S),a}^T || \mathbf{A}_{\ell^S,a}^S) \quad (1)$$

$$\mathcal{L}_{\text{IR}}^{\ell^S} = \text{MSE}(\mathbf{H}_{m(\ell^S)}^T, \mathbf{W}^H \mathbf{H}_{\ell^S}^S), \quad (2)$$

where $m(\cdot)$ is layer mapping function that returns teacher layer $m(\ell^S) \in [1, L]$. Note that KLD and MSE are Kullback-Leibler divergence and mean squared error, respectively. We denote \mathbf{A} and \mathbf{H} as MHA and IR. T and S are superscripts for the teacher and student model, and a and A_h indicate the index and the total number of multi-attention heads, respectively. Note that \mathbf{W}^H is a learnable weight matrix for matching the dimension between representations of the teacher and student. Consistent with previous studies (Sun et al., 2020; Jiao

et al., 2020), we observe that sequential training of ILD and original KD (Hinton et al., 2015) shows better than joint training of ILD and original KD. We conduct an experimental study on sequential training of ILD and original KD from our preliminary experiments. All the detailed descriptions of the scope of our empirical study are in Appendix C.1.

3.1 Layer Mapping: Distill Only the Last Transformer Layer

One of the biggest challenges of ILD methods is establishing a proper layer mapping function that determines layers of the teacher and student models to transfer knowledge. In this section, we observe that transferring layer-to-layer information leads student models to overfit training samples and is the primary reason for the degradation of student performance. Based on our findings, we suggest that the last layer distillation (Wang et al., 2020, 2021) is promising layer mapping method. Our empirical analyses can explain the suggested technique’s success in terms of mitigating overfitting.

Main Observations. We compare three distillation strategies: last Transformer layer distillation (L-ILD), layer-to-layer distillation using uniform layer mapping (U-ILD), and optimal many-to-

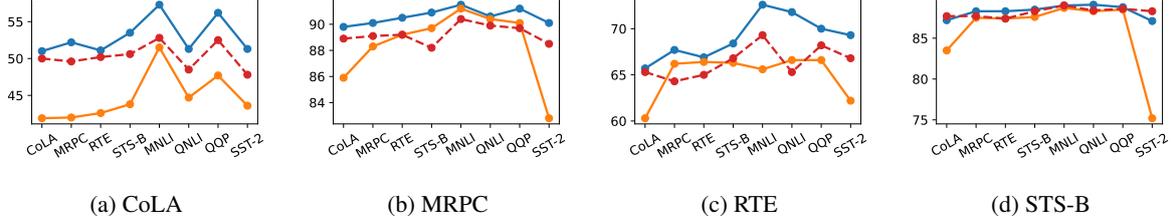

Figure 5: Comparisons for performance of ILD on different supplementary tasks. All students are BERT_{Small}, distilled MHA and IR from BERT_{BASE} teachers with L-ILD (blue) and U-ILD (orange). We present the results of prediction layer KD on the supplementary tasks in red dotted lines. All results are averaged over 20 runs.

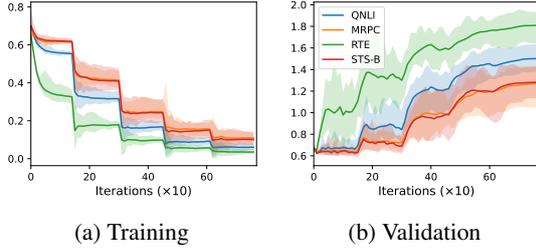

Figure 6: The mean (solid lines) and range (shaded region) of training and validation loss during fine-tuning BERT after conducting ILD on different supplementary tasks, across 20 random trials.

many layer mapping using the EMD (EMD-ILD) proposed in Li et al. (2020). In Figure 2, L-ILD (blue box) outperforms other baselines on all four datasets (MRPC, RTE, SST-2, QNLI) in terms of the test performance and variance reduction over the random trials. Note that the U-ILD, which is a commonly used mapping function (Sun et al., 2019; Jiao et al., 2020), leads to performance degradation in most fine-tuning tasks.

We conduct same experiments on the student model with different initialization (BERT_{Small}; Turc et al. 2019) as shown in Figure 3. We observe that L-ILD has a higher performance regardless of the size of the dataset or initialized point. However, the performance gap between L-ILD and other mapping functions gets smaller when the dataset size becomes larger, and the student model is well pre-trained. On the other hand, although EMD-ILD alleviates the difficulties in layer mapping between the teacher and student, it exhibits lower performance than L-ILD. We find that performances of EMD-ILD vary across the pre-trained methods while performances of L-ILD are not. These results validate that the inaccurate layer mapping between the intermediate Transformer layers is not the primary problem of ILD; instead, intermediate Transformer layer distillation itself is the main problem in the fine-tuning stage.

Analysis. To better understand about the performance degradation of distilling the knowledge of intermediate Transformer layers, we evaluate the generalizability of the student models of different layer mapping functions by following Zhang et al. (2019); Jeong and Shin (2020). We add Gaussian noise over $\mathcal{N}(0, \sigma^2 I)$ with different noise radius σ to the embedding vectors of the three models (L-ILD, U-ILD, EMD-ILD) and then evaluate their cross-entropy loss on the training set. More generalizable models are robust to the noisy embeddings, hence they have a lower training loss although the magnitude of noise becomes larger.

As shown in Figure 4, transferring knowledge of the intermediate Transformer layers leads the student model to the flat minima that are robust of noise and more generalizable (Hochreiter and Schmidhuber, 1997; Keskar et al., 2016). We further conduct the loss surface (Zhang et al., 2021) and linear probing (Aghajanyan et al., 2021a) analyses for evaluating the generalizable representations of PLMs during fine-tuning and report the results in Appendix E.1.

3.2 Training Data: Use Supplementary Tasks

In this section, we investigate the performance of ILD in terms of training datasets for transferring knowledge from teacher to student model. We observe that conducting ILD even on the last Transformer layer has the risk of overfitting to the training dataset of target task (TT). The Previously suggested augmentation module in Jiao et al. (2020) generates 20 times the original data as augmented samples, requiring massive computational overhead for generating. From our observation, we find that conducting ILD via supplementary tasks (ST, Phang et al. 2018) is a simple and efficient method for overfitting problem. Based on our observation, we study to find the condition for appropriate ST, which robustly improves the performance of ILD.

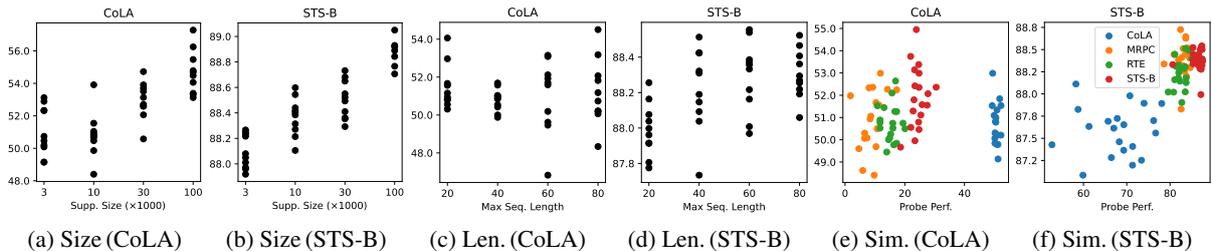

Figure 7: The conditions for appropriate supplementary tasks. The student models trained on supplementary tasks that have large datasets, longer effective sequence length, and high similarity with the target task tend to have higher performances. Size, Len., and Sim. denote the size of the dataset, effective sequence length, and similarity.

Main Observations. As shown in Figure 5, in most downstream tasks, except for STS-B, the performance of combining ILD with other STs is superior to that when using the original dataset. Among the tasks with small dataset (CoLA, MRPC, RTE, STS-B), although STS-B exhibits superiority as an ST for ILD, all student models with ILD on CoLA exhibit the worst performance for all TTs. For large tasks (MNLI, QNLI, QQP, SST-2) as STs, student models trained on MNLI and SST-2 exhibit the best and worst performance for all TTs.

Analysis. To understand performance gain from using STs, we compare the loss dynamics for fine-tuning of RTE task using the cross-entropy loss after conducting ILD on the TT (RTE) and STs (MRPC, STS-B, QNLI). Notably, the student model with ILD on RTE shows a faster decrease and increase in the training and validation loss, respectively, than the student model with ILD on the STs, as shown in Figure 6. From the results, we verify that conducting ILD over TT incurs memorization of the student model to training data of TT while performing ILD over ST prevents this memorization yet effectively transfers knowledge of the teacher model.

3.2.1 Ablation Study

Although the combination of ST with ILD generally improves the performances of student models, decreased performances are observed in some cases. These results emphasize the need to select appropriate ST. In this section, we present exploratory experiments on synthetic datasets extracted from the English Wikipedia corpus to provide further intuition for the conditions of convincing STs.

Dataset Size. According to the results in Figure 5, student models trained on STs with large datasets, such as MNLI and QQP, perform better. We conducted experiments on synthetic datasets extracted

from the Wikipedia corpus with different dataset sizes to validate our observations. The results in Figure 7a and 7b indicate that as the size of the synthetic datasets grows larger, the performance of the student models improves.

Effective Sequence Length. A surprising result of Figure 5 is that ILD on single sentence tasks such as SST-2 or CoLA exhibits lower performances than those of the smaller sentence pair tasks. This phenomenon is much more evident in U-ILD. Motivated by these results, we conducted experiments on synthetic datasets with the same dataset size of 30k and different effective sequence lengths (measured without considering [PAD] tokens). Figures 7c and 7d show that as the effective sequence length of the datasets increases, so do the performances of the student models.

Task Similarity. Finally, we investigate the effect of task similarity between TTs and STs. We only use datasets in the GLUE benchmark for computing the similarity and do not use synthetic Wikipedia datasets. To measure the task similarity, we use the probing performance of the TT after performing ILD for each ST, following Pruksachatkun et al. (2020). We conduct ILD on different STs and then conduct probing and fine-tuning on the TT. Figure 7e and 7f summarize the correlation between the probing and fine-tuning performances for CoLA and STS-B as the TT. The fine-tuning performances get better as the probing performances get better, and it is proven that ILD is better when done on an ST that has a high correlation with the TT.

4 Method: Consistency Regularized ILD

In this section, we propose a simple yet effective ILD method for improving the robustness of the student models called consistency regularized ILD (CR-ILD) that applies interpolation-based regularization (Sohn et al., 2020; Zheng et al., 2021) on

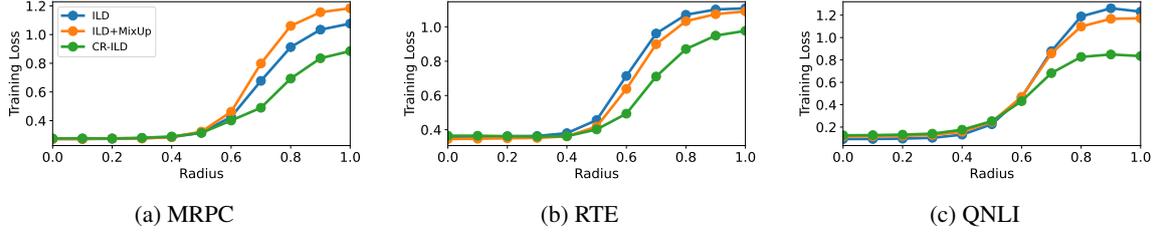

Figure 8: Comparison of training loss of different distillation approaches (ILD, ILD+MixUp, and CR-ILD) with increasing Gaussian noise: models trained with CR-ILD are more tolerant to noise which verify that our CR-ILD leads model to flat minima which have higher generalization.

Algorithm 1 Consistency Regularized ILD

Input: embedding layers $\mathbf{W}_e^T, \mathbf{W}_e^S$, model parameters Θ_T, Θ_S , training dataset \mathcal{D} , MixUp hyperparameter α , warmup iteration T , regularization coefficient $w_{\text{MHA}}^{\text{CR}}, w_{\text{IR}}^{\text{CR}}$

Output: Θ_S

- 1: initialize $t \leftarrow 0$
 - 2: **for** each minibatch \mathbf{B} **do**
 - 3: sample $|\mathbf{B}|$ pairs of $(\mathbf{x}_i, \mathbf{x}_j)$ for $\mathbf{x}_i, \mathbf{x}_j \in \mathbf{B}$
 - 4: sample $\lambda \sim \text{Beta}(\alpha, \alpha)$
 - 5: $\mathbf{h}_i^S = \mathbf{W}_e^S \mathbf{x}_i, \mathbf{h}_j^S = \mathbf{W}_e^S \mathbf{x}_j$
 - 6: $\mathbf{h}_i^T = \mathbf{W}_e^T \mathbf{x}_i, \mathbf{h}_j^T = \mathbf{W}_e^T \mathbf{x}_j$
 - 7: $\tilde{\mathbf{h}}_i^S = \text{Mix}_\lambda(\mathbf{h}_i^S, \mathbf{h}_j^S)$
 - 8: $\tilde{\mathbf{h}}_i^T = \text{Mix}_\lambda(\mathbf{h}_i^T, \mathbf{h}_j^T)$
 - 9: compute R_{MHA} and R_{IR} from $\tilde{\mathbf{h}}_i^S, \mathbf{h}_i^S, \mathbf{h}_j^S$
 - 10: compute \mathcal{L}_{MHA} and \mathcal{L}_{IR} from $\tilde{\mathbf{h}}_i^S, \tilde{\mathbf{h}}_i^T$
 - 11: $\tilde{w}_{\text{MHA}}^{\text{CR}} = \max(\frac{t}{T}, 1) \cdot w_{\text{MHA}}^{\text{CR}}$
 - 12: $\tilde{w}_{\text{IR}}^{\text{CR}} = \max(\frac{t}{T}, 1) \cdot w_{\text{IR}}^{\text{CR}}$
 - 13: $\mathcal{L} \leftarrow \sum_{k \in \{\text{MHA}, \text{IR}\}} \mathcal{L}_k^M + \tilde{w}_k^{\text{CR}} R_k$
 - 14: update Θ_S using gradient descent methods
 - 15: update $t \leftarrow t + 1$
 - 16: **end for**
-

MHA and IR of the student models. Our method efficiently enhances the generalization by leading the student model to the flat minima (Section 3.1) and introducing appropriate ST (Section 3.2). We first introduce the proposed method and then provide analyses of CR-ILD.

4.1 Proposed Method: CR-ILD

To implement the CR, we apply MixUp (Zhang et al., 2018), which is an interpolation-based regularizer to improve the robustness in NLP (Chen et al., 2020). The direct application of MixUp to NLP is not as straightforward as images, because the input sentences consist of discrete word tokens. Instead, we perform MixUp on the word

embeddings at each token by following Chen et al. (2020); Liang et al. (2021). Thus, MixUp samples with embeddings $\mathbf{h}_i, \mathbf{h}_j$ from sentences $\mathbf{x}_i, \mathbf{x}_j$ and $\lambda \in [0, 1]$ are generated as:

$$\text{Mix}_\lambda(\mathbf{h}_i, \mathbf{h}_j) = \lambda \cdot \mathbf{h}_i + (1 - \lambda) \cdot \mathbf{h}_j,$$

Note that $\lambda \sim \text{Beta}(\alpha, \alpha)$ is randomly sampled value from Beta distribution with hyperparameter $\alpha \in (0, \infty)$ for every batch.

Then, we introduce our CR-ILD, as follows:

$$R_{f_\theta} = d(f_\theta(\text{Mix}_\lambda(\mathbf{h}_i, \mathbf{h}_j)), \text{Mix}_\lambda(f_\theta(\mathbf{h}_i), f_\theta(\mathbf{h}_j))),$$

where f_θ denotes the Transformer layer outputs (e.g., MHA and IR) of the model with parameter θ and embedded input $\mathbf{h}_i, \mathbf{h}_j$. Note that $\text{Mix}_\lambda(f_\theta(\mathbf{h}_i), f_\theta(\mathbf{h}_j)) = \lambda \cdot f_\theta(\mathbf{h}_i) + (1 - \lambda) \cdot f_\theta(\mathbf{h}_j)$ is interpolation of outputs from $\mathbf{h}_i, \mathbf{h}_j$. $d(\cdot, \cdot)$ is a distance metric for regularization, with KLD for MHA and MSE for IR. For example, we have:

$$R_{\text{MHA}} = \text{KLD}(\text{MHA}(\text{Mix}_\lambda(\mathbf{h}_i, \mathbf{h}_j)) \parallel \text{Mix}_\lambda(\text{MHA}(\mathbf{h}_i), \text{MHA}(\mathbf{h}_j)))$$

$$R_{\text{IR}} = \text{MSE}(\text{IR}(\text{Mix}_\lambda(\mathbf{h}_i, \mathbf{h}_j)), \text{Mix}_\lambda(\text{IR}(\mathbf{h}_i), \text{IR}(\mathbf{h}_j)))$$

for CR terms of MHA and IR. Hence, the overall loss function of CR-ILD is as follows:

$$\mathcal{L} = \mathcal{L}_{\text{MHA}}^M + \mathcal{L}_{\text{IR}}^M + \tilde{w}_{\text{MHA}}^{\text{CR}} R_{\text{MHA}} + \tilde{w}_{\text{IR}}^{\text{CR}} R_{\text{IR}},$$

where $\tilde{w}_{\text{MHA}}^{\text{CR}}$ and $\tilde{w}_{\text{IR}}^{\text{CR}}$ are coefficients for regularization. As the student models are underfitted to training dataset in the early training phase, we first set the coefficients to zero and gradually increase the values to $w_{\text{MHA}}^{\text{CR}}$ and $w_{\text{IR}}^{\text{CR}}$, respectively. Note that both $\mathcal{L}_{\text{MHA}}^M$ and $\mathcal{L}_{\text{IR}}^M$ are computed by outputs from the teacher and student model with the same MixUp samples as inputs through Eq. (1) and Eq. (2). All ILD loss and CR term are computed from the last Transformer layer outputs based on Section 3. We describe the overall algorithm of CR-ILD in Algorithm 1.

Table 1: 6-layer student results on GLUE development set averaged over 4 runs. † indicates reported results from the Park et al. (2021). Other results are from our re-implementation based on officially released code of original works (Sun et al., 2019; Jiao et al., 2020; Li et al., 2020).

4.2 Analysis on CR-ILD

In this section, we provide analytical results of CR-ILD to obtain further intuition on our proposed methods. Our CR-ILD regularizes the student model to not learn an undesirable bias by (1) encouraging generalizable student via incurring consistent predictions between MixUp and original samples and (2) generating appropriate ST through MixUp operation.

To validate that our CR-ILD makes more generalizable functions empirically, we conduct a similar experiment with Figure 4 for comparing three models (ILD, ILD+MixUp, CR-ILD) as shown in Figure 8. ILD+MixUp is the simple combination of ILD and MixUp, which is the same as CR-ILD with w_{MHA}^{CR} , and w_{IR}^{CR} for zero. Note that we only use the last Transformer layer for all ILD methods in Figure 8. From the results, we obtain that our CR-ILD effectively regularizes the student model not to overfit training data and to be robust to noise injected in embedding spaces. Moreover, it is noteworthy that this smooth regularization is from CR-ILD, whereas the naive application of MixUp does not regularize the student model efficiently.

Here, we introduce our theoretical analysis that CR-ILD explicitly leads the functions (i.e., MHA, IR) to be convex which is smooth for all data points.

Theorem 4.1 (Informal). *Assume that f_θ satisfies the Assumption A.2. With the second order Taylor approximation for λ in Definition A.1, the \mathcal{L}_{mix}*

becomes $\hat{\mathcal{L}}_{mix}$ which can be represented as:

$$\hat{\mathcal{L}}_{mix} = \mathcal{L}_{std} - \frac{2\alpha + 1}{(4\alpha + 4)|I|} \sum_{j \in I} D_{\ell,j} H_{\ell,j}^{-1} D_{\ell,j}^\top, \\ + \frac{\alpha + 1}{(8\alpha + 4)|I|^2} \sum_{i,j \in I} R^*(f_\theta(\mathbf{h}_i), f_\theta(\mathbf{h}_j), \mathbf{y}_i, \mathbf{y}_j)$$

where $H_{\ell,j} = \text{Hess}_\ell(f_\theta(\mathbf{h}_j), \mathbf{y}_j)$, and $D_{\ell,j} = D_\ell(f_\theta(\mathbf{h}_j), \mathbf{y}_j)$.

The detailed form of $R^*(f_\theta(\mathbf{h}_i), f_\theta(\mathbf{h}_j), \mathbf{y}_i, \mathbf{y}_j)$ can be found in Appendix A. Theorem 4.1 states that the regularization effect of CR-ILD that makes the significant performance gain of CR-ILD. When we assume that the Hessian can be approximated by the gradient square or outer product of the gradients as in the Gauss-Newton method, the first negative term can be treated as nearly constant. We have the positive term, which performs regularization, and the near-constant negative term. As we discussed earlier, the trainable part of regularizing term reduces the offset related to curvature information. Furthermore, the regularization scheme of CR-ILD can be explained variously. If we assume that the set of data has a non-empty interior, $f(\mathbf{h})$ becomes a linear function, therefore, we can say there is a trend that the function is regularized as a simple smooth function.

Moreover, thanks to MixUp (Zhang et al., 2018; Liang et al., 2021) operation, we can effectively generate the appropriate ST (Section 3.2.1) via:

- From the MixUp operation, the possible number of MixUp samples can be increased infinitely with the choice of original samples

Table 2: The performance averaged over 4 runs on the GLUE development set of 6-layer student models, which were trained on a 1k down-sampled GLUE training set or a GLUE training set under symmetric label noise. We use officially released codes for the re-implementation of PKD (Sun et al., 2019), TinyBERT (Jiao et al., 2020), and BERT-EMD (Li et al., 2020). For label noise experiments, we do not consider STS-B for computing average values.

and λ . This operation increases the dataset size with high task similarity since the MixUp samples are created from the interpolation of the original target task.

- If sentence \mathbf{x}_i contains more word tokens than sentence \mathbf{x}_j , then the extra word embeddings are mixed up with embeddings of [PAD] tokens. This operation lengthens the effective sequence length of the dataset in Section 3.2.1, which improves the performance of ILD.

From our analysis, we verify that our proposed CR-ILD can effectively transfer the knowledge of teacher models with less overfitting on the training dataset.

5 Experiments

To verify the effectiveness of CR-ILD, we compare the performance of ours with previous distillation methods on the standard GLUE and ill-conditioned GLUE benchmark. The descriptions for experimental setup are in Appendix B and C.

5.1 Main Results

Standard GLUE. Following the standard setup (Sun et al., 2019), we use the BERT_{BASE} as the teacher and 6-layer Truncated BERT (Sun et al., 2019) and BERT_{Small} (Turc et al., 2019) as the student models. Table 1 summarizes that Ours consistently achieve state-of-the-art performances for almost GLUE benchmark, except for SST-2 and STS-B for BERT_{Small}. Despite the simplicity

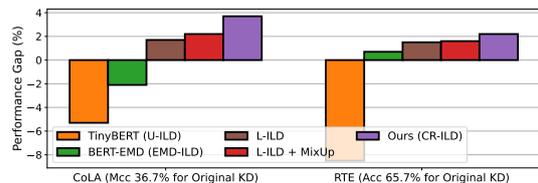

Figure 9: Ablation study on the standard GLUE (CoLA, RTE) with Truncated BERT and BERT_{BASE} as student and teacher models, respectively.

and efficiency of our proposed method, we obtain strong empirical performance.

Ill-conditioned GLUE. To verify the robustness of our proposed method, we further conduct the experiments on ill-conditioned GLUE, a synthetic dataset with downsampling or injecting label noise to the GLUE benchmark. Since STS-B is a regression task, we cannot inject noise into STS-B. Hence, we do not consider the STS-B task in label noise experiments. The detailed descriptions for ill-conditioned GLUE are in Appendix B. Table 2 demonstrate that our proposed method alleviates the overfitting and enhances the performance of the student model under few-samples training datasets or the presence of 30% of label noise. The results for other noise rate are in Appendix C. The experimental results encourage us to use our method on real-world applications which have a high risk of overfitting on the training datasets. Notably, our proposed method achieve higher performance than the teacher model under the presence of label noise.

5.2 Ablation Study

To obtain further intuition on CR-ILD, we conduct an ablation study on each component (*i.e.*, L-ILD, ST through MixUp, and CR) of our method. Our experiments are conducted on the standard GLUE benchmark with Truncated BERT (Sun et al., 2019) as the student models and BERT_{BASE} as the teacher models. Figure 9 summarizes that all our findings are meaningful, as the performance improves with each addition of a component.

6 Conclusion

This paper introduces a better use of ILD that transfer knowledge by using outputs of Transformer layers of the teacher and the student models. We found that existing ILD methods may lead the student model to overfit the training dataset of target tasks and degenerate the generalizability. Furthermore, we investigated that conducting the ILD (1) only for the last Transformer layer and (2) on supplementary tasks can alleviate the overfitting problems. Based on our observations, we proposed consistency-regularized ILD that incurs smoother functions and enhance the generalizability of the student models. Our proposed method effectively distills the knowledge of teacher models by (1) encouraging the flat minima of function from consistency regularization between original embeddings and MixUp embeddings of the student models and (2) efficiently generating appropriate supplementary tasks demonstrated in our findings via MixUp operation. The experimental results showed that our proposed method could achieve state-of-the-art performance on various datasets, such as the standard and ill-conditioned GLUE benchmarks.

Limitations

Our work handles the over-fitting of the student network caused by the layer mapping between the teacher and the student networks, which is widely used in Jiao et al. (2020); Li et al. (2020). Although we show that our proposed regularization technique can mitigate the over-fitting of the student, the relationship between layers inside the model and the hidden state of tokens in one layer (Park et al., 2021) was not sufficiently considered. In addition, we back up our proposed idea with theoretical analysis and extensive experiments in sentence classification. We plan to perform token classification and question-answering experiments to expand our methods to other tasks.

Ethics Statement

Our work complies with all ethical considerations. We hope our work contributes to environmental issues by reducing the computation cost of large PLMs.

Appendix

Revisiting Intermediate Layer Distillation for Compressing Language Models: An Overfitting Perspective

A Theoretical Analysis of CR-ILD

This section gives the theoretical argument that CR-ILD gives additional explicit regularization. We analyze the effect of the MixUp objective function beyond the standard loss function when the CR condition is satisfied. We use the below formulation for objective functions. **For readability, we partially apply one column style for this section.**

Definition A.1 (Objective Functions). Let us define $\mathcal{D}_\lambda := \text{Beta}(\alpha, \alpha)$, $\tilde{\mathbf{h}}_{ij} := \lambda \mathbf{h}_i + (1 - \lambda) \mathbf{h}_j$, and $\tilde{\mathbf{y}}_{ij} := \lambda \mathbf{y}_i + (1 - \lambda) \mathbf{y}_j$. Consider the index set I . Then the objective functions can be written as:

$$\mathcal{L}_{\text{std}} := \frac{1}{|I|} \sum_{i \in I} \ell(f_\theta(\mathbf{h}_i), \mathbf{y}_i) \quad \mathcal{L}_{\text{mix}} := \mathbb{E}_{\lambda \sim \mathcal{D}_\lambda} \left[\frac{1}{|I|^2} \sum_{i, j \in I} \ell(f_\theta(\tilde{\mathbf{h}}_{ij}), \tilde{\mathbf{y}}_{ij}) \right],$$

We assume that CR loss is always optimized during training. That is, if CR loss is 0, each pair of function values in the loss coincides. Therefore, we can write the first assumption as follows:

Assumption A.2 (Continuation of f_θ (\spadesuit)). we assume that f_θ has continuation on the expanded domain $\{\lambda \mathbf{h}_i + (1 - \lambda) \mathbf{h}_j : \lambda \in [0, 1], i, j \in I\}$ and the for any convex combination, function value becomes:

$$f_\theta(\lambda \mathbf{h}_i + (1 - \lambda) \mathbf{h}_j) = \lambda f_\theta(\mathbf{h}_i) + (1 - \lambda) f_\theta(\mathbf{h}_j)$$

Note also that this continuation can always be well defined if $\{\mathbf{h}_i\}_{i \in I}$ are in general position. Under this assumption, the MixUp loss possesses a regularization effect, which stabilizes the functional outcomes.

Theorem A.3. Assume that f_θ satisfies the Assumption A.2. With the second order Taylor approximation for λ , the \mathcal{L}_{mix} becomes $\hat{\mathcal{L}}_{\text{mix}}$ which can be represented as:

$$\begin{aligned} \hat{\mathcal{L}}_{\text{mix}} = \mathcal{L}_{\text{std}} &+ \frac{\alpha + 1}{(8\alpha + 4)|I|^2} \sum_{i, j \in I} \left\| (f_\theta(\mathbf{h}_j), \mathbf{y}_j) - (f_\theta(\mathbf{h}_i), \mathbf{y}_i) + (2\alpha + 1) H_{\ell, j}^{-1} D_{\ell, j}^\top \right\|_{H_{\ell, j}}^2 \\ &- \frac{2\alpha + 1}{(4\alpha + 4)|I|} \sum_{j \in I} D_{\ell, j} H_{\ell, j}^{-1} D_{\ell, j}^\top, \end{aligned}$$

where $H_{\ell, j} = \text{Hess}_\ell(f_\theta(\mathbf{h}_j), \mathbf{y}_j)$, and $D_{\ell, j} = D_\ell(f_\theta(\mathbf{h}_j), \mathbf{y}_j)$.

Note also that the expectation on higher order of λ exponentially decreases as $\mathbb{E}_{\mathcal{D}_\lambda}[\lambda^n] \sim 2^{-n}$, if α is sufficiently large. The above formulation indicates that the MixUp training with consistency regularization gives further regularization terms, which stabilizes function values $f_\theta(\mathbf{h}_i)$.

A.1 Derivation of the Theorem A.3

Let us write $\mathbf{v}_{\theta, ij}^x = f_\theta(\mathbf{h}_i) - f_\theta(\mathbf{h}_j)$, $\mathbf{v}_{\theta, ij} = (\mathbf{v}_{\theta, ij}^x, \mathbf{y}_i - \mathbf{y}_j)$. We first state the second-order Taylor approximation of loss function ℓ :

$$\begin{aligned} \mathcal{L}_{\text{mix}} &= \mathbb{E}_{\lambda \sim \mathcal{D}_\lambda} \left[\frac{1}{|I|^2} \sum_{i, j \in I} \ell(f_\theta(\tilde{\mathbf{h}}_{ij}), \tilde{\mathbf{y}}_{ij}) \right] \\ &\stackrel{\spadesuit}{=} \mathbb{E}_{\lambda \sim \mathcal{D}_\lambda} \left[\frac{1}{|I|^2} \sum_{i, j \in I} \ell(\lambda f_\theta(\mathbf{h}_i) + (1 - \lambda) f_\theta(\mathbf{h}_j), \lambda \mathbf{y}_i + (1 - \lambda) \mathbf{y}_j) \right] \\ &\stackrel{\text{Taylor}}{=} \underbrace{\frac{1}{|I|} \sum_{i \in I} \ell(f_\theta(\mathbf{h}_i), \mathbf{y}_i)}_{=: \mathcal{L}_{\text{std}}} + \frac{1}{|I|^2} \sum_{i, j \in I} \left[\frac{1}{2} D_{\ell, j} \mathbf{v}_{\theta, ij} + \frac{1}{2} \frac{\alpha + 1}{4\alpha + 2} \mathbf{v}_{\theta, ij}^\top H_{\ell, j} \mathbf{v}_{\theta, ij} \right], \end{aligned}$$

since $\mathbb{E}_{\lambda \sim \mathcal{D}_\lambda}[\lambda] = 1/2$ and $\mathbb{E}_{\lambda \sim \mathcal{D}_\lambda}[\lambda^2] = (\alpha + 1)/(4\alpha + 2)$. Then,

$$\begin{aligned}
& \mathcal{L}_{\text{mix}} \mathcal{L}_{\text{std}} + \frac{1}{2|I|^2} \sum_{i,j \in I} \left[D_{\ell,j} \mathbf{v}_{\theta,ij} + \frac{1}{2} \frac{\alpha + 1}{2\alpha + 1} \mathbf{v}_{\theta,ij}^\top H_{\ell,j} \mathbf{v}_{\theta,ij} \right] \\
&= \mathcal{L}_{\text{std}} + \frac{1}{2|I|^2} \sum_{i,j \in I} \left[-\frac{2\alpha + 1}{2\alpha + 2} D_{\ell,j} H_{\ell,j}^{-1} D_{\ell,j}^\top + \right. \\
&\quad \left. \frac{1}{2} \frac{\alpha + 1}{2\alpha + 1} \left(\mathbf{v}_{\theta,ij} + \frac{2\alpha + 1}{\alpha + 1} H_{\ell,j}^{-1} D_{\ell,j}^\top \right)^\top H_{\ell,j} \left(\mathbf{v}_{\theta,ij} + \frac{2\alpha + 1}{\alpha + 1} H_{\ell,j}^{-1} D_{\ell,j}^\top \right) \right] \\
&= \mathcal{L}_{\text{std}} + \frac{\alpha + 1}{(8\alpha + 4)|I|^2} \sum_{i,j \in I} \|\mathbf{v}_{\theta,ij} + (2\alpha + 1) H_{\ell,j}^{-1} D_{\ell,j}^\top\|_{H_{\ell,j}}^2 - \frac{2\alpha + 1}{(4\alpha + 4)|I|} \sum_{j \in I} D_{\ell,j} H_{\ell,j}^{-1} D_{\ell,j}^\top.
\end{aligned}$$

B Dataset Description

Standard GLUE. The GLUE benchmark (Wang et al., 2019) cover four tasks: natural language inference (RTE, QNLI, MNLI), paraphrase detection (MRPC, QQP, STS-B), sentiment classification (SST-2), and linguistic acceptability (CoLA). We mainly focus on four tasks (RTE, MRPC, STS-B, CoLA) that have fewer than 10k training samples. While BERT fine-tuning on these datasets is known to be unstable, the ILD on few samples is under-explored. The evaluation metrics for each task of GLUE benchmark are accuracy (MNLI, SST-2, QNLI, QQP, RTE), Mcc (CoLA), F1 score (MRPC), and spearman correlation (STS-B). We utilize original split of train, validation (development) dataset for our experiments.

Ill-conditioned GLUE. We use two types of modification on GLUE benchmark, including down-sampling for few-sample GLUE and injecting label noise for corrupted GLUE. For generating few-samples GLUE, we randomly down-sample 1k-sized dataset for each task by following Zhang et al. (2021). For corrupted GLUE, we follow the experimental setups of Jin et al. (2021) and inject uniform randomness into a fraction of labels. All other attributes are same for the standard GLUE. Also, we do not modify the development dataset of GLUE benchmark.

Extracted Wiki Corpus in Section 3.2.1 To generate synthetic data, we randomly generate the sample which is consist of two sentences from the Wikipedia corpus (version: enwiki-20200501 from Huggingface). We filter the generated sample by sequence length (for experiments of effectiveness of sequence length). We generate new dataset for every single experiment instead of conducting numerous experiment trials to reduce the randomness.

C Additional Description for Experiments

C.1 Scope of Empirical Study in Section 3

Transformer-based Language Models. Transformer encodes contextual information for input tokens (Vaswani et al., 2017). We denote the concatenation of input vectors $\{\mathbf{x}_i\}_{i=1}^{|\mathbf{x}|}$ as $\mathbf{H}_0 = [\mathbf{x}_1, \dots, \mathbf{x}_{|\mathbf{x}|}]$. Then, the computation for encod-

ing vectors via stacked Transformer layers is via:

$$\mathbf{H}_\ell = \text{Transformer}_\ell(\mathbf{H}_{\ell-1}), \ell \in [1, L].$$

The attention mechanism in Transformer improves the performance of NLP significantly and becomes essential. For the ℓ -th Transformer layer, the output for a self-attention head $\mathbf{O}_{\ell,a}$, $a \in [1, A_h]$ is via:

$$\begin{aligned} \mathbf{Q}_{\ell,a} &= \mathbf{H}_{\ell-1} \mathbf{W}_{\ell,a}^Q, \mathbf{K}_{\ell,a} = \mathbf{H}_{\ell-1} \mathbf{W}_{\ell,a}^K, \\ \mathbf{A}_{\ell,a} &= \text{SoftMax}\left(\frac{\mathbf{Q}_{\ell,a} \mathbf{K}_{\ell,a}^\top}{\sqrt{d_k}}\right), \\ \mathbf{V}_{\ell,a} &= \mathbf{H}_{\ell-1} \mathbf{W}_{\ell,a}^V, \mathbf{O}_{\ell,a} = \mathbf{A}_{\ell,a} \mathbf{V}_{\ell,a}, \end{aligned}$$

where the previous layer’s outputs $\mathbf{H}_{\ell-1} \in \mathbb{R}^{|\mathbf{x}| \times d_h}$ are linearly projected to a triple of queries, keys, and values using parameter matrices $\mathbf{W}_{\ell,a}^Q, \mathbf{W}_{\ell,a}^K, \mathbf{W}_{\ell,a}^V \in \mathbb{R}^{d_h \times d_k}$, respectively. Note that A_h is the number of attention heads.

Multi-Head Attention. Many approaches (Jiao et al., 2020; Sun et al., 2020; Wang et al., 2020) train the student, making the MHA of the student (\mathbf{A}^S) imitate the MHA of the well-optimized teacher (\mathbf{A}^T).

$$\mathcal{L}_{\text{MHA}}^{\ell^S} = \frac{1}{A_h} \sum_{a=1}^{A_h} \text{KLD}(\mathbf{A}_{m(\ell^S),a}^T \parallel \mathbf{A}_{\ell^S,a}^S),$$

where KLD is KL-divergence as the loss function. Note that $m(\cdot)$ is the layer mapping function for input as student layer $\ell^S \in [0, M]$ and output as teacher layer $m(\ell^S) \in [1, L]$. We compare the KLD and mean squared error (MSE) for the loss function, and report the results that KLD shows better performance in Table 3.

Table 3: Comparison between KLD and MSE as the loss function for MHA distillation.

	CoLA	MRPC	RTE	STS-B
MHA (KLD)	38.1 (1.5)	89.3 (0.5)	67.0 (0.8)	89.1 (0.1)
MHA (MSE)	37.6 (0.7)	89.1 (0.5)	66.5 (1.3)	89.0 (0.1)
MHA (KLD) + IR	38.4 (1.3)	89.3 (0.3)	67.2 (1.1)	89.1 (0.1)
MHA (MSE) + IR	38.0 (1.7)	89.1 (0.3)	66.3 (0.9)	89.1 (0.1)

Intermediate Representation. Additionally, we study IR, common distillation objective regardless of the network architectures. The MSE between the IR of the teacher (\mathbf{H}^T) and student (\mathbf{H}^S) is used as the knowledge transfer objective:

$$\mathcal{L}_{\text{IR}}^{\ell^S} = \text{MSE}(\mathbf{H}_{m(\ell^S)}^T, \mathbf{W}^H \mathbf{H}_{\ell^S}^S).$$

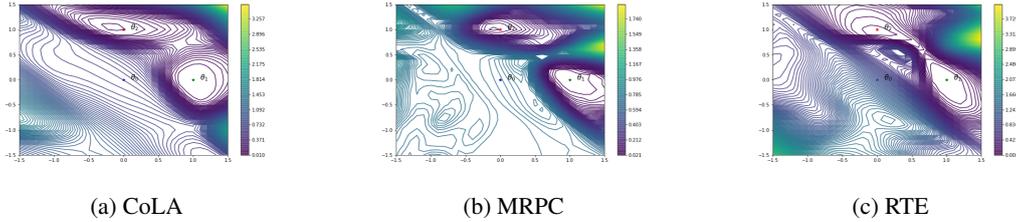

Figure 10: 2D loss surfaces in the subspace spanned by $\delta_1 = \theta_1 - \theta_0$ and $\delta_2 = \theta_2 - \theta_0$ on MRPC and RTE. $\theta_0, \theta_1, \theta_2$ denote the parameters of the Truncated BERT (blue), Last model (green) and Uniform model (red).

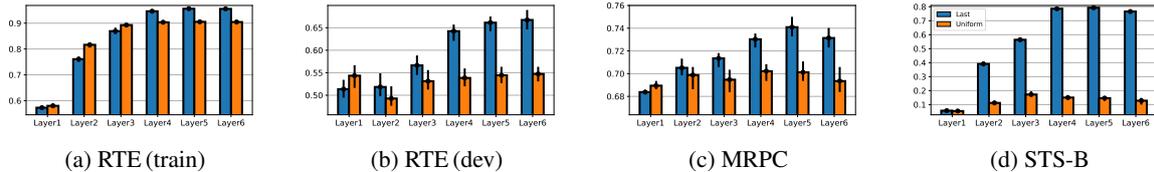

Figure 11: Results from our layer-wise (x -axis) probe comparing student models trained on RTE with L-ILD and U-ILD., respectively. The student model trained with L-ILD have more generalizable representations than U-ILD.

Note that \mathbf{W}^H is learnable weight matrix for matching the dimension between representations of the teacher and student. We further compare the IR and patience (Sun et al., 2019) in Table 3.

Table 4: Comparisons between Pool and Patience as representation for IR distillation.

	RTE (RTE)	STS-B (STS-B)	RTE (MNLI)	STS-B (MNLI)
Pool	60.6 (1.2)	86.2 (0.3)	69.9 (0.8)	89.2 (0.1)
Patience	66.2 (1.0)	88.3 (0.4)	68.8 (0.5)	88.8 (0.2)
Pool + MHA	67.2 (1.1)	89.1 (0.1)	70.6 (1.0)	89.6 (0.1)
Patience + MHA	66.5 (1.5)	88.4 (0.2)	68.7 (1.2)	88.4 (0.2)

Prediction Layer. The most standard form of KD is logit-based KD (Hinton et al., 2015) for training prediction layer.

$$\mathcal{L}_{PL} = \text{CE}(\mathbf{z}^T/t, \mathbf{z}^S/t).$$

We use the cross-entropy (CE) as the loss function with inputs \mathbf{z}^S and \mathbf{z}^T as the logit vectors of the student and teacher. We compare the sequential and joint training ILD (i.e., MHA, IR) and prediction layer distillation (PLD) and report the results that sequential training shows better in Table 5.

Table 5: Comparisons between Sequential and Joint

	RTE (RTE)	STS-B (STS-B)	RTE (MNLI)	STS-B (MNLI)
Sequential	67.2 (1.1)	89.1 (0.1)	70.6 (1.0)	89.6 (0.1)
Joint	66.7 (1.5)	88.8 (0.2)	68.9 (1.4)	89.3 (0.2)

D Experimental Setup

In this section, we describe the setup for our experimental results. Note that all single experiments

are conducted on a single NVIDIA GeForce RTX 2080Ti GPU.

D.1 Setup for Section 3 and Section 4

For teacher model, we fine-tune the uncased, 12-layer BERT_{BASE} model with batch size 32, dropout 0.1, and peak learning rate 2×10^{-5} for three epochs. For student model, we mainly use with 6-layer BERT model with initialize point as Truncated BERT (Sun et al., 2019) and BERT_{Small} (Turc et al., 2019). For fine-tuning student model, under the supervision of a fine-tuned BERT_{BASE}, we firstly perform ILD for 20 epochs with batch size 32 and learning rate 5×10^{-5} as follows Jiao et al. (2020). Then, we conduct prediction layer distillation (PLD) for 4 epochs with choosing batch size 16 and learning rate from 2×10^{-5} . Unlike the logit-based KD, we only use PLD term and do not use supervision from true labels. while We utilize GLUE (Wang et al., 2019) benchmark for exploratory experiments and set the maximum sequence length is set to 128 for all tasks.

D.2 Setup for Section 5

For achieve higher performance with our methods, we conduct hyper-parameter search as follows:

- Peak learning rate (ILD): [2×10^{-5} , 5×10^{-5}]
- Batch size (PLD): [16, 32]
- MixUp parameter (α): [0.5, 1.0, 2.0, 3.0]

For other hyper-parameter settings are not in the list, we use same parameter values as described in

Table 6: The performance averaged over 4 runs on the GLUE development set of 6-layer student models, which were trained on GLUE training set under symmetric label noise (10% and 20%). We use officially released codes for the re-implementation of PKD (Sun et al., 2019), TinyBERT (Jiao et al., 2020), and BERT-EMD (Li et al., 2020). For label noise experiments, we do not consider STS-B for computing average values.

Model	#Params	#FLOPs	Speedup	CoLA	MNLI	SST-2	QNLI	MRPC	QQP	RTE	STS-B	AVG
<i>Under the presence of uniform (symmetric) label noise (Jin et al., 2021; Liu et al., 2022) with 10% noise rate</i>												
BERT _{BASE}	110M	22.5B	1.0x	54.0	83.1	91.1	90.0	90.6	89.7	67.5	-	80.9
KD	67.5M	11.3B	2.0x	44.9	81.6	90.6	88.9	88.7	89.6	65.0	-	78.5
PKD	67.5M	11.3B	2.0x	45.2	81.2	90.5	89.0	89.1	89.4	65.4	-	78.5
TinyBERT	67.5M	11.3B	2.0x	35.4	81.9	90.1	88.3	88.3	89.6	59.9	-	76.2
BERT-EMD	67.5M	11.3B	2.0x	48.2	81.3	90.5	88.0	89.2	89.1	66.1	-	78.9
Ours	67.5M	11.3B	2.0x	50.1	82.0	90.7	89.2	89.2	89.6	66.5	-	79.6
<i>Under the presence of uniform (symmetric) label noise (Jin et al., 2021; Liu et al., 2022) with 20% noise rate</i>												
BERT _{BASE}	110M	22.5B	1.0x	50.8	82.4	90.0	88.6	87.7	87.9	63.2	-	78.7
KD	67.5M	11.3B	2.0x	42.7	81.5	90.1	88.4	87.6	88.1	64.6	-	77.6
PKD	67.5M	11.3B	2.0x	41.8	81.4	89.4	87.9	87.5	88.0	63.0	-	77.3
TinyBERT	67.5M	11.3B	2.0x	31.6	81.8	89.0	87.7	87.6	88.0	56.7	-	74.6
BERT-EMD	67.5M	11.3B	2.0x	40.7	81.0	89.7	87.6	88.0	87.9	64.6	-	77.1
Ours	67.5M	11.3B	2.0x	44.6	81.9	89.8	88.6	88.1	88.2	65.2	-	78.1

main text or Appendix D.1. We find that 2×10^{-5} is the best peak learning rate of ILD for all tasks except for STS-B. For batch size of PLD stage, RTE, MNLI and QNLI shows higher performance with batch size of 32 and other tasks shows higher performance with batch size of 16. For α , a hyperparameter for MixUp operation in CR-ILD, we choose the value of 1.0 by the result of our hyperparameter search. All hyperparameter search are conducted by using **grid search** with **averaged three runs**.

E Further Experiments on BERT

E.1 Further Observation for Section 3.1

Loss Surface Analysis. To get further intuition about the performance degradation of distilling the knowledge of intermediate Transformer layers, we provide loss surface visualizations of the U-ILD and L-ILD settings. The parameters of the Truncated BERT, the Last model (student model trained with L-ILD), and the Uniform model (student model trained with U-ILD) are $\theta_0, \theta_1, \theta_2$, respectively. In the subspace spanned by $\delta = \theta_1 - \theta_0$ and $\delta = \theta_2 - \theta_0$, we plot two-dimensional loss surfaces $f(\alpha, \beta) = \mathcal{L}(\theta_0 + \alpha\delta_1 + \beta\delta_2)$ centered on the weights of Truncated BERT θ_0 . As shown in Figure 10, transferring knowledge of the intermediate Transformer layers leads the student model to sharp minima, which results in poorer generalization (Hochreiter and Schmidhuber, 1997; Keskar et al., 2016). Thus, the knowledge from the intermediate Transformer layer causes the student

model to overfit the training dataset and reduce the generalization.

Linear Probing Analysis. Probing experiments can be used for evaluating the degradation of the generalizable representations of PLMs during fine-tuning. Similar to Aghajanyan et al. (2021b), we conduct the probing method by first freezing the representations from the model trained on one downstream task, and then fine-tuning linear classifiers on top of all Transformer layers to measure the generalization performance of the layers of the teacher and student models.

Through probing experiments, we observe that the lower-level representations of the student model related to U-ILD are overfitted to the training dataset of the target task. Figure 11a shows that the probing performances for 1 to 3 layers of the student model with U-ILD are higher than those of the Last model on the training set of RTE. According to Howard and Ruder (2018); Zhang et al. (2021), it is crucial to train PLMs so that lower layers have general features and higher layers are specific to target tasks. The overfitting of lower layers to the target task leads to performance degradation in the higher layers, as illustrated in Figure 11b. Moreover, for the other tasks, the student models with L-ILD have higher probing performance for all layers than the Uniform models, except for the performance of the first layer on MRPC as indicated in Figure 11c and 11d.

E.2 Experimental Results for Different Label Noise Ratio

We conduct additional experiments on the GLUE benchmark with different label noise ratios (10% and 20% of uniform label noise) as shown in Table 6. While BERT-EMD (Li et al., 2020) shows the second best performance in small noise ratio (10%) and achieve better performance than the original KD, the original KD and PKD (Sun et al., 2019) present the higher performance in severe noise rate (20% in Table 6 and 30% in Table 2) than BERT-EMD. Surprisingly, our CR-ILD (Ours) shows the best performance for all noise ratios consistently which verifies that our proposed method encourages the distilling of the knowledge effectively and prevents overfitting on the training datasets.

F Further Experiments on Encoder-Decoder Models

F.1 T5: Study on Encoder-Decoder Models

In this section, we apply our approaches to T5 to generalize our result from the encoder-based model to the encoder-decoder model. First, we explain our experimental setup in the experiments conducted on T5. Secondly, we examine (1) two findings (last Transformer layer, supplementary task) and (2) our proposed method, CR-ILD suggested with the experiments on BERT can boost the performance of T5 model as well as the encoder-based model.

F.2 Experimental setup

We experiment with our proposed training strategies on the encoder-decoder model. As a teacher model, we use T5_{BASE} fine-tuned to the target task with batch size 8, learning rate 1×10^{-3} for ten epochs, which follows a training scheme for fine-tuning T5 on an individual GLUE task proposed in (Raffel et al., 2020). As a student model, we use the pre-trained T5_{Small}. During the distillation, we distill the knowledge from the teacher model to the student model consecutively, similar to the training scheme described in the experimental setup of BERT distillation. We first distill the knowledge using the given distillation objective (i.e., attention, intermediate states) depending on the task. Unlike the BERT experiments, we fine-tune the T5 model on the target task after the ILD since the performance decreases in a few tasks when we apply logit-based KD (Hinton et al., 2015). To distill the transformer layers and the intermediate states, we use methods proposed by (Wang et al.,

2021) and (Jiao et al., 2020). Specifically, before distilling the attention scores, we applied relation heads proposed in (Wang et al., 2021) and calculated attention scores since the number of attention heads of the student and the teacher differs. After matching the number of relation heads, we distill attention scores of relation head and the hidden states, using the methods of (Jiao et al., 2020). Regarding the supplementary tasks, we use the same hyperparameters as the ILD experiments. In CR-ILD experiments, we set w_{MHA}^{CR} as 0.2 and 0.3 for the MRPC and RTE task individually.

F.3 Experimental Results: Last Transformer Layer and Supplementary Task

In this section, we focus on whether two findings from the experiments on BERT show consistent results in the experiments on T5.

Last Transformer Layer. We evaluate the superiority of distilling the last Transformer layer knowledge in T5 models. Unlike BERT, T5 has an additional Transformer layer of the decoder network and cross-attention (CA). Therefore, we also conduct additional comparisons between the distillation on the decoder network and the distillation on both the encoder and decoder network, as well as the comparison between the last Transformer layer mapping and uniform layer mapping. Furthermore, we examine the effectiveness of the distillation on the cross-attention when we distill the knowledge in the decoder network.

In Figure 12a, 12b, and 12c, the blue boxes, and the orange boxes denote the distillation on the decoder network, the distillation on both the encoder and decoder network, respectively. In most cases, distilling only from the decoder network tends to show higher results than distilling from the encoder and decoder network. In addition, distilling the last Transformer layer shows better performance than the distilling Transformer layers uniformly. Lastly, compared to distilling the self-attention and the cross-attention of the last Transformer decoder layer (green bar in Figure 12), distilling only the self-attention of the last Transformer decoder layer (the first blue bar) shows better performance. In conclusion, We observe that distilling knowledge from only the last layer of the decoder network shows the highest performance across the target tasks. This result is consistent with the previous results of the experiments on BERT.

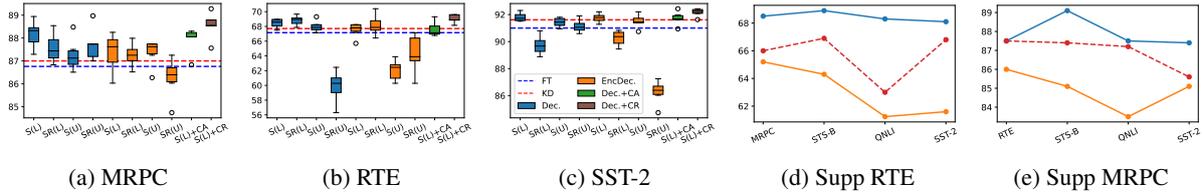

Figure 12: We compare the performance for different layer mapping functions and distillation objectives in (a)-(c). The distillations of the last layer, uniform layer mapping, self-attention, and IR are denoted by L, U, S, and R, respectively. The blue (Enc.) and orange (Dec.) bar denote the application of ILD to the decoder network only and to both encoder and decoder network, respectively. We also denote ILD with CA and CR as the green and brown bars in (a)-(c), respectively. (d)-(e) are results for using ST for TTs of MRPC and RTE. We only distill self-attention of the last layer of the decoder when using ILD with ST and CR

Supplementary Task We further evaluate the effectiveness of the supplementary tasks on ILD for the encoder-decoder models. Figure 12d and 12e summarize the performance of RTE and MRPC tasks, depending on the supplementary task initialization. Blue, red and orange lines denote distilling self-attention of the last Transformer layer, logit-based distillation, and fine-tuning, respectively. Using the distillation on the self-attention of the last Transformer layer, initialization from the supplementary task training shows better performance than PLM initialization regardless of the supplementary task.

F.4 Experimental Results: CR-ILD

In this section, we examine whether our CR-ILD method could mitigate the over-fitting of the student model when the teacher and the student are T5 models. In Figure 12a, 12b, and 12c, the brown box denotes to distill the self attention of last Transformer decoder layer with the consistency regularization, CR-ILD. In order to see the difference according to the presence or absence of the consistency regularization, we compare the brown box and the first blue box, which denotes to distill the self attention of last Transformer decoder layer without CR-ILD. In the all tasks (MRPC, RTE, and SST-2), the consistency regularization boost the performance of the student model. That is, the effect of the consistency regularization is consistent with the result of the experiment on BERT.

Implicit Temporal Reasoning for Evidence-Based Fact-Checking

Liesbeth Allein, Marlon Saelens, Ruben Cartuyvels, Marie-Francine Moens

Department of Computer Science

KU Leuven, Belgium

{liesbeth.allein,ruben.cartuyvels,sien.moens}@kuleuven.be

Abstract

Leveraging contextual knowledge has become standard practice in automated claim verification, yet the impact of temporal reasoning has been largely overlooked. Our study demonstrates that time positively influences the claim verification process of evidence-based fact-checking. The temporal aspects and relations between claims and evidence are first established through grounding on shared timelines, which are constructed using publication dates and time expressions extracted from their text. Temporal information is then provided to RNN-based and Transformer-based classifiers before or after claim and evidence encoding. Our time-aware fact-checking models surpass base models by up to 9% Micro F1 (64.17%) and 15% Macro F1 (47.43%) on the MultiFC dataset. They also outperform prior methods that explicitly model temporal relations between evidence. Our findings show that the presence of temporal information and the manner in which timelines are constructed greatly influence how fact-checking models determine the relevance and supporting or refuting character of evidence documents.¹

1 Introduction

Automatically verifying information and flagging engineered falsities have been high on the political, media, and - subsequently - research agenda for quite some *time* (European Commission, 2022). However, the role of time in machine-assisted fact-checking has been inadequately investigated. Time can affect the veracity of previously uttered claims and the relevance of supporting or refuting evidence. This is evident in research, for example, where newly acquired knowledge may question, confirm, or refute established facts. This study proposes to ground claims and associated evidence in

¹The code of this paper is publicly available: <https://github.com/Marlon668/VerificationClaimsWithTimeAttribution>.

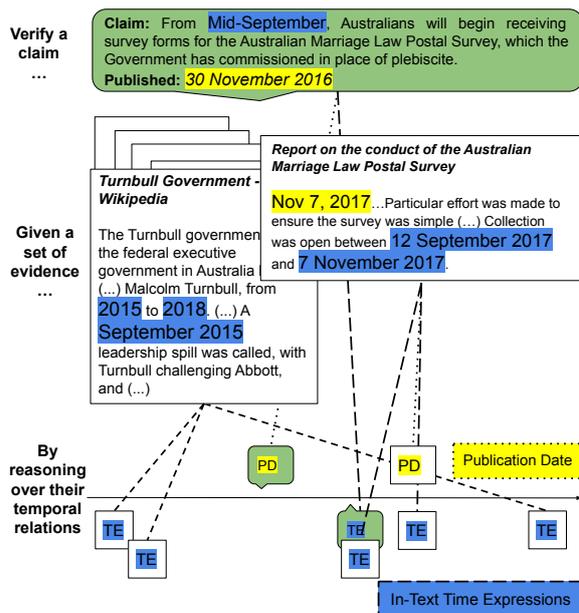

Figure 1: An evidence-based fact-checking model verifies a given claim against a set of Web documents serving as supporting or refuting evidence. In this study, we let the model implicitly reason over the temporal aspects of the claim and evidence, and their relations. For this, both inputs are grounded at two levels on a shared timeline: at the document level using their publication dates (in yellow, dotted line) and at the content-level using time expressions in their text (in blue, dashed line).

time and incorporate temporal reasoning abilities in the claim verification process of computational fact-checking models (Figure 1). Here, temporal reasoning is implicit since the models are not expected to make explicit predictions about time. They instead learn from data how to leverage temporal information.

Grounding a claim or evidence document in time is a complex task. On the one hand, it can be achieved through document-level grounding, which involves positioning the entire document on a timeline based on its publication date. On the other hand, a document may discuss several events that have occurred in the past, present, or future. To fa-

Facilitate more fine-grained grounding on the content level, time expressions in the text are used to place the document on multiple positions on a timeline. Such expressions can be explicit (e.g., 27 June 2022), implicit (e.g., Christmas 2022), and relative (e.g., mid-September), which may require additional temporal information for grounding (Strötgen and Gertz, 2013; Leeuwenberg and Moens, 2019). In this study, we ground claims and evidence on both the document and content level. This is accomplished by extracting and normalising their publication date and in-text time expressions, and subsequently relating them in terms of distance in time. This enables fact-checking models to reason over the temporal relations between a claim and its evidence on more than one level.

Contributions This study demonstrates that reasoning over temporal aspects and relations of claims and evidence not only improves fact-checking models’ prediction performance but also influences their estimation of the relevance and the supporting/refuting character of the evidence. The effects on performance are even reinforced when claims and evidence are grounded at both the document and content level, showing the appropriateness of multi-level temporal reasoning in automated fact-checking.

2 Related Work

Automated fact-checking is usually a two-phase process consisting of claim detection/selection and claim verification (Zeng et al., 2021; Guo et al., 2022). Time is arguably important in both phases. When detecting and ultimately selecting claims to fact-check, fact-checkers heed the current interest of the public in certain topics and election cycles, and rank the claims accordingly (Allein and Moens, 2020). Moreover, many selected claims mention dates or time periods (Hidey et al., 2020). Shaar et al. (2020) looked in the past and filtered out claims that are semantically similar to previously fact-checked claims to expedite the claim selection process.

While evidence-based claim verification has been widely studied (Zhong et al., 2020; Liu et al., 2020; Chen et al., 2021; Si et al., 2021; Jin et al., 2022; Xu et al., 2022; Hu et al., 2022), few studies explicitly focused on incorporating temporal reasoning in the verification process. Zhou et al. (2020) constructed (entity, value, time)-tuples representing supposedly temporal facts and verified

their correctness using probabilistic graphical models. Allein et al. (2021) constrained the evidence ranking in fact-checking models on time using silver-standard evidence rankings respecting four assumptions on temporal relevance. Instead of verifying the temporal correctness of claim tuples or explicitly enforcing time-dependent evidence rankings, we let fact-checking models reason *implicitly* over temporal aspects of claims and evidence in natural language when checking the claims.

3 Task Description

Classifier f takes a textual claim c and an associated set of N text documents $\{e_i\}^N$ serving as evidence of c , and returns a claim veracity label y .

$$f : c, \{e_i\}^N \rightarrow y \quad (1)$$

To allow f to reason over temporal aspects of c and e_i , we extract and normalise publication dates and time expressions in c and e_i , and assign them to time buckets. Temporal representations c_t and $e_{i,t}$ are sequences of time bucket indices and are given as additional input to f :

$$f : c, c_t, \{e_i\}^N, \{e_{i,t}\}^N \rightarrow y \quad (2)$$

4 Two-Level Grounding and Reasoning

To obtain temporal representations c_t and $e_{i,t}$, we ground c and e_i in time by positioning them on a joint timeline using either their *publication date* ($c_t = c_t^{doc}$; $e_{i,t} = e_{i,t}^{doc}$) or *in-text time expressions* ($c_t = c_t^{con}$; $e_{i,t} = e_{i,t}^{con}$). A fact-checking model can then reason over their temporal aspects and relations at the *document level* or the *content level*, respectively (Figure 2).

4.1 Reasoning at Document Level

The publication date of c serves as reference point for grounding e_i . This way, we lay bare the temporal relation between c and e_i at the document level. We adopt the approach of Allein et al. (2021) and compute the distance in days $\Delta_{pub} \in \mathbb{Z}$ between the publication date of c and that of e_i , where $\Delta_{pub} < 0$ indicates that e_i was published before c , $\Delta_{pub} = 0$ indicates that e_i and c were published on the same day, and $\Delta_{pub} > 0$ indicates that e_i was published after c . The publication date of e_i is then assigned to a time bucket $b_{pub} \in T^{doc}$ given Δ_{pub} . Ultimately, the document-level temporal representation of e_i , $e_{i,t}^{doc}$, is a sequence of indices corresponding to b_{pub} in T^{doc} , with $|e_{i,t}^{doc}| = 1$ since e_i

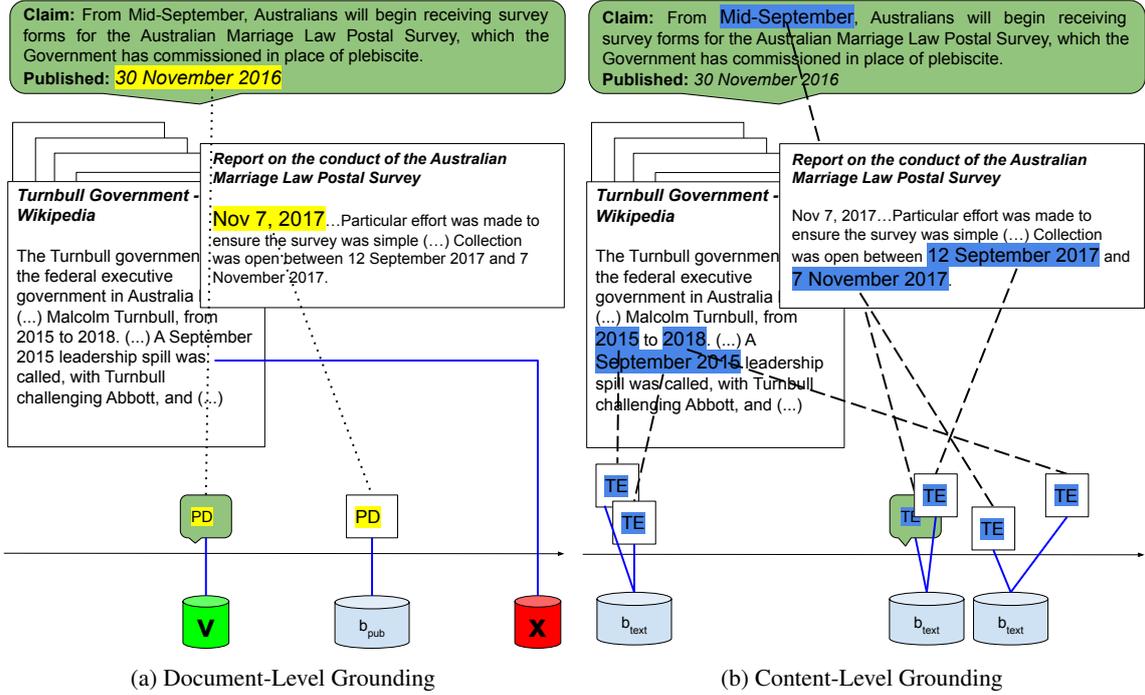

Figure 2: Illustration of two-level grounding: (a) at the document level using publication dates (PD) and (b) at the content level using in-text time expressions (TE). All PD and TE are assigned to time buckets b_{pub} and b_{text} , respectively. \checkmark means that a publication date was found (only for claims) and \times that no publication date was found.

has only one publication date. When a publication date for e_i could not be extracted, $e_{i,t}^{doc}$ corresponds to the index of a dedicated time bucket indicating date unavailability. Lastly, the document-level temporal representation of the claim, c_t^{doc} , merely indicates the availability of a publication date for the claim. We motivate and discuss the choice of T^{doc} in Section 4.3.

4.2 Reasoning at Content Level

While the document-level approach grounds c and e_i as whole documents, the content-level approach places them on various positions on a timeline using time expressions found in their text. Each time expression in e_i and c is first extracted and normalised, and its distance in days $\Delta exp \in \mathbb{Z}$ to the publication date of c is computed. They are then assigned to time buckets $b_{text} \in T^{con}$ given Δexp . The choice of T^{con} is discussed in Section 4.3. The content-level temporal representation of e_i is $e_{i,t}^{con}$ is a sequence of indices where each index corresponds to a $b_{text} \in T^{con}$. The length of $e_{i,t}^{con}$ equals the number of time expressions found in e_i , and the j^{th} element of $e_{i,t}^{con}$ corresponds to the index of the time bucket of the j^{th} time expression in e_i . A time bucket index can occur multiple times in $e_{i,t}^{con}$. The same grounding procedure is applied to obtain

content-level temporal representation c_t^{con} for c . In contrast to c_t^{doc} , c_t^{con} does not merely reflect the availability of a publication date for c but grounds time expressions in the claim text with respect to the claim’s own publication date. The content-level grounding approach allows a fact-checking model to reason over the temporal aspects of the events discussed in e_i and c , and their temporal relation to the publication date of c .

4.3 Creating Time Buckets

Time buckets $b_{pub} \in T^{doc}$ and $b_{text} \in T^{con}$ represent time intervals with respect to the publication date of c (e.g., $b_{pub} = [1, 4]$ indicates that e_i was published between 1 and 4 days after c had been published). Following the cluster hypothesis of [Jardine and van Rijsbergen \(1971\)](#) which states that documents in a cluster contain similar information, the similar information in a bucket is the distance in time to c . For document-level grounding and reasoning, the construction and choice of T^{doc} goes as follows: (1) Δpub for each e_i in the training set is computed; (2) all Δpub are ordered in ascending order; (3) and, finally, all Δpub are subdivided in 20 quantiles, containing a similar number of e_i ($\mu = 8530.5, \sigma = 266.87$). Each quantile represents one bucket b_{pub} . Various numbers of quantiles

were tested, and 20 returned the best performance on the validation set. Three buckets denoting a lacking publication date for e_i , an available publication for c , and a lacking publication date for c are added; hence, $|T^{doc}| = 23$. A similar procedure is applied for constructing T^{con} using Δexp ($|T^{con}| = 24$, $\mu = 13390.75$, $\sigma = 2050.4$). However, no extra buckets b_{text} denoting (un)availability of date are added. An overview of all b_{pub} and b_{text} can be found in Appendix A. Note that the intervals of b_{pub} and b_{text} become smaller when its bounds approach 0, allowing for more fine-grained reasoning for evidence published around or at the same time as the claim. Time buckets approaching 0 (i.e., e_i situates around the same time as c) have smaller intervals than those far from 0, with even a dedicated time bucket for those evidence published or discussing events happening on the same day as the claim. The advantage of using such time buckets is that the model is more robust against bias towards larger buckets. In the fact-checking models, each bucket corresponds to a unique embedding stored in a randomly-initialised time embedding matrix, which is updated during model training.

5 Methodology

5.1 Fact-Checking Model

We take the Joint Veracity Prediction and Evidence Ranking model introduced in [Augenstein et al. \(2019\)](#) as base model (Figure 3). Taking c and e_i represented by their word embeddings $w \in \mathbb{R}^{D_1}$, the text encoder encodes them to their latent representations $h(c)$ and $h(e_i) \in \mathbb{R}^{D_2}$. Metadata m linked to c is encoded in parallel, yielding $g(m)$. Next, $h(c)$, $h(e_i)$, and $g(m)$ are combined into a joint claim-evidence representation s_i using the matching approach introduced by [Mou et al. \(2016\)](#):

$$s_i = [h(c); h(e_i); h(c) - h(e_i); h(c) \cdot h(e_i); g(m)] \quad (3)$$

with $[\cdot]$ denoting concatenation, and $[\cdot]$ the dot product. The evidence scorer projects each s_i to $o_i \in \mathbb{R}$, forming evidence score vector $o \in \mathbb{R}^N$. The label scorer projects each s_i to its label score vector $q_i \in \mathbb{R}^L$ forming scoring matrix $Q \in \mathbb{R}^{N \times L}$, with L the number of veracity labels. $o^T \cdot Q$ gives a final score vector for all labels L , to which a softmax is applied to obtain a probability distribution over all veracity labels.

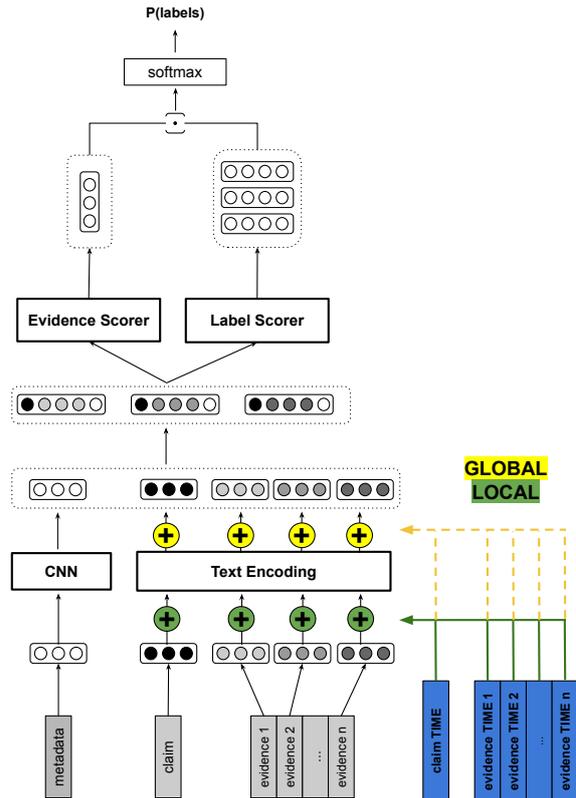

Figure 3: Overview of the fact-checking model, where temporal information on claim and evidence (in blue) is integrated before text encoding (local level; in green) or after text encoding (global level; in yellow).

5.2 Incorporating Temporal Reasoning

Temporal representations c_t and $e_{i,t}$ are transformed to their time embeddings, \hat{c}_t and $\hat{e}_{i,t}$, and given as additional model input. The embedding dimensions depend on the stage at which they are integrated in the model.

Local integration c_t and $e_{i,t}$ are integrated before encoding claim and evidence c and e_i to $h(c)$ and $h(e_i)$. Time embeddings $\hat{c}_t, \hat{e}_{i,t}$ for each time bucket index in c_t and $e_{i,t}$ are taken from the embedding matrix and projected onto the same dimension as the word embeddings $w \in \mathbb{R}^{D_1}$ of tokens in c and e_i using a linear transformation layer l .

For **document-level reasoning** (DL_{loc} , eq. 4), the embeddings (there is max. one publication date; hence one time embedding per document) are prepended to those of c and e_i . These are then sent to the text encoder.

$$\begin{aligned} c &= [l(\hat{c}_t^{doc}); w_0, \dots, w_{|c|}] \\ e_i &= [l(\hat{e}_{i,t}^{doc}); w_0, \dots, w_{|e_i|}] \end{aligned} \quad (4)$$

For **content-level reasoning** (CL_{loc} , eq. 5), local integration is more complex. Firstly, c_t^{con} and $e_{i,t}^{con}$ may refer to more than one time bucket as there may be more than one time expression in c and e_i . Secondly, the position of a time expression and the predicate it belongs to may provide rich information about a mentioned event. We first identify the type of each token in c and e_i (see Table 1).

Position, predicate, and time expression marking									
Tokens	Storm	Al-	berto	expected	to	make	landfall	to-	morrow
Type	O	O	O	O	O	B-PRED	O	B-TIME	TIME
Pos	/	/	/	/	/	+2	/	/	/
Time	/	/	/	/	/	/	/	0	/

Table 1: Additional sentence preprocessing when integrating c_t^{con} and $e_{i,t}^{con}$ at the local level. The predicate (PRED) and the time expressions (TIME) are marked, with B indicating their first token, and the token distance between B-TIME and B-PRED is computed.

We then introduce three new embeddings: predicate embedding $pr \in \mathbb{R}^{D_1}$ marks the predicate, position embedding $po \in \mathbb{R}^{D_1}$ marks the position of the predicate, and expression embedding $te \in \mathbb{R}^{D_1}$ marks the time expression. These additional embeddings are learned during training. The word embedding w of a token in c depends on that token’s type (same for e_i and $e_{i,t}^{con}$):

$$w = \begin{cases} \gamma w + (1 - \gamma)(l(\hat{c}_{t,j}^{con}) + te) & \text{if B-TIME} \\ \gamma w + (1 - \gamma)te & \text{if TIME} \\ \gamma w + (1 - \gamma)(pr + po) & \text{if B-PRED} \\ \gamma w + (1 - \gamma)pr & \text{if PRED} \\ w & \text{otherwise} \end{cases} \quad (5)$$

Embedding $\hat{c}_{t,j}^{con}$ refers to the embedding of time bucket b_{text} to which the j^{th} time expression in c refers.

Global integration c_t and $e_{i,t}$ are integrated after c and e_i have been transformed by the text encoder to their latent representations $h(c)$ and $h(e_i) \in \mathbb{R}^{D_2}$. An embedding for each time bucket in c_t and $e_{i,t}$ is taken and projected onto the same embedding space \mathbb{R}^{D_2} using a linear transformation layer k . If c_t or $e_{i,t}$ are represented by more than one time bucket, the embeddings are averaged. Fusion is performed using a weighted sum. For **document-level reasoning** (DL_{glob}):

$$\begin{aligned} h(c) &= \alpha h(c) + (1 - \alpha)k(\hat{c}_t^{doc}) \\ h(e_i) &= \alpha h(e_i) + (1 - \alpha)k(\hat{e}_{i,t}^{doc}) \end{aligned} \quad (6)$$

And for **content-level reasoning** (CL_{glob}):

$$\begin{aligned} h(c) &= \alpha h(c) + (1 - \alpha)\text{Avg}(k(\hat{c}_t^{con})) \\ h(e_i) &= \alpha h(e_i) + (1 - \alpha)\text{Avg}(k(\hat{e}_{i,t}^{con})) \end{aligned} \quad (7)$$

with Avg the average. We also experiment with a **combination of document-level and content-level reasoning** ($DL+CL_{glob}$, eq. 8) where temporal information from both levels is provided to the model:

$$\begin{aligned} h(c) &= \alpha h(c) + \beta k(\hat{c}_t^{doc}) \\ &+ (1 - \alpha - \beta)\text{Avg}(k(\hat{c}_t^{con})) \\ h(e_i) &= \alpha h(e_i) + \beta k(\hat{e}_{i,t}^{doc}) \\ &+ (1 - \alpha - \beta)\text{Avg}(k(\hat{e}_{i,t}^{con})) \end{aligned} \quad (8)$$

6 Experiments

6.1 Dataset

Experiments are conducted on MultiFC² (Augenstein et al., 2019), a large-scale dataset containing 34,924 English claims from various fact-checking websites (= ‘domains’) where each claim is associated with at most 10 *a posteriori* retrieved Web documents (319,721 documents in total). It also provides metadata on speaker, category, tags, and linked entities regarding the claim. We refer to Augenstein et al. (2019) for a more detailed description of the data. Although other datasets for fact-checking have been proposed (Zeng et al., 2021), they either lack naturally occurring claims, publication dates, or multiple evidence documents (Thorne et al., 2018; Jiang et al., 2020; Ostrowski et al., 2021; Schuster et al., 2021). Nonetheless, the large size, wide diversity of topic and data sources, and high quality of the MultiFC dataset should be sufficient for showcasing the appropriateness of our approach.

6.2 Time Extraction and Normalisation

In this section, we discuss the procedure for extracting and normalising publication dates and in-text time expressions.

6.2.1 Publication Dates

The dataset provides the publication date of a claim as structured metadata. The date is represented as Year-Month-Day using rule-based temporal tagger HeidelTime (Strötgen and Gertz, 2013). The publication date of an evidence document, however,

²The data is publicly available on CodaLab.

is not given in the metadata. Since its publication date is often communicated before the ellipsis ('...') at the beginning of its text, we can automatically extract the date from the text (Allein et al., 2021). If we cannot extract a date at that position, we look for occurrences of 'published' or 'posted' in combination with a date. We again use HeidelTime for structuring the publication dates. In total, we obtain a publication date for 34,808 (99.67%) claims and 213,165 (66.67%) evidence documents.

6.2.2 In-Text Time Expressions

Extracting and normalising in-text time expressions is more challenging as they can be implicit or relative. Since in-text time expressions are usually not annotated in datasets used for fact-checking, we need to reside to pretrained methods for extracting them. We implement the Open Information Extraction (OIE) model of Stanovsky et al. (2018), which parses a sentence and labels its arguments. In this work, we focus on temporal arguments (*ArgM - TMP*). Since inaccurate use or absence of capital letters has been shown to decrease the performance of OIE models (Alam and Awan, 2018), the OIE model is expected to return a high number of inaccurate parses for capitalised news headlines – which make up a large portion of the claims in the data. We therefore implement a pretrained Named Entity Recognition (NER) model (Peters et al., 2017) to first detect people, locations, and organisations in the text. Then, the first token of each entity is capitalised while all other tokens are lowercased. Although capitalised temporal expressions such as weekdays and holidays are automatically lowercased too, we observed a higher quality of OIE parses when adopting this approach. We normalise the extracted temporal expressions using HeidelTime. The document creation time (DCT) of a piece of information, in this study the publication date, is used as reference point for normalising in-text temporal expressions. In total, we obtain 321,278 in-text time expressions.

Quality assessment Implementing pretrained extraction and normalisation models inevitably introduces noise in the data. We therefore manually assess the quality of the NER, OIE, and HeidelTime models to ensure that the noise is limited. The assessment is performed on a randomly selected set of 10 claims and their accompanying evidence documents (104 in total) from the dataset, and performance is measured using precision (P),

recall (R), and F1. Regarding NER, we investigate whether all entities have been recognised and completely extracted. The label correctness does not need to be evaluated. NER performance is 0.9054/0.9134/0.9094 (P/R/F1). For the OIE task, we assess whether all temporal expressions have been correctly extracted and parsed. OIE performance is 0.9608/0.5568/0.7050 (P/R/F1), indicating that while quite some time-related expressions have not been extracted, those found have been correctly parsed. Lastly, we evaluate the normalisation of the found expressions: HeidelTime performance is 0.9736/0.8409/0.9024 (P/R/F1). In all, we deem the quality of the pretrained extraction and normalisation models sufficiently high.

6.3 Experimental Setup

Hyperparameter settings Both c and e_i are tokenised³ and represented using word embeddings (size = 300 (BiLSTM); 768 (DistilRoBERTa)). We experiment with two neural text encoders for encoding c and e_i : a two-layered bidirectional LSTM with skip-connections (dropout = 0.1, hidden size = 128) and a pretrained Sentence-DistilRoBERTa, which is a faster, distilled version of Sentence-RoBERTa (Sanh et al., 2019; Reimers and Gurevych, 2019). For sake of brevity, we continue to refer to this model as RoBERTa. Metadata m is represented as a one-hot vector and encoded by a CNN (filter size = 3, kernel size = 3) with ReLU activation and 1D max pooling. The label scorer consists of two fully-connected layers (hidden size = 100; 50), both with ReLU activation. The evidence scorer is a fully-connected layer (hidden size = 100) with Leaky ReLU activation. All parameters except those of the pretrained RoBERTa model are initialised following a Xavier Uniform distribution. More detailed settings for reproducing the experiments, such as hyperparameter tuning, is provided in Appendix B.

Pretraining and fine-tuning The experiments are conducted on the disjunct, label-stratified train (80%), validation (10%), and test set (10%) provided by Augenstein et al. (2019). We adopt the pretraining and fine-tuning setup of Allein et al. (2021) to ensure transparent comparison. During pretraining, the model is trained on all 26 fact-checking domains where each domain is only presented once in each epoch (batch size = 32 (BiL-

Table 2: Average test results over three (BiLSTM) and two (RoBERTa) runs - with standard deviation in brackets - aggregated over all 26 fact-checking domains. Experiments are conducted for document-level (DL) and content-level (CL) temporal reasoning, where temporal information is integrated before (*loc*) or after (*glob*) encoding.

STM); 16 (RoBERTa)), mitigating model bias towards larger domains. After each epoch, the batch order is randomly shuffled, and Adam with linear scheduler ($\text{lr} = 1e^{-4}$ (BiLSTM)) or RMSprop ($\text{lr} = 2e^{-4}$ (RoBERTa)) optimizes the model parameters using the cross-entropy loss on the prediction output. The best-performing model for each fact-checking domain is selected based on the validation loss. Each domain-specific model is then fine-tuned on only data from that domain and the best-performing model is again selected based on the validation loss.

7 Results

Table 2 reports model performance on the test set, aggregated over all domains, in terms of Micro F1 and Macro F1⁴. The results show that the effect of temporal reasoning depends on (a) the level at which temporal information is integrated in the model (global vs. local), (b) the grounding/reasoning level (document vs. content), and (c) the model architecture (BiLSTM vs. RoBERTa). Regarding the integration level, global integration (*glob*) substantially surpasses local integration (*loc*) for document-level reasoning (both models; .5501/.3343 \rightarrow .6006/.4271 [BiLSTM]; .5640/.3357 \rightarrow .6973/.5608 [RoBERTa]) and content-level reasoning (.5685/.3601 \rightarrow .6882/.5744 [RoBERTa]). Regarding the temporal grounding and reasoning level, the results show that the combination setup where claim and evidence are grounded at both the document and content level (DL+CL) yields the overall highest performance for BiLSTM (.6417/.4743), while marginally improving RoBERTa by 2% Macro F1 (.5739). Lastly, temporal reasoning ap-

pears to impact the prediction performance of the less parameterised BiLSTM model more strongly than that of the Transformer-based RoBERTa model: .5520/.3239 \rightarrow .6417/.4743 [BiLSTM]; .6952/.5532 \rightarrow .6947/.5739 [RoBERTa]. A similar effect was observed by [Allein et al. \(2021\)](#), who explicitly modeled temporal relations between a claim and its evidence by constraining model parameters on evidence rankings following various assumptions on temporal relevance. This could be attributed to the expressive power of large pre-trained Transformers-based language models and the orders of magnitude of their pretraining set size.

Table 3 shows the comparison between our best performing set-up with the baseline from [Augenstein et al. \(2019\)](#) and the model with explicit temporal reasoning from [Allein et al. \(2021\)](#). Overall, our approach outperforms the baseline and the explicit temporal reasoning approach, especially on the Macro F1-score. This demonstrates the appropriateness of our implicit, two-level temporal reasoning method over an approach without temporal reasoning and one that explicitly models temporal relations using only publication dates.

8 Discussion

Weighting text and time We ran experiments with various weight values (α, β, γ) for combining the text features of a claim and its evidence with their temporal information⁵. Table 2 presents the best-performing weight values for each setting based on the validation loss. When reasoning over the document-level temporal relations (DL), the results suggest that higher importance should be attributed to the text of the claim and its evidence

⁴Computed using the [scikit-learn Python package](#).

⁵A full overview of tested values and the tuning approach is provided in [Appendix A](#).

	Micro F1	Macro F1	Micro F1	Macro F1
No temporal reasoning (Augenstein et al., 2019)	.5520	.3239	.6952	.5532
Explicit temporal reasoning (Allein et al., 2021)	.6265	.3673	.5921 [†]	.3135 [†]
Implicit temporal reasoning (Ours)	.6417	.4743	.6947	.5739

Table 3: Results of our implicit temporal reasoning approach vs. the baseline results of Augenstein et al. (2019) (our implementation) and the explicit temporal reasoning method of Allein et al. (2021), with a BiLSTM and a Transformer text encoder. [†]: DistilBERT (Sanh et al., 2019) instead of RoBERTa.

rather than to their temporal information. However, this is the opposite when reasoning at the content level (CL). The combined setup (DL+CL) aligns with (CL) by attributing more importance to time than text. This suggests that specially in-text time expressions carry useful information for fact-checking a claim.

Impact on evidence relevance and label scores

We analyse how and to which extent temporal reasoning influences a model’s assessment of the relevance (o_i) and supporting/refuting nature (q_i) of evidence in relation to a claim. Since the model computes o_i and q_i for each evidence document associated with the claim, a ranking of all evidence can be derived based on either o_i or q_i . We then measure the difference in such rankings between the base and the best-performing temporal models. Following Allein et al. (2021), we rely on the Spearman’s rank correlation r_s , which is a non-parametric, distribution-independent metric for computing the correlation between two rankings. The correlation between the base model and the temporal reasoning models with regard to evidence relevance ranking is very weak, with $0 < |r_s| < 0.19$ for both BiLSTM and RoBERTa. Also between the temporal models, those correlations are generally very weak. Interestingly, the impact of implicit temporal reasoning on a fact-checking model’s estimation of evidence relevance is arguably as strong as when performing explicit temporal reasoning (Allein et al., 2021). The correlations fall within the range of $.17 < |r_s| < .24$. The correlations regarding label scoring (q_i) are comparable to those for evidence ranking, ranging from weak ($0.2 < |r_s| < 0.39$) and to very weak. We can thus conclude that a model’s estimation of the relevance and supporting/refuting nature of evidence documents is strongly influenced not only by the ability to reason over time, but also by the way a claim and its evidence are grounded on a timeline.

Importance of time in final prediction While we have shown that temporal reasoning strongly influences relevance estimations and label scores per evidence document, we now measure how much the time-aware fact-checking models rely on temporal information for their final veracity predictions. For this, we attribute the prediction of the models to the input using integrated gradients (Sundararajan et al., 2017). This attribution technique measures the attribution strength of text and time features on the final prediction. We focus on the base BiLSTM model and its best-performing temporal variants. Given the high dimensionality of text and time embeddings, the attribution strengths across all dimensions are summed to obtain a total attribution value for claim, evidence, and time (c_t and $e_{i,t}$). Figure 4 illustrates the attribution values of a single data entry and presents the ranking of evidence text and time according to their attribution strength. The models typically attributed the prediction to both the claim and evidence, with a stronger emphasis on the collected evidence than on the claim. However, when time information was introduced, the attribution strength of claim and evidence texts strongly decreased, especially when evidence was grounded at the content level (CL/DL+CL). This indicates that time indeed influences model prediction.

Interestingly, the attribution ranking of temporal information was found to be distinct from that of the content, as demonstrated by the example in Figure 4. The publication dates that are closer to that of the claim obtain higher attribution strength than those far from the claim. In line with this, statistical correlation testing between $e_{i,t}$ and label scores q_i - where each label score in q_i for $e_{i,t}$ in the same bucket is compared to the label score in q_i for $e_{i,t}$ in different buckets - show that evidence contained within the same time bucket tend to prefer the same prediction labels as their label rankings strongly correlate ($\rho = 0.7$). We can thus conclude that time

influences both interim and final prediction.

9 Conclusion

Grounding claims and associated evidence documents on a shared timeline and implicitly reasoning over their temporal relations noticeably improves the verification performance of automated fact-checking models. Time plays a dual role in this process, serving both as a source of information for verifying claims, as well as influencing the evaluation of the relevance and supporting or refuting nature of evidence documents. Further research may look into integrating temporal reasoning in claim detection and evidence retrieval processes

or implementing even more sophisticated temporal reasoning during claim verification by examining the temporality of events discussed in a claim and their relation to the evidence.

Limitations

The limitations of this work mainly originate from the data and the use of pretrained models for grounding claims and evidence documents in time. Since the evidence documents were retrieved after the claim had been fact-checked by giving the claim verbatim to a search engine and selecting the first ten search results, their quality and relevance to the claim is not ensured. As a result, evidence-based fact-checking models risk relying on spurious signals in the evidence documents for predicting a claim’s veracity. Moreover, the evidence documents are presented as short snippets which only reflect small parts of the full Web documents. This not only affects content representation, but it also limits temporal information extraction since many time expressions may have been omitted from the shortened text. Regarding temporal information extraction and normalisation, we had to rely on pretrained models to obtain temporal representations of claims and its associated evidence documents. This not only introduces noise in the input data, but also requires time-expensive preprocessing.

Ethics Statement

Automated fact-checking technology aims to assist people in distinguishing between verified and unverified content in professional contexts and during their daily information consumption. Nevertheless, the fact-checking models constructed in this paper - like all fact-checking models - should be deployed with caution and its predictions should never be taken as final without further human evaluation. Computational predictions are anything but flawless, and incorrect predictions may unjustly discredit the person or group who uttered the fact-checked statement(s).

A Time Buckets

Table 4 presents an overview of time buckets b_{pub} with their interval bounds used for document-level grounding, while Table 5 presents time buckets b_{text} with their interval bounds used for content-level grounding.

B Reproducibility Settings

This section contains settings for reproducing the experiments in this paper.

Computing infrastructure The BiLSTM models were trained on a Skylake processor type with one compute node, 9 cores per node, one GPU (GPU partition of Skylake) and 5 GB memory per core. The DistilRoBERTa models were trained on a Cascadelake processor type with one compute node with 4 cores per node, one GPU and 5 GB memory per core.

Average runtime Preprocessing, i.e., extraction of timex annotations via Heideltime, open information extraction (where before this a correction of uppercase characters is done via Named Entity Recognition), and construction of the dataset where claims and evidence are already put into buckets and the predicates and timexes are marked in the text of all the data took approximately 150 hours. Training a BiLSTM model for each domain took on average 45 hours, while a DistilRoBERTa model took 72 hours.

Table 5: Overview of time buckets b_{text} with their interval bounds.

Number of model parameters BiLSTM: 16,129,125 learnable parameters per model; DistilRoBERTa: 82,933,601 learnable parameters per model.

Number of training and evaluation runs Without parameterisation by α , β , and γ : 150 epochs pretraining, 100 epochs fine-tuning (both BiLSTM and DistilRoBERTa). With parameterisation: 600 epochs pretraining, 300 epochs fine-tuning (BiLSTM); 800 epochs pretraining, 300 epochs fine-tuning (DistilRoBERTa).

Hyperparameter bounds We *manually* tested following combinations for α when integrating the time attribution vectors at the global level for document-level (DL) or content-level reasoning: $\alpha \in \{0.10, 0.25, 0.50, 0.75, 0.90\}$. Final α -values: BiLSTM (DL_{glob}): $\alpha = 0.10$; BiLSTM (CL_{glob}): $\alpha = 0.25$; DistilRoBERTa (DL_{glob}): $\alpha = 0.75$ (see Figure 5); DistilRoBERTa (CL_{glob}): $\alpha = 0.10$. We tested following combinations for γ when integrating the time attribution vectors at the local level for content-level reasoning (CL): $\gamma \in \{0.10, 0.25, 0.50, 0.75, 0.90\}$. Final γ -values: BiLSTM (CL_{loc}): $\gamma = 0.50$; DistilRoBERTa (CL_{loc}): $\gamma = 0.10$. We tested following combinations for α and β when grounding the time attribution vectors at both the document and content level (DL+CL): $[(\alpha = 0.20, \beta = 0.20), (\alpha = 0.20, \beta = 0.35), (\alpha = 0.20, \beta = 0.40), (\alpha = 0.20, \beta = 0.55), (\alpha = 0.20, \beta = 0.60), (\alpha = \frac{1}{3}, \beta = \frac{1}{3}), (\alpha = 0.35, \beta = 0.20), (\alpha = 0.35, \beta = 0.55), (\alpha = 0.40, \beta = 0.20), (\alpha = 0.40, \beta = 0.40), (\alpha = 0.55, \beta = 0.20), (\alpha = 0.55, \beta = 0.35), (\alpha = 0.60, \beta = 0.20)]$. Final α - and β -values: BiLSTM (DL+CL_{glob}): $(\alpha = 0.20, \beta = 0.40)$; DistilRoBERTa (DL+CL_{glob}): $(\alpha = 0.20, \beta = 0.20)$. We performed a hyperparameter search trial of 100 epochs pretraining for each combination of hyperparameters. The criteria used to select the final hyperparameter values are the prediction performance (Micro/Macro F1) on the validation loss and the evolution of the validation loss (visualised on a plot, see Figure 5).

Other parameters tested

- Without linear scheduler;
- With linear scheduler with warm up;
- With linear learning scheduler;

- Learning rates: 0.001, 0.005, 0.0002 (only for RMSprop), 0.0001, 0.00001 (for pretraining and fine-tuning);

Active PETs: Active Data Annotation Prioritisation for Few-Shot Claim Verification with Pattern Exploiting Training

Xia Zeng, Arkaitz Zubiaga
Queen Mary University of London
{x.zeng, a.zubiaga}@qmul.ac.uk

Abstract

To mitigate the impact of the scarcity of labelled data on fact-checking systems, we focus on few-shot claim verification. Despite recent work on few-shot classification by proposing advanced language models, there is a dearth of research in data annotation prioritisation that improves the selection of the few shots to be labelled for optimal model performance. We propose Active PETs, a novel weighted approach that utilises an ensemble of Pattern Exploiting Training (PET) models based on various language models, to actively select unlabelled data as candidates for annotation. Using Active PETs for few-shot data selection shows consistent improvement over the baseline methods, on two technical fact-checking datasets and using six different pretrained language models. We show further improvement with Active PETs-o, which further integrates an oversampling strategy. Our approach enables effective selection of instances to be labelled where unlabelled data is abundant but resources for labelling are limited, leading to consistently improved few-shot claim verification performance.¹

1 Introduction

As a means to mitigate online misinformation, research in automated fact-checking has experienced a recent surge of interest. Research efforts have resulted in survey papers covering different perspectives (Thorne and Vlachos, 2018; Kotonya and Toni, 2020; Nakov et al., 2021; Zeng et al., 2021; Guo et al., 2022) and novel datasets with enriched features (Augenstein et al., 2019; Chen et al., 2019; Ostrowski et al., 2021; Jiang et al., 2020; Schuster et al., 2021; Aly et al., 2021; Saakyan et al., 2021). Recent work has addressed various challenges, e.g. generating and utilising synthetic data (Atanasova et al., 2020; Pan et al., 2021; Hatua et al., 2021), joint verification over text and tables (Schlichtkrull

et al., 2021; Kotonya et al., 2021), investigating domain adaptation (Liu et al., 2020; Mithun et al., 2021), achieving better evidence representations and selections (Ma et al., 2019; Samarinas et al., 2021; Si et al., 2021; Bekoulis et al., 2021), and performing subtasks jointly (Yin and Roth, 2018; Jiang et al., 2021; Zhang et al., 2021a).

As a core component of a fact-checking system, a claim validation pipeline consists of document retrieval, rationale selection and claim verification (Zeng et al., 2021). Our main focus here is claim verification, the task of assessing claim veracity with retrieved evidence. It is typically treated as a natural language inference (NLI) task: given a claim and an evidence, the aim is to predict the correct veracity label out of “Support”, “Neutral” and “Contradict”. Substantial improvements have been achieved in the performance of claim validation models when a considerable amount of training data is available (Pradeep et al., 2021; Li et al., 2021; Zeng and Zubiaga, 2021; Zhang et al., 2021b; Wadden et al., 2021). However, where new domains needing fact-checking emerge, collecting and annotating new relevant datasets can carry an impractical delay. Availability of unlabelled data can often be abundant, but given the cost and effort of labelling this data, one needs to be selective in labelling a small subset. In these circumstances, rather than randomly sampling this subset, we propose to optimise the selection of candidate instances to be labelled through active learning, such that it leads to overall improved few-shot performance.

To the best of our knowledge, our work represents the first such effort in proposing an approach leveraging an active learning strategy for the claim verification problem, as well as the first in furthering Pattern Exploiting Training (PET) with an active learning strategy. To achieve this, we propose Active PETs, a novel methodology that enables the ability to leverage an active learning strategy

¹Our code is available here: https://github.com/XiaZeng0223/active_pets.

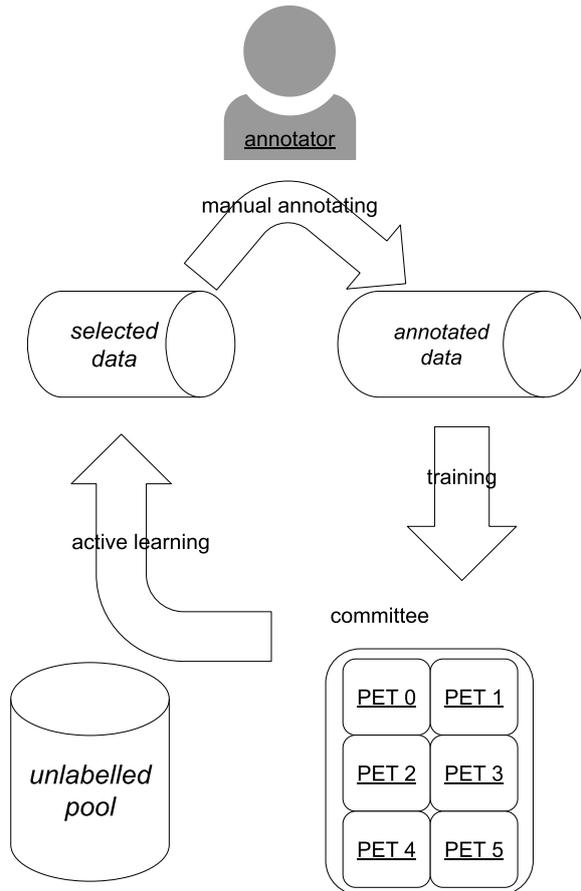

Figure 1: Illustration of the data annotation prioritisation scenario with a committee of 6 PETs. For each iteration, firstly the committee retrieves k new unlabelled samples ($k=10$ in our experiments), secondly the human annotators label them, lastly each of the PET based on different PLMs is trained individually with all of the labelled samples at hand. Our experiments start from 0 labelled samples and end at 300 labelled samples.

through a committee of PETs. Figure 1 illustrates the application of the active learning strategy on data annotation prioritisation.

By exploring effective prioritisation of unlabelled data for annotation and making better use of a small amount of labelled data, we make the following novel contributions:

- we are the first to study data annotation prioritisation through active learning for few-shot claim verification;
- we are the first to study the extensibility of PET to enable active learning, by proposing Active PETs, a novel ensemble-based cold-start active learning strategy that enables multiple pretrained language models (PLMs) to collectively prioritise data instances;
- we further investigate the effect of oversam-

pling on mitigating the impact of imbalanced data selection on few-shot learning, when guided by active learning;

- we conduct further corpus-based analysis on the selected few-shot data instances, which highlights the potential of Active PETs to lead to improved lexical and semantic characteristics that benefit the task.

Our results show consistently improved performance of Active PETs over the baseline active learning strategies on two datasets, SCIFACT (Wadden et al., 2020) and Climate FEVER (Diggelmann et al., 2021). In addition to improved performance over the baselines, our research emphasises the importance of the hitherto unexplored data prioritisation in claim verification, showing remarkable performance improvements where time and budget are limited.

2 Background

2.1 Claim Verification

Claim verification is typically addressed as an NLI problem (Thorne and Vlachos, 2018). Recent progress has enforced a closed-world reliance (Pratapa et al., 2020) and incorporated multiple instance learning (Sathe and Park, 2021). While data scarcity poses a major challenge on automated fact-checking (Zeng et al., 2021), research on few-shot claim verification is limited to date. Lee et al. (2021) investigated a perplexity-based approach that solely relies on perplexity scores from PLMs. Their model was tested on binary claim verification, as opposed to the three-way classification in our work. Zeng and Zubiaga (2022) introduced SEED, a vector-based method that aggregates pairwise semantic differences for claim-evidence pairs to address the task of few-shot claim verification. While their model addresses three-way classification, the experiments are only conducted in ideal scenarios where oracle evidences are available. To the best of our knowledge, however, no work has investigated the use of active learning in the context of claim verification. To further research in this direction, we propose Active PETs, a model that incorporates active learning capabilities into PET (Schick and Schütze, 2021a,b). PET has shown competitive performance in a range of NLP classification tasks, but its adaptation to the context of automated fact-checking and/or active learning settings has not been studied.

2.2 Active Learning

Active Learning (AL) is a paradigm used where labelled data is scarce (Ein-Dor et al., 2020). The key idea is that a strategic selection of training instances to be labelled can lead to improved performance with less training (Settles, 2009). Active learning methods are provided with an unlabelled pool of data, on which a querying step is used to select candidate instances to be annotated with the aim of optimising performance of a model trained on that data. The goal is therefore to optimise performance with as little annotation –and consequently budget– as possible. Traditional active learning query strategies mainly include uncertainty sampling, query-by-committee (QBC) strategy, error/variance reduction strategy and density weighted methods (Settles, 2012). Recent empirical studies have revisited the traditional strategies in the context of PLMs: Ein-Dor et al. (2020) examined various active learning strategies with BERT (Devlin et al., 2019), though limited to binary classification tasks. Schröder et al. (2022) conducted experiments with ELECTRA (Clark et al., 2020), BERT, and DistilRoBERTa (Sanh et al., 2019) respectively, while limiting the scope to uncertainty-based sampling.

Recent efforts on combining active learning with PLMs go into both warm-start and cold-start strategies. Warm-start strategies require a small initial set of labelled data to select additional instances, while cold-start strategies can be used without an initial set of labelled data. Ash et al. (2020) proposed Batch Active learning by Diverse Gradient Embeddings (BADGE) that samples a batch of instances based on diversity in gradient loss. Margatina et al. (2021) proposed Contrastive Active Learning (CAL), the state-of-the-art (SOTA) warm-start strategy that highlights data with similar feature space but maximally different predictions. Furthermore, Active Learning by Processing Surprisal (ALPS) (Yuan et al., 2020), the SOTA cold-start strategy, utilises masked language model (MLM) loss as an indicator of model uncertainty. We use BADGE, CAL and ALPS for baseline comparison, please see detailed descriptions in section 4.3.

To the best of our knowledge, QBC strategies (Seung et al., 1992; Dagan and Engelson, 1995; Freund and Haussler, 1997) that utilise a committee of models remains to be explored with PLMs, as previous studies limit their scope at measuring single model uncertainty. Nowadays various PLMs are publicly available that applying an ensemble-based

query strategy on a downstream task becomes realistic, especially in few-shot settings where the computation required is relatively cheap. Furthermore, previous studies always perform fine-tuning to get classification results from PLMs. Our work presents the first attempt at integrating an active learning strategy into PET, which we investigate in the context of claim verification for fact-checking.

3 Methodology

In this section, we first describe PET, then introduce our model Active PETs, and finally describe the oversampling mechanism we use.

3.1 Pattern Exploiting Training

Pattern Exploiting Training (PET) (Schick and Schütze, 2021a,b) is a semi-supervised training procedure that can reformulate various classification tasks into cloze questions with natural language patterns and has demonstrated competitive performance in various few-shot classification tasks. To predict the label for a given instance x , it is first reformulated into manually designed patterns that have the placeholder $[mask]$. Then, the probability of each candidate token for replacing $[mask]$ is calculated by using a pretrained language model, where each candidate is mapped to a label according to a manually designed verbaliser.

3.2 Proposed method: Active PETs

Having a large pool of unlabelled data, our objective is to design a query strategy that selects suitable candidates to be labelled, such that the labelled pool of instances leads to optimal few-shot performance. Our query strategy is rooted in the intuition that disagreement among different PETs in a committee can capture the uncertainty of a particular instance.

Based on the assumption that performance of different language models is largely dependent on model size (Kaplan et al., 2020), we introduce a weighting mechanism: each PET is first assigned a number of votes V_i that is proportional to its hidden size,² and ultimately all votes are aggregated. Algorithm 1 presents the pseudo-code for executing a single query iteration with Active PETs.

²For example, if we use a committee formed of only base models that have 6 hidden layers and large models that have 12 hidden layers, proportionally each of the base models is allocated one vote and each of the large models is allocated two votes.

Algorithm 1 A Single Query Iteration

Require: The last trained Committee of PETs C , unlabelled data pool U , query size k

```

for  $PET_i \in C$  do
   $v_i \leftarrow Size(PET_i) / \min_{PET_i \in C} Size(PET_i)$ 
end for                                ▷ assign number of votes
for instance  $x \in U$  do
  for  $PET_i \in C$  do
     $V_{x_i} \leftarrow resize(\hat{y}_{x_i}, v_i)$ 
  end for                                ▷ predict label and vote
   $S_x = - \sum_{V_{x_i} \in V_x} \frac{V_{x_i}}{|V|} \log \frac{V_{x_i}}{|V|}$ 
end for                                ▷ calculate entropy scores
return  $Sort(S)[ : k ]$                     ▷ return top k instances

```

We then quantify the disagreement by calculating vote entropy (Dagan and Engelson, 1995):

$$score_x = - \sum_{\hat{y}} \frac{vote(x, \hat{y})}{count(V)} \log \frac{vote(x, \hat{y})}{count(V)} \quad (1)$$

where \hat{y} is the predicted label, x is the instance, $vote(x, \hat{y})$ are the committee votes of \hat{y} for the instance x , and $count(V)$ is the number of total assigned votes. It can be viewed as a QBC generalisation of entropy-based uncertainty sampling that is designed to combine models of different sizes.

3.3 Data Oversampling

One of the risks of the proposed active learning strategy is that the resulting training data may not be adequately balanced, which can impact model performance. An accessible solution is oversampling: resample the instances from the minority class with replacement until balanced. Note that this does not increase the labelling effort as instances are repeated from the labelled pool. Instead of random resampling (Japkowicz, 2000), we propose a novel technique of integrating resampling with the committee’s preference. For each minority class, we start resampling from the instance that has the highest disagreement score to the instance that has the lower disagreement score. In highly imbalanced cases, resampling is repeated from the highest to lowest priority until the overall label distribution is balanced. Algorithm 2 presents the pseudo-code for executing the training loop with the option of conducting oversampling with Active PETs.

Algorithm 2 Training

Require: Labelled and sorted data D , A initial Committee of PETs C

```

if Oversampling then
   $c \leftarrow \max_{class \in D} count(data \in class)$ 
   $D \leftarrow resize_{\forall class \in D}(class, c)$ 
end if                                ▷ oversampling
for  $PET_i \in C$  do
   $PET_i \leftarrow train(PET_i, D)$ 
end for                                ▷ train the committee of PETs
return  $C$                                 ▷ return trained PETs

```

4 Experimental Settings

Here we present the datasets and models used.

4.1 Datasets

SCIFACT			
	‘Support’	‘Neutral’	‘Contradict’
UP	266 (9.31%)	2530 (88.55%)	61 (2.14%)
Test	150 (33.33%)	150 (33.33%)	150 (33.33%)
cFEVER			
	‘Support’	‘Neutral’	‘Contradict’
UP	1789 (24.78%)	4778 (66.19%)	652 (8.66%)
Test	150 (33.33%)	150 (33.33%)	150 (33.33%)

Table 1: Label distribution of SCIFACT and cFEVER. UP = unlabelled pool of training data.

We choose real-world datasets with real claims, SCIFACT and Climate FEVER, known to be challenging, technical and free of synthetic data.³

SCIFACT provides scientific claims with their veracity labels, as well as a collection of scientific paper abstracts, some of which contain rationales to resolve the claims. In addition, it provides the oracle rationales that can be linked to each claim.

For SCIFACT, we perform the pipeline including abstract retrieval and claim verification. For the abstract retrieval step, we use BM25 to retrieve the top 3 abstracts, skipping the more specific rationale selection, as the SOTA system for this dataset suggested (Wadden et al., 2021). We chose BM25 based on high recall results reported in previous work (Pradeep et al., 2021). We merge original SCIFACT train set and dev set and redistribute the data to form a test set that contains 150 instances

³See data samples in Appendix A.

for each class and use the rest in the unlabelled pool. The reformulated data is highly imbalanced as presented in Table 1.

Climate FEVER (cFEVER) is a challenging large-scale dataset that consists of claim and evidence pairs on climate change, along with their veracity labels. As it does not naturally provide options of setting up retrieval modules, we directly use it on the task of claim verification. Similarly we reserve 150 instances for each class to form a test set and leave the rest in the unlabelled pool. Data in the unlabelled pool is heavily skewed, as shown in Table 1.

4.2 Active PETs

Committees of five to fifteen models are common for an ensemble-based active learning strategy (Settles, 2012). Here we form a committee of 6 PETs with 3 types of PLMs: BERT-base, BERT-large (Devlin et al., 2019), RoBERTa-base, RoBERTa-large (Liu et al., 2019), DeBERTa-base and DeBERTa-large (He et al., 2021). Given the commonalities between the NLI and claim verification tasks, we use the PLM checkpoints already fine-tuned on MNLI (Williams et al., 2018).

Despite a line of research in optimising PET patterns and verbalisers (Tam et al., 2021), that is not our main focus. We use the following pattern and verbaliser for PET: `[claim]? [mask], [evidence]`; “Support”：“Yes”, “Contradict”：“No”, “Neutral”：“Maybe”, as they yielded best performance on NLI tasks in our preliminary experiments. Figure 2 provides an example of performing claim verification using PET.

There are two steps in our approach: (1) an ensemble method is used for data annotation prioritisation, after which data is selected and annotated, and (2) with the data instances drawn and annotated, we train a PET model that uses a single PLM to make the predictions. An ensemble method is key in step (1) to support the combined decision-making of choosing instances to annotate, but not in step (2) for the PET model which runs on a single PLM. Hence, results are presented for individual PETs, even if in all cases the ensemble is involved in the underlying prioritisation step. We test two variants: **Active_PETs** with no oversampling, and **Active_PETs-o** with the oversampling described in Section 3.3.

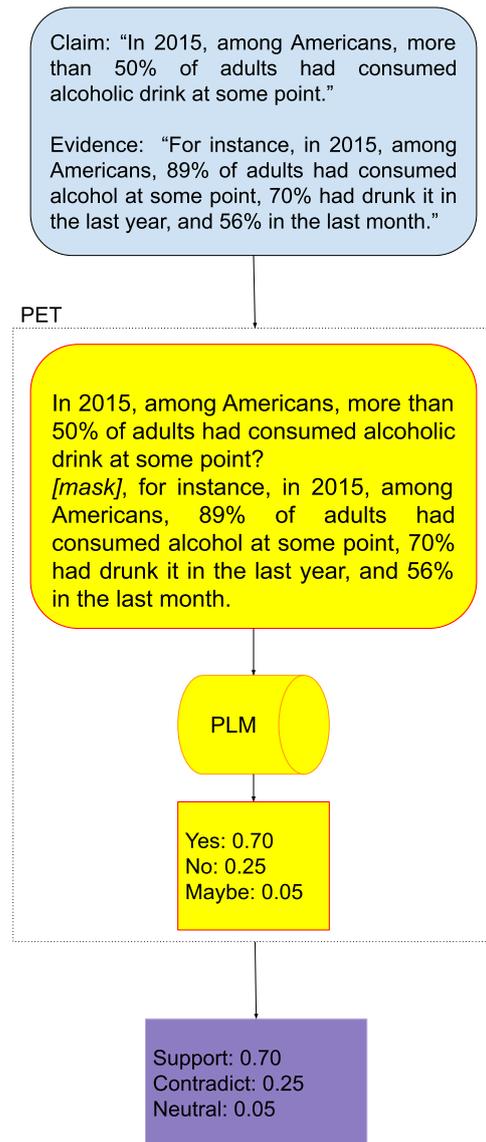

Figure 2: An example of doing claim verification with PET.

4.3 Baselines

We compare our method to four baselines: random sampling, BADGE, CAL and ALPS.

4.3.1 Random sampling

For random sampling, we run each experiment over 10 different sampling seeds ranging from 123 to 132, and present the averaged results.

4.3.2 BADGE

BADGE (Ash et al., 2020) optimises for both uncertainty and diversity. Gradient embeddings g_x are first computed for each data in the unlabelled pool, where g_x is the gradient of the cross entropy loss with respect to the parameters of the model’s last layer. It then applies k-MEANS++ clustering

on the obtained gradient embeddings, and batch selects instances that differ in feature representation and predictive uncertainty.

Though BADGE is proposed as a warm-start method, the required initial set of labelled data is only used for the initial training the model. In our experiments on claim verification, PLMs that are already finetuned on a similar task NLI are used, hence, BADGE can be used for cold-start sampling.

4.3.3 CAL

CAL (Margatina et al., 2021), the SOTA warm-start strategy, highlights contrastive data points: data that has similar model encodings but different model predictions. Unlike BADGE, an initial labelled set of data is essential for CAL. It first calculates the [CLS] embeddings for all of the data and then runs K-Nearest-Neighbours (KNN) to obtain the k closest labelled neighbours for each unlabelled instance. It further calculates predictive probabilities from the model and measures Kullback-Leibler divergence on it. Finally it selects unlabelled instances whose predictive likelihoods diverge the most from their neighbours.

While CAL achieves SOTA performance as a warm-start strategy, its dependence on an initial labelled set of data makes it incompatible in the same few-shot active learning settings without an initial labelled set. However, for comprehensive comparison purposes, we still include it as a baseline starting at 100 labelled instances that are obtained from random sampling with 10 different random seeds.

4.3.4 ALPS

ALPS (Yuan et al., 2020), the SOTA cold-start active learning method, also aims to take both model uncertainty and data diversity into account. It calculates surprisal embeddings to represent model uncertainty. Specifically, for each instance x , it is passed through the masked language modelling head of a PLM and then 15% of the tokens in x are randomly selected to calculate the cross entropy against their target tokens. The surprisal embeddings go through L2-normalisation and then get clustered to select the top samples.

4.4 Training Details

Hyperparameters. As in few-shot settings we lack a development set, we follow previous work (Schick and Schütze, 2021a,b) and use the following hyperparameters for all experiments: $1e^{-5}$ as

learning rate, 16 as batch size, 3 as the number of training epochs, 256 as the max sequence length.⁴

Labelling budget. We set it to a maximum of 300. We experiment with all scenarios ranging from 10 to 300 instances with a step size of 10.

Checkpoints. We always use the PLM checkpoints from the last iteration to perform active learning, but always train the initial PLMs which have never been trained on any fact-checking datasets.

5 Results

We next discuss results for our experiments.

5.1 Results on SCIFACT

Figure 3 presents experimental results on SCIFACT, where the unlabelled pool is large, heavily imbalanced and the domain is technical. Each subfigure shows results for a different PET among the six under consideration.

Data retrieved with Active PETs brings substantial improvements for all of the models, often from the very beginning but consistently as the number of shots increases from around 50 instances. Despite the performance fluctuations, training using data sampled with Active PETs rarely underperforms the baselines for SCIFACT. With Active PETs, Bert-base peaks at 0.352, RoBERTa-base peak at 0.345; DeBERTa-base peaks at 0.385; BERT-large peaks at 0.380; RoBERTa-large peaks at 0.409; DeBERTa-large peaks at 0.541. Generally, Active PETs shows a 10 to 20% increase in F1 scores, compared with various baselines.

Moreover, with Active PETs-o, i.e. when oversampling is further integrated with Active PETs, we observe a significant performance increase. Models tend to learn better from the beginning; the increase trend has less fluctuation; and the overall F1 scores are much higher. In this case, Bert-base peaks at 0.497, RoBERTa-base peak at 0.539; DeBERTa-base peaks at 0.551; BERT-large peaks at 0.548; RoBERTa-large peaks at 0.514; DeBERTa-large peaks at 0.587. This highlights the potential of oversampling, which increases the number of instances without additional labelling budget.

Among the baselines, we observe that training with data retrieved from all baselines failed to lead to any effective outcomes for BERT-base and DeBERTa-base within a labelling budget of 300 instances. While BADGE and CAL lead to some improvements over BERT-large and RoBERTa-large

⁴See further details for reproducibility in Appendix B.

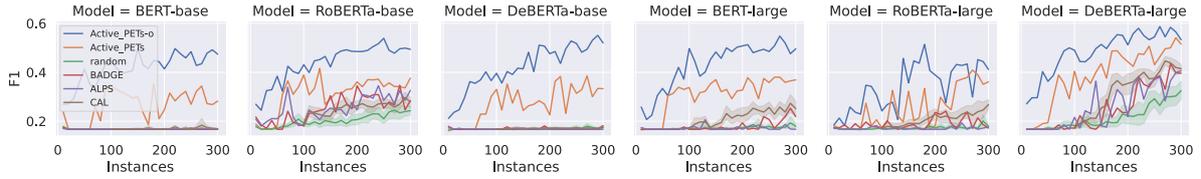

Figure 3: Few-Shot F1 Performance on SCIFACT claim verification.

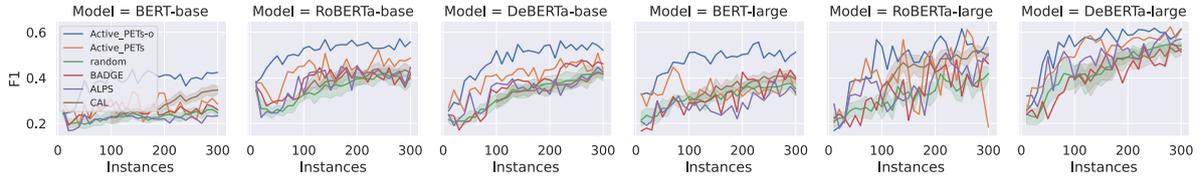

Figure 4: Few-Shot F1 Performance on cFEVER claim verification.

when given over 100 instances, random and ALPS failed to bring any improvements. Baseline results are better with RoBERTa-base and DeBERTa-large, but underperform Active PETS.

5.2 Results on cFEVER

Figure 4 presents F1 scores on cFEVER, where the unlabelled pool is large, imbalanced and the domain is somewhat technical. In this case, models generally achieve higher F1 scores than on SCIFACT. First of all, we observe that Active PETS outperforms random baseline in a more stable manner. It is over 10% higher than random most of the time, although it shows large performance fluctuations on RoBERTa-large. With Active PETS, Bert-base peaks at 0.34, RoBERTa-base peak at 0.524; DeBERTa-base peaks at 0.508; BERT-large peaks at 0.447; RoBERTa-large peaks at 0.612; DeBERTa-large peaks at 0.624. Moreover, Active PETS-o leads to a further performance boost, and more importantly, smooths out the large performance fluctuations. It is about 20% better than the random baseline most of the time. Specifically, Bert-base peaks at 0.438, RoBERTa-base peak at 0.571; DeBERTa-base peaks at 0.562; BERT-large peaks at 0.557; RoBERTa-large peaks at 0.615; DeBERTa-large peaks at 0.618.

When it comes to the baselines, the baselines do not struggle as much in the worst cases. Even if BERT-base’s performance merely increased with most of the baselines, all of the other models managed to improve within the budget. With random sampling, RoBERTa-base, DeBERTa-base, BERT-large and RoBERTa-large all roughly peak at around 0.4, while DeBERTa-large is much better

and peaks at around 0.5. BADGE, CAL and ALPS are in general better than random, but achieves lower F1 scores than Active PETS, especially in few-shot settings when the labelling budget is below 100.

6 Ablation Study

With SCIFACT we designed a slightly different pipeline where we conduct both evidence retrieval and claim verification – a setting that wasn’t provided with cFEVER. To assess the impact of the addition of the evidence retrieval component on SCIFACT, we further perform ablation experiments on SCIFACT with oracle evidence.

With oracle evidence, the number of “Neutral” claim-evidence pairs are significantly reduced, resulting in a more balanced overall label distribution. After reserving 100 instances from each class for the test set, the unlabelled pool has 765 instances in total, where “Support” takes 46.54%, “Neutral” takes 38.43% and “Contradict” takes 15.03%. As shown in Figure 5, overall few-shot performance is much better and active learning demonstrates lesser performance gains. Sampling with baseline active learning strategies in general leads to similar results as random sampling. Surprisingly, coupling Active PETS with oversampling when the labelled pool is reasonably balanced, still maintains performance advantages across models. Under this setting, Bert-base peaks at 0.645, RoBERTa-base peak at 0.655; DeBERTa-base peaks at 0.766; BERT-large peaks at 0.68; RoBERTa-large peaks at 0.657; DeBERTa-large peaks at 0.86.

As demonstrated above, active learning is much

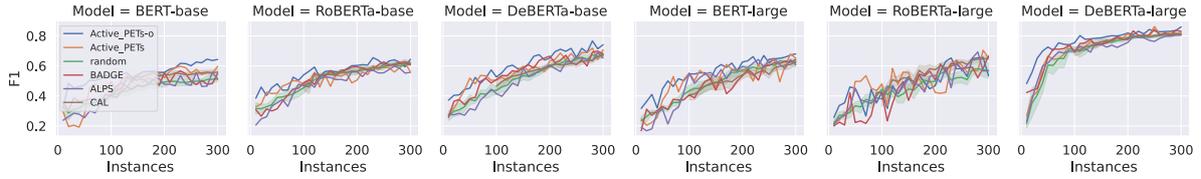

Figure 5: Few-Shot F1 Performance on Oracle SCIFACT claim verification.

more helpful for SCIFACT in a real-world setting than in an oracle setting. We could expect that if this finding generalises to cFEVER, active learning in a real-world setting involving evidence retrieval could possibly lead to larger performance gains.

7 Analysis

To better understand the impact of data prioritisation, we delve into the labelled data. In the interest of focus, we compare Active PETs with the SOTA cold-start method ALPS by analysing the best-performing PLM DeBERTa-large where 300 instances are selected.

7.1 Balancing Effects

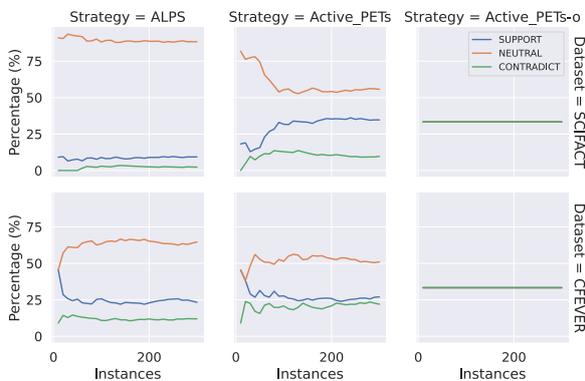

Figure 6: Label Distribution of data obtained with active learning by DeBERTa-large. The upper row is for SCIFACT and the lower row is for cFEVER.

We first look at the distribution of labels for the selected data. Figure 6 shows remarkable difference on label distribution for different active learning strategies. ALPS samples over 80% data from “Neutral”, less than 10% from “Support” and very few from “Contradict” for SCIFACT; over 60% data from “Neutral”, over 20% from “Support” and less than 20% from “Contradict” for cFEVER. They correlate well with original label distribution of each unlabelled pool, as presented in table 1. It suggests that ALPS is not sensitive to label

distribution. However, Active PETs manages to sample a much more balanced distribution out of the extremely skewed original distribution. For SCIFACT, despite the initial few iterations, Active PETs samples less than 60% data from “Neutral”, less than 40% data from “Support”, around 10% data from “Contradict”; for cFEVER, Active PETs samples less than 60% data from “Neutral”, over 20% data from “Support”, around 20% data from “Contradict”. In both datasets, label distribution from Active PETs are significantly more balanced than ALPS. Finally, the strategy with oversampling returns perfectly balanced distribution as expected. We identify a strong correlation between label distribution and classification performance.

7.2 Linguistic Effects

Aiming at providing further insights into data quality, we conduct corpus-based linguistic analysis to investigate lexical richness and semantic similarity.

Lexical Richness			
	ALPS	Active_PETs	Active_PETs-o
SCIFACT	0.0362	0.0387	0.0447
cFEVER	0.0389	0.0413	0.0503
Semantic Similarity			
	ALPS	Active_PETs	Active_PETs-o
SCIFACT	0.7921	0.8031	0.8054
cFEVER	0.7449	0.7744	0.7841

Table 2: Lexical richness is measured with Maas Type-Token Ratio (MTTR) scores and Semantic Similarity is measured by cosine similarity scores on embeddings of claims and evidences.

7.2.1 Lexical Richness

A popular metric for calculating lexical richness is Type-Token Ratio (TTR), where the total number of unique tokens is divided by the total number of tokens. We use Maas Type-Token Ratio (Maas TTR) (Maas, 1972), a logarithmic variant of TTR,

which is demonstrated to be less sensitive to the length of the text (McCarthy and Jarvis, 2007):

$$a^2 = \frac{\log N - \log V}{\log N^2} \quad (2)$$

where N is the number of tokens in the corpus and V is the number of unique tokens in the corpus.

As shown in the upper part of Table 2, data selected by ALPS has the lowest lexical richness, while Active PETs leads to higher lexical richness for both datasets. Even more surprisingly, when integrating Active PETs with oversampling, the corpus has even higher score at lexical richness, despite that there are multiple duplicated instances in the corpus. One possibility is that training data with higher lexical richness may convey more useful information, as a bigger vocabulary enables more precise expressions.

7.2.2 Semantic Similarity

To investigate the overall data diversity, we calculate the average semantic similarity of all possible claim-evidence pairs in the corpus.⁵ We obtain embeddings of claims and evidences with the PLM at interest, namely DeBERTa-large that has been trained on MNLI. For each embedded claim, we calculate its cosine similarity score with all embedded evidences in the corpus. The average of all similarity scores is then obtained. The lower part of Table 2 shows that ALPS leads to lowest overall semantic embedding similarity scores and Active PETs leads to higher scores. Integrated with oversampling, Active PETs leads to even higher similarity scores. It correlates well with the design of the strategies: ALPS explicitly encourages data diversity, while Active PETs focuses on committee uncertainty. One possible explanation is that data diversity is not as beneficial when the unlabelled pool contains less relevant instances: in the case of SCIFACT and cFEVER datasets, the majority of the unlabelled pool belongs to the “Neutral” class where the evidence is not enough to reach a verdict for the claim.

8 Conclusions

We present the first study on data annotation prioritisation for claim verification in automated fact-checking. With our novel method Active PETs, we demonstrate the potential of utilising a committee of PETs to collaboratively select unlabelled

⁵Note that if we only calculate the retrieved pairs, the average similarity scores are approximately 1 for all strategies.

data for annotation, furthering in turn the extensibility of PET to active learning for the first time. Experiments on the SCIFACT and cFEVER datasets demonstrate the effectiveness of our proposed method, particularly in dealing with imbalanced data. Our proposed model consistently outperforms the random, BADGE, CAL and ALPS baselines by a margin. Further integration with an oversampling strategy that does not impact labelling effort leads to consistent performance improvements in all tested settings. Data that is more balanced shows to have higher lexical richness and semantic similarity, leading to better training results. While we have shown its effectiveness for claim verification here, in the future we aim to investigate Active PETs in other downstream tasks.

9 Limitations

We focus on demonstrating the effectiveness of Active PETs in scenarios where the labelling budget is limited and the label distribution is very imbalanced, as they are major challenges for automated fact-checking. Active PETs is shown to be particularly beneficial with low labelling budgets and becomes less so when the labelling budget increases and/or the unlabelled pool is balanced. Furthermore, as Active PETs is built on PET, it inherits the limitations from PET, e.g. a pattern-verbaliser pair (PVP) is required for any classification tasks. Note that a good selection of tested PVPs that cover common NLP tasks are publicly available.

Our experiments are only conducted with PLMs that are of base and large sizes, e.g., BERT-base and BERT-large, due to limited computing resources. Future work may further experiment with giant models like T5-11b and GPT-3. Another interesting direction would be to extend the proposed voting mechanism such that giant models and tiny models can both contribute effectively in the same committee, e.g., GPT-3 and DistillBert. Ideally, despite that GPT-3 is much larger than DistillBert, the extended voting mechanism should still allow DistillBert to contribute effectively.

A Example Appendix

We present example instances from SCIFACT and cFEVER datasets in this section.

B Reproducibility Appendix

We present further experimental details here for reproducibility.

Number of parameters in each model The number of parameters for BERT-base, BERT-large, RoBERTa-base, RoBERTa-large, DeBERTa-base, DeBERTa-large is 109484547, 335144963, 124647939, 355362819, 139194627 and 406215683 respectively.

Computing infrastructure We use High Performance Compute cluster supported by the university. Each experiment is run with 8 compute cores, 11G RAM per core and a single NVIDIA A100 GPU.

Run time Table 4 reports the average run time of executing a sampling iteration of 150 unlabelled instances and a training iteration with the sampled data over three datasets. It serves as a good indicator for comparing the efficiency among different

active learning methods. As CAL requires an initial labelled set of data, we report the total run time of an iteration of using the random method for 75 instances and an iteration of using CAL method for another 75 instances. Table 5 further reports the total run time of the best method Active PETs-o on different datasets. The actual run time highly correlates with the size of the unlabelled pool for each datasets.

Our key focus has been on resource-efficiency and performance, with a lesser focus on runtime, hence there can be room for optimisation in future work, including: (1) optimising the code e.g. through parallelisation of the ensembled models which are now run sequentially, (2) using DL optimisation libraries such as deepspeed, and (3) using dynamic step sizes to reduce the number of iterations, e.g. increase step size if initial iterations lead to balanced samples. In a real-world, deployed scenario, one would also need to account for the time needed by humans to perform the annotation (in our case simulated).

Abstract

Table-to-text generation aims at automatically generating text to help people conveniently obtain salient information in tables. Recent works explicitly decompose the generation process into content planning and surface generation stages, employing two *autoregressive* networks for them respectively. However, they are computationally expensive due to the non-parallelizable nature of autoregressive decoding and the redundant parameters of two networks. In this paper, we propose the first totally *non-autoregressive* table-to-text model (Plan-then-Seam, PTS) that produces its outputs in parallel with one single network. PTS firstly writes and calibrates one plan of the content to be generated with a novel *rethinking* pointer predictor, and then takes the plan as the context for seaming to decode the description. These two steps share parameters and perform iteratively to capture token inter-dependency while keeping parallel decoding. Experiments on two public benchmarks show that PTS achieves 3.0 ~ 5.6 times speedup for inference time, reducing 50% parameters, while maintaining as least comparable performance against strong two-stage table-to-text competitors¹.

1 Introduction

Table-to-text generation (Lebret et al., 2016a; Wiseman et al., 2017) is a long-standing problem that aims to generate natural language descriptions of structured table data. A good table-to-text system can help end users better identify the informative elements and their relations from a table. Therefore, developing table-to-text systems is of tremendous value in a wide range of applications, such as biography generation (Lebret et al., 2016a), basketball news generation (Wiseman et al., 2017), advertising text generation (Shao et al., 2019), and table-based question answering (Yu et al., 2019).

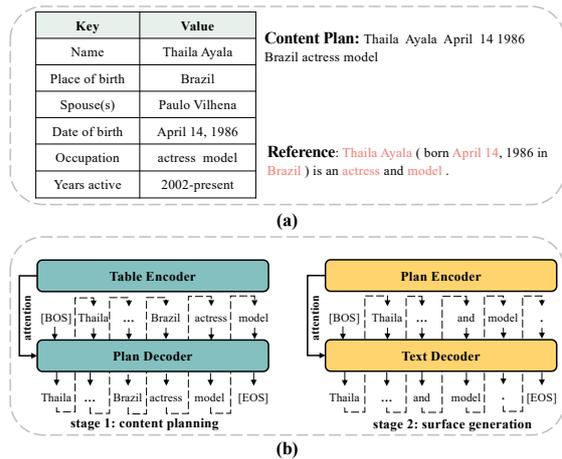

Figure 1: (a): example of table-to-text generation from WikiBio. Tokens from the content planning are colored in red. (b): two-stage model, which disentangles table-to-text generation into two stages: content planning and surface generation.

Recently, neural network-based approaches have made significant progress in this field. The modern neural models for table-to-text generation can be roughly categorized into one-stage models and two-stage models. One-stage models generate natural language descriptions directly from the table by simply relying on representation learning to generate well-organized fluent descriptions. Along this line, some studies propose to modify the model architectures to effectively learn from structured table (Liu et al., 2018; Gong et al., 2019), while some other works introduce auxiliary tasks to help the encoder capture a more accurate semantic representation (Liu et al., 2019; Li et al., 2021). The major drawback of one-stage models is the lack of interpretability and controllability, making the models prone to suffer from unfaithful hallucinations (Wiseman et al., 2017).

To alleviate the aforementioned shortcoming of one-stage models, some researchers propose a two-stage paradigm for table-to-text generation (Puduppully et al., 2019; Su et al., 2021), which explicitly

decomposes the whole generation process into two separate stages: content planning and surface generation (illustrated in Figure 1). The content planning model generates an intermediate sequence that specifies the tokens to be verbalized. The generated plan provides some interpretability and controllability, thus can potentially reduce the risk of hallucinations (Puduppully et al., 2019). The surface generation model then completes the description based on the intermediate plan.

Although two-stage models have some superiority over one-stage models, they are often computationally intensive. The cause of the high computational cost is two-fold. Firstly, most two-stage models use autoregressive (AR) decoders, which is quite time-consuming due to their non-parallelizable nature, especially for long sequences (Gu et al., 2018). Secondly, the two-stage systems often consist of two different models, which usually double the parameter scale (see Section 4.4). The increased parameter scale may introduce more computation overhead and thus slow down the inference speed. These disadvantages limit the deployment of current neural table-to-text systems in practical applications. Recently, non-autoregressive (NAR) generation has attracted much attention because it can significantly accelerate inference speed for text generation (Gu et al., 2018; Stern et al., 2019; Qian et al., 2021a). However, as demonstrated in our preliminary experiments (see also Section 4.4), applying the NAR models directly to table-to-text generation may suffer from lower generation quality because NAR models do not explicitly model the content planning procedure, which can provide good initial input for NAR decoder.

In this work, we propose to reduce the computational cost of two-stage models through a unified NAR framework, which is called *Plan-then-Seam* (PTS). PTS is an iterative NAR table-to-text model. Specifically, PTS first generates the content plan in the first iteration. Then it fills in the other surface tokens in subsequent multiple iterations to seam the intermediate plan tokens. Note that PTS conducts the content planning and surface generation tasks in a single model, thus the model size is smaller than previous two-stage models. Moreover, since PTS is a NAR model, it is more efficient than the AR counterparts. Given that fully NAR content planning may ignore the dependency between planned tokens, we introduce a rethinking pointer predictor, which can better calibrate the planning conditioned

on the generated ones. Our contributions can be summarized as follows:

- We are the first work concerning the computational cost (parameter and inference efficiency) problem in table-to-text. Contrastly, previous works only focus on how to improve the model performance. We hope this can raise more attention to the computational cost problem in table-to-text.
- Regarding methodology, we present the first totally NAR² framework for table-to-text generation, achieving a desired quality–efficiency trade-off. Further, we introduce a rethinking mechanism to improve the NAR planning capability of the model. We demonstrate that initializing the decoder with a good content plan is the key to improving the NAR model.
- Experiments show that, compared with previous strong two-stage competitors, our method can achieve a $3.0 \sim 5.6\times$ speedup with only 50% model parameters without degrading the generation quality.

2 Related Work

Table-to-text generation has long aroused interest in the Natural Language Generation (NLG) community (Kukich, 1983; Reiter and Dale, 1997). Recently, neural models have been the mainstream for this task and made impressive progress. Models for this task can be mainly categorized into two types: one-stage models and two-stage models. One-stage models generate text directly from structured data through a neural encoder-decoder architecture (Sutskever et al., 2014). They simply rely on representation learning to improve the generation. Liu et al. (2018) propose a structure-aware seq2seq architecture, which incorporates the filed information as the additional inputs to the table encoder. Some works design hierarchical table encoder which model table’s representation from the row and column levels (Gong et al., 2019). Liu et al. (2019); Li et al. (2021) introduce auxiliary supervision tasks to help the encoder capture a more accurate semantic representation of the tables. However, one-stage methods are prone to produce unfaithful hallucinations and uncontrollable generation (Wiseman et al., 2017).

As the improvement, neural two-stage models (Ma et al., 2019; Puduppully et al., 2019;

²This means both content planning and surface generation are non-autoregressive.

Moryossef et al., 2019; Puduppully and Lapata, 2021; Su et al., 2021) decompose the table-to-text generation into content planning and surface generation stages. In general, content planning is implemented by Pointer Networks (Vinyals et al., 2015). The explicit content planning mechanism not only decomposes the complex table-to-text generation into two easier tasks but also makes the generation process more interpretable and controllable by generating an intermediate representation. However, the hallucination problem persists in the surface generation stage as it is autoregressive (AR). To address this issue, SANA (Wang et al., 2021) proposes an edit-based non-autoregressive (NAR) surface generation model that generates texts through iterative insertion and deletion operations while maintaining an AR planning stage. Existing two-stage methods solely pay attention to improving the generation quality while ignoring its efficiency. Compared with one-stage models, two-stage methods double the number of parameters. Additionally, the AR generation is slow at inference time. These problems hinder the practical deployment of current neural table-to-text models.

3 Methodology

Given a region of a table as input, table-to-text generation is to produce a natural language description $Y = \{y_1, \dots, y_n\}$ to describe the selected table region. This paper proposes the first totally non-autoregressive table-to-text model, *Plan-then-Seam* (PTS). As depicted in Figure 2, PTS consists of three major components, a table encoder, a non-autoregressive content planning decoder (NAR-P), and a non-autoregressive seaming decoder (NAR-S), which collaborate to generate a description for a source table in an iterative manner. At the first iteration, NAR-P generates content planning sequence in a fully non-autoregressive manner by conditioning on the source table. At the subsequent iterations, NAR-S seams the content planning tokens by inserting connective tokens between them to generate a fluent description. Next, we will describe the proposed PTS in detail.

3.1 Table Encoder

As shown on the left of Figure 2, the source table is a collection of key-value pairs in which each value may contain several tokens. Following LeBret et al. (2016a), we first linearize the source table by flattening all its values to a record se-

quence $T = \{r_1, r_2, \dots, r_K\}$. Each record r_i is represented as a 4-tuple (w_i, k_i, p_i^+, p_i^-) , where w_i is the value token, k_i is its key name. p_i^+ and p_i^- are the relative positions of w_i , where p_i^+ counts from the beginning and p_i^- counts from the end of the sentence. For example, the key-value pair <Name, Thaila Ayala> is represented as two records: (Thaila, Name, 1, 2) and (Ayala, Name, 2, 1). We adopt four trainable embedding matrices to convert each record represented by (w_i, k_i, p_i^+, p_i^-) into dense vectors e_{w_i} , e_{k_i} , $e_{p_i^+}$, and $e_{p_i^-}$. We concatenate these embeddings and use a linear projection to map the four vectors into e_i , which serves as the initial representation of the corresponding record r_i :

$$\mathbf{e}_i = \text{ReLU}(\mathbf{W}_e[e_{w_i}; e_{k_i}; e_{p_i^+}; e_{p_i^-}] + \mathbf{b}_e), \quad (1)$$

where \mathbf{W}_e and \mathbf{b}_e are trainable parameters. $[\cdot; \cdot]$ denotes the vector concatenation operation. Finally, we transform $\{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_K\}$ into contextual sequence representation $\mathbf{H}^e = \{\mathbf{h}_1^e, \mathbf{h}_2^e, \dots, \mathbf{h}_K^e\}$ with the Transformer encoder (Vaswani et al., 2017).

3.2 Non-autoregressive Content Planning Decoder

We utilize the Transformer decoder layer (Vaswani et al., 2017) as the basic building block of the content planning component. We also remove the causal mask in self-attention modules to realize parallel generation. As shown in Figure 2, given the initial decoder input $y^0 = [\text{BOS}][\text{EOS}]$, non-autoregressive planning decoder (NAR-P) aims to generate the planned sequence (e.g., $y^p = \text{Thaila Ayalia actress model}$). y^p specifies the records that are to be verbalized (*what to say*) in the description and the order in which they are described. To this end, NAR-P consists of three major components: a placeholder predictor π^l , a pointer predictor π^p , and a token deleter π^d . These components work in a serial fashion. First, the placeholder predictor π^l determines the number of plan tokens to be inserted:

$$\pi^l(l|y^0, T) = \text{Softmax}(\mathbf{W}_l[\mathbf{h}_0^{d_1}; \mathbf{h}_1^{d_1}]), \quad (2)$$

where $\mathbf{h}_0^{d_1}$ and $\mathbf{h}_1^{d_1}$ are respectively the decoder states of two symbol tokens in y^0 , $\mathbf{W}_l \in \mathbb{R}^{L \times 2d}$ is the projection matrix and L is the pre-defined maximal placeholder number. $\pi^l(l) \in \mathbb{R}^L$ denotes the probability distribution of possible placeholder numbers, and we choose the one l with the

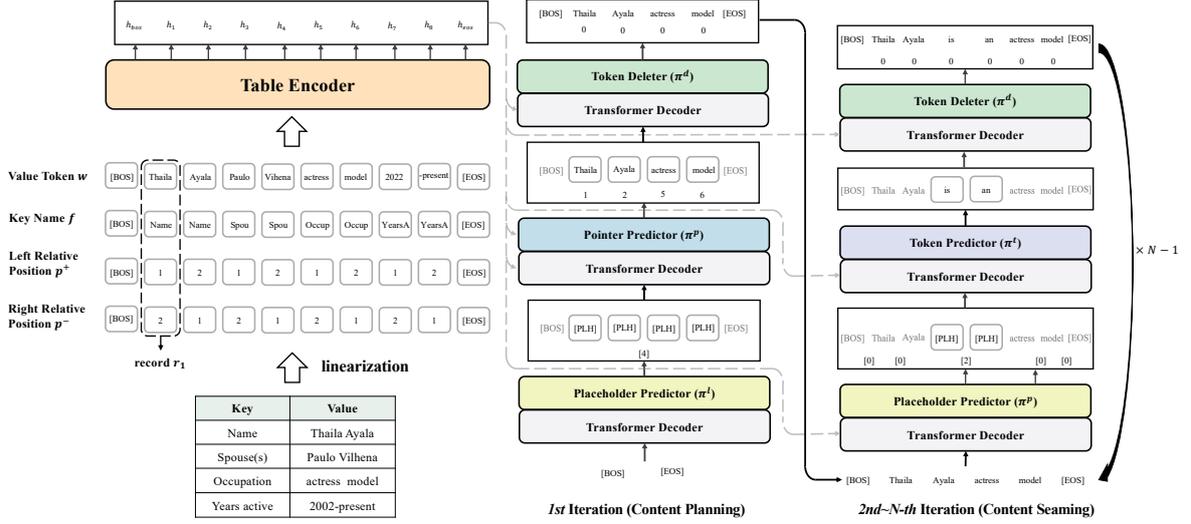

Figure 2: An overview of our Plan-then-Seam non-autoregressive table-to-text model. The modules with the same color share the parameters. The left part contains an example of how to linearize a table, where Spou, Occup, and YearsA denote Spouse(s), Occupation, and Years active, respectively.

highest probability. We insert l placeholders [PLH] between [BOS] and [EOS] to obtain the placeholder sequence y^l .

Then, we need to replace each [PLH] in y^l with an actual token. y^l is firstly passed into the Transformer decoder layer to generate the decoder state $\mathbf{h}_i^{d_2}$ of each placeholder. As all plan tokens are from the source table, we then introduce a pointer predictor π^p that selects tokens from T to reduce hallucinations. Specifically, for the i -th placeholder, we calculate the confidence scores α_j^i of copying the j -th record in T as a plan token by:

$$\pi^p(\alpha_j^i | y^l, T) = \text{Softmax}(\mathbf{W}_p[\mathbf{h}_i^{d_2}; \mathbf{h}_j^e]). \quad (3)$$

Then we replace each placeholder with the most possible record to get y^r .

Last, considering the predictor π^p may copy incorrect or repetitive tokens, we build a token deleter π^d to remove these false plan tokens. For the i -th token in y^r , π^d is employed to decide whether it is required to be deleted or not:

$$\pi^d(d_i | y^r, T) = \text{Softmax}(\mathbf{W}_d \mathbf{h}_i^{d_3}), \quad (4)$$

where $\mathbf{h}_i^{d_3}$ is the representation generated by transformer decoder. $\pi^d(d_i) \in [0, 1]$ is the predicted probability of the deletion operation. The token with $\pi^d(d_i) > 0.5$ is deleted, which yields the final content plan y^p .

Rethinking Pointer Predictor Although non-autoregressive models can accelerate the generation process, they are based on the assumption

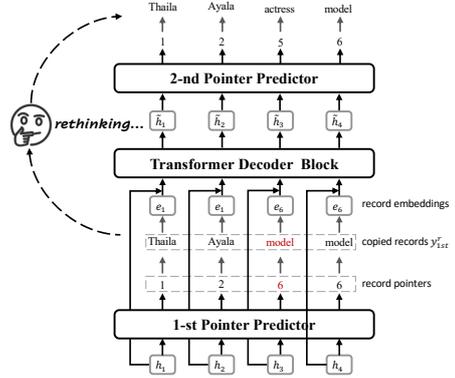

Figure 3: Architecture of the proposed rethinking pointer predictor. Our basic idea is to augment the non-autoregressive predictor with inter-token dependencies.

that the generated tokens are conditionally independent with each other (Gu et al., 2018). As a result, the pointer predictor may suffer from incoherence or repetition (Qian et al., 2021a). We believe that the pointer predictor would produce a better plan by partially observing generated plan tokens. Motivated by this intuition, we adapt the naive pointer predictor and propose its variant *rethinking* pointer predictor. As illustrated in Figure 3, the rethinking pointer predictor first employs a naive pointer predictor to generate a primary record plan $y_{1st}^r = \{r_1, r_2, r_6, r_6\}$, then calibrate it with another pointer predictor. Particularly, for each record r_i in y_{1st}^r , we concatenate its embedding e_i with the transformer hidden state h_i and further process it by a linear layer $\hat{h}_i = W_f[h_i; e_i]$. \hat{h}_i is fed into a transformer decoder block (removing

causal attention) to rebuild representation for the token at i -th position in y_{1st}^r by conditioning on the source table T and the generated plan y_{1st}^r . By looking at the tokens in other positions, the 2-nd pointer predictor can determine if the token at the i -th position is incorrect or repeated with others. The *rethinking* process helps the model adjust the incorrect tokens in y_{1st}^r to generate a precise plan. Moreover, to improve the confidence of y_{1st}^r , both pointer predictors are supervised by the ground truth plan when training.

3.3 Non-autoregressive Content Seaming

Decoder

After obtaining the content plan y^p , at the seaming stage, the non-autoregressive seaming decoder (NAR-S) constructs a fluent description y by iteratively inserting the connective tokens into y^p . Specifically, we employ y^p as the initial input of NAR-S. In each iteration, similar to NAR-P, NAR-S also firstly predicts the number of placeholders should be inserted into at every consecutive position pairs in the generated sentence of the previous iteration, then replace placeholders with actual tokens, and finally delete abundant tokens. NAR-S share parameters in placeholder predictor π^l and token deleter π^d with NAR-P. The difference is that NAR-S replaces the pointer predictor π^p with a token predictor π^t that replaces the placeholders with actual tokens from the predefined vocabulary rather than copies from the table. For example, as shown on the right of Figure 2, given the content plan *Thaila Ayalia actress model*, NAR-S inserts two tokens, *is* and *an*, between *Ayalia* and *actress* in the first iteration.

3.4 Training

We joint train the content planning and seaming tasks and the final learning objective is:

$$\mathcal{L} = \lambda \mathcal{L}_{plan} + \mathcal{L}_{seam}, \quad (5)$$

where λ is the hyper parameter. Next, we describe them in detail.

The content planning learning objective consists of three sub-goals: $\mathcal{L}_{plan} = \mathcal{L}_l^p + \mathcal{L}_p^p + \mathcal{L}_d^p$. Given the source table T , the ground truth content plan y^{p*} as well as its pointers $y^{idx} = \{y_i^{idx}\}_{i=1}^{|y^{p*}|}$ with each entry pointing to an input record in T , the placeholder predictor learning objective \mathcal{L}_l^p is computed as follows:

$$\mathcal{L}_l^p = -\log \pi^l(l_0^* | y^0, T), \quad (6)$$

where l_0^* is the length of ground truth plan y^{p*} . And then, we replace all the tokens in y^{p*} with [PLH] to get y^l , which is utilized to train the pointer predictor:

$$\mathcal{L}_p^p = -\sum_{i=1}^{|y^{p*}|} \log \pi^p(\alpha_{y_i^{idx}}^i | y^l, T). \quad (7)$$

To train the deletion predictor, we apply the pointer predictor π^p to y^l to yield y^r . The loss for deletion predictor is calculated as:

$$\mathcal{L}_d^p = -\sum_{i=1}^{|y^r|} \log \pi^d(d_i | y^r, T), \quad (8)$$

where d_i is the golden deletion operation at the i -th position, and is set as 1 if y_i^r is same with y_i^{p*} , otherwise 0.

The seaming loss also consists of three parts: $\mathcal{L}_{seam} = \mathcal{L}_l^s + \mathcal{L}_p^s + \mathcal{L}_d^s$. Its training process is very similar to content planning task. The biggest difference between them is the initial input. Given a source table, a plan and a reference (T, y^{p*}, y^*), we follow previous works (Gu et al., 2019; Wang et al., 2021) to construct an intermediate sequence y^m as the initial input to NAR-S. Specially, we first calculate the longest common subsequence \hat{y} between y^{p*} and y^* . And then we apply random deletion on y^* except the part of \hat{y} to obtain y^m . Last, the three subgoals are calculated as following:

$$\mathcal{L}_l^s = -\sum_{i=1}^{|y^m|} \log \pi^l(l_i^* | y^m, T), \quad (9)$$

$$\mathcal{L}_p^s = -\sum_{i=1}^{|y^*|} \log \pi^t(y_i^* | y^l, T), \quad (10)$$

$$\mathcal{L}_d^s = -\sum_{i=1}^{|y^*|} \log \pi^d(d_i | y^t, T), \quad (11)$$

where l_i^* is the number of placeholder that should be inserted between y_i^m and y_{i+1}^m . l_i^* is obtained by calculating the Levenshtein distance (Levenshtein et al., 1966) between y^m and y^* . y^t is yielded by applying π^t on y^l .

3.5 Inference

As mentioned above, PTS is an iterative NAR model. Different from the previous iterative NAR model, at the first iteration, PTS first utilizes NAR-P to generate the content plan in a fully NAR manner, where NAR-P alternately performs placeholder

prediction, pointer prediction, and deletion operation. In the subsequent iterations, it uses the generated plan as the initial decoder input for NAR-S, which iteratively fills in the other surface tokens between the content planning tokens. We stop the seaming process when the current text does not change or the predefined maximum iteration has been reached.

4 Experiment

4.1 Datasets and Evaluation Metrics

Following Wang et al., we conduct experiments on two datasets, WikiBio (Lebret et al., 2016b) and WikiPerson (Wang et al., 2018). Both datasets are designed to generate descriptions from a Wikipedia table. Specifically, WikiBio aims to generate the first sentence of a biography. The average length of the description is 26.1 tokens. Different from Wikibio, the reference of WikiPerson contains multiple sentences to cover as many factors in the source table as possible. The average length of the description in WikiPerson is 70.6. We use the official training, development, and test splits for both datasets, which are 582,657/72,831/72,831 in WikiBio and 250,186/30,487/29,982 in WikiPerson. We use these two datasets for two considerations. First, this paper focuses on the inference speed and generation quality of models with similar frameworks. The similar input structures allow us to use the same encoder architecture and prevent us from designing an additional one. Second, the different output length distributions of the two datasets facilitate us to compare the models’ performance and efficiency.

We use BLEU (Papineni et al., 2002) and ROUGE-L to evaluate the fluency, and PARENT (Dhingra et al., 2019) to examine the faithfulness. We also employ inference latency to evaluate the inference speed of the involved approaches. Specifically, Latency is the average time to run an epoch on the test dataset while the batch size is set to 32 with one NVIDIA Tesla V100 GPU.

4.2 Baselines

To rule out the effect of model architecture on the inference speed, we only compare our method to some representative baselines built on the Transformer (Vaswani et al., 2017) model:

- TABLETRANSFORMER is a transformer-based model that replaces the naive transformer encoder with the table encoder.

- LEVT (Gu et al., 2019) is an iterative NAR model. In the first iteration, the decoder input is initialized by “[BOS][EOS]”.
- CONTENT-PLAN (Pudupully et al., 2019) is a representative two-stage method that firstly uses a pointer network to generate the content plan and then uses a pointer generator to complete the remaining text. To make a fair comparison, we reimplement it using Transformer. See Appendix B.2 for more details.
- SANA (Wang et al., 2021) is also a two-stage method. The major difference between SANA and CONTENT-PLAN lies in that SANA uses a LEVT for surface token generation. Additionally, SANA integrates hard constraints by forbidding the LEVT from deleting planned tokens.

4.3 Implementation Details

Our method is implemented by fairseq (Ott et al., 2019). For fair comparison, all the involved systems use a similar configuration. Specifically, the vocabulary sizes on WikiBio and WikiPerson are 30K and 50K, respectively. The dimensions of token embedding, key embedding and position embedding are set to 420, 80, and 50, respectively. All Transformer components used in our methods adopt the base Transformer setting with $d_{model} = 512$, $d_{hidden} = 2048$, and $n_{head} = 8$. The depth is 6 for both the encoder and the decoder. Please refer to Appendix B.1 for more details about training setting. During inference, the maximum iterations of the NAR model is 10 and 40 in WikiBio and WikiPerson, respectively. We conduct experiments over 4 different random seeds and report the average scores.

4.4 Main Results

Table 1 shows the performance of our method and the baselines. For WikiBio, the NAR LEVT model are approximately $3\times$ faster than the AR TABLETRANSFORMER model. However, the description quality of LEVT is much lower than TABLETRANSFORMER, regarding both fluency (-1.27 BLEU) and faithfulness (-4.62 PARENT-F1). Moreover, we observe that two-stage approaches can outperform the one-stage ones (e.g., SANA vs. LEVT), indicating the superiority of explicitly content planning. However, they double the parameters scale and increase the inference latency. Surprisingly, our proposed method can combine the advantages

(b) Results on WikiPerson

Table 1: Results on WikiBio and WikiPerson test sets. Results marked with “†” are copied from previous studies while the other results are implemented in this work. Latency and I_{DEC} denote the average inference time and the average number of decoder iterations, respectively. Mean (±s.d.) over 4 seeds.

of both the two kinds of baselines. On both WikiBio and WikiPerson, our approach can achieve comparable description quality with the strong two-stage baseline (i.e., SANA), while maintaining the model size and the inference speed. Compared with SANA, our model does not require external constraints to guarantee the appearance of planned tokens in the final output. The results also demonstrate the effectiveness of the newly proposed rethinking mechanism, confirming that the inter-dependency between different positions is essential for NAR-P, which can provide a better starting point for NAR-S. Additionally, we notice that the latency increase without rethinking. We believe this is because removing this module reduces the content planning capability of the model, which in turn lowers the quality of the initial input to NAR-S, making the model require more iterations to satisfy the termination condition. The results on WikiPerson show a similar trend to WikiBio. An obvious difference is that the inference speed is much slower for all models, since the average description length is longer than WikiBio (70.6 vs. 26.1). When generating longer sentences,

the speedup of our method over the AR baseline is much higher. On both datasets, our method can achieve high description quality and inference efficiency at the same time.

4.5 Analysis and Discussion

Due to the page limit, we have placed more experimental results and analyses in Appendix A.

Content Planning As mentioned above, explicit content planning is important for table-to-text generation. We thus further investigate the content planning performance in Table 2. We compare our method with two baselines: POINTERNETWORK and NAR-P. POINTERNETWORK is a widely used planning method for two-stage models (Puduppully et al., 2019; Wang et al., 2021). The results indicate that our proposed PTS model performs comparable with POINTERNETWORK. NAR-P has a same architecture with PTS, the difference is that NAR-P is totally trained with the content planning task, while PTS is trained to perform both content planning and seaming. The results show that training the model with both content planning and seaming does not significantly affect the planning perfor-

PTS-PLAN	52.27	97	60
w/o rethinking	51.67	92	58

Table 2: Performance of different content planning models. “NAR-P” is solely trained using the content planning objective, while “PTS-PLAN” is to use the final PTS model to perform content planning.

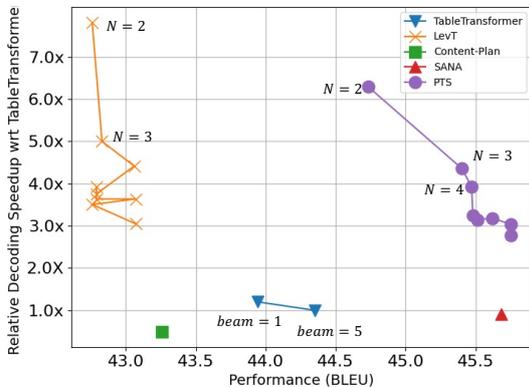

Figure 4: Quality-Speed trade-off on the WikiBio test set. Quality is estimated by BLEU. For clarity, the inference speed is measured by the relative speedup with respect to TABLETRANSFORMER with beam size = 5. $N \in [1, 10]$ denotes the maximum iteration number.

mance, which implies that learning the two tasks with a unified model does not decrease the model’s planning ability.

Quality-Speed Trade-off Since PTS is an iterative NAR model, it is easy to balance the description quality and the inference speed by changing the number of the iterations. As shown in Figure 4, PTS achieves comparable performance with substantially higher speed up than the other involved models. For PTS, increasing the iteration number can improve the description quality while reduce the inference speed. In practice, we can change the iteration number to meet different requirements under various application cases.

Tokens Generated at the Seaming Stage To build a deeper understanding of the proposed PTS model, we investigate the problem of which tokens

who	1.64%
Total	64.18%

Table 3: Top 15 tokens generated by our proposed PTS at the seaming stage on WikiBio test set. -lrb- and -rrb- represent (and), respectively.

are most likely to be generated by PTS at the seaming stage on the WikiBio test set. Specifically, we first remove the words generated at the planning stage from the descriptions generated by PTS to obtain a word set. Then, we count the token frequency for the word in the set. We present the top 15 frequent tokens in Table 3. As we can see, at the seaming stage, PTS is more likely to generate connective tokens, e.g., punctuation, and copulas, than the specific tokens existing in the input table, such as name, time, etc. And the connective tokens are mainly used to link planning words (seaming). The observation is consistent with our motivation and design that PTS first copies content from the input table to construct a plan sequence and then inserts tokens from a pre-defined vocabulary between plan tokens to generate a fluent description. We believe this make our approach more interpretable and controllable.

5 Human Evaluation

To verify whether the system performance is consistent with what the automatic metrics show, we further conduct a human evaluation on the WikiBio test set. We randomly sample 50 instances from each model’s generated outputs. Then, we invite three graduate students, whose English level is very high to understand the text, to score each generated text from 1 to 5 in terms of two criteria: Fluency (is

Models	Fluency	Faithfulness
TABLETRANSFORMER	3.24 \pm 0.77	2.89 \pm 0.86
LEVT	2.75 \pm 0.89	2.57 \pm 0.78
CONTENT-PLAN	3.18 \pm 0.32	3.01 \pm 0.72
SANA	3.31 \pm 0.74	3.26 \pm 0.69
OURS	3.42 \pm 0.58	3.42 \pm 0.59

Table 4: Human evaluation results on WikiBio test set.

the sentence fluency?) and Faithfulness (is the sentence related to the input table?). For each criterion, we average the scores from all annotators as the final score. When evaluating, each annotator is provided the input tables as the references and does not know which model the generated text comes from. The results are summarized in Table 4. As we can see, the overall trend of the human evaluation is similar to the automatic metrics in Table 1. First, the two-stage systems have an advantage over the one-stage ones in generating result fidelity. Second, our method is competitive to these table-to-text baselines regarding generation fluency and faithfulness. Meanwhile, our approach performs better than the LEVT transferred from machine translation. These results indicate that introducing the content planning process in the NAR process and using its results as the initial decoder input can significantly improve the NAR model.

6 Conclusion

We propose a unified non-autoregressive framework, Plan-then-Seam (PTS), for table-to-text generation. Given a source table, PTS first generates the content plan in a fully NAR manner. Then we iteratively fill in the other surface tokens. Experimental results demonstrate that PTS achieves a 3.0 \sim 5.6 speedup with only 50% model parameters compared with previous two-stage table-to-text models, without degrading the description quality. Further analysis reveals that the success of PTS comes from the proposed NAR-P with a rethinking mechanism, whose content planning performance is comparable with AR models. By changing the iteration number, PTS can balance the generation quality and inference efficiency for various practical application requirements.

Limitations

As described in the paper, the content planning ability is important for table-to-text models. However, the planning performance of all the involved methods is still far from satisfactory. We will explore

more advanced methods to improve the content planning performance. Moreover, we train all the models on WikiBio and WikiPerson from scratch, and the training cost is rather expensive: 2.5 days using 4 NVIDIA V100 32G GPUs. Lastly, this paper does not compare the pre-trained language models (PLMs) (Devlin et al., 2019; Raffel et al., 2020), though our approach may also benefit from some pre-trained table encoders, such as TAPAS (Müller et al., 2021). The main reasons why we do not consider PLMs are that PLMs will bring an unfair comparison and bring more variables and may make our work lose focus. See Appendix B.2 for detailed justification. In the future, we will explore how pre-trained models, e.g., pre-trained table encoder TAPAS, can be used to improve our model’s performance and accelerate the training process.

Ethics Statement

We consider our work can make more researchers in table-to-text pay attention to the computational cost problem, which may benefit from saving the cost of the online table-to-text model. We experimented on the public datasets with no discriminatory or insulting sentences.

+ Golden Plan	55.50	79.59 / 51.92 / 61.14

Table 6: Effect of golden plan on two-stage methods.

A More Experimental Results

A.1 Token Repetitions and Diversity

Previous works manifest NAR model tends to predict the same token with high confidence, but at different positions, which is caused by the multi-modality problem. Therefore, we doubt whether the NAR table-to-text generation has any preference towards token repetitions and diversity. We measure the percentage of repetitive tokens in the generated sent as a proxy metric for the multi-modality problem (Gu et al., 2018). Additionally, we utilize Distinct-1 and Distinct-2 (Li et al., 2016) to evaluate the diversity of the output text. All results are summarized in Table 5. We observe that the AR model TABLETRANSFORMER significantly reduces the lexical diversity. Therefore, to better train the non-autoregressive model, AR model is usually used as a teacher model to reduce the complexity of the training corpus (Knowledge Distillation) (Gu et al., 2018). And then, LEVT tends to generate repetitive tokens. We can see that, when explicitly modelling the content planning, two-stage methods can increase the tokens diversity. Especially, the content planning can substantially reduce the tokens repetitions for NAR models (e.g., LEVT vs. SANA and OURS).

A.2 Performance Bottleneck of Two-stage Model

We provide the ground-truth content plan to the models at the second stage, and the results are summarized in Table 6. When fed with the golden plan, all the two-stage models achieves better fluency

and faithfulness. The results indicate that the quality of content planning is a important bottleneck for two-stage table-to-text approaches.

A.3 Case Study

Table 7 shows the descriptions generate by PTS from the test set of WikiBio. First, we observe that when the number of tokens in the generated plan is relatively small, the 1-st pointer predictor can generate a precise content plan. However, when the number of planning tokens increases, it tends to produce repetitive and incorrect ones. We consider this is because the fully NAR generation cannot accurately model the dependencies between planning tokens. After introducing the *rethinking* mechanism, the 2-nd pointer predictor can determine if the token is incorrect or repeated with others and calibrate it by looking at the tokens in other positions. Therefore, the model can generate a more precise plan.

B More Implementation Details

B.1 Training and Hyper-parameter Settings

All models are optimized by Adam (Kingma and Ba, 2015). We use the same learning rate schedule as presented in Vaswani et al. (2017). The maximum value of the learning rate is $5e-4$ and the warmup step is set to 10K. The maximum training step is set to 300K. We use the validation BLEU for early stopping and explore $\lambda = [0.05, 0.08]$. During inference, we use beam search with a beam size 5 for the autoregressive models and the maximum decoding lengths are set to 80 and 160 in WikiBio and Wikiperson. For non-autoregressive models, we set the maximum iterations as 10 and 40 in WikiBio and WikiPerson, respectively.

B.2 Experimental Setting Details

To rule out the effect of model architecture on the inference speed and make a fair comparison, we only compare our method to some table-to-text models built on the Transformer model. For the one-stage models, we chose the autoregressive TableTrasforme and non-autoregressive LevT. For the two-stage methods, we compare with Content-Plan and SANA. Both planning generation and tableau generation of the former are autoregressive, while the second stage of the latter is a non-autoregressive process. All these baselines employ the same table encoder as ours. Additionally, the original Content-Plan is implemented by LSTM.

To make a fair comparison, we re-implemented Content-Plan by replacing its LSTM-based encoder and decoder with Transformer-based ones. And the transformer setting is the same as our model.

We do not consider the pre-trained models (PLMs) in this paper, though our model’s performance may be significantly improved by initializing our table encoder with the pre-trained one, such as TAPAS (Herzig et al., 2020). The reasons why we do not consider PLMs are as follows:

- We consider PLMs will bring an unfair comparison. Because most PLMs (e.g., TAPAS, T5 (Raffel et al., 2020)) are pre-trained on Wikipedia data, and WikiBio and WikiPerson are built from Wikipedia. It may lead to data leakage. Moreover, to our best knowledge, most of the works in the NAR machine translation (please refer to Appendix C) do not compare with PLMs.
- This paper focuses on comparing inference speed and quality under a similar model architecture rather than improving the model performance. And our experimental setting is fair, and all the baselines employ a similar setting as our model. Additionally, in related domains such as neural machine translation, previous work (Zhu et al., 2020) indicates that simply initializing the encoders of sequence-to-sequence models with the pre-trained BERT (Devlin et al., 2019) will actually hurt the performance. And directly fine-tuning NAR sequence-to-sequence models initialized by BERT is very unstable and sensitive to the learning rate (Guo et al., 2020). Therefore, though pre-trained checkpoint may benefit our model, it will bring more variables and may make our work lose focus. We leave this for future work.

B.3 Content Plan Annotation

We follow previous work (Wang et al., 2021) to employ the heuristic method to obtain the content plan annotation for WikiBio and WikiPerson. Specifically, we start by counting the tokens that appear both in the table and in the corresponding description. Then we remove the stop tokens in the tokens collection and sort the rest of the tokens by their positions in the description in ascending order. The sorted sequence is regarded as the content planning sequence. We refer the readers to Wang et al. (2021)’s paper for more details.

C Non-autoregressive Neural Machine Translation

Recently, autoregressive (AR) models have achieved outstanding performances in natural language generation tasks (Raffel et al., 2020). However, AR is quite time-consuming when generating target sentences, especially for long sentences. To overcome this problem and accelerate decoding, Gu et al. (2018) first propose the non-autoregressive generation (NAR) for machine translation, which generates all the target tokens in parallel and hugely increases the inference speed. Therefore, much attention has been attracted to NAR with impressive progress (Stern et al., 2019; Qian et al., 2021a; Song et al., 2021; Qian et al., 2021b). However, compared with AR models, the generation quality is sacrificed because NAR breaks the conditional dependence assumption that prevents a model from properly capturing the highly multi-modal distribution of target translations, which is called the "multi-modality" problem (Gu et al., 2018). To mitigate the problem, some studies (Lee et al., 2018; Stern et al., 2019; Ghazvininejad et al., 2019; Gu et al., 2019; Saharia et al., 2020) propose the iterative NAR models which need N iterations for inference and keep the non-autoregressive property in every iteration step. More specifically, the generated results of the previous iteration will be fed into the decoder again for refinements. In this way, partial target information is provided in each iteration step.

A corpus of metaphors as register markers

Markus Egg and Valia Kordoni
Humboldt-Universität zu Berlin
Unter den Linden 6, 10117 Berlin
{markus.egg, evangelia.kordoni}@hu-berlin.de

Abstract

The paper presents our work on corpus annotation for metaphor in German. Metaphors denote entities that are similar to their literal referent, e.g., when *Licht* ‘light’ is used in the sense of ‘hope’. We are interested in the relation between metaphor and register, hence, the corpus includes material from different registers.

We focussed on metaphors that can serve as register markers and can also be reliably identified for annotation. Our results show huge differences between registers in metaphor usage, which we interpret in terms of specific properties of the registers.

1 Introduction

This paper presents ongoing work on annotating a German corpus for metaphor. We are interested in metaphors as register markers, therefore, the corpus includes material from a number of different registers. We annotate all the metaphors in the corpus but nevertheless put emphasis on a subgroup of metaphors which we believe can function as register markers.

The paper is structured as follows. After outlining the underlying theoretical concepts of metaphor and register and reviewing previous work, we introduce the corpus. Then we present the annotation results, which show huge differences in metaphor usage between the different registers in the corpus. These differences are then correlated with specific properties of registers.

2 Theoretical background

In this section, we introduce the two phenomena of metaphor and register, and the way in which they are related.

2.1 Metaphor

Metaphors involve a semantic shift of an expression in context. They refer to an entity that is similar

to the referent of the literal interpretation of the metaphor. Theories reconstruct this similarity in different ways (for an overview see e.g. Ritchie, 2013). E.g., *vorbeirasen* ‘rush by’ in the temporal sense in (1) is metaphorical and shares with the literal, spatial interpretation the notion of a very fast development:

- (1) das letzte Jahr ist nur so vorbei gerast
‘the last year has rushed by’

Metaphors can be assigned a degree of conventionalisation, from innovative to fully conventionalised. We distinguish conventionalised and non-conventionalised metaphors (see Section 3 for details), e.g., the metaphor in (1) is non-conventionalised.

A small number of metaphors like *Blumen* ‘flowers’ in (2) is signalled openly by ‘metaphor flags’, among them *wie* ‘like’ or *praktisch* ‘in effect’, but most metaphors are not.

- (2) Wir sind wie Blumen praktisch, geerdet.
‘In effect, we are like flowers, earthed.’

In ‘extended metaphor’ (or ‘metaphor chains’), several metaphors in a discourse are based on the same kind of similarity (Reijnierse et al., 2020). E.g., once the word *Licht* ‘light’ is introduced as a metaphor for hope, other words related to light like *anzünden* ‘enkindle’ or *Kerze* ‘candle’ can emerge as metaphors for hope-related phenomena, too (as ‘introduce hope’ and ‘source of hope’, respectively).

Finally, ‘potential metaphor’ combines tokens of an expression with basic and metaphorical senses in the same discourse. E.g., in one of our texts the term *dunkel* ‘dark’ is used in its basic sense ‘without physical light’ before it is used metaphorically in the sense of ‘bad’. Potential metaphors typically participate in extended metaphor structures.

- (3) in dem Dunkel, in dem Wurzelbereich bei

dem Weizen
'in the dark zone, in the rhizosphere of the
wheat'

- (4) die dunkle Erde elterlicher Übermüdung
'the dark soil of parental fatigue'

2.2 Register

Register refers to the influence of situational and functional context on intra-individual linguistic variation (Biber and Conrad, 2009). Systemic-Functional Linguistics (SFL) decomposes register into field, tenor, and mode (Halliday and Hasan, 1985). 'Field' refers to the nature of a linguistic interaction, including its subject matter and its purpose. 'Tenor' targets the participants, in particular, their statuses and social relationships. 'Mode' is about the role of language in the interaction, e.g., whether it is oral or literal, or a monologue or a dialogue.

When metaphors are alternatives to reference via literal expressions, they are optional ways of referring to an entity. This allows intra-individual variation in establishing reference to be influenced by and to influence the situational and functional embedding of a discourse, viz., register. Thus, metaphors can contribute to establishing a specific register or indicate compliance with it.

This relation of metaphors and registers is due to the fact that the function of a metaphor depends on the discourse it is part of (Goatly, 2011). For instance, the function of metaphors can be influenced by the relations between the interlocutors, in that peers strive to build and maintain rapport, whereas experts want to offer explanations to non-experts. Such differences can result in different realisations of the metaphors. For example, Deignan et al. (2013) report that metaphors in the form of a simile ('A is like B') are more likely in expert-non-expert communication than in exchanges between peers.

2.3 Which metaphors for register?

The perspective on metaphor as register marker (or as a marker for other phenomena) raises issues with the state of the art in metaphor annotation, as it was established by Steen et al. (2010) and introduced into computational approaches to metaphor by Shutova and Teufel (2010) and Shutova et al. (2013): In these approaches, all metaphorical expressions are annotated, irrespective of their degree of conventionalisation.

To be able to function as a marker for register, however, metaphors must be free choices in the linguistic system, whose optional use can then be reused to mark a specific register. In contrast, any metaphor whose use is necessitated by the language system cannot be employed for the purpose of register.

For example, in the description of temporal constellations it is often not possible not to use highly conventionalised spatial metaphors, e.g., to express the fact that one time span is located *before* or *inside* another one. I.e., these interpretations of prepositions belong to the lexicon as parts of polysemous sense structures. Since they are not created by a productive metaphorical interpretation and are obligatory irrespective of register, they cannot function as metaphorical register markers.

Steen (2015) comes to similar conclusions about highly conventionalised metaphors and focuses on 'deliberate' metaphors, i.e., those that are intended to be recognised as such by the recipient. We believe that this is the group of metaphors that is also relevant for the relation between metaphor and register.

However, deliberate metaphor is hard to define in formal terms (see e.g. Krennmayr, 2011 and Reijnierse et al., 2018), which raises doubts as to whether it can be annotated with sufficient accuracy. Therefore we based our conclusions predominantly on deliberate metaphors that are recognisable with high accuracy in our corpus, viz., those with a metaphor flag, and non-conventional, extended, and potential metaphor.

3 Previous work

The interdependence between metaphor and register has been investigated for specific registers, e.g., academic discourse (Littlemore, 2001; Herrmann, 2015; Beger, 2015), fiction (Dorst, 2015), newspapers (Krennmayr, 2011) or educational discourse (Cameron, 2003). Functions of metaphors were correlated with SFL features of metaphors (Goatly, 2011; Steen et al., 2010). E.g., the latter claim that metaphor is used in informational registers (like news, fiction, or academic discourse) to express content to a much larger extent than in conversation. Berber Sardinha (2015) investigates the influence of metaphor-related features on register variation.

The group of Gerald Steen created and annotated the VU Amsterdam Metaphor Corpus (187,000

subcorpus	hierarchical/equal	distant/close	oral/literal	dialogue/monologue
speeches	E	D	L	M
sermons	H	C	L	M
commentaries	H	D	L	M
light fiction	E	C	L	M
debates	E	D	O	D

Table 1: SFL register properties of the subcorpora

words from the British National Corpus) with the four registers academic discourse, newspaper texts, fiction, and conversations (Steen et al., 2010).

Shutova and Teufel (2010) and Shutova et al. (2013) annotated a corpus of 13,700 words according to whether the words were used metaphorically or literally. They report different frequencies of metaphors for specific registers, in particular, a very low frequency of metaphor in spoken language. Bizzoni and Lappin (2018) compiled a corpus of 200 sets of metaphorical sentences and potential paraphrases (rated for their aptness). Zayed et al. (2020) created a corpus of 1,500 metaphorical verbs with a direct object.

Steen et al. (2010) developed detailed guidelines for the annotation of their corpus (later adapted to German in Herrmann et al., 2019). They define the context-based sense of an expression as a metaphor if it differs from another, more ‘basic’ sense of the expression (e.g., one which is more concrete or related to bodily action). These senses must be similar but not subsumable under a common hypernym, like in the case of the contextual temporal sense of *vorbeirasen* ‘rush by’ in (1). Senses are defined by suitable dictionaries; if both senses appear in the dictionaries, the metaphor counts as conventionalised, if only the basic sense does, it is regarded as non-conventional.

4 Our approach

4.1 The corpus

To investigate the relation of metaphor and register, we have compiled a corpus that integrates a wide range of register variation. Its five parts (of eventually 30,000 words each) are parliament speeches from the German Parlamentsreden-Korpus (Blaette, 2017), news commentaries (the Potsdam Commentary Corpus; Stede, 2004), sermons, light fiction (written by amateurs for their peers), and debates from competitions of the organisation ‘Jugend debattiert’ (Kemmann, 2013).

Table 1 shows the distribution of SFL register properties in the corpus. We vary two dimensions of *tenor*, viz., hierarchy vs. equality and distance vs. closeness, and the two *mode* dimensions of dialogue vs. monologue and of spoken vs. written register. Following Koch and Oesterreicher’s (1994) distinction of conceptual literality vs. orality, speeches and sermons are classified as literal (they are prepared and fixed in advance), despite their oral presentation.

subcorpus	reference	persuasion
speeches	+	o
sermons	o	+
commentaries	+	+
light fiction	-	-
debates	o	+

Table 2: Biber dimension properties of the subcorpora

The subcorpora also represent the variation we expected along two important Biber (2009) dimensions (Table 2). For ‘situation-dependent vs. elaborated reference’ (how dependent is reference on the situational context), we expect that commentaries and speeches relate to concrete extralinguistic situations and individuals, whereas debates and sermons are more abstract deliberations, and fiction is highly detached from reality. Thus, the anticipated level of situation dependence for reference is low for fiction, medium for debates and sermons, and high for commentaries and parliamentary speeches. For ‘overt expression of persuasion’, the expected level is high for debates, sermons, and commentaries, moderate for speeches (whose influence on actual decision making in politics is usually quite low), and low for fiction.

4.2 The annotation

For the annotation, we use the INCEption tool (Klie et al., 2018). Metaphors are annotated independently by two annotators. Inter-annotator agreement for the metaphor classification according to

subcorpus	metaphor flags**	conventionalised metaphor***	non-conventionalised metaphor*	extended metaphor***	potential metaphor***
speeches	0%	15.13%	.12%	.01%	0%
sermons	.02%	10.14%	.24%	.29%	.27%
commentaries	.05%	11.40%	.26%	.12%	.01%
light fiction	.04%	4.06%	.14%	.04%	0%
debates	0%	10.38%	.15%	.09%	0%

* = significant at $p < .05$; ** = significant at $p < .01$; *** = significant at $p < .0001$

Table 3: Metaphor counts for the subcorpora

subcorpus	metaphor flags	conventionalised metaphor***	non-conventionalised metaphor*	extended metaphor***
highly persuasive	.03%	10.88%	.23%	15%
medium or not persuasive	.02%	9.91%	.14%	.02%

Table 4: Metaphor counts for highly persuasive subcorpora

Krippendorff’s (2011) alpha emerged as .89. The annotation includes a layer of syntactic structure, derived by the Stanza package (Qi et al., 2020), to allow the identification of syntactic constellations for analyses of their metaphorical potential in future work.

To distinguish degrees of conventionalisation of the metaphors, we also fell back on suitable lexical resources, in our case, the *Duden* dictionary and the *Digitales Wörterbuch der deutschen Sprache*¹: When the context-based sense of the expression qualifies as metaphorical according to definition of Steen et al. (2010) (see Section 3), we check if it is listed in at least one of the lexical resources along with the basic sense of the expression. If yes, the metaphor is classified as conventionalised, otherwise, we assume that it is non-conventionalised, like (1).

We created guidelines for the annotation, starting out from the guidelines of Steen et al. (2010) and Herrmann et al. (2019). The corpus and the guidelines will be made available to the research community after their finalisation. See Egg and Kordoni (2022) for a more detailed description of the guidelines.

5 Results

The results of our annotation are summarised in Table 3 (percentages are calculated for word tokens²),

¹www.duden.de and www.dwds.de

²Extended and potential metaphors as a whole are counted only once. The participating metaphors are then counted separately as conventionalised or non-conventionalised metaphors.

showing clear differences in metaphor usage between the different registers. First, the level of conventionalised metaphors is high for speeches, medium for sermons, commentaries, and debates, and low for fiction. Also, metaphor flags are extremely rare in general, which parallels the results of Steen et al. (2010).

Potential metaphor is restricted almost exclusively to sermons. As soon as we omit sermons from consideration in the evaluation of our corpus, potential metaphor does not exhibit a correlation to register anymore ($p = .33$). Consequently, we omit it from further investigations into interdependencies between metaphor types and register properties.

Non-conventionalised and extended metaphors pattern similarly, occurring mostly in sermons and commentaries. We argue that this is due to the fact that these registers are highly persuasive. This correlation is less visible in the debates, which we put down to the time pressure of oral discourse, a conflicting factor impeding the creation of these types of metaphor. Table 4 summarises the counts of highly persuasive against the other registers and shows that the correlations are significant for these two types of metaphor.

Next, we investigated a potential interdependence between metaphoricality and the distinction in oral and literal discourse (summarised in Table 5). Our results first show that oral and literal discourse do not differ significantly for conventionalised and non-conventionalised metaphor. What is more, our oral register did not exhibit a significantly lower

subcorpus	metaphor flags*	conventionalised metaphor	non-conventionalised metaphor	extended metaphor
literal	.033%	10.62%	.21%	.12%
oral	.000%	10.38%	.17%	.09%

Table 5: Metaphor counts for literal and oral subcorpora

subcorpus	metaphor flags*	conventionalised metaphor***	non-conventionalised metaphor**	extended metaphor***
hierarchical	.04%	11.01%	.25%	.17%
equal	.01%	10.07%	.15%	.03%

Table 6: A competing hypothesis: hierarchy

score for extended metaphor as well, even though this kind of metaphor is non-local in that it is based on more than one expression in the discourse, as two or more expressions have to share the same kind of metaphorical similarity. In contrast, conventionalised and non-conventionalised metaphor are local in that they are based on single expressions.

There is a difference between the extended metaphors in debates and in the other registers, however, which has to do with the fact that debates are dialogues that consist of comparatively short turns of different speakers: We found that many extended metaphors are the result of the collaboration of different speakers, in that one speaker introduces a metaphor with a specific kind of similarity and other speakers subsequently pick up this metaphor or use metaphors that exhibit the same kind of similarity.

To sum up, our results for the oral register of debates thus suggest that previous very low metaphoricality scores for oral discourse as in [Steen et al. \(2010\)](#) might not be related to orality in general but to the conversational nature of their data, which calls for further investigation of differences within oral registers.

As for individual registers, our data first suggest a mixed pattern for fiction, like in [Reijnierse et al. \(2019\)](#) in that it is low on conventionalised metaphors but occupies a middle position w.r.t. non-conventionalised and extended metaphor. At the same time, the register in the corpus that conveys the highest degree of register marking are sermons: they exhibit a high degree of non-conventional metaphors, also, extended and potential metaphor emerge as clear register markers for sermons.

6 Conclusion

We presented current work on a German corpus with different registers, which is annotated for metaphors. Future work will use the corpus to investigate the metaphoric potential of specific syntactic constellations (like verb-object and adjective-noun) and include metonymy as another register-sensitive phenomenon ([Deignan et al., 2013](#); [Littlemore, 2015](#)).

Also, our results suggest that further research on oral registers is called for to delimit the actual interdependence between metaphor and the distinction between oral and literal registers. As a first step in this direction, we will include TEDx talks into our corpus, which complement the debates in that they are also oral but at the same time monologic and not persuasive. Other registers we plan to look into are sales talks and classroom interactions.

Limitations

In our study, we have argued for a correlation between forms of metaphor (non-conventional, extended, and potential) and persuasiveness. However, we are at this stage not yet in a position to rule out the competing hypothesis that there is a relation between metaphor and tenor in that metaphor correlates with a hierarchical difference between the interlocutors. Table 6 shows that this hypothesis would be significant for the corpus in its present form, which shows that the inclusion of further registers into the corpus is needed in order to distinguish between the competing hypotheses.

Ethics Statement

We took great care in the compilation of the corpus to include only material that can be published in

this form in order to be able to make the corpus available to the scientific community.

The debates consist of material produced by minors (16-18 years). In the corpus, we anonymised the names of the debaters throughout as ‘Speaker 1-4’. At the same time, we transcribed only debates that had already been made public on the Youtube canal of ‘Jugend debattiert’ (URL) in order to include only material whose publication had already been accepted by the respective speakers. At the same time, we contacted the spokesperson of ‘Jugend debattiert’ and got his consent on our activities as far as they include the debates.

The other material is either taken from already licenced corpora (for the parliament speeches and the commentaries) or has an appropriate CC license. Still, we contacted the authors to inform them about our project and to confirm their willingness to have their material included in our corpus.

Translate First Reorder Later: Leveraging Monotonicity in Semantic Parsing

Francesco Cazzaro* Davide Locatelli* Ariadna Quattoni

Universitat Politècnica de Catalunya
name.lastname@upc.edu

Xavier Carreras

dMetrics
xavier.carreras@dmetrics.com

Abstract

Prior work in semantic parsing has shown that conventional seq2seq models fail at compositional generalization tasks. This limitation led to a resurgence of methods that model alignments between sentences and their corresponding meaning representations, either implicitly through latent variables or explicitly by taking advantage of alignment annotations. We take the second direction and propose TPOL, a two-step approach that first translates input sentences monotonically and then reorders them to obtain the correct output. This is achieved with a modular framework comprising a *Translator* and a *Reorderer* component. We test our approach on two popular semantic parsing datasets. Our experiments show that by means of the monotonic translations, TPOL can learn reliable lexico-logical patterns from aligned data, significantly improving compositional generalization both over conventional seq2seq models, as well as over other approaches that exploit gold alignments. Our code is publicly available at <https://github.com/interact-erc/TPol.git>

1 Introduction

The goal of a semantic parser is to map natural language sentences (NLs) into meaning representations (MRs). Most current semantic parsers are based on deep sequence-to-sequence (seq2seq) approaches and presume that it is unnecessary to model token alignments between NLs and MRs because the attention mechanism can automatically learn the correspondences (Dong and Lapata, 2016; Jia and Liang, 2016). However, recent work has shown that such seq2seq models find compositional generalization challenging, i.e., they struggle to predict unseen structures made up of components observed at training (Lake and Baroni, 2018; Finegan-Dollak et al., 2018).

*Equal contribution

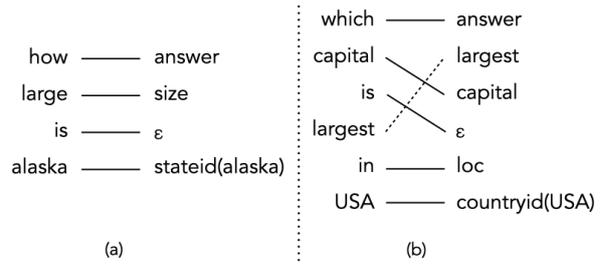

Figure 1: Examples from the GEOALIGNED dataset. (a) is a monotonic alignment, (b) is non-monotonic.

This limitation motivated the resurgence of approaches that model alignments between NL sentences and their corresponding MRs more similarly to classical grammar and translation-based parsers (Herzig and Berant, 2021). Alignments can be modeled either implicitly through latent variables (Wang et al., 2021), or explicitly by leveraging gold alignment annotations (Shi et al., 2020; Liu et al., 2021a). We take the second direction and exploit a recently released multilingual dataset for semantic parsing annotated with word alignments: GEOALIGNED (Locatelli and Quattoni, 2022), which augments the popular GEO benchmark (Zelle and Mooney, 1996).

Figure 1 shows some examples of the annotations provided. One key observation is that a significant percentage of the alignments are monotonic, i.e., they require no reordering of the target MR (Figure 1a), as opposed to non-monotonic alignments (Figure 1b). This suggests that learning reliable lexico-logical translation patterns from aligned data should be possible. If there are simple patterns, shouldn't an ideal model be able to exploit them?

With this in mind, we propose TPOL, a Two-step Parsing approach that leverages monotonic translations. TPOL introduces a modular framework with two components: a *Monotonic Translator* and a *Reorderer*. The Translator is trained from pairs of NLs and MRs, where the MRs have been permuted to be monotonically aligned. Hence,

the Translator’s output will be an MR whose order might not correspond to that of the gold truth. For this reason, the Reorderer is trained to restore the correct order of the original MR.

Our experiments on GEOALIGNED demonstrate that compared to a multilingual BART model (Liu et al., 2020), TPOL achieves similar performance on the random test split but significantly outperforms on the compositional split across all languages. For example, on the query split in English, mBART obtains 69.4% in exact-match accuracy and TPOL obtains 87.8%. This result also improves on the 74.6% obtained by SPANBASED (Herzig and Berant, 2021), another approach that leverages alignment annotations.

Because most semantic parsing datasets do not contain alignment information, we experiment with alignments generated automatically. On GEO, TPOL trained with automatic alignments still outperforms mBART, and in particular on the English query split it improves by almost 10 points. Furthermore, we show competitive results on the popular SCAN dataset (Lake and Baroni, 2018).

In summary, the main contributions of this paper are:

1. We propose TPOL, a modular two-step approach for semantic parsing which explicitly leverages monotonic alignments;
2. Our experiments show that TPOL improves compositional generalization without compromising overall performance;
3. We show that even without gold alignments TPOL can achieve competitive results.

2 Related Work

Recently, the semantic parsing community has raised the question of whether current models can generalize compositionally, along with an effort to test for it (Lake and Baroni, 2018; Finegan-Dollak et al., 2018; Kim and Linzen, 2020). The consensus is that conventional seq2seq models struggle to generalize compositionally (Loula et al., 2018; Keysers et al., 2020). Moreover, large pre-trained language models have been shown not to improve compositional generalization (Oren et al., 2020; Qiu et al., 2022b). This has prompted the community to realize that parsers should be designed intentionally with compositionality in mind (Lake, 2019; Gordon et al., 2020; Weißenhorn et al., 2022).

It has also been pointed out that compositional architectures are often designed for synthetic datasets and that compositionality on non-synthetic data is under-tested (Shaw et al., 2021).

Data augmentation techniques have been proposed to improve compositional generalization (Andreas, 2020; Yang et al., 2022; Qiu et al., 2022a). Another strategy is to exploit some level of word alignments. In general, there has been a resurgent interest in alignments as it has been shown that they can be beneficial to neural models (Shi et al., 2020). It has also been conjectured that the lack of alignment information might hamper progress in semantic parsing (Zhang et al., 2019). As a result, the field has seen some annotation efforts in this regard (Shi et al., 2020; Herzig and Berant, 2021; Locatelli and Quattoni, 2022).

Alignments have been modeled implicitly: Wang et al. (2021) treat alignments as discrete structured latent variables within a neural seq2seq model, employing a framework that first reorders the NL and then decodes the MR. Explicit use of alignment information has also been explored: Herzig and Berant (2021) use alignments and predict a span tree over the NL. Sun et al. (2022) recently proposed an approach to data augmentation via sub-tree substitutions. In text-to-SQL, attention-based models that try to capture alignments have been proposed (Lei et al., 2020; Liu et al., 2021b), as well as attempts that try to leverage them directly (Sun et al., 2022).

Our two-step approach resembles statistical machine translation, which decomposes the translation task into lexical translation and reordering (Chang et al., 2022). Machine translation techniques have previously been applied to semantic parsing. The first attempt was by Wong and Mooney (2006), who argued that a parsing model can be viewed as a syntax-based translation model and used a statistical word alignment algorithm. Later a machine translation approach was used on the GEO dataset, obtaining what was at the time state-of-the-art results (Andreas et al., 2013). More recently, Agarwal et al. (2020) employed machine translation to aid semantic parsing.

3 Preliminaries: Word Alignments

This section briefly explains word alignments, showing the difference between monotonic and non-monotonic alignments, and illustrates the notion of monotonic translations.

Assume that we have a pair of sequences $\mathbf{x} = x_1, \dots, x_n$ and $\mathbf{y} = y_1, \dots, y_m$, where n and m are the respective sequence lengths. A bi-sequence is defined as the tuple (\mathbf{x}, \mathbf{y}) . In our application, \mathbf{x} is a NL sentence, and \mathbf{y} is its corresponding MR. For example:

$\mathbf{x} =$ which city has the highest population density?
 $\mathbf{y} =$ answer(largest(density(city(all))))

A word alignment is a set of bi-symbols \mathcal{A} , where each bi-symbol defines an alignment from a token in the NL to a token in the MR. For instance, the bi-symbol (x_i, y_j) aligns token x_i to token y_j . In our example, the tokens "which" and "answer" could be paired by a bi-symbol (which, answer).

If a token x_i does not align to anything in \mathbf{y} , an ε is introduced in \mathbf{y} : the resulting bi-symbol (x_i, ε) corresponds to a deletion. In our example, the token "has" in the NL can be deleted with a bi-symbol (has, ε). Similarly, if a token y_j is not aligned to a token in \mathbf{x} , an ε is introduced in \mathbf{x} : (ε, y_j) is an insertion. In our example, the token "all" in the MR is inserted with bi-symbol $(\varepsilon, \text{all})$.

The bi-symbols in \mathcal{A} are all one-to-one. Hence, to map a single token to a phrase, i.e., to multiple tokens, it is necessary to choose a head token in the phrase, while the remaining tokens require insertion or deletion. In our example, the token "density" in the MR corresponds to "population density" in the NL, and, if "density" is chosen as the head token in the NL, "population" needs a deletion: the alignment will be given by the bi-symbols (population, ε) and (density, density).¹ Following this strategy, this notation can account for one-to-many and many-to-one alignments with deletion and insertion operations.

Figure 2a shows a possible bi-sequence word alignment for the aforementioned example. Each bi-symbol is conveniently represented by a horizontal line connecting the tokens it aligns.

Alignments can be monotonic or non-monotonic. An alignment is monotonic if it does not involve any *crossing*, i.e., a mapping that does not require reordering tokens. In our example, the alignment is non-monotonic because the bi-symbol (city,city) crosses over others. By permuting the MR, we can obtain a monotonic translation of the NL: Figure

¹Locatelli and Quattoni (2022) showed that annotators are consistent in the way they pick head-tokens, and reported high inter-annotator agreement scores on GEOALIGNED.

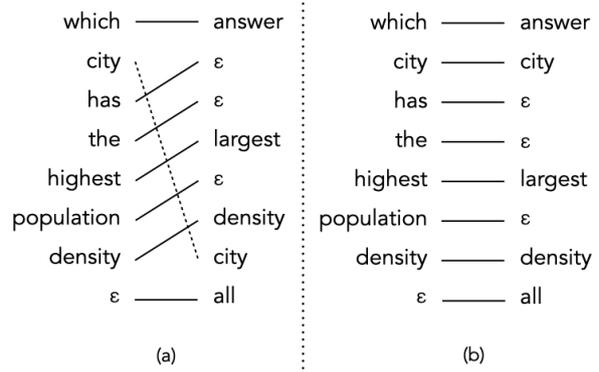

Figure 2: (a) A possible alignment for an NL-MR pair. (b) The corresponding monotonic translation. For simplicity, we removed the brackets and question mark.

2b shows such permutation. The next section illustrates how TPOL can leverage these translations.

4 Translate First Reorder Later

We propose TPOL, a two-step parsing approach with a modular framework made up of two components: a *Monotonic Translator* and a *Reorderer*. Figure 3 shows how our semantic parser takes an input sentence \mathbf{x} and predicts the corresponding MR \mathbf{y} . In the first step, \mathbf{x} is fed to the Translator, which outputs a monotonic translation \mathbf{z} . In other words, \mathbf{z} is the target MR that has been permuted so that it aligns monotonically to the input NL. Then, in a second step, \mathbf{z} is fed to the Reorderer, which is trained to place the MR tokens back into the correct order to produce the final prediction \mathbf{y} .

The main idea behind TPOL is decomposing the task into lexical translation and reordering, to learn more reliable translation patterns. We purport that modeling monotonic alignments eases the learning of novel pattern combinations of seen structures, improving compositional generalization.

An alternative approach would be to permute the NL inputs rather than the MRs monotonically. We do not follow this direction due to the observation that in semantic parsing, multiple NLs can map to the same MR. In other words, the NL domain is larger than that of the MRs, and thus we believe that learning to reorder the MRs is more feasible.

4.1 Monotonic Translator

The Monotonic Translator is responsible for making an initial prediction of the MR sequence, which will contain the correct tokens in monotonic order. To create the training bi-sequences, we use alignment information and permute the gold MR

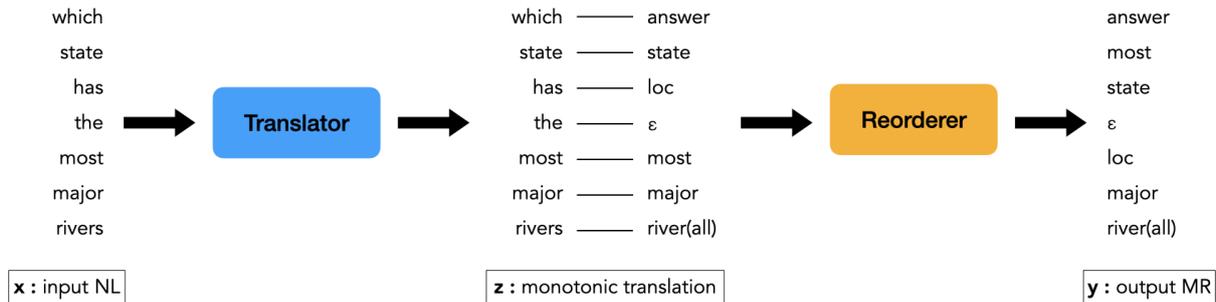

Figure 3: The TPOL parsing approach. An input sentence x is fed to the *Monotonic Translator* that predicts an intermediate monotonic MR z . This is in turn fed to the *Reorderer*, which outputs the final prediction y .

sequences to obtain a monotonic mapping with the NL. As a concrete example, consider the non-monotonic alignment in Figure 2a, and its monotonic translation in Figure 2b.

The translation task can be formulated in various ways. In our implementation, we work with two alternative approaches: a seq2seq Translator, and a tagger Translator. In the seq2seq formulation, x is fed into an encoder network, which produces a hidden vector. The hidden vector is fed to a decoder network which produces the output z , i.e., the monotonically aligned MR. This can be implemented, for example, with a BART model (Lewis et al., 2020), which uses a bidirectional encoder and a left-to-right decoder. In our experiments, we use the multilingual version of BART (Liu et al., 2020). In the tagging formulation, the Translator assigns an MR token to each token in x , obtaining the monotonic translation z by explicitly aligning in a token-by-token fashion. We implement this with a BERT model (Devlin et al., 2019) and we use its classification head as the tagger.

A crucial difference between the seq2seq and the tagger Translator is that the latter needs x and z to be the same length. The seq2seq Translator can learn to perform deletion operations from the raw NL, without needing epsilons in the input to perform insertions. By contrast, the tagger Translator needs insertions to be performed on x before predicting z . In general, NL sequences are significantly longer than the MR sequences, i.e., most epsilons are in the MR sequence. In other words, deletions are more frequent than insertions.

However, for some datasets, some alignments contain epsilons in the NL sequence: at prediction time, we will not know where insertions might occur, and thus we need a way to predict them. For this purpose, for every token followed by an epsilon in the train split, we add an epsilon after it

at test time. We saw that this strategy was sufficient in our experiments. Alternatively, this step could be done by a trained model or with a rule-based system similar to Ribeiro et al. (2018).

4.2 Reorderer

The Reorderer module is responsible for taking the monotonic predictions of the Translator and putting them back into the correct order to obtain the final prediction. This model is trained from pairs of MR sequences (z, y) where the input z is a monotonically permuted MR and the output y is the target MR in its correct order. These training pairs can be generated from the alignment annotations.

Similarly to the Translator module, the Reorderer can be implemented both as a seq2seq model and as a tagger. We use mBART in the seq2seq formulation and BERT as a tagger in our experiments. Note that we do not enforce the output to be a permutation of the input.

5 Experiments

5.1 Datasets

We test TPOL on two semantic parsing datasets, training with gold and automatically generated alignments in multiple languages, on standard IID partitions and the more challenging compositional ones.

5.1.1 GEOALIGNED

GEOALIGNED (Locatelli and Quattoni, 2022) augments the popular GEO semantic parsing benchmark (Zelle and Mooney, 1996) with token alignment annotations. The dataset contains questions about US geography and corresponding meaning representation using the FunQL formalism (Kate et al., 2005). In total, there are 880 examples, all annotated with token alignments. We evaluate on three partitions: question (?), query (Q) and length

(LEN). The question partition is a standard IID split where test and train are sampled from the same distribution. The query partition, introduced by [Finegan-Dollak et al. \(2018\)](#), is designed to be compositional by ensuring that the templates of the MRs in the test set are never seen during training. The length partition, introduced by [Herzig and Berant \(2021\)](#), assigns the longest sequences to the test.

The dataset comes in English, Italian and German: in this way we can test our approach across different languages. In our experiments, we do not anonymize constants: in other words, we keep the original NL and MR sequences which include names of cities, states, etc. We follow [Wang et al. \(2021\)](#) in removing brackets.

5.1.2 SCANSP

SCANSP ([Herzig and Berant, 2021](#)) is a set of navigational commands presented in natural language paired with action sequences. It is based on the SCAN dataset by [Lake and Baroni \(2018\)](#), which does not contain program MRs. [Herzig and Berant \(2021\)](#) translated the sequences into programs to obtain a semantic parsing version of the dataset. Besides the IID split, we test on the compositional partitions based on the "right" (RX) and "around right" (ARX) primitives from [Loula et al. \(2018\)](#). SCANSP has 20,910 commands distributed roughly as 12,000 train, 3,000 validation, and 4,000 test examples.

The SCANSP dataset does not come with alignments. Therefore we employ the IBM models ([Brown et al., 1993](#)) to generate them automatically using the GIZA++ toolkit ([Och and Ney, 2003](#)). We also do this for GEO to compare the performance of TPOL when trained with gold and automatic alignment annotations.

5.2 Models for comparisons

We compare with competitive baselines and state-of-the-art models that do not leverage alignments and competing models that do.

- **LSTM**: a standard seq2seq model with a bi-directional LSTM encoder and an LSTM decoder with attention ([Bahdanau et al., 2015](#)). We use pre-trained GloVe embeddings for the three languages: English ([Pennington et al., 2014](#)), Italian and German ([Ferreira et al., 2016](#)).

- **mBART** ([Liu et al., 2020](#)): a multilingual version of BART ([Lewis et al., 2020](#)), a pre-trained

Transformer-based seq2seq model that has been successfully applied to parsing ([Bevilacqua et al., 2021](#)).

- **mT5** ([Xue et al., 2021](#)): a multilingual version of T5 ([Raffel et al., 2020](#)), pre-trained on the mC4 dataset ([Xue et al., 2021](#)).

- **SPANBASED** ([Herzig and Berant, 2021](#)): a semantic parser that predicts a span tree over an input utterance trained with gold alignment trees. The authors provided annotations for the English version of GEO and SCANSP. For the other languages of GEO we train without gold alignments. We use their model without the lexicon, as that would be unfair with respect to the other models.

- **LEAR** ([Liu et al., 2021a](#)): a model that learns to recombine structures recursively by predicting a latent syntax tree and assigning semantic operations to non-terminal nodes. LEAR explicitly uses alignments using a phrase table.

- **REMOTO** ([Wang et al., 2021](#)): a model that first reorders the tokens in the NL and then predicts the MR. REMOTO is not trained with gold alignments.²

5.3 Evaluation metric

We follow the standard practice of using exact-match accuracy for evaluation: the predicted MR is correct only if it is the same as the gold.

5.4 Main Results

We report the results of our experiments in Table 1. For TPOL, the choice of the modules' architecture is validated on the development set, and we report a performance breakdown in Section 7.

We first consider the results of TPOL trained with gold alignments. On the GEO dataset, the LSTM and mT5 achieve the lowest performance in all the partitions. Looking at the question partition (?), the models show similar performance to mBART and SPANBASED, which is not surprising as the test split does not require compositional generalization. On the query partition (Q), designed to test for compositional generalization, TPOL shows significant improvements over all the other models across all languages. In English it obtains 87.3% outperforming mBART (69.4%), SPANBASED (74.6%) and LEAR (84.1%). In Italian and German, it obtains 81.6% and 69.4% respectively, while mBART 67.4% and 56.3%. On

²For LEAR and REMOTO, we report results directly from the respective papers, noting that in their setting constants, such as names of states, cities, and so on, are anonymized.

Model	GEO											
	EN			IT			DE			SCANSP		
	?	Q	LEN	?	Q	LEN	?	Q	LEN	IID	RX	ARX
LSTM	52.9	24.9	5.0	46.4	18.1	4.3	42.9	17.6	3.2	100	24.4	1.1
mT5	80.0	60.0	19.3	73.2	44.9	20.4	68.2	47.8	18.6	100	41.2	99.8
mBART	87.5	69.4	27.5	86.6	76.4	23.3	75.5	56.3	18.2	100	99.4	100
LEAR	-	84.1	-	-	-	-	-	-	-	-	-	-
SPANBASED	87.7	74.6	55.0	-	-	-	-	-	-	100	100	100
- gold	66.4	51.8	24.6	49.6	37.3	10.4	40.4	21.4	5.0	100	100	100
REMOTO	75.2	43.2	23.2	-	-	-	55.6	22.3	16.6	100	-	-
TPOL	87.3	87.8	41.9	85.9	81.6	31.3	73.3	69.4	22.9	-	-	-
- gold	85.8	79.0	35.6	83.6	75.1	20.2	73.8	60.7	17.5	100	99.4	100

Table 1: Exact-match accuracy of all models on GEOALIGNED and SCANSP datasets. ? stands for question, Q for query and LEN for the length partition. RX stands for right and ARX for around right partitions. LEAR and REMOTO both anonymize constants in GEO, and the results are taken directly from the respective papers.

the length partition (LEN), TPOL does better than all the baselines across all languages, except for SPANBASED, which fares better on LEN(English). This is only the case, however, when gold alignments are provided.

Looking at the results obtained without gold alignments, TPOL shows considerable improvements over REMOTO and SPANBASED. In particular, it improves on the English query partition obtaining 79% against 43.2% and 51.8%, respectively. Furthermore, the accuracy does not drop significantly compared to TPOL trained with gold alignments. We tested using automatic alignments from IBM models 3, 4, and 5 and picked the best out of the three. In general, all lead TPOL to achieve similar performance.

Finally, looking at SCANSP, as expected, the models designed for compositional generalization achieve perfect performance on the dataset. What is surprising is that also mBART can do so, contrary to other deep models. With some internal testing, we have seen that this is not the case for English BART, as opposed to the multilingual version. We hypothesize that model size and pre-training might be a factor of success for mBART.

6 Error Analysis

Table 3 shows a breakdown of performance of TPOL on the English version of GEOALIGNED. The results indicate the exact-match accuracy achieved by the two modules: we can check whether the model struggles more with the trans-

lation or reordering step. To analyze the Translator’s performance, we regard the monotonically aligned MRs as the gold truth. For the Reorderer, we provide it with the monotonically aligned MRs in input. In other words, the evaluation of the Reorderer assumes that the Translator makes a correct prediction.

The performance of the two modules is fairly similar, and, by comparing these results with Table 1, we see that the accuracy of each component is not much higher than the overall accuracy, suggesting that neither component is hampering performance more than the other. The only exception seems to be in the length partition, where the Reorderer does considerably better than the Translator.

Table 2 shows the breakdown of the performance over monotonically and non-monotonically aligned MRs. We can observe that, compared to SPANBASED, TPOL generally presents smaller drops in performance over the non-monotonic sequences. For instance, in the question partition, SPANBASED drops from 94.7% over the monotonic examples to 73.7% over the non-monotonic, while TPOL drops from 89.9% to 81.4%. When we look at the query partition, we see that for both of these models, the drop is much higher than the one on the question partition: SPANBASED goes from 89.6% to 39.8%, while TPOL drops from 93.7% to 69.9%. In other words, both models struggle more with non-monotonic examples when compositional generalization is required. TPOL, however, still performs significantly better.

Model	GEO EN					
	?		Q		LEN	
	MN	NMN	MN	NMN	MN	NMN
mBART	90.4	81.0	67.1	76.5	29.2	25.1
SPANBASED	94.7	73.7	89.6	39.8	68.1	35.9
TPOL	89.9	81.4	93.7	69.9	55.5	23.2

Table 2: Performance breakdown of TPOL over monotonic (MN) and non-monotonic (NMN) sequences in GEOALIGNED English. In Appendix B we report the number of MN and NMN examples.

Module	GEO EN		
	?	Q	LEN
Translator	86.1	86.2	42.5
Reorderer	87.6	87.3	57.1

Table 3: Performance breakdown of TPOL modules.

Surprisingly, mBART shows the opposite trend on the query partition, with the non-monotonic accuracy being higher than the monotonic one. By contrast, most of TPOL’s improved performance comes from better modeling of the monotonic sequences (67.1% \rightarrow 93.7%). TPOL’s results suggest that regular patterns in the non-monotonic sequences can be learned. Its generalization problems can be attributed to the difficulty of learning the more challenging non-regular patterns in a small dataset. On the other hand, mBART appears to have the capacity to model these challenging reorderings better. Still, this comes at the cost of failing on the regular monotonic ones, leading to a lower performance overall.

Interestingly, the SPANBASED approach shows a similar improvement on monotonic sequences compared to mBART (67.1% \rightarrow 89.6%). This suggests that exploiting lexico-logical alignments allows models to capture the simpler patterns that mBART fails to learn. Most of TPOL’s gains over SPANBASED come from better modeling the non-monotonic examples in the query partition (39.8% \rightarrow 69.9%). This shows that the two-step approach offers the best of both worlds: it can capture the simple monotonic patterns while maintaining reasonable performance over the more complex alignments on which SPANBASED fails.

Figure 4 shows the average drop in performance of the different models trained with automatic IBM alignments compared to the same model trained

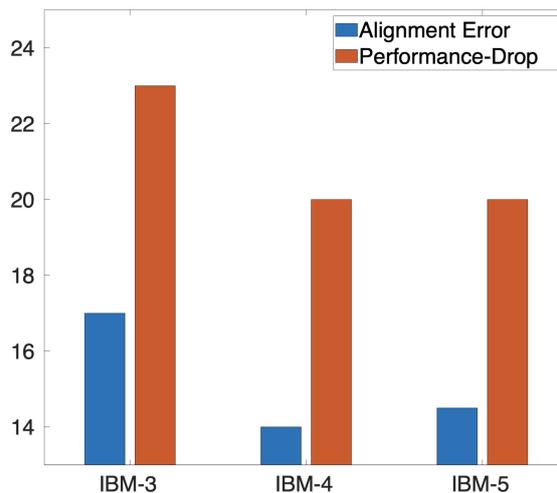

Figure 4: Average error of IBM alignment models over all partitions and languages on GEOALIGNED. We also plot the average drop in performance for each TPOL model trained with IBM alignments with respect to the corresponding one trained with gold alignments.

with gold alignments. We also report the corresponding alignment error, calculated as the percentage of bi-symbols that differ from the gold annotations from GEOALIGNED. We observe that, in general, higher alignment error is associated with a higher drop in performance. This validates the importance of the alignment information and points to improving the unsupervised alignment algorithm as a natural line of future work. We believe that one possible reason for the drop in performance when training with IBM alignments might be because the GEO dataset is of relatively small size, and the IBM models might have difficulty learning good alignments. That would explain why in contrast to GEO, the performance over SCAN is not affected by automatic alignments since SCAN is a much larger dataset.

7 Architecture study

We emphasize here that our approach is an abstract, high-level methodology and does not place any constraint on the underlying architectures of the two components. We believe that different architectures, particularly specialized ones for each module, could be beneficial for parsing performance. We encourage further work to be carried out in this regard. To this purpose, we present some architectural studies using BERT (Devlin et al., 2019) and mBART (Liu et al., 2020) as components. We employ them as both Translator and Reorderer, examining all possible combinations. As explained in Section 4.1, mBART is used as a standard seq2seq model, and BERT is employed with a classification head to function as a tagger for every input token.

Additionally, when mBART is used as a Reorderer, we introduce a silver training setting. In the normal setting, the Reorderer is trained by taking the gold alignment annotations and outputting the meaning representation. In the silver setting, we use the predictions of the Translator model as training input. By doing so, the Reorderer trains on inputs that mimic more closely what it will actually receive at test time: this is done straightforwardly for a seq2seq model like mBART, while for our BERT tagger, every token in input needs to be aligned with a token in output, and when the input is corrupt it is not possible to achieve the same training technique.

In Table 4, we present the results for our different architectural components. To distinguish among the different model combinations, we use a [Translator]2[Reorderer] naming convention, meaning that mBART2BERT uses mBART as the Translator and BERT as the Reorderer. We observe that our two-step approach seems to be robust overall.

We can discern trends in different architecture combinations, which can be helpful when choosing an architecture for a specific task. One important observation is that the architectures that use BERT as a Translator are consistently better than the ones using mBART over the compositional partitions. We hypothesize that the BERT Translator can achieve higher compositional generalization because it can better leverage alignment information to predict unseen combinations of observed training patterns. We believe this is because a tagger’s predictions can be more naturally broken into parts that can be recombined. In contrast, encoder-decoder architectures fare better on the IID partition but struggle to generalize to unseen patterns. One possible reason is that these models have a harder time inducing local patterns that can be recombined since they encode and decode complete structures all at once.

8 Conclusion

Seq2seq models have become increasingly popular in semantic parsing. However, they are limited in their abilities to generalize to unobserved structures. Here, we proposed TPOL: a two-step parsing approach that leverages alignment annotations with a modular framework composed of a Translator and a Reorderer.

We showed that TPOL improves compositional generalization over conventional seq2seq models and over competing models that also leverage alignment information. Our results also showed that our approach is robust when trained with automatically generated alignments, demonstrating competitive results on two semantic parsing datasets.

We have experimented with two possibilities for the Translator and Reorderer, but we believe

that different architectural components could further improve performance. The divide-and-conquer strategy of breaking the problem into two simpler sub-tasks is designed to enable further component specialization.

9 Limitations

Regarding the limitations of our approach, our experiments used the standard FunQL meaning representation. Transitioning to a different meaning representation might need some adaptation of the framework. In particular, the alignments between NL and MRs for other meaning representations might require more insertion and deletion operations. We might also expect that other MRs might require more reordering.

A second limitation of our work is training with gold alignments. We partially address this by training TPOL with automatic alignments obtained with the IBM models. Still, we believe there is room for more work to be done so that this approach can be more easily scaled to datasets that do not have alignment annotations.

Despite TPOL's partial improvements on the length test splits, this type of partition remains challenging for all models. Here, models are required to generate predictions of greater length than what they have seen during training. This requires complex compositional productivity skills, i.e., recombining known constituents into larger structures. Further work is needed to address the limitation of the current state-of-the-art on compositional productivity benchmarks.

A Experimental details

For our experiments with TPOL we report the average of three runs for every result. We select the hyperparameters with grid search on the development set performance stopping when there is no more improvement. We choose the learning rate among $1e^{-4}$, $1e^{-5}$ and $1e^{-6}$ and the batch size between the bounds of 4 and 32. Usually the best performing models choose a learning rate of $1e^{-5}$ and batch size of 8. An experiment takes about 20 minutes on a single Nvidia V100 GPU. Our BERT (110M parameters) and mBART (680M parameters) implementations are taken from the transformers library (Wolf et al., 2020). We use for English *bert-base-uncased*, for Italian *dbmdz/bert-base-italian-uncased* and for German *dbmdz/bert-base-german-uncased*. For mBART we use *facebook/mbart-large-50*. For mT5 we use the *google/mt5-small* pre-trained checkpoint from the Transformers library.

B GEOALIGNED statistics

Table 5 provides statistics from the English version of GEOALIGNED (Locatelli and Quattoni, 2022). In particular, we report the number of examples that fall in the monotonic (MN) and non-monotonic (NMN) categories.

Category	GEO EN		
	?	Q	LEN
MN	194	154	162
NMN	86	51	118

Table 5: Number of examples that belong to the monotonic (MN) and non-monotonic (NMN) categories in GEOALIGNED English.

PePe: Personalized Post-editing Model utilizing User-generated Post-edits

Abstract

Incorporating personal preference is crucial in advanced machine translation tasks. Despite the recent advancement of machine translation, it remains a demanding task to properly reflect personal style. In this paper, we introduce a personalized automatic post-editing framework to address this challenge, which effectively generates sentences considering distinct personal behaviors. To build this framework, we first collect post-editing data that connotes the user preference from a live machine translation system. Specifically, real-world users enter source sentences for translation and edit the machine-translated outputs according to the user's preferred style. We then propose a model that combines a discriminator module and user-specific parameters on the APE framework. Experimental results show that the proposed method outperforms other baseline models on four different metrics (*i.e.*, BLEU, TER, YiSi-1, and human evaluation).

1 Introduction

Language usage is strongly influenced by the state of the individual, which can be considered by multiple attributes such as age, gender, socioeconomic status, and occupation (Tannen et al., 1991; Pennebaker et al., 2003). Taking these aspects into account in the machine translation task, we need personalized translations to reflect individual characteristics that vary from person to person; thus, the translation system should consider not only fluency and content preservation, but also personal style.

However, most existing neural machine translation (NMT) models ignore personal style (Mirkin et al., 2015). Previous studies attempt to address this problem by personalizing the NMT models, but in these studies the definition of personal style

Figure 1: Example of a *personal post-editing* triplet (*i.e.*, source (*src*), machine translation (*mt*), and post-edit (*pe*)) given the source text in English and the translated text in Korean. A post-edited sentence does not only contain error correction of an initial machine translation result but also reflects individual preference. For instance, a human post-editor modifies the word "primarily" to "primary," but also change "공헌" to its synonym "기여" while keeping the rest as it is (*e.g.*, "research").

is often over-simplified (Rabinovich et al., 2017; Sennrich et al., 2016; Si et al., 2019). For example, Rabinovich et al. (2017) and Sennrich et al. (2016) define the personal style as politeness and gender respectively, which is not sufficient to tackle the multifarious character of an individual. Namely, previous works defined the personal style in a constrained form.

In contrast with previous studies, we propose a method based on an APE framework and newly utilize post-editing data to capture diverse personal traits in translation. Originally, the need for post-editing data is to improve the quality of machine-translated sentences in an APE task (Simard et al., 2007; Pal et al., 2016; Correia and Martins, 2019). However, we suggest that the post-editing data can also be adequate references for personalized translation if various users post-edit sentences according to their preferences. In this respect, we collect a **user-generated post-editing** dataset called USP through a live translation system. After the system translates a source sentence (*src*) to a target sentence, *i.e.*, machine-translated sentence (*mt*), each

user edits the translated result according to their purpose or preferences, *i.e.*, post-edited sentence (*pe*). We collect (*src*, *mt*, *pe*) triplets called *personalized post-editing* triplets for each user and an example is depicted in Fig 1.

Along with the personalized post-editing data, we develop a model which utilizes user parameter and a discriminator module. The user-specific parameters allow the model to adapt to each user in that the model can consider inter-personal variations. These parameters are aggregated with the output word probability such that the generation word probability distribution differs by each particular user. Moreover, since the prevalence of pre-trained language models encourages significant performance improvements on various natural language generation tasks (Song et al., 2019; Lewis et al., 2019; Correia and Martins, 2019), we exploit the pre-trained language model (LM) but do not fully lean on it. We assume that not all the features from the pre-trained LM contribute to capturing the distinct taste of users that are departing from the neutral and standardized patterns. Thus, our discriminator module, inspired by adversarial training (Goodfellow et al., 2014), attempts to dismantle the unnecessary features from a pre-trained LM, while tuning the model to incorporate a personal style. The details will discuss in Section 3.

Experiments on our dataset and speaker annotated TED talks dataset (Michel and Neubig, 2018) (SATED) demonstrate that the proposed approach generates diverse translations for different users.

In summary, our contributions include the following:

- To the best of our knowledge, this is the first work that leverages the APE framework to a personalized translation task.
- We propose a personalized post-editing model based on user-generated post-edits, which is able to capture the inter-personal variations that consist of multiple attributes.
- Extensive experimental results show that the proposed method robustly reflects personal traits and consistently outperforms baselines in three different quantitative metrics and human evaluation results.

2 Related Work

Our work is closely related to the recent work on personalized neural machine translation and auto-

matic post-editing.

Personalized neural machine translation.

Standard NMT systems are not able to consider the personal preference in a machine-translated output (Mirkin et al., 2015). Mima et al. (1997) is the early paper that proposes a concept of reflecting an author’s properties, such as gender, dialog domain, and role in the translation. However, including Mima et al. (1997), most studies conduct a limited range of personalized translations, which address only a single attribute (*e.g.*, politeness) (Sennrich et al., 2016; Rabinovich et al., 2017).

Turchi et al. (2017) and Karimova et al. (2018) fine-tune the model on the human post-edits to improve the NMT quality, which can be viewed as a naive approach to handle the personalized translation without attribute labels. Wuebker et al. (2018) extend this approach to adjust only a small number of parameters, but still requires extensive training resources. Meanwhile, Michel and Neubig (2018) and Huan et al. (2021) propose a generalized form of a personalized translation method, which are closely related work with ours. Michel and Neubig (2018) cast this problem as an extreme form of domain adaptation, while Huan et al. (2021) introduce cache module and contrastive learning to increase the diversity on dissimilar users. However, the reference sentences for personalized translation were constructed by a few professional translators, not by a variety of people with diverse characteristics; personal preferences reflected in the dataset are limited. Our user-generated post-edits are edited by a large number of people who provide the original sentences.

Automatic post-editing. Prior to the emergence of the transformer (Vaswani et al., 2017), RNN based APE models (Pal et al., 2016; Junczys-Dowmunt et al., 2016; Junczys-Dowmunt and Grundkiewicz, 2017) are actively studied. Subsequently, as self-attention based models show significant improvements on various downstream tasks, transformer based models also prevail in the APE task. Specifically, a popular approach is to set a separate encoder for the source and machine-translated (MT) output. Separately encoded representations are joined in the following encoder (Pal et al., 2018) or fused in the decoder (Tebbifakhr et al., 2018; Junczys-Dowmunt and Grundkiewicz, 2018). More recently, Correia and Martins (2019) improve the performance of APE tasks by leveraging a

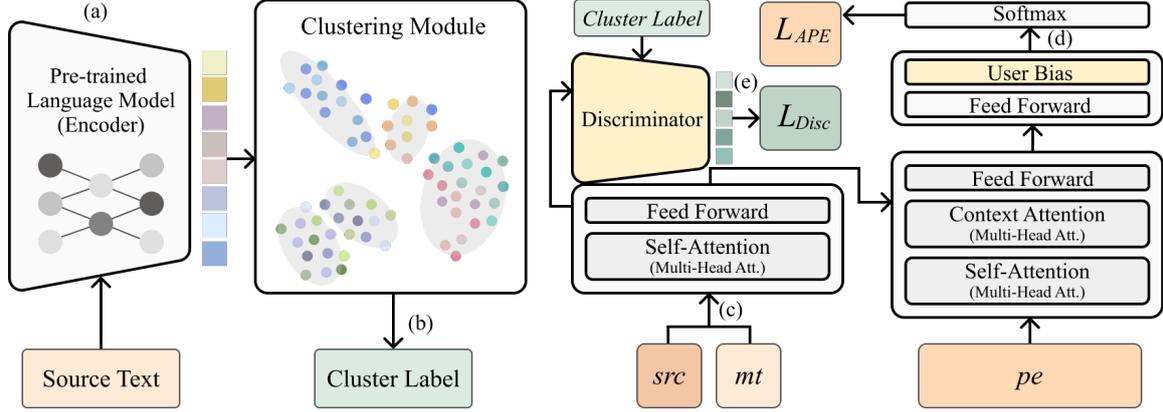

Figure 2: An overview of our proposed method. PePe consists of two parts: 1) Clustering module that relies on pre-trained LM encoder and Gaussian mixture model. 2) APE architecture that includes an auxiliary discriminator and user-specific parameters.

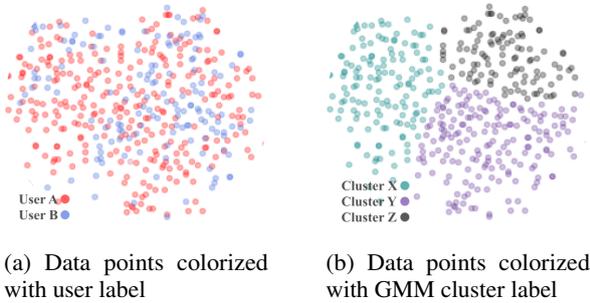

Figure 3: Source sentences of USP embedded with the pre-trained LM. (a) and (b) shows the discrepancy between the user data distribution and the contextual similarity-based data distribution.

pre-trained LM. Compared to these studies, our work is the first attempt to examine the neural network based APE model for personalized translation. There is a study where they use an APE module for domain adaptation (Isabelle et al., 2007), but the explored one is based on a statistical machine translation system.

3 Proposed Method

Overview: It is challenging to generate appropriate translations that impose personal variations. To address such a demanding problem, we take a detour by applying an APE framework. We propose PePe, a personalized post-editing model utilizing user-generated post-edits. PePe includes a discriminator module to allow the model to dismantle the pre-trained LM features. Specifically, we maximize the discriminator loss to encourage the encoder to throw away irrelevant pre-trained LM features, while minimizing the APE loss to guide the model

to utilize the pre-trained LM features that are useful for personalization. In addition, PePe utilizes user-specific parameters to capture the personal style. User-specific parameters are combined at the end of the decoder layer to adjust the prediction of the word probability, i.e., the word choice based on a user preference. Our strategy does not require expensive supervision on the personal style, such as explicit attribute labeling or an attribute-tailored model architecture.

The overall architecture of PePe is illustrated in Fig. 2. The two following subsections will describe the modules shown in Fig. 2-(a), (b), (c), (d), and (e), respectively.

3.1 Contextual Similarity vs. User-specific Style

The pre-trained LM is well known for capturing the contextual similarity that is useful to define the label for in-domain data (e.g., sports, IT, and economy). However, the user-specific style is far from those domains; it does not coincide with contextual similarity yet involves somewhat arbitrary traits (i.e., user preferences). Hence, we argue that some of the features from a pre-trained LM distract personalized translation, which rather requires generating biased results to meet the individuals' needs. Fig. 3 demonstrates the discrepancy between the user data distribution and the contextual similarity-based data distribution.

We map the sampled sentences from USP to the embedding space of the pre-trained LM. Each sentence is encoded with RoBERTa (Liu et al., 2019) and visualized using t-SNE (van der Maaten and Hinton, 2008). The data on both sides show the same embedding representations obtained from the

same set of sentences, but labeling is different. The data items in Fig. 3a are color-coded by the users, whereas those in Fig. 3b are color-coded by the semantic cluster labels obtained from the Gaussian mixture model (GMM) (Rasmussen, 2000), which allocates the similar sentences to the same label based on the RoBERTa embedding of each.

In Fig. 3b, semantically similar points, which are close in embedding space, belong to the same clusters. However, the red and blue points in Fig. 3a, which indicate sentence representations from two different users, are distributed unruly instead of being grouped by semantic similarity. In other words, the fine-grained style differences of each user are somewhat distant from the contextual similarity of the sentences; thus it is hard to distinguish user-specific preferences when the model is highly oriented to learning the contextual similarity.

3.2 Generating Cluster Labels based on Pre-trained LM

Inspired by the finding in Section 3.1, we devise a discriminator module that uses the semantic cluster labels to unlearn the features from the pre-trained LM that are unnecessary to reflect the personal styles. Before introducing the details about PePe, we describe how to generate the semantic cluster labels from a pre-trained LM in an unsupervised manner. We first encode *src* into encoded vectors using a pre-trained LM¹ as shown in Fig 2-(a). Based on these encoded vectors, semantic cluster labels are generated by GMM (Rasmussen, 2000) as illustrated in Fig 2-(b). A Gaussian mixture is a function made up of the k number of Gaussian components, where k is the number of clusters² and is a hyperparameter. Specifically, in GMM, $\sum_{i=1}^k \pi_i p_i(\mathbf{h}|\theta_i)$ represents the distribution of data point \mathbf{h} , where \mathbf{h} is an encoded vector of the first token of *src*, *i.e.*, [CLS] token, π_i is the probability of each Gaussian fitting the data, and p_i is the Gaussian density function parameterized by θ_i . We assign each sentence to a Gaussian that best describes the data, and the Gaussian corresponds to the semantic cluster label. The label, *i.e.*, $T = t_1, \dots, t_k$, is then used as a classification label for our discriminator, which is described in the following subsection.

¹Though we use RoBERTa as a pre-trained LM to generate cluster labels, other pre-trained LMs can also be used in our approach.

²Ten clusters are used for all the experiments in the main paper.

3.3 PePe: Personalized Post-editing Model utilizing User-generated Post-edits

We adopt BERT-based Encoder-Decoder APE model (Correia and Martins, 2019) called Dual-Source BERT (DS-BERT) as our backbone, which is based on transformer (Vaswani et al., 2017) with pre-trained multilingual BERT (Devlin et al., 2019). DS-BERT uses a single encoder which is used to encode both the *src* and the *mt* by concatenating them with the specialized token [SEP] as described in Fig 2-(c).

Our model also learns to generate $y = [y_1, \dots, y_n]$, *i.e.*, *pe*, from x , *i.e.*, *src*, and $\tilde{y} = [\tilde{y}_1, \dots, \tilde{y}_m]$, *i.e.*, *mt*, by maximizing the likelihood,

$$P(y|x, \tilde{y}; \theta_{APE}) = \prod_{i=1}^n P(y_i|x, \tilde{y}, y_{<i}; \theta_{APE}),$$

where y_i is the i -th target word and $y_{<i} = y_1 \dots y_{i-1}$ is the partial translation result. θ_{APE} represents the parameters for translating source sentence into post-edited sentence with machine-translated result \tilde{y} .

In order to adapt user-specific linguistic styles, we add user-specific parameters before the softmax layer in the decoder as shown in Fig 2-(d), *i.e.*,

$$P(y_i|x, \tilde{y}, y_{<i}; \theta_{APE}, \theta_{user}) = f(FFN(o_i) + \theta_{user}),$$

where FFN and f are a feed-forward network and softmax function, respectively. o_i is the output for the i -th target word from the decoder. $\theta_{user} \in \mathbb{R}^V$ is a user-specific embedding vector from a set of trainable user embedding matrix $U \in \mathbb{R}^{N \times V}$ where N is the number of users and V is the size of vocabulary.

The model is then optimized by minimizing \mathcal{L}_{APE} defined as

$$\mathcal{L}_{APE} = - \sum_{i=1}^n \log P(y_i|x, \tilde{y}; \theta_{APE}, \theta_{user}).$$

Furthermore, as shown in Fig 2-(e), we introduce a discriminator module to unlearn the contextual similarity feature learned from a pre-trained LM. To train the discriminator, we compute the discriminator loss \mathcal{L}_{Disc} defined as

$$\mathcal{L}_{Disc} = \sum_i^k t_i \log(\tilde{t}_i),$$

where k is the number of classes (*i.e.*, the number of Gaussians we pre-defined) and t_i is the ground-truth label of the semantic cluster. \tilde{t}_i represents the

output from the discriminator which is a single-layer feed-forward network for the classification of semantic cluster labels. We use the first token of a source sentence to extract a sentence representation from the encoder and pass it to the discriminator as an input. Note that we use the gradient ascent method to prevent the encoder from classifying the clusters. In this way, we diminish the unnecessary feature from pre-trained LM, while our APE loss function incorporated with user-specific parameters leads the model to capture the user-specific style.

Finally, PePe optimizes a combination of two losses, \mathcal{L}_{Disc} and \mathcal{L}_{APE} , with an adjustment rate β , *i.e.*,

$$\mathcal{L}_{Train} = \beta \cdot \mathcal{L}_{Disc} + (1 - \beta) \cdot \mathcal{L}_{APE}.$$

4 Experiments

In this section, we qualitatively and quantitatively demonstrate the effectiveness of our proposed method. We validate PePe, described in Section 3, against other baseline methods using a real-world user dataset USP. We also provide a detailed explanation for the dataset. Moreover, through extensive experiments and analyses, we show that PePe can incorporate inter-personal variations into a target sentence. We provide training details in Appendix A.

4.1 Dataset

We collect the user-generated post-editing dataset, USP, from a publicly available online translation system³ (*e.g.*, Google Translate). Fig 4 illustrates the user experience flow. The users enter the sentences they want to translate, and the system provides the corresponding outputs that are generated by the high-quality commercialized machine translator. From the machine-translated outputs, users can start to edit the translated sentences according to their preference by clicking the “post-edit” button. Consequently, when the users click the “Finish” button after completing the changes, a triplet of the source sentence, machine-translated output, and personalized post-edit is sent to our database. Note that the origin of post-edited sentences is each particular user, which makes USP contains inter-personal variation, unlike existing APE datasets.

³We collected data only from users who consent to the data collection for research purposes. In addition, there is no privacy issue because de-identification had taken for the collected data.

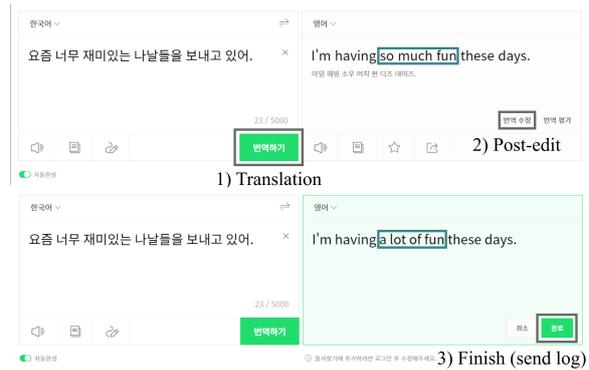

Figure 4: Illustration of the user experience flow for post-edit log generation.

Since we collect USP from the real-world users’ inputs that contain various noises (*e.g.*, unedited, duplicated, or meaningless examples), we preprocess the data to eliminate these noises. Furthermore, most users only edited few examples, which are not sufficient to represent their style. Therefore, we select the users who left more than 100 samples, *i.e.*, 30 users with 7K sentences and 70 users with 9K sentences for $en \rightarrow ko$ and $ko \rightarrow en$ USP dataset, respectively. For users who left less than 100 samples, we aggregate the samples (*i.e.*, 0.12M sentences) and utilize them as training data for the task-adaptive pre-training (Gururangan et al., 2020). The discriminator module and user-specific parameters are not used in the task-adaptive pre-training and only the parameters for DS-BERT are utilized for the pre-training stage. Details of data preprocessing are in Appendix A.

Additionally, we adopt a Speaker Annotated TED (SATED) dataset (Michel and Neubig, 2018) containing more than 2,000 sets of speaker style-contained source sentences, which is publicly available. We select the dataset to show the robustness of our model regarding different datasets and languages.

4.2 Experimental Setup

Evaluation metric. We use three different metrics to evaluate how well our proposed model preserves the content and incorporates the personal preferences. BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores are considered to assess the translated sentence where the ground-truth sentence is a *pe* sentence. We also leverage YiSi-1 (Lo, 2019) that computes the semantic similarity of phrases between the model output and *pe*, which can be sensitive to detailed styles. We

Methods	<i>en</i> → <i>ko</i>			<i>ko</i> → <i>en</i>		
	BLEU↑	TER↓	YiSi-1↑	BLEU↑	TER↓	YiSi-1↑
(1) Uncorrected	64.9 (-5.6)	21.1 (+1.2)	87.3 (-1.1)	75.1 (-3.5)	17.7 (+1.4)	88.9 (-0.8)
(2) DS-BERT	68.4 (-2.1)	21.1 (+1.2)	87.6 (-0.8)	77.1 (-1.5)	17.6 (+1.3)	89.1 (-0.6)
(3) DS-BERT + Full Bias	68.6 (-1.9)	20.9 (+1.0)	88.0 (-0.4)	78.0 (-0.6)	16.9 (+0.6)	89.6* (-0.1)
(4) DS-BERT + Factor Cell	67.5 (-3.0)	22.1 (+2.2)	88.0 (-0.4)	76.5 (-2.1)	18.4 (+2.1)	89.2 (-0.5)
(5) DS-BERT + User CLS	69.0 (-1.5)	20.9 (+1.0)	87.1 (-1.3)	78.1 (-0.5)	16.5 (+0.2)	89.4 (-0.3)
(6) DS-BERT + User Token	68.8 (-1.7)	20.5 (+0.6)	87.0 (-1.4)	74.3 (-4.3)	21.6 (+5.3)	88.5 (-1.2)
(7) PePe	70.5	19.9	88.4	78.6	16.3	89.7
(8) -discriminator	68.6 (-1.9)	20.9 (+1.0)	88.0 (-0.4)	78.0 (-0.6)	16.9 (+0.6)	89.6* (-0.1)
(9) -(8) & user bias	68.4 (-2.1)	21.1 (+1.2)	87.6 (-0.8)	77.1 (-1.5)	17.6 (+1.3)	89.1 (-0.6)
(10) -(9) & pre-training	60.2 (-10.3)	31.9 (+12.0)	86.3 (-2.1)	67.6 (-11.0)	28.7 (+12.4)	87.6 (-2.1)

Table 1: Quantitative comparison with the baselines on the USP dataset that contains *en*→*ko* language pairs and vice versa. (8) to (10) denotes the ablation results. The ablation study is designed to verify each module in PePe. User bias in (9) denotes the user-specific parameters located at the end of the decoder, and pre-training in (10) denotes the task-adaptive pre-training stage. The bold represents the significant difference ($p < 0.05$) against other baselines. We conduct the t-test with five runs and report the average score of it. * means that there is no significant difference in the scores between the model and PePe.

also conduct a human evaluation, which will be described in the following section.

Baseline Methods. We compare the performance of our method with the following baselines. Since this is the first attempt to personalize the translation using post-edits, we newly adjust existing personalized translation methods onto the APE framework for comparisons.

1) Uncorrected is the same as *mt* in personalized post-editing data, which is generated from the online MT system. No correction was made on it. **2) DS-BERT** is a transformer based post-editing model (Correia and Martins, 2019) that we adopt as our backbone in the method section. DS-BERT is a general approach in the recent APE task. To our knowledge, the recently proposed state-of-the-art APE models (Yang et al., 2020; Oh et al., 2021) are either based on the Dual-Source Transformer (Junczys-Dowmunt and Grundkiewicz, 2018) or DS-BERT. We believe that demonstrating the feasibility of personalized post-editing using a fundamental APE model is more suitable than models that use APE task-specific techniques. **3) DS-BERT + Full bias** (Michel and Neubig, 2018) utilizes additional user bias vectors on the decoder’s output. **4) DS-BERT + Factor bias** (Michel and Neubig, 2018) uses factorized user bias on the output of the decoder. User-independent biases are shared with all users. However, the user-specific vector can adjust each user-independent vector’s magnitude. **5) DS-BERT +**

User CLS is a multi-task composed of a user classification and APE task. The first token of an encoder input is used to stand for user identity. The corresponding output vector is used to classify a ground-truth user label. A single layer of a feed-forward neural network is used for the classifier. **6) DS-BERT + User Token** (Sennrich et al., 2016) adds a token at the start of each post-edited sentence to indicate the user for each sentence. We train the model in a teacher-forcing manner.

4.3 Quantitative Evaluation

Results using automatic metrics and human evaluation are presented in this section. PePe consistently outperforms the baselines on all datasets we considered. We also show the robustness of PePe regarding the different number of users, data distributions, and language pairs.

Performance of PePe against other baselines.

(1) to (7) in Table 1 shows the personalized translation results of varied baselines. Our proposed method outperforms the six baselines with the non-trivial margin both on *en*→*ko* and *ko*→*en* USP dataset. For instance, BLEU score increased in the range of 1.7 to 5.6, YiSi-1 increased in the range of 0.4 to 1.4, and TER decreased in the range of 0.6 to 2.2 over baselines, in *en*→*ko* dataset. Consistent results from these three different metrics verify that PePe easily figure out distinct taste of users while preserving source contents. Especially, experiments in *en*→*ko* dataset show the most out-

Metrics	PePe	DS-BERT	Uncorr.
Style - 1st	59.6	18.1	22.2
Style - 2nd	21.0	39.1	39.9
Style - 3rd	19.5	42.6	37.9
Non-Style	3.94(1.08)	3.60(1.19)	3.82(1.16)

Table 2: Human evaluation on $en \rightarrow ko$ USP dataset. Style and non-style factors are both surveyed. For the style factor, each score represents the proportion. For instance, 59.6% of evaluators choose PePe as the first place among other models. For the non-style factor, a Likert scale from 1 to 5 evaluates fluency and source contents preservation. We report the average score and the standard deviation.

Model	$en \rightarrow de$	$en \rightarrow fr$
	BLEU \uparrow	BLEU \uparrow
Michel and Neubig (2018)	27.2	38.5
DS-BERT	30.4	42.2
PePe	31.2	43.7

Table 3: Experiments on the SATED dataset. PePe outperforms DS-BERT on different language pairs even for a synthetic post-editing dataset. The bold represents the best score among the baselines and significantly ($p < 0.05$) outperforms DS-BERT.

standing performance gains since the data mostly come from the users whose first language is Korean; the users can reflect the linguistic preference more naturally on this dataset.

Ablation study. The comparison between PePe and (8) in Table 1 shows the importance of the discriminator module. When we exclude the discriminator module, the BLEU and TER scores are decreased on both $en \rightarrow ko$ and $ko \rightarrow en$. The results of the vanilla APE model (*i.e.*, (9) in Table 1) show that the user-specific parameters are also significant for personalized translation. Moreover, when we do not adopt the APE task-adaptive pre-training (*i.e.*, (10) in Table 1), the performance of the model drops even further. Overall, our ablation study demonstrates that each component is essential for the task.

Human evaluation. To validate the advantage of our approach, we conduct human evaluations. Human evaluation can be a reasonable measurement choice to evaluate the personalization task because even sophisticated evaluation metrics can fail to capture the abstract (*i.e.*, high-level) user behavior

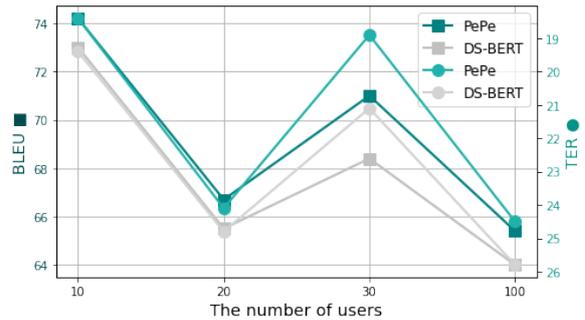

Figure 5: Robustness on the number of users. The dark squares denote the BLEU score, and the light circles denote the TER score. The number of clusters is equally adopted as ten for all cases. The users are randomly selected from the USP dataset.

reflected in the *pe* sentence. We hired 20 Korean-English who are bilingual and engaged in the fields of linguistics and machine learning for human evaluation. We randomly select 30 source sentences and generate corresponding target sentences from Uncorrected, DS-BERT, and PePe before carrying out two types of questions to compare different metrics. 1) We ask participants to annotate generated sentences along with fluency and content preservation. Sentences are measured on a Likert scale from 1 to 5. 2) We take three sentences generated from three different models. Participants rank these sentences from first to third, *i.e.*, asking which sentence is most similar to the ground-truth *pe* that contains distinct writing styles.

As reported in Table 2, PePe is ranked 1st by most evaluators. PePe not only achieved the best score on style evaluation but also on non-style factors (*i.e.*, fluency and contents preservation), which is essential for the translation task. DS-BERT achieves the lowest score on both measures, indicating that the ambiguous reflection of style is worse than none. The human evaluation results are consistent with our quantitative results measured by automatic metrics.

Robustness of our model. Table 3 shows the personalized translation results on $en \rightarrow de$ and $en \rightarrow fr$ SATED dataset. Since the dataset is initially constructed for the machine translation task where post-edited sentences do not exist, we utilize target sentence (*i.e.*, *mt*) in the place of *pe* and independently generate *mt* from a particular translation model (*i.e.*, pre-trained transformer based NMT model). Regardless of the language, the results demonstrate that PePe and DS-BERT, which leverages triplets (*src*, *mt*, *pe*), outperform Michel and Neubig (2018)

<i>en</i> → <i>ko</i>	
<i>src</i>	<u>Immediately</u> provide non-monetary <u>benefits</u> as required.
<i>mt</i>	필요에 따라 즉시 비화폐성 편익 을 제공하십시오.
PePe	요구된대로 비화폐성 혜택 을 즉시 제공한다.
<i>pe</i>	요구되어진 비화폐성 혜택 을 즉시 제공한다.
<i>src</i>	Choose this option to make the current preset load whenever a new multi Instrument is created.
<i>mt</i>	새 멀티 계측기 가 생성될 때마다 현재 사전 설정된 로드 를 만들려면 이 옵션을 선택하십시오.
PePe	새 multi instrument 가 생성될 때마다 현재 preset 을 만들려면 이 옵션을 선택하십시오.
<i>pe</i>	새 multi instrument 가 생성될 때마다 현재 preset load 를 만들려면 이 옵션을 선택하십시오.
<i>ko</i> → <i>en</i>	
<i>src</i>	겨울왕국 2 속에 나오는 장면이 있다.
<i>mt</i>	there is a scene in winter kingdom 2 .
PePe	there is a scene in frozen 2 .
<i>pe</i>	there is a scene in frozen 2 .
<i>src</i>	<u>관사</u> 아래에 있는 모음코드가 이렇게 바뀌어진다.
<i>mt</i>	the vowel code under the official building changes like this.
PePe	the vowel code under the article changes like this.
<i>pe</i>	the vowel code under the article changes like this.

Table 4: Qualitative examples of post-edited sentences generated from PePe. User-specific parts in *pe* and corresponding parts in *mt* are colored. We highlight the post-edited words in PePe with bold if the words are identical to *pe*. Corresponding parts in *src* are underlined. Our model finds an appropriate combination of attributes in accordance with sentences and users.

that relies on paired sentences (*src*, *mt*). In addition, the results also show that even if *pe* is not edited from the *mt*, PePe translates the source sentence close to the ground-truth target sentence that connotes the speaker’s characteristics.

Fig. 5 shows that our model works well regardless of the number of users. Grey-colored lines are the performance of the baseline model, and colored lines are the performance of PePe. TER axis is reversed on the graph to make consistency with the BLEU score. Note that the higher points denote a better score than the lower points.

Furthermore, we conduct additional experiments that show the robustness of our approach regarding the number of clusters and adjustment rates, which are hyperparameters. We represent the results in Appendix B.

4.4 Qualitative Analysis

To understand how user-specific preferences are incorporated into the sentences, we qualitatively analyze the post-edited results of our model as shown in Table 4. A typical example of the multi-attribute correction appears in the first row, which changes the sentence structure and the preferred word choices. Our model tends to retain the overall meaning of the source sentence while precisely treating an abstractive personal behavior. The output of PePe in the second row tends to keep loanwords in English instead of translating them into Korean (*i.e.*, “*multi instrument*”, “*preset load*”),

while *mt* suffers from generating sentences that consider those preferences. An example of changing a homonym to a suitable word is shown in the last row. Since “*official building*” and “*article*” are homonyms in Korean, PePe chooses the word that is appropriate for the semantic meaning of the sentence. We further provide several examples that consider the multidimensional attributes in Appendix C. In either a single attribute or a multi attributes case, our model properly reflects distinct preferences.

5 Conclusion

In this work, we propose a personalized post-editing method, PePe, utilizing user-generated post-edits. Based on the APE framework, PePe leverages two modules, 1) user-specific parameters and 2) a semantic cluster-based discriminator module. These modules lead to reflect the multifarious interpersonal variations, where the former allows the model to learn user-dependent probabilities for each word while the latter unlearns the detrimental features in a pre-trained language model and maintains advantageous effects of the transfer learning. We empirically demonstrate that PePe reflects fine-grained user preference in a variety of settings. To the best of our knowledge, this work is the first attempt to utilize the APE framework with the user-generated post-edits for personalized translation. We believe that our work can draw more attention toward personalized translation, which is the ul-

timate direction that the neural translation model should go forward.

6 Limitations

Promising future work is analyzing the pattern of personalization depending on language pairs. Depending on the nationality of users, the pattern of personalization may appear differently due to cultural differences, and extensive experiments on various language pairs are required to analyze this. In addition, if anyone can access the personalized model, there is a potential risk that the model can be abused to disguise itself as a specific individual. Therefore, there is a need for a strategy of limiting the authority to access the personalized model or verifying a person who uses the personalized model.

Supplementary Material

This material complements our paper with additional experimental results and miscellaneous details. Section A provides the implementation details. Section B addresses the additional experiments that show the robustness of our model against a varied number of clusters and adjustment rates. In Section C, we demonstrate the variety of qualitative examples of post-edited sentences generated from PePe.

A Training details

Data Preprocessing. For the data preprocessing, we first filter out the duplicate lines and normalize the data such that each line represents a single sentence. Also, we exclude sentence that is longer than 100 words. Then, we utilize term frequency inverse document frequency (TF-IDF) to compute the user similarity score and filter out the noisy users. To be specific, we form a document for each user by aggregating *src*. If a particular user has a lower than 0.1 similarity score, we exclude those users. We assume that if a user has a lower similarity score with others, then those users may contain noisy sentences. After preprocessing noisy data for USP, we divide the dataset into train/valid/test, which results in 5,207, 1,001, and 1,125 samples for Korean to English language pair, and 6,330, 1,360, and 1,357 samples for English to Korean. Since we split into train/valid/test for each user, the user appearing in the train dataset guarantees to appear in the test dataset.

Training and Inference Procedures. The main difference between training and inference procedures is the existence of a discriminator module. In other words, the clustering module and the discriminator are not utilized during the inference procedure. However, similar to the training procedure, we utilize the trained user-specific bias vector that corresponds to the user ID of each input sentence while generating a post-edited sentence.

Evaluation and HyperParameter Details. We evaluate all experiments based on SacreBLEU⁴, TER⁵, and YiSi-1⁶ scores. Since YiSi-1 requires pre-trained word embedding vectors, we utilize fastText⁷ to pretrain word embeddings. For the

Hyperparameters	Value
Pre-trained LM	BERT-base-multilingual
Learning rate	0.00005
Batch size	512
Accumulation step	2
Optimizer	AdamW
Dropout	0.1
Label smoothing	0.1
Random seed	42, 101, 1215, 1129, 909
Decoding strategy	Beam search
Beam size	3

Table 5: Hyperparameter settings. AdamW (Loshchilov and Hutter, 2019) is the Adam (Kingma and Ba, 2015) optimizer with weight decay.

hyper-parameter settings, we use 10 clusters with 0.3 adjustment rates for all the experiments in the main paper. We select the combination of hyperparameters by manual tuning, which achieves the highest performance in the validation set based on the TER metric. Conditions for early-stopping and decoding are equally applied to the baselines. We follow the settings of hyperparameters in Correia and Martins (2019) except sharing the weight of the encoder and the decoder. We conducted all the experiments five times, and the random seeds used were 42, 1215, 101, 909, and 1129. We selected the highest performance learning rate value between 0.00005 and 0.0001. We report the configuration of our best model in Table 5.

Environment Details. All experiments in Table 1 is examined with CentOS Linux release 7.8.2003, Tesla P40 GPU, and Intel Xeon CPU E5-2630. Results in Table 3 are examined with Ubuntu 16.04.6, Intel Xeon processor, and Tesla V100-PCIE-32GB GPU. The versions of the libraries we used in all experiments are 3.7.6 for Python and 1.4.0 for Pytorch.

B Robustness to the number of cluster and hyperparameter

In the main paper, we conduct all experiments with 10 cluster labels. However, to be useful for the varied settings, it is crucial to demonstrate the model’s robustness to the number of clusters and adjustment rate. Here we provide the results trained on 30 cluster labels with various adjustment rates from 0.1 to 0.5. Identical with Table 1, we utilize *en*→*ko* dataset of 30 users. Table 6 indicates that PePe

Models	BLEU \uparrow	TER \downarrow
Uncorrected	64.9	21.1
DS-BERT	68.5	21.1
PePe (k30, m0.1)	70.2	20.2
PePe (k30, m0.2)	69.7	20.3
PePe (k30, m0.3)	69.9	19.9
PePe (k30, m0.4)	69.0	20.8
PePe (k30, m0.5)	70.2	20.3

Table 6: Experiments on various hyperparameter settings on a USP dataset. k denotes the number of clusters and m denotes the adjustment rate.

consistently generates high-quality sentences, regardless of the hyperparameters.

C Additional qualitative examples

This section provides additional qualitative examples from PePe. We choose the samples from the inference results of USP dataset, and both $ko \rightarrow en$ and $en \rightarrow ko$ language pairs are reported. As shown in Table 7, Table 8, Table 9, Table 10, Table 11, and Table 12, the tables are organized according to the typical personalization cases (*i.e.*, error correction, word choice, politeness, and multiple attributes). **Red color** represents error correction case, **Yellow color** represents word choice case, and **Green color** represents politeness case. Each case also accompanies the insertion and deletion of the words (*i.e.*, tokens). Sentences inferred from PePe show that it well reflects the personal traits of each user and the characteristics of each language.

D Importance of personalized translation

The importance of stylized translation can stand out in certain scenarios, such as the translation of everyday conversations. For example, when an English speaker uses a translator to talk to a German speaker, he or she may wish to communicate with a translation result that includes an individual’s personality rather than a normal translation of a neutral tone (e.g., replacing with a word that the user likes to use). At this time, our personalized translation methodology can be used to deliver translation results containing the user’s personality to the German speaker without post-processing. We believe that in order for a translation model to be utilized in the everyday conversation of various users, it is ultimately important to consider the individuality of each user beyond fluency.

Abstract

In multi-turn dialog understanding, semantic frames are constructed by detecting intents and slots within each user utterance. However, recent works lack the capability of modeling multi-turn dynamics within a dialog in natural language understanding (NLU), instead leaving them for updating dialog states only. Moreover, humans usually associate relevant background knowledge with the current dialog contexts to better illustrate slot semantics revealed from word connotations, where previous works have explored such possibility mostly in knowledge-grounded response generation. In this paper, we propose to amend the research gap by equipping a BERT-based NLU framework with knowledge and context awareness. We first encode dialog contexts with a unidirectional context-aware transformer encoder and select relevant inter-word knowledge with the current word and previous history based on a knowledge attention mechanism. Experimental results in two complicated multi-turn dialog datasets have demonstrated significant improvements of our proposed framework. Attention visualization also demonstrates how our modules leverage knowledge across the utterance.

1 Introduction

In conventional task oriented dialog systems, natural language understanding (NLU) modules aim to transform utterances into meaningful semantic representations for dialog management (Weld et al., 2021; Zhang et al., 2020). It mainly detects associated dialog acts or intents and extracts key slot information as so-called ‘semantic frames’ (Abbeduto, 1983), shown in Table 1. Humans usually associate relevant knowledge and previous contexts with current utterance’s entities to understand an utterance. Similarly, models’ prediction of overall intent semantics and slot values can benefit from act relations such as ‘Inform’ may follow ‘Request’ acts, and background knowledge which is usually

Speaker	Utterance
1. User	Is there something that’s maybe a good intelligent comedy ?
Act & Slots:	<i>Request (genre: comedy)</i> <i>(intelligent; related to; well_informed)</i> <i>(comedy; related to; comic)</i> <i>(comedy; is a; drama)</i>
2. System	Whiskey Tango Foxtrot is the only Adult comedy I see playing in your area . Would you like to try that?
Act & Slots:	<i>Inform (movie: Whiskey Tango Foxtrot)</i> <i>Inform (genre: Adult comedy)</i> <i>Inform (distance limits: in your area)</i> <i>Confirm_question</i>
Knowledge:	<i>(foxtrot; related to; dance)</i> <i>(foxtrot; related to; rhythm)</i> <i>(adult; capable of; work)</i> <i>(area; is a; region)</i>

Table 1: Excerpt of a single turn within a dialog with corresponding dialog acts, slots and knowledge samples that are related to **keywords** in the utterance.

represented as triples in knowledge graphs (Wang et al., 2021a).

However such intuition has not been emphasized when automating NLU tasks. In early attempts of NLU systems, utterances were isolated and analyzed separately for user intents and semantic slots (Raymond and Riccardi, 2007; Liu et al., 2017). Models that maximize the joint distribution likelihood were proposed to allow transitions between two tasks (Liu and Lane, 2016; Wang et al., 2018; Wu et al., 2021a; Li et al., 2018a). While driven by large pretrained corpora, these methods still fall short of employing complete dynamic interactions within dialogs, especially in multiple intent cases (Qin et al., 2019; Rashmi Gangadharaiah, 2019; Qin et al., 2020). Some works have then integrated dialog contexts for more robust NLU (Wang et al., 2019; Gupta et al., 2019; Su et al., 2021; Wu et al., 2021c). However, many of them could not capture dialog flows well with RNN encoders or explain how contexts should affect the slot filling task.

Publicly available models like BERT or XLNet

provide universal contextualized representations that could be adapted for learning task-oriented contexts. However, it may not give full play to its value when tagging some rare words like *Foxtrot* together with *Tango* as *Movie* in Table 1 that may appear in a domain-specific dataset. One can pretrain these models beforehand emphasizing such phrase relationship which nevertheless tends to be time-consuming and computationally expensive. Therefore, directly integrating external knowledge like a knowledge graph (KG) becomes a more tractable solution (Liu et al., 2019; Zhang et al., 2019b; Wu and Juang, 2022b).

However, there are mainly three challenges lying in the way of such integration: (1) **Heterogeneous information fusion**: the vector space of KG entities is inconsistent with that of the pre-trained models. (2) **Knowledge noise**: overwhelming knowledge for models may adversely cause redundant noises for more ambiguity. Many works in knowledge grounded dialog generation has applied term-level denoising (Zheng et al., 2021) or filtering techniques (Wang et al., 2021b) to refine the adopted knowledge for better semantic considerations. (3) **Inter-token knowledge sharing**: Wang et al. (2019) predicts a slot for a given word along with its own associated knowledge. However, real sentences may contain phrases where knowledge between words should be shared to probably enrich the entire utterance semantics. To overcome these challenges and ground knowledge in contextual NLU, which is less explored in the research community, we propose a **Context and Knowledge Awareness NLU Framework (CKA-NLU)** to effectively incorporate relevant knowledge and dialog history in dialog understanding.

The key ingredients lie in how we can efficiently integrate relevant knowledge and previous history for understanding. We first introduce a context attention module to retrieve context-aware representations. Different from previous works of determining a given word’s slot based on its own knowledge, our objectives require models to aggregate both previous dialog contexts and all intra-sentence knowledge facts together to formulate context-attended knowledge vectors in the same space. Such vectors are a weighted combination of all knowledge facts based on the aggregated information until the current turn. We use attention masks and filtering to remove adversarial effects from redundant knowledge noises. Finally

we adopt these context-attended vectors for NLU tasks with RNN decoders. Experiment results have shown superior performances of our methods that beat all competitive baselines.

Our contributions are as follows:

1. We propose a novel CKA-NLU framework that incorporates inter-word knowledge with inter-sentence contexts to fill the void of relevant knowledge exploration for important NLU tasks.
2. We demonstrate the benefits of adopting knowledge for token-level slot filling and dialog history for sentence-level intent detection.
3. Experimental and attention visualization results show that our model achieves superior performances over several competitive baselines and demonstrates how our model adopts the knowledge.

2 Problem Formulation

For each utterance $x_n = \{w_1^n, w_2^n, \dots, w_T^n\}$ in a task-oriented dialog \mathbf{X} with N utterances, given the domain ontology of a dialog act set \mathbf{A} and a slot set \mathbf{S} , we aim to find one or more acts $\{a_i^n\}$ ¹ and a sequence of slot tags $\{s_1^n, s_2^n, \dots, s_T^n\}$ to construct a semantic frame. Namely, we hope to maximize the joint log likelihood of \mathbf{A} and \mathbf{S} in Eq 1 given a parametrized model θ , its context $\mathbf{C}_n = \{x_1, \dots, x_{n-1}\}$ and associated knowledge $\mathbf{K}_n = \phi(K_G, x_n)$ for the current utterance x_n . We deem K_G as an external large knowledge base with knowledge represented as triples (head h , relation r , tail t) and $\phi(\cdot)$ helps to extract related knowledge pairs for x_n (§3.2.1). It will be critical to match correct knowledge based on current dialog history and the utterance for better dialog understanding.

$$\mathcal{L}(\mathbf{A}, \mathbf{S}) \triangleq \sum_n \log P(A_n, S_n | x_n, \mathbf{C}_n, \mathbf{K}_n; \theta) \quad (1)$$

3 Methodology

3.1 Context Attention

Our overall framework is illustrated in Figure 1. To allow information flow across the dialog, we first encode the entire dialog with a token-level BERT (Devlin et al., 2019) encoder and a turn-level context-aware transformer encoder. Instead of concatenating all sentences which may cause an extreme sequence length, we first generate the token-level representations $\mathbf{H} = \{h_1, h_2, \dots, h_N\}$

¹Dialog acts and intents are equivalent and interchangeably used in this paper.

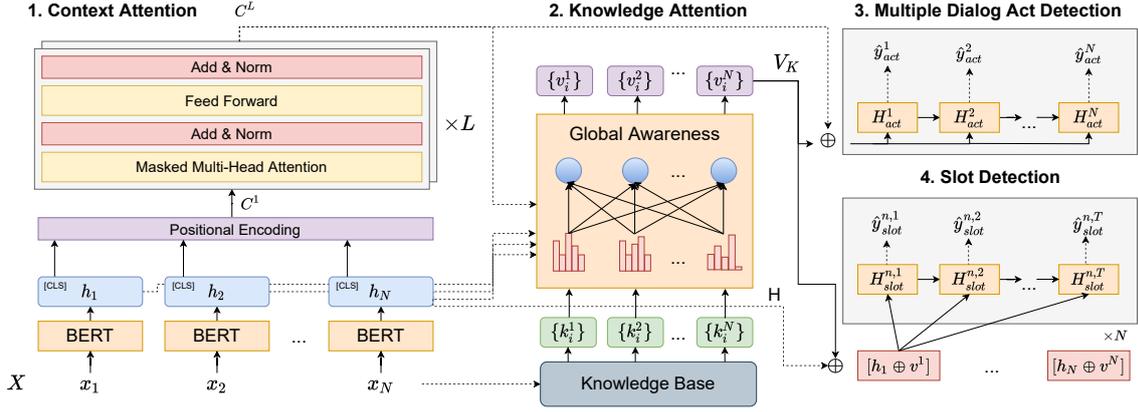

Figure 1: Illustration of our proposed framework for joint dialog act detection and slot filling in multi-turn dialogs. It consists of context and knowledge attention modules, and two LSTM-based decoders. The utterance-level representations will be encoded with the context attention module and token-level representations will interact with their corresponding knowledge in three proposed awareness submodules.

for each utterance x_n in a dialog X by taking vectors from each [CLS] token. During testing at turn n , we may directly reuse these calculated representations $\{h_1, h_2, \dots, h_{n-1}\}$ until turn $n - 1$.

In contrast with other contextual NLU (Wang et al., 2019; Gupta et al., 2019) with hierarchical components, we introduce a GPT-like unidirectional transformer encoder with the hidden size H_a to encode $\mathbf{H} \in \mathbb{R}^{N \times H_b}$. It consists L layers of masked multi-head self-attention (MHA), point-wise feed forward network (FFN), residual sublayer and layer normalization. The future time steps are masked for training since we will not have access to future utterances during testing. We will send \mathbf{H} as the first layer input \mathbf{C}^1 and iteratively encode it with two sublayers in Eq 2. Each head $\mathbf{C}_i \in \mathbb{R}^{N \times (H_a/h)}$ will be first mapped into a query \mathbf{C}^Q , a key \mathbf{C}^K and a value \mathbf{C}^V which participate in the multi-head self-attention. Here $f(\cdot)$ is softmax function. Finally, we will obtain the final contextual dialog representations \mathbf{C}^L .

$$\mathbf{C}^1 = \text{FFN}(\text{MHA}(\mathbf{C}^{1-1}, \mathbf{C}^{1-1}, \mathbf{C}^{1-1})) \quad (2)$$

$$\text{MHA}(\mathbf{C}_i^Q, \mathbf{C}_i^K, \mathbf{C}_i^V) = f\left(\frac{\mathbf{C}_i^Q (\mathbf{C}_i^K)^T}{\sqrt{H_b}}\right) \mathbf{C}_i^V \quad (3)$$

$$\text{FFN}(x) = \max(0, x \mathbf{W}_1 + b_1) \mathbf{W}_2 + b_2 \quad (4)$$

3.2 Knowledge Attention

Humans could naturally associate contexts with relevant knowledge to predict semantics. Here we elaborate on how we can leverage current contexts

$\mathbf{C}^L = \{c_n^L\}$ and a relevant knowledge base K_G to induce the intents and slots for each utterance x_n .

3.2.1 Knowledge extraction

The first step is to gather all necessary knowledge triples $\gamma = \{h, r, t\}$, which are head h and tail t entities with their relation r , related to the current utterance $x_n = \{w_1^n, w_2^n, \dots, w_T^n\}$. For each word w_i^n , we first retrieve a list of triples with the exactly same head entity being w_i^n from a knowledge base K_G . If no head entities are matched, we instead seek entities that has a substring of w_i^n . Each triple in the pretrained K_G (Bordes et al., 2013) has a pre-given relation weight $w_r \in [0, 1]$. For each w_i^n , we select $|K|$ triples that have the largest $|K|$ weights as the final word-level knowledge k_i^n . We will finally obtain a T length knowledge sequence $\mathbf{K}_n = \{k_1^n, k_2^n, \dots, k_T^n\}$ gathered from each word w_i^n . In case of non-alphabetic or out-of-vocabulary (OOV) words with no match in K_G , we instead replace their \mathbf{K}_n as zero vectors to represent agnosticism of knowledge.

3.2.2 Global awareness

To improve the heterogeneous information fusion between contexts and knowledge, after obtaining the knowledge sequence $\mathbf{K}_n = \{k_i^n\}$ (i.e. total $T \times |K|$ triples $\gamma = \{h, r, t\}$), we aim to obtain the context-attended knowledge sequence $\mathbf{V}_K = \{v_i^n\}$ by selecting the most appropriate knowledge (i.e., removing redundant knowledge noise) within the entire sentence, given each word w_i^n and its previous dialog history c_n^L . Different from the term-level denoising like Zheng et al. (2021) and Wang et al. (2019), to allow phrase-level knowledge sharing,

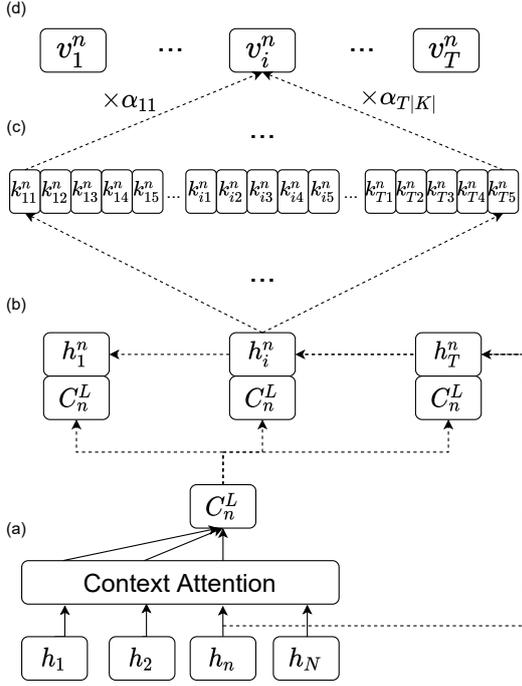

Figure 2: Knowledge Attention Diagram. (a) Context Attention module will first process the dialog history and produce context-aware vectors for each utterance. (b) Token-level representation will be concatenated with the context-aware vector. (c) The fused vector will be used to calculate the attention weights for every knowledge vector in the utterance. (d) The final context-attended knowledge vector will be the weighted combination of all knowledge vectors.

for each word, we aim to globally select all related knowledge in the sentence after seeing previous turns C_n^L . This will allow us to possibly consider knowledge of words in the same phrase.

Shown in Figure 2, we calculate the vector v_i^n where r_{ij}^n , t_{ij}^n are j -th relation and j -th tail entity vectors for the word w_i^n . \mathbf{W}^H , \mathbf{W}^R , \mathbf{W}^T are learnable matrices during training. $[\cdot]$ is the concatenation of two vectors:

$$v_i^n = \sum_{i=1}^T \sum_{j=1}^{|K|} \alpha_{ij} [r_{ij}^n; t_{ij}^n] \quad (5)$$

$$\alpha_{ij} = \exp(\beta_{ij}) / \sum_{i'=1}^T \sum_{j'=1}^{|K|} \exp(\beta_{i'j'}) \quad (6)$$

$$\beta_{ij} = (\tilde{h}_i^n \mathbf{W}^H) (\tanh(r_{ij}^n \mathbf{W}^R + t_{ij}^n \mathbf{W}^T))^T \quad (7)$$

$$\tilde{h}_i^n = [h_i^n; c_n^L] \quad (8)$$

We first concatenate the token-level representations for each word h_i^n in the utterance x_n with its context vector c_n^L , which entails the embedded information from previous turns (Eq 8). Then we use \tilde{h}_i^n

to calculate the attention weight α_{ij} with any of the knowledge (r_{ij}^n, t_{ij}^n) related to this utterance (Eq 6, 7). Eventually, we linearly combine all knowledge vectors together to formalize the context-attended knowledge vector v_i^n (Eq 5). Additionally, to avert the noise from zero-vectors of non-alphabetic word knowledge, we introduce an attention mask to calculate α_{ij} only on the non-zero knowledge vectors.

3.3 Semantic Decoder

After obtaining the context-attended knowledge $\mathbf{V}_K = \{v_i^n\}$, context vectors \mathbf{C}^L and initial token-level vectors \mathbf{H} , we adopt two BiLSTMs to predict multiple dialog acts and slots which exhibit the sequential information in BIO scheme.

$$\mathbf{H}_{\text{act}} = \text{BiLSTM}([\tilde{\mathbf{H}}; \mathbf{V}_K]) \quad (9)$$

$$\mathbf{H}_{\text{slot}} = \text{BiLSTM}([\mathbf{H}; \mathbf{V}_K]) \quad (10)$$

For dialog act detection, we concatenate \mathbf{V}_K with the fused context $\tilde{\mathbf{H}} = ([\mathbf{H}; \mathbf{C}^L]) \mathbf{W}^H$ from the attention mechanism and serve as the inputs of BiLSTM. For slot filling, since the task focuses more on token-level information for decision, we only concatenate raw token-level representations and \mathbf{V}_K to be inputs of another BiLSTM, which empirically works better. Finally, we can generate logits $\hat{y}_{\text{act}} = \sigma(\mathbf{H}_{\text{act}} \mathbf{W}_{\text{act}})$ by transforming \mathbf{H}_{act} with $\mathbf{W}_{\text{act}} \in \mathbb{R}^{H_L \times |\mathcal{Y}^a|}$ and a sigmoid function σ . H_L is LSTM hidden size and $|\mathcal{Y}^a|$ is the size of dialog act set. Likewise, we compute $\hat{y}_{\text{slot}} = \text{softmax}(\mathbf{H}_{\text{slot}} \mathbf{W}_{\text{slot}})$. Total loss will be the combination between the binary cross entropy loss based on \hat{y}_{act} and the cross entropy loss based on \hat{y}_{slot} as shown in Eq 11, 12. Finally, the joint objective is formulated as the sum of \mathcal{L}_a and \mathcal{L}_s .

$$\mathcal{L}_a \triangleq - \sum_{n=1}^N \sum_{a=1}^{|\mathcal{Y}^a|} (y_a^n \log(\hat{y}_a^n) + (1 - y_a^n) \log(1 - (\hat{y}_a^n))) \quad (11)$$

$$\mathcal{L}_s \triangleq - \sum_{n=1}^N \sum_{t=1}^T \sum_{s=1}^{|\mathcal{Y}^s|} (y_s^{(n,t)} \log(\hat{y}_s^{(n,t)})) \quad (12)$$

4 Experiment Setting

4.1 Experimental setup

We evaluate our proposed framework on two large-scale dialog datasets, i.e. Microsoft Dialog Challenge dataset (MDC) (Li et al., 2018b) and Schema-Guided Dialog dataset (SGD) (Rastogi et al., 2019). MDC contains human-annotated conversations in

three task-completion domains (movie, restaurant, taxi) with total 11 dialog acts and 50 slots. **SGD** entails large-scale task-oriented dialogs over 20 domains ranging from travel, weather to banks, etc. It has total 18 dialog acts and 89 slots. To compare the relevant knowledge usage in different domains and save computational resources, we randomly select 1k dialogs for each domain in MDC and two restaurant and flights domains from SGD for total 5k dialogs in 6:1:3 train, validation, test ratio. For SGD, Restaurant domain is chosen to compare with that of MDC and Flights domain is the one not existing in MDC. Each utterance is labeled with one or more dialog acts and several slots.

4.2 Baselines

We compare our models with several competitive baselines which sequentially include more features:

- **MID-SF** (Rashmi Gangadharaiyah, 2019) considers joint multi-intent and slot detection in use of BiLSTMs.
- **ECA** (Chauhan A., 2020) encodes the dialog context with LSTM for joint tasks.
- **KANLUM** (Wang et al., 2019) extracts knowledge from the knowledge base and incorporates dialog history for joint tasks.
- **ERNIE** (Zhang et al., 2019b): We take ERNIE backbone to integrate knowledge entities and take the token and entity outputs for intent detection and slot filling directly.
- **LABAN** (Wu et al., 2021b) leverages label information to construct a latent semantic space for utterance projection. It is mainly for the multiple intent detection task only.
- **CASA-BERT** (Gupta et al., 2019) encodes the context with sentence2token and DiSAN which we replace with BERT for fair comparison with other BERT-based models.

We also perform several variations of our proposed framework to conduct the ablation study with the following detailed descriptions.

- **Less-Relevant knowledge triples (LR-KA)**: We replace the top $|K|$ knowledge triples with the less related knowledge triples ranked from $|K| \sim 2|K|$ (from relation weights in K_G) to perform sensitivity analysis on the quality of knowledge.
- **Word-Level knowledge attention (WL-KA)**: We use the attention-based filter (AF) (Wang et al., 2021b) to perform token-level knowledge

attention instead of sentence-level attention in our framework.

- **Transformer decoder (Trans)**: We replace the semantic decoder (§ 3.3) with a transformer decoder to both predict dialog acts and slots.

4.3 Implementation details

We adopt the pretrained **BERT_{base}** (Devlin et al., 2019) as our utterance encoder. Context attention transformer has $L = 6$ -layer attention blocks with 768 head size and 4 attention heads. The max sequence length is 60. We use ConceptNet knowledge base (Speer et al., 2018) to obtain relevant knowledge for attention. It involves many crowd-sourced and expert-created resources like DBpedia, OpenCyc and WordNet with 1.5M word entities connected with weighted edges (relation). Each word or relation is represented as a dense 100-dim vectors by adopting TransE (Bordes et al., 2013) learning mode. Each knowledge also contains an ExternalURL to represent the external source. We retrieve $|K| = 5$ most related knowledge from each word based on weights assigned on the edges. Both LSTMs have 256 hidden units. We use the batch size of 2 dialogs for MDC and 1 for SGD. In all training, we use Adam optimizer with learning rate as $5e-5$. The best performance on validation set is obtained after training 30 epochs on each model. For metrics, we report the dialog act accuracy (exact match) and slot filling F1 score. Here we only consider a true positive when all BIO values for a slot is correct and forfeit ‘O’ tags.

5 Main Results

5.1 Main results

Table 2 shows our main results on the joint task performance. MID-SF with only LSTMs has relatively inferior performance on both datasets especially in SGD. ECA by taking dialog contexts into consideration has much greater increase in SGD than in MDC. ERNIE and KANLUM have better slot filling performance which suggests the importance of further knowledge induction. Leveraging BERT-based encoder seems to substantially increase semantic visibility in ERNIE, CASA-BERT and our proposed framework, while introducing dialog contexts additionally gives better dialog act detection performance in CASA-BERT and our model. Eventually, our proposed framework beats all baselines both in MDC and substantially in SGD, by more

Table 3: Ablation Results of joint tasks (%) by removing some key components of our proposed model: CKA-NLU.

efficiently incorporating external knowledge and dialog contexts with the proposed global awareness attention mechanism.

5.2 Ablation analysis

To better estimate the effectiveness of each module of our best model, we conduct ablation experiments in Table 3. We ablate or replace each component from CKA to observe the performance drops. First, we could see knowledge quality may affect the performance of joint tasks where most performance drops are observed with LR-KA, while we found that slot accuracy may increase if the overall extracted knowledge is less relevant to utterances. To note, the word matching accuracies in the knowledge base are 78.12% (MDC) and 80.97% (SGD), which indicates that there is still about 20% of zero vectors introduced as redundant noises. Second, considering global knowledge across the entire sentence has overall better performance than only word-level knowledge, where knowledge of some phrases should be treated jointly. Finally, we see a single transformer decoder may still entangle the act and slot information by updating gradients simultaneously with poorer performance.

By removing the entire knowledge attention module, we could see a larger accuracy decrease in slot filling tasks, denoting the necessity of external knowledge in enriching the current word representations. By substituting a LSTM on top of BERT

for our context attention module (CA), we obtain poorer performance in dialog act detection. By replacing two LSTMs with fully connected layers after knowledge attention, the performance drops especially in SGD. Overall, we observe dialog act detection relies more on contexts while slot filling tasks may concentrate on inter-utterance relations where external knowledge benefits more instead.

5.3 Further Discussion

Could knowledge amend the data scarcity? We also study how knowledge could contribute to the joint tasks when resources are scarce. Figure 3 shows the performance changes with different numbers of training data. We found that inducing the knowledge will have the positive effect on both tasks. In the few-shot setting, we see the performance difference enlarges where knowledge becomes beneficial to enrich the external information aside from data itself. However, knowledge becomes less useful when we have extreme low dataset particularly for slot detection in MDC. Introducing more MDC data at a certain point may contradict with the external knowledge data base that possibly makes models hard to generalize, while it helps dialog act detection that amends the training instability from data scarcity.

Does global knowledge help non-alphabetic slots? We are interested if knowledge for other words would also help with the slot prediction of

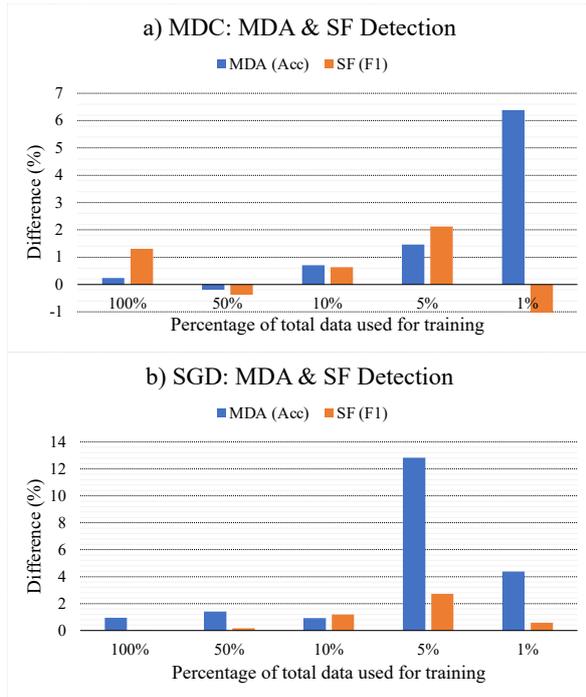

Figure 3: NLU performance gain by using knowledge in CKA-NLU with a subsample (%) of the original training data of two datasets: MDC and SGD.

non-alphabetic words. Table 4 shows the results for each non-alphabetic slot for our global and local attention models. Since there is no knowledge for the non-alphabetic words, we observe an overall 2% increase by inducing global attention. Contexts are beneficial especially for slots associated with rating, money and address, which should be likely inferred by other keywords near them. However, introducing more knowledge noises may not help to predict time and zip code since they are rather independent to contexts.

5.4 Knowledge Attention

In Figure 4, we visualize the attention heatmap of tokens with their slot labels vs. all knowledge triples from each token. First, we focus on the rows of the heat map. Without attached knowledge for the words like numbers or punctuations, their attention weights are perceived blank across all tokens in the utterance. Second, for valid attention weights, we found the knowledge corresponding to keywords like ‘you’, ‘with’, ‘restaurant’ and ‘antioch’ are most adopted for overall knowledge representations across all the utterance. It elucidates that the model will mostly grasp knowledge in words especially tagged as valued slots (non-O tag) for overall semantic understanding. Interest-

Slot	CKA-NLU (%)	WL-KA (%)	Δ (%)
address	17.39	0.00	+17.39
price	66.67	50.00	+16.67
critic_rating	34.48	23.08	+11.41
dress_code	50.00	44.44	+5.56

zip_code	77.65	84.44	-6.80
pickup_time	75.19	82.29	-7.09
total	65.83	63.80	+2.03

Table 4: F1 scores of non-alphabetic slots in overall SGD dataset when using all (CKA-NLU) or word-level (WL-KA) knowledge.

ingly, this collection of knowledge is more emphasized on predicting a word to be non-valued than those words with valued slots. For the columns, we could see for non-valued words, they will rely on knowledge of valued words like ‘restaurant’ and ‘antioch’, than the knowledge related to itself. It substantiates the belief that the overall semantics of the utterance may be driven by these valued words.

In Table 5, we further show an utterance example with some highlighted words including ‘you’, ‘restaurant’ and ‘Antioch’ with their extracted knowledge and weights for semantic detection. We take the average of all attention weights across all tokens for that knowledge triple; then normalized across the knowledge triples in the same word (head). We could see ‘you’ as an object is most adopted to clarify the user being offered and informed counts. Then we observe that the knowledge triple (*restaurant, atl, city*) where *restaurant is at a location of the city* is most recognized to illustrate the relations of restaurant and city tags. Finally, knowledge for ‘Antioch’ keyword is mostly relevant to a country which is conducive when the system seldom sees this word during training. But without further contexts, our model believes ‘Antioch’ is more of a part of Turkey.

6 Related Work

Intent detection and slot filling are two main NLU tasks (Weld et al., 2021). Many classification or clustering approaches (Sarıkaya et al., 2011; Raymond and Riccardi, 2007; Liu et al., 2017; Wu and Juang, 2022a) had been proposed for single intent detection. However, treating two tasks separately may experience error propagation. Liu and Lane

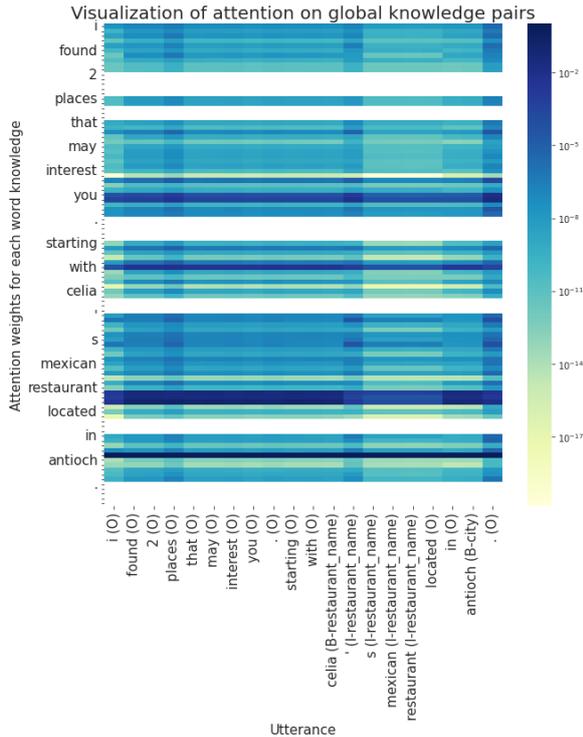

Figure 4: Attention visualization of a single utterance example with respect to all knowledge related to each word. We denote an utterance with tokens followed by their predicted tag in x-axis. For y-axis, each word will have five knowledge triples with each as a single tick. The blank area is where attention weights are zero.

(2016) first proposed an attention-based LSTM network to model the correlations between intents and slots. Li et al. (2018a) proposed the gating mechanism for better self-attention on joint tasks, which is not scalable for longer sequences. Wang et al. (2018) instead proposed the bi-model to directly model the cross impacts and Zhang et al. (2019a) utilized capsule neural networks. Memory networks are also popular choices to model long-range dependency (Wu et al., 2021a). However, a single utterance may have many intents. Qin et al. (2019) proposed a stack-propagation networks to predict intents on each token. Rashmi Gangadhariah (2019) and Qin et al. (2020) considered the dynamic interactions between two tasks by jointly detecting multiple intents. Wu et al. (2021b) extended the multiple intent scenario with zero-shot cases. These methods nevertheless restrict their resources to current utterances for prediction where we consider the multi-turn dialogs jointly where dialog acts could be context-sensitive (Bothe et al., 2018).

Contexts and knowledge Contexts are also crit-

Utterance Example in Figure 4	
Utterance	I found 2 places that may interest you. Starting with Celia's Mexican restaurant located in Antioch.
Dialog acts	Offer, Inform Count
Slots	O O O O O O O O O B-res I-res I-res O O B-city
Keyword	Knowledge
you	(hc, noun) (0.29), (hc, object) (0.7) (rel, guys) (6e-4)
restaurant	(isa, establishment) (8e-9), (atl, hotel) (0.2) (atl, town) (0.14), (atl, city) (0.65)
Antioch	(rel, orontes) (4e-5), (rel, swiss) (2e-2) (rel, usa) (5e-2), (ptof, turkey) (0.9)

Table 5: The utterance example in Figure 4 for joint task prediction. Knowledge (Relation, Tail) related to three keywords as head are presented with their attention weights (number after the knowledge). We only show the top four knowledge adopted for each keyword based on the attention weights. ‘hc’ represents ‘has context’, ‘rel’ represents ‘related to’, ‘atl’ represents ‘at location’ and ‘ptof’ represents ‘part of’.

ical for dialog understanding. Bertomeu et al. (2006) first studied the contextual phenomena in words. Bhargava et al. (2013) and Shi et al. (2015) then introduced contextual signals to the joint intent-slot tasks. Advanced hierarchical structures are also emphasized to encode multi-turn dialog contexts efficiently (Chauhan A., 2020; Wang et al., 2019; Gupta et al., 2019; Wu et al., 2021c). Knowledge is also another important resource to induce commonsense for understanding. It is widely adopted for knowledge-enhanced pretraining to enrich representations (Liu et al., 2019; Zhang et al., 2019b). In task-oriented dialogs, main emphasis lies in the interaction with task-related knowledge bases (Madotto et al., 2020; Yang et al., 2020). Most of works also focus on open-domain dialog response generation (Zhao et al., 2020; Wang et al., 2021b; Rashkin et al., 2021; Zheng et al., 2021) or task-specific responses (Wang et al., 2021a). However, commonsense knowledge is seldom adopted in NLU. Wang et al. (2019) tried to apply knowledge in NLU but it is not suitable for complex dialog modeling. To amend the gap in modeling such knowledge and context interactions, we follow these previous works’ paradigms and explore the mechanisms of characterizing their mutual effects.

7 Conclusion

In this paper, we propose a novel BERT-based knowledge-augmented network to effectively incorporate dialog history and external knowledge in the joint NLU tasks. Compared to recent works

which consider only intra-word knowledge, we instead raise the knowledge awareness by selecting all relevant knowledge triples in an utterance with the current dialog contexts. We found that our framework is verified to be effective in two complex multi-turn dialog datasets where contexts and knowledge are crucial in dialog act detection and slot filling respectively. The visualization shows that our models adopt some key knowledge in particular words and learn to grasp useful information for better interpretability. These context-attended knowledge vectors could be easily applied to downstream dialog state tracking or management tasks.

Limitations

The possible limitations for our works are two-folds. First, the scalability of our method is subject to the size of the knowledge base and the number of incorporated knowledge since selecting from larger knowledge candidates may require more computational memory and training time but with higher performance. Exact string matching between context words and knowledge entities is relatively simple and could be replaced with more advanced semantic matching techniques, which nevertheless may increase model complexity. Second, depending on the domains of datasets to apply, too many out-of-vocabulary words (OOV) with no match in the knowledge base may affect the model performance and our future works will investigate a better solution to replace zero-vectors that are associated with non-alphabetic words.

A Additional Experimental Setting

We use huggingface transformers (Wolf et al., 2020) to implement our framework and we use two Nvidia 2080Ti GPUs for all model training. The number of model parameters is around 146M. It takes 30 minutes to train 30 epochs for a single model.

MCoNaLa: A Benchmark for Code Generation from Multiple Natural Languages

Abstract

While there has been a recent burgeoning of applications at the intersection of natural and programming languages, such as code generation and code summarization, these applications are usually English-centric. This creates a barrier for program developers who are not proficient in English. To mitigate this gap in technology development across languages, we propose a multilingual dataset, MCoNaLa, to benchmark code generation from natural language commands extending beyond English. Modeled off of the methodology from the English Code/Natural Language Challenge (CoNaLa) dataset, we annotated a total of 896 NL-Code pairs in three languages: Spanish, Japanese, and Russian. We present a systematic evaluation on MCoNaLa by testing state-of-the-art code generation systems. Although the difficulties vary across three languages, all systems lag significantly behind their English counterparts, revealing the challenges in adapting code generation to new languages.¹

1 Introduction

There are an increasing number of applications related to “code intelligence”, such as code summarization (Allamanis et al., 2016; Hu et al., 2018; Ahmad et al., 2020) and natural language (NL) to code generation (Ling et al., 2016; Rabinovich et al., 2017; Yin et al., 2018a; Xu et al., 2020; Norouzi et al., 2021; Wang et al., 2021), accompanied by code-specific tasks and benchmarks (Oda et al., 2015; Zhong et al., 2017; Yin et al., 2018b; Lu et al., 2021). However, in the cases where these benchmarks include natural language, that language is almost invariably English.

There are a few exceptions, but most of them either focus on languages of specific domains (Sherborne and Lapata, 2021; Sherborne et al., 2020;

^{*}Equal contribution.

Spanish	¿Cómo sumar el campo 'precio' de todos los elementos del modelo 'Precompra' en Django? (How to sum the 'precio' field of all the elements of the 'Precompra' model in Django?) <code>totaldos = Precompra.objects.aggregate(Sum(precio)).values()[0]</code>
Japanese	2次元配列arrの要素となっている1次元配列から先頭の値のみを抜き出す (Extract only the first value from the 1D array that is the element of the 2D array 'arr') <code>arr[0]</code>
Russian	Установить кодировку 'my_encode' для переменных окружения пользователя 'username' (Set 'my_encode' encoding for 'username' environment variables) <code>os.environ('username').decode(my_encode)</code>

Figure 1: Examples in the MCoNaLa dataset, that aim to generate general-purpose Python code snippets from source intent of multiple natural languages.

Moradshahi et al., 2020) or types of code (Oda et al., 2015; Liang et al., 2021), or contain NL intents collected via automatic translation (Li et al., 2021) (Appendix A). However, similarly to how Kwiatkowski et al. (2019) argue that “natural questions” are necessary to appropriately benchmark QA systems, we argue that ensuring the naturalness and coverage of questions is essential for benchmarking code generation systems as well.

A dataset for English code generation based on natural programming questions is the CoNaLa dataset (Yin et al., 2018a). It is based on natural developer questions harvested from the Stack Overflow (SO) question answering forum. In fact, in addition to English, SO also supports four other languages (Spanish, Portuguese, Japanese, and Russian) that have strong developer communities and engage in non-English programming environments. In this work, we utilize this resource to construct the MCoNaLa dataset, consisting of 341, 210, and 345 manually curated parallel samples with natural intents in Spanish, Japanese, and Russian, along with corresponding Python code snippets. Like CoNaLa, these snippets are collected from language-specific SO sites and annotated by na-

tive speakers who are also proficient in the Python programming language.

To provide insights in the state of code generation on this new resource, we conduct comprehensive experiments with three state-of-the-art text generation models in the context of cross-lingual transfer, by unifying training and testing NL via translation (Ruder and Sil, 2021; Shi et al., 2021; Shima and Mitamura, 2010; Hartrumpf et al., 2008), or utilizing a multilingual NL encoder such as MBART (Liu et al., 2020). Our results suggest that cross-lingual NL-to-Code generation is challenging. Among all languages and experiment settings, the highest average BLEU score is 7.28, far behind that of English, which achieves 33.41, presumably because English resembles Python more than other NLs. In addition, we find models with task-specific modules and training outperform generic seq2seq models, yet the discrepancy between languages are consistent across all baseline models. In all, our corpus and experiments demonstrate the varied difficulty of the NL-to-Code generation task under different languages, emphasizing the need to develop a language-comprehensive approach to code intelligence.

2 The MCoNaLa Dataset

2.1 Task Definition

Concerning the task of answering natural language questions with machine-executable programs, our focus is to build a benchmark dataset to evaluate models for their ability to encode NL *intents* in multiple languages and generate code *snippets*. For each example in Figure 1, the *intent* above asks how to achieve a particular goal, and the *snippet* below responds with a piece of Python code.

2.2 Annotation Workflow

Our goal is to collect *intent-snippet* parallel data in multiple natural languages. In this section, we outline the main workflow for data annotation: (1) language source selection, (2) valid SO post identification, and (3) parallel sample annotation.

Language source and selection Besides the English version, Stack Overflow also has forums available in four other languages: Spanish, Portuguese, Japanese, and Russian. Data annotation in each language requires a native speaker of that language, who should also be proficient in both English and Python. Due to the high cost and difficulty of hiring

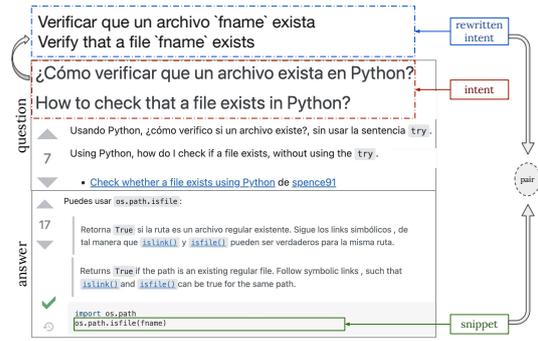

Figure 2: Illustration of the annotation process.

reliable annotators with such a specialized skill set, we only employ one Upwork annotator for each of Spanish, Japanese, and Russian. From the official SO data dump² dated March 2021, we obtained all posts in these languages. However, we were unsuccessful in finding a Portuguese-speaking annotator at the time of corpus collection.

Identifying how-to questions Following Yin et al. (2018a), annotators are first asked to identify valid posts that contain how-to type questions, which are imperative utterances seeking particular goals achievable by code. They are often in the post title or description, such as the example in Figure 2.

Posts are sent in 100-sample batches, and then categorized by annotators. To improve annotation efficiency, we bootstrapped a MBART how-to question classifier, with English examples, then iteratively multilingual samples. It achieves an accuracy of 72.50%. We then automatically filter the probable invalid posts using this classifier and designate the rest for manual annotation. We collect all valid posts and extract questions as raw intents, for subsequent parallel data annotation.

Collecting intent-snippet pairs For each post, we ask the annotators to find at most three snippets of Python code that correctly answer the extracted question. However, questions from post title or description are often ambiguous, especially in respective context of answer snippet, such as the example in Figure 2, that the question does not specify the names of “data” and “list” variables to allow precise code implementation. To disambiguate the intent and align it with a snippet, we ask annotators to rewrite the intent by: (1) specifying variable names appearing in the answer snippet, and (2) clarifying commands with reference question descriptions. Concretely, variable names and data types in the rewritten intent

²<https://archive.org/details/stackexchange>

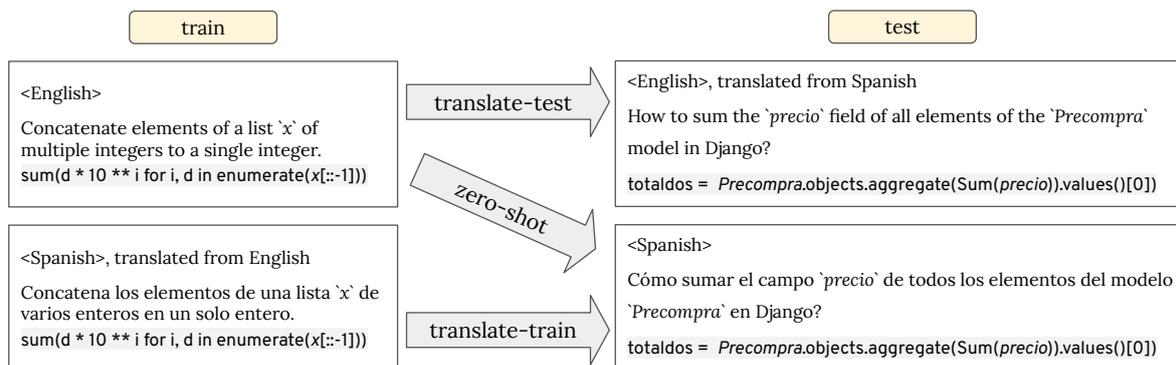

Figure 3: Example usage on the original English and Multilingual samples in three settings.

need to be surrounded by the ASCII grave accent marks (e.g., ``data``), string literals or file paths should use singular typographic quotation marks (e.g., `'file1.txt'`, `'https://www.abc.com/'`).

The final MCoNaLa dataset consists of 341, 210, and 345 intent-snippet pairs in Spanish, Japanese, and Russian. It is noteworthy that the goal of MCoNaLa is to benchmark cross-lingual NL-to-Code generation task and mainly for testing purposes, instead of curating large-scale dataset for training. While its size is relatively small given the collection difficulty, we show that it can reliably inform significant method improvements (§ 3.3). We believe it is important for our dataset to be representative of the naturally occurring questions in respective language environments.

2.3 Quality Analysis

To ensure high data quality as intended, we checked 15 random samples from each language subset. Each rater score NL intents and code snippets from 1 to 5 based on their correctness and specificity.

The results demonstrate the high quality of our dataset, achieving 4.78, 4.65, 4.78 points on Spanish, Japanese, and Russian intents; and 4.84, 4.89, 4.78 points on their corresponding code snippets. Meanwhile, three raters present high agreement – the Fleiss’ Kappa measure is 64.29 for NL intents and 69.49 for code snippets – both numbers indicate substantial agreement among the raters.

3 Method

To provide insights about evaluating on MCoNaLa, we demonstrate potential dataset usage in three train-test settings (§ 3.1), and propose to adapt three baseline models from either multilingual (NL) or code understanding to achieve both ends (§ 3.2).

Because the size of MCoNaLa allows only testing purposes, we resort to its larger English counter-

part, CoNaLa (Yin et al., 2018a), to allow training. CoNaLa contains 2,879 manually annotated samples and 600k samples extracted from English SO forum and API documents, which can serve as a sufficient source for training. Given this usage, we denote the three test languages as *target* languages.

3.1 Train-Test Settings

We adopt three settings from two paradigms (Hu et al., 2020) as illustrated in Figure 3: (1) translating intents in train (*translate-train*) or test (*translate-test*) sets to bridge the language gap, (2) using multilingual encoder to transfer from English to target languages (*zero-shot*).

For each target language, we can align the languages of training and testing intents and use a monolingual encoder. The *translate-train* setting translates English intents in CoNaLa to each target language for training and then tests with MCoNaLa samples. *translate-test* translates MCoNaLa intents in three target languages into English. Because it is not feasible to manually translate 600K+ intents, we use existing multilingual machine translation (MMT) models to automate translation. We benchmarked several open-source options, as elaborated in § 4.2, and settled on the M2M-124 model used on the FLORES-101 dataset (Goyal et al., 2022).

Also, we can train models on English samples and directly evaluate on MCoNaLa samples in target languages *zero-shot*, requiring models to encode multiple NLs, further, transfer the code generation ability from English context to target ones.

3.2 Baseline Models

We introduce three baseline methods targeting the above train-test settings. We encourage readers to refer to the original papers for more details.

In a monolingual context, models should function in target languages for *translate-train* and En-

glish for *translate-test*. TRANX (Yin and Neubig, 2018) is a BiLSTM-based encoder-decoder model that uses a transition-based abstract syntax parser to map NLs into formal meaning representations (MR) such as Python programs. It is agnostic to input languages and hence can be evaluated on both translated settings. TAE (Norouzi et al., 2021) is the state-of-the-art method on CoNaLa by training a generic transformer with an added target autoencoder (TAE) objective. However, it is built with (English-)BERT and is intended for English scenarios, therefore only tested on *translate-test*.

As is required by *zero-shot* evaluation, we adopt a multilingual model, MBART (Liu et al., 2020), which is a seq2seq model pre-trained on 25 natural languages including our target ones. Note that MBART can also function in monolingual contexts, for both *translate-train* and *translate-test* settings.

3.3 Experiment

We train baseline models in their available settings, then tokenize the generated and reference code snippets following Yin and Neubig (2018) to evaluate the BLEU-4 scores. We report the average scores of five rounds using different random seeds.

Model	Setting	Language				
		en	es	ja	ru	avg.
MBART	translate-test		2.38	3.07	2.04	2.50
	translate-train	25.20	2.64	3.45	2.65	2.91
	zero-shot		2.49	1.83	2.28	2.20
TRANX	translate-test	32.26	2.46	8.34	8.12	6.31
	translate-train		2.44	6.11	6.02	4.86
TAE	translate-test	33.41	2.39	9.90	9.56	7.28

Table 1: BLEU scores of baselines for various train-test settings in English (en) and target languages (es, ja, ru).

In Table 1, first, scores on target languages average to at most 7.28, much lower than 33.41 on English, revealing the similarity of English and Python, and the difficulty of generating code from other languages. Second, models with code-specific designs and training (TRANX and TAE) performs better in general. The lower scores of MBART potentially suggest a certain representation gap between NL and PL. Third, results on two code-specific models show consistent variations across languages: scores are lower for Spanish, but rise similarly on Japanese and Russian. As we will discuss in § 4.1, this is possibly due to the distributional gap between languages with varied complexity.

3.4 Significance Test

To verify the effectiveness of MCoNaLa, we perform significance tests (Dror et al., 2018) to show its capability of showing significant differences between systems. We conduct paired bootstrap resampling tests with each pair of models in their available settings, using a sample rate of 0.5 and a sample size of 10,000.

Setting	Language	Win Rate (%)			Tie	p-value
		MBART	TRANX	TAE		
translate-test	es	0.532	0.402	-	0.066	0.468
		0.522	-	0.396	0.102	0.478
		-	0.508	0.448	0.044	0.492
	ja	0.000	1.000	-	0.000	0.000
		0.000	-	1.000	0.000	0.000
		-	0.002	0.998	0.000	0.002
	ru	0.000	1.000	-	0.000	0.000
		0.000	-	1.000	0.000	0.000
		-	0.001	0.998	0.001	0.002
translate-train	es	0.592	0.408	-	0.000	0.408
	ja	0.000	1.000	-	0.000	0.000
	ru	0.000	1.000	-	0.000	0.000

Table 2: Significance testing results between each pair of baseline models. ‘-’ marks the model not in the pair.

In both *translate-test* and *translate-train* settings of Table 2, code-specific systems (TRANX and TAE) significantly outperform MBART on Japanese and Russian. However, no significant differences are shown in Spanish, as expected given its relative difficulty. With significance testing, one can obtain reliable results even on a small dataset. While small sizes are not entirely desirable for informative evaluation, we view them as practical reflections of data scarcity, supporting our call for more non-English resources.

4 Analysis

4.1 Variations between Languages

We first study the differences in size and snippet length between languages subsets in MCoNaLa. As listed in Table 3, snippet lengths vary across languages, and the average snippet length in Spanish is around 2.5/1.3 times of that in Japanese/Russian. A longer snippet is presumably more complex, suggesting that snippets in Spanish samples are harder to generate, and hence models perform poorer.

4.2 Intent Auto-translation

In § 3.1 we use MMT models for intent translation. To optimize translation quality, we compare three best performing MMT models: OPUS-MT (Tiedemann and Thottingal, 2020), M2M-

original intent (English)	Prepend string 'hello' to all items in list 'a'
translated intent (Spanish)	Preparación (<u>prepare</u>) de la cadena 'hello' a todos los elementos en la lista 'a'
snippet	['hello(0)'.format(i) for i in a]
original intent (English)	add a colorbar to plot 'plt' using image 'im' on axes 'ax'
translated intent (Japanese)	画像'im'を使ってax'の軸にカラーバーを追加
snippet	plt.colorbar(im, ax=ax)
original intent (English)	extend dictionary 'a' with key/ value pairs of dictionary 'b'
translated intent (Russian)	расширить словарь 'a' с ключевыми/ значительными (<u>significant</u>) парами словаря 'b'
snippet	a.update(b)

Figure 4: Examples showing that the translation errors or omits critical words in the original intent.

Language	Size	# Snippet Tokens		
		average	max	min
English	2,879	18.2	170	2
Spanish	341	42.6	343	4
Japanese	210	17.7	94	2
Russian	345	32.0	243	3

Table 3: Data size and snippet length (in number of tokens) of MCoNaLa samples between target languages.

100 (Fan et al., 2021), and M2M-124 used in FLORES-101 (Goyal et al., 2022). Since comparing in *translate-train* needs intensive re-training with different model translations, we ablate in the *translate-test* setting, using each model to translate test intents and evaluate NL-to-Code respectively.

Baseline	MMT	Language		
		Spanish	Japanese	Russian
MBART	M2M-124	2.38	3.08	2.04
	OPUS-MT	2.28	3.21	2.46
	M2M-100	1.83	2.79	2.00
TRANX	M2M-124	2.46	8.41	8.09
	OPUS-MT	2.46	5.09	5.00
	M2M-100	2.04	7.38	8.48
TAE	M2M-124	2.39	9.88	9.57
	OPUS-MT	3.15	3.89	5.30
	M2M-100	2.21	8.20	9.32

Table 4: Comparing MMT models under *translate-test*.

As in Table 4, their results are close, but M2M-124 tends to be more stable across languages and baselines. Despite its relative superiority, its translation quality may still lag behind human performance, with more examples in § 4.3.

4.3 Quality of Auto-translation

To better measure the quality of translated intents, we manually check the semantic alignment be-

tween the original and translated intents, with the assistance of the Google Translate API and dictionaries. Concretely, we take 20 English CoNaLa intents and check if their semantics preserve after being translated into three target languages (*translate-train*). We similarly examine 20 MCoNaLa intents in each target language and check their English translations (*translate-test*). We use the M2M-124 translations given its best results. As shown in Figure 4, MMT translations are still sub-optimal: often mis-translate, even omit, the key words. This is especially severe on verbs that indicate certain Python operations. Hence, the translation step may impair intent-snippet alignment, being one of the major factors to the poor results in translated settings.

5 Conclusion

In this work, we extend the task of NL-to-Code generation from English-centric to multilingual scenarios. We establish the MCoNaLa benchmark that contains NL intent and code snippet pairs available in Spanish, Japanese, and Russian. Our benchmark serves for the multilingual code generation task, requiring models of both multilingual understanding and code synthesis. We conduct systematic experiments on three baseline models and show varying difficulty across languages and settings. We hope to reveal the necessity to develop, and serve as a solid test bed for language-comprehensive approaches regarding code intelligence.

Acknowledgements

We thank all the annotators for their hard work. This work was supported by the National Science Foundation under grant number 1815287.

Limitations

Although the MCoNaLa dataset makes a first step to include more natural languages aside from English, it is currently limited to the languages supported by the StackOverflow forum, since SO provides the source data for the MCoNaLa creation. This can be mitigated by extending to more languages using programming forums in other languages that have a similar purpose to SO. Besides, MCoNaLa dataset only supports literal evaluation methods such as BLEU. Given the executable nature of Python programs, it is beneficial to support more evaluation metrics such as functional correctness, robustness, and conciseness.

Ethics Statement

The MCoNaLa dataset is built to serve as a testbed for evaluating code generation systems from natural languages extending beyond English, given that an English-centric setting can harm universal accessibility to language technologies.

We hire annotators who are proficient in target languages and assist them with clearly documented instructions, flexible annotation interfaces (e.g., Google Sheets), and automated methods (e.g., using a neural classifier to filter out possibly invalid cases) to optimize the annotation efficiency. We carefully check in line with our instructions and standards, to ensure the quality of both the question posts given and the annotation results back from our annotators. We emphasize the differences between samples in different languages, because they are natural reflections of the questions that programmers asked in each specific language, similar to many works in fields such as multilingual question answering (Clark et al., 2020) and named entity recognition (Nothman et al., 2013). We reckon that it is of paramount importance to evaluate on data that was originally produced in the target language, and results may be less reliable otherwise.

Nevertheless, with the advances in models capable of generating code from natural language inputs, we should be aware of the potentially harmful usage such as concealing malicious code (Wallace et al., 2020), or generating code with security vulnerabilities (Verdi et al., 2020; Pearce et al., 2021).

A Related Work

Natural Language to Code Generation Datasets

There have been several benchmark datasets for NL-to-Code generation, such as Hearthstone (Ling et al., 2016), Django (Oda et al., 2015), CONCODE (Iyer et al., 2018), and CoNaLa (Yin et al., 2018a). Other examples include datasets for problem solving, such as HumanEval (Chen et al., 2021), MBPP (Austin et al., 2021), and APPS (Hendrycks et al., 2021). A number of methods have been proposed to mine intent-snippet pairs for the purpose of code search, summarization, or generation. While our work falls in the line of mining from SO (Wong et al., 2013; Iyer et al., 2016; Yao et al., 2018; Yin et al., 2018b), other work also attempts to exploit other data sources such as API documentation (Chatterjee et al., 2009; Movshovitz-Attias and Cohen, 2013; Xu et al., 2020), code comments (Wong et al., 2015), specialized sites (Quirk et al., 2015), and developer communications (Panichella et al., 2012). One prior methodology to automatically collect large-scale parallel data is using heuristics to extract intent-snippet pairs (Chatterjee et al., 2009; Wong et al., 2013; Zagalsky et al., 2012), but this often results in compromised data quality (Xu et al., 2020). Our work resorts to a manual annotation strategy that often yields accurately aligned intent-snippet pairs.

Multilingual Learning While the bulk of code-related tasks have their NL components in English, program developers native in other languages cannot enjoy the advances in code intelligence techniques, leading to the current lacunae in multilingual learning. Our work intends to mitigate this gap by facilitating NL-to-Code generation in multiple languages beyond English. To enable language understanding across multiple languages, a number of works propose to train language models with corpus in multiple languages (Devlin, 2018; Liu et al., 2020; Conneau et al., 2020; Xue et al., 2021). In addition to multilingual training, other data augmentation techniques commonly used in machine translation (MT), such as back-translation (Edunov et al., 2018), monolingual (Sennrich et al., 2016; Siddhant et al., 2020) or generalized data augmentation (Xia et al., 2019), also inspired our experiments. However, these techniques have rarely been utilized for NL-conditioned code generation. We present preliminary attempts in the experiments.

Augmenting pre-trained language models with audio feature embedding for argumentation mining in political debates

Abstract

The integration of multimodality in natural language processing (NLP) tasks seeks to exploit the complementary information contained in two or more modalities, such as text, audio and video. This paper investigates the integration of often under-researched audio features with text, using the task of argumentation mining (AM) as a case study. We take a previously reported dataset and present an audio-enhanced version (the Multimodal USElecDeb60To16 dataset). We report the performance of two text models based on BERT and GloVe embeddings, one audio model (based on CNN and Bi-LSTM) and multimodal combinations, on a dataset of 28,850 utterances. The results show that multimodal models do not outperform text-based models when using the full dataset. However, we show that audio features add value in fully supervised scenarios with limited data. We find that when data is scarce (e.g. with 10% of the original dataset) multimodal models yield improved performance, whereas text models based on BERT considerably decrease performance. Finally, we conduct a study with artificially generated voices and an ablation study to investigate the importance of different audio features in the audio models.

1 Introduction

In recent years, there has been an increasing interest in multimodal classification, which refers to the task of automatically classifying an input based on multiple modalities or sources of information, such as text, images and audio (Baltrušaitis et al., 2018). Multimodal approaches are beneficial as they can reduce the subjectivity of classification with a single modality and improve the accuracy of the overall classification. However, finding the best representations (especially those that work well with other modalities), aligning and fusing them, and getting the models to co-learn are difficult challenges to overcome (Morency and Baltrušaitis, 2017). A large body of literature has

focused on the combination of image and text for applications like emotion recognition (Illendula and Sheth, 2019), fake news detection (Nakamura et al., 2020), image classification (Guillaumin et al., 2010), or document image classification (Jain and Wigington, 2019). Much less attention has been paid to combining audio with text.

Audio can convey a variety of information about the pitch or intonation of the speaker that can indicate variance in emotional state as well as better identify modes of communication like sarcasm that have been difficult for models to detect. The integration of audio has successfully improved classification tasks like multimodal sentiment analysis and emotion recognition when compared with classic NLP models (Yao et al., 2020; Ho et al., 2020). In this paper, we focus on a less explored NLP area in terms of multimodality: argumentation mining (AM). AM is the computational study of arguments to develop models that can automatically identify, extract, and represent arguments in text or other forms of digital communication such as audio or video. AM has traditionally focused on textual data such as news articles, blog posts, and online comments, but the advantages of using audio to detect arguments have not been extensively explored.

In this work, we expand on an existing AM dataset of US political debates (USElecDeb60To16 by Haddadan et al. 2019) by including audio. We test the performance of several multimodal AM models in different variations of the same dataset, e.g., after balancing the labels and with fractional datasets. Our contribution is three-fold: i) a new fully aligned audio dataset, expanding on an existing AM dataset (Section 3), adding balanced and fractional subsets for researchers to experiment with; ii) original multimodal benchmarking results for this dataset highlighting where audio feature embeddings add most value compared to text-only models (Section 4); iii) analysis of audio features importance, including performance comparison of

human and computerized voices (Section 5) and an ablation study (Section 6).

2 Related work

Multimodal approaches including audio have been mostly used for sentiment analysis or emotion recognition (Yang et al., 2022; Cai et al., 2019), often using the IEMOCAP dataset, one of the oldest datasets that contains 12 hours of dialogue recordings with emotion labels in text, audio and video format (Busso et al., 2008). In recent years newer datasets have been released, such as the SAVEE (Jackson and Haq, 2014) and RAVDESS databases (Livingstone and Russo, 2018), the MELD dataset (Poria et al., 2018), and the CNU-MOSEI dataset (Zadeh et al., 2016). Generally, audio-textual multimodal approaches contain separate pipelines for audio and text features, sometimes connected through attention layers. For instance, Cai *et al.* (2019) combined GloVe embeddings in a bidirectional long-short term memory (Bi-LSTM) array for text with a combination of a convolutional neural network (CNN) and a Bi-LSTM array for the audio. Likewise, Yoon et al. (2018) used GloVe embeddings and recurrent neural networks (RNN) for both audio and text, reaching accuracies of 71.8 % with the IEMOCAP dataset. Atmaja and Akagi (2020) used either LSTM or CNN (not at the same time) for the acoustic pipeline and LSTM with Fast-Text and GloVe embeddings. Ho et al. (2020) used a multi-level multi-head fusion attention using bidirectional encoder representations (BERT) for the text representations, achieving improved accuracies in three different datasets.

Audio features in this domain have been generally embedded using low level descriptors (LLDs), such as mel-frequency cepstral coefficients (MFCCs) (Atmaja and Akagi, 2020; Ho et al., 2020). MFCCs are computed from the mel spectrogram of the audio signal by performing a discrete cosine transform (DCT) of its log to reduce its dimensionality in a way that is highly related to the raw signal, but approximating the human auditory system and often yielding higher classification performance (Singh et al., 2021). As LLDs do not contain global information about the utterance, high-level statistical functions (HSFs), such as mean, kurtosis and quadratic error, among many others, can also be used. Yao et al. (2020) compared the performance in speech emotion recognition of a HSF classifier based on a deep neural

network (DNN), a LLS classifier based on a recurrent neural network (RNN) and a raw-signal mel-spectrogram classifier based on a CNN, finding similar performance between the HSF and LLD models, and a slightly lower performance for the model using the raw signal, showing the benefits of the low level representations. The use of RNN with LLDs has been shown to offer benefits by considering the temporal dimension of an utterance (Xie et al., 2019), but several researchers have started to use both CNNs and RNNs in combination to learn both temporal and local features in the frequency domain (Zhao et al., 2019; Singh et al., 2021; Yao et al., 2020). Whereas MFCCs are the feature of choice for the great majority of applications, the list of remaining LDDs are virtually endless, including the zero crossing rate, chroma vector, entropy of energy, Hammarberg index, spectral slope, harmonic difference, among many others (Atmaja and Akagi, 2020). While some efforts have been made towards standardization of audio features (Eyben et al., 2016), the choice is generally pragmatic and depends on the package used by the researcher, with openSMILE toolkit (Eyben et al., 2013), Librosa (McFee et al., 2015) and PyAudioAnalysis (Giannakopoulos, 2015) being those most commonly chosen ones.

On the other hand, AM research has focused on a diverse set of applications using the text modality alone, from online interactions (Ghosh et al., 2014) and tweets (Alsinet et al., 2019) to argumentative essays (Stab and Gurevych, 2014) and political debates (Lawrence and Reed, 2017; Visser et al., 2021). Regarding multimodal AM, Lippi and Torroni (2016) presented a first step towards the use of audio features from speech to improve argument detection. In this paper, they used raw input signals, which were passed through a speech recognition API to obtain the text. Then they used bag of words and bi-grams together with discrete HSF features from MFCCs, namely minimum, maximum, average and standard deviation, to train a support vector machine in an argument classification task. The results were positive towards the addition of audio, although the performance was modest due to the small size of the dataset and the limitations of the text and audio representations. The only other work that considered multimodal aspects used the M-arg dataset (Mestre et al., 2021). There, the authors analyzed argumentative relations in the 2016 US presidential debates using text and audio, building an

argumentation mining pipeline based on BERT embeddings for text and a combination of a Bi-LSTM and a CNN for the audio. Although the dataset, annotated for "support" and "attack" between sentences, was rather small and heavily unbalanced towards the "neither" class, the authors reported a slight improvement when considering audio and text together in a multimodal model. Surprisingly, audio features alone showed a better performance than the text-only model based on BERT encodings, suggesting that in small datasets, when the performance of BERT-based models suffers, audio features might provide a handy supplement to classify arguments. The effect of specific audio features on performance was not assessed.

Here, we build upon a previous dataset (USElecDeb60To16) presented by [Haddadan et al. \(2019\)](#), which contained English transcripts of the US presidential debates from 1960 to 2016 labelled with more than 29k annotations of argument components and their boundaries. We used the original videos from the debates to obtain aligned timestamps at the sentence level following the work of [Mestre et al. \(2021\)](#), thus enabling the task of multimodal AM with a total of 28,850 aligned and annotated sentences. Concurrently to the submission of our work, [Mancini et al. \(2022\)](#) also presented and released a multimodal dataset, using the same videos and alignment process, with 26,791 sentences. Both datasets are complementary, although our dataset is slightly larger as we did not drop any of the debate videos (see next section). [Mancini et al. \(2022\)](#) compare datasets and architectures from the two previously mentioned works by [Lippi and Torroni \(2016\)](#) and [Mestre et al. \(2021\)](#), as well as their new dataset, finding generally positive results to the addition of audio. In our work, we report an audio feature analysis, as well as the impact of using computerized voices, and we investigate the benefit of multimodal models on both balanced and fractional small data subsets.

3 Methodology

3.1 Dataset construction

In their USElecDeb60To16 dataset, [Haddadan et al. \(2019\)](#) reported the performance of several models for argument classification, with the highest weighted F-score of 0.673 for the argumentative component classification (ACC) of premise, claim and other. They also collapsed all the premise/claim annotations into one single label,

"argument", and attempted argumentative sentence detection (ASD), with a weighted F-score of 0.843 using an LSTM array. We used this dataset in its collapsed version (argument/other) for ASD to assess whether the addition of audio could improve the reported performance (F-score of 0.843) and to simplify the task using only 2 classes as a first step to studying the potential of multimodal AM. For this, we needed to add the audio of the debates with sentence-level timestamps.

Videos from each debate were downloaded from the YouTube channel of the Commission for Presidential Debates.¹ Before starting the audio alignment process, we fixed a small number of inconsistencies in the dataset resulting from errors in the original transcripts. Some were simple, like sentences lacking a space between periods, which made sentence tokenization algorithms fail. In a couple of debates, full paragraphs were missing from the transcript, possibly due to an error in the original web scraping algorithm by [Haddadan et al. \(2019\)](#). Older debates also had serious transcription issues in the original source, such as full sentences or paragraphs missing or speeches being repeated twice in the transcript. Regarding videos, older ones also had issues, such as debate 5 (the first Carter-Ford Debate in 1976), in which the audio was lost during live transmission, and commentators, not presidential candidates, spoke for almost half an hour. This was not reflected in the transcript, and we had to manually edit the video to match the transcript. For two debates (the first and second Clinton-Bush-Perot debates of 1992), the Commission decided to split the transcript into two parts, even though the debates occurred uninterrupted. Therefore, we split the videos in two to match the transcript. Others had cuts or repeated segments that lasted from a few seconds to several minutes, and we were forced to adapt the original dataset to reflect these changes. Whereas preceding researchers [Mancini et al. \(2022\)](#) were forced to remove full or part of the debates from their multimodal dataset to account for these issues, we rigorously edited the USElecDeb60To16 dataset and videos to reduce unsystematic data loss error, such that we could provide an enhanced comprehensive dataset to researchers for further investigation. We want to highlight that this error reduction does not cast any doubt on the quality and substantive find-

¹<https://www.debates.org/voter-education/debate-transcripts/>

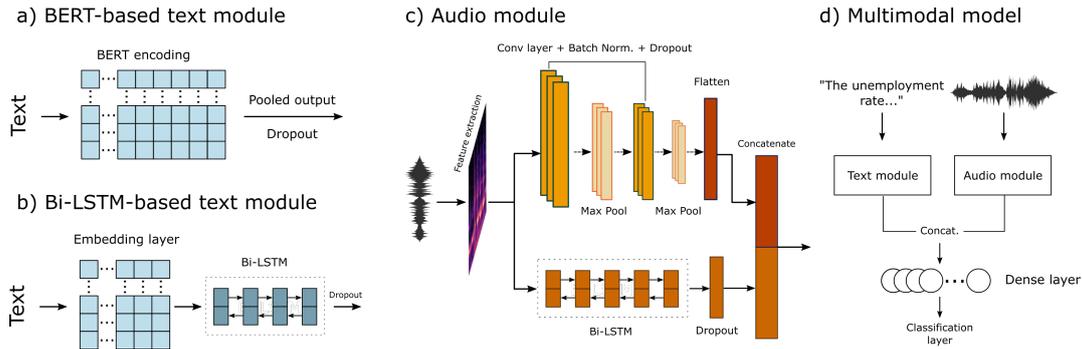

Figure 1: Model architectures used in this paper. a-c) Generic architectures of the text and audio modules. d) Multimodal model that combines text and audio modules.

ings of that preceding work, as it mostly relates to sentence omission.

We aligned the transcripts with the audio using the Aeneas Forced Alignment (v. 1.7.3) tool as proposed by Mestre et al. (2021). Two researchers manually checked every debate for major misalignment (and fixed them) until we obtained an almost perfectly aligned text. After alignment, our dataset contained 28,850 labelled sentences (76.15% of them arguments), with timestamps indicating start and ending times in the audio file. We present the extended dataset we call Multimodal USElecDeb60To16, with the collapsed original annotations, alongside timestamps to match the audio, instructions for obtaining the videos and scripts to extract the audio features, in our GitHub repository page (Mestre et al., 2023).²

3.2 Model architectures

We used the architectures proposed by Mestre et al. (2021), which showed the potential of multimodal argumentation mining in our dataset (Figure 1). We considered two text modules based on GloVe and BERT (Devlin et al., 2018). The former used Wikipedia-trained 200-dimensional GloVe embeddings, whose maximum length was given by its 99th percentile to eliminate very long sentences. They were passed through a Bi-LSTM, followed by a dropout layer, a dense layer and an output layer with softmax activation. The latter module consisted of a BERT pre-processor³ and a BERT encoder with L=12 hidden layers, a size of H=768 and A=12 attention heads.⁴ Its pooled output was also followed by a dropout layer and a dense layer.

³bert_en_uncased_preprocess v.3

⁴bert_en_uncased_L-12_H-768_A-12 v.4

The audio module was inspired by Cai et al. (2019). For each utterance in audio form, the Python library Librosa was used for audio feature extraction (McFee et al., 2015). We extracted the following LLD features: MFCCs (Klapuri and Davy, 2006), spectral centroids (Klapuri and Davy, 2006), spectral bandwidth (Klapuri and Davy, 2006), spectral roll-off (McFee et al., 2015), spectral contrast (Jiang et al., 2002a), and a 12-bit chroma vector (McFee et al., 2015). Motivation for selection of features and evaluation is further described in Section 6. For each sentence, the features were concatenated to form a tensor of $(45, T)$, where T is the duration of the utterance. All utterances were padded with zeros to have the same length T_{max} , which was defined by the 99th percentile duration of all utterances. Each utterance was passed in parallel through a CNN and a Bi-LSTM to find both local and temporal features. The CNN consisted of two convolutional layers, two maxpool layers and batch normalization layers. Outputs from both modules were flattened, concatenated and passed through dropout and dense layers.

The multimodal model was a combination of the text and audio modules in which the inputs were the text string and its corresponding audio, each passed in parallel. We considered two multimodal models: one with a BERT text module and another one with a Bi-LSTM text module.

3.3 Hyperparameter tuning

We developed a robust methodological framework to tune the hyperparameters for each model. Model training was performed in a High Performance Computing (HPC) cluster in dedicated GPUs (with either nodes of 4 GTX1080 Ti GPUs or nodes of 2 Nvidia Volta V100 GPUs). The hyperparam-

Table 1: Models’ performance for original and balanced datasets. Errors indicate standard deviation after 5 replicates.

ter training was assisted by the Python package Ray[tune] (Liaw et al., 2018), which allows distributed parallel hyperparameter tuning with different search strategies and schedulers. We defined our hyperparameter search as shown in the appendix (Table A1), including training parameters like the learning rate and batch size, and also architecture-dependent parameters like the kernel size of the CNN or whether the text embeddings should be retrained or not. To search over the defined hyperparameter space, we used the Tree-structured Parzen Estimator algorithm (Bergstra et al., 2011), which considers the performance of previous iterations of the search to choose the next hyperparameters to test, implemented in the HyperOpt library for parallel optimization (Bergstra et al., 2013). The training was implemented in TensorFlow and we included Keras callbacks after each epoch of training to update the hyperparameter search algorithm. We implemented an early stopping scheduler algorithm that monitored validation loss at each epoch, stopping the training before overfitting, with a minimum change of $1e-4$ and a patience of 3 epochs. We considered implementing other schedulers like Asynchronous Successive Halving Algorithm (ASHA), which stops unpromising trials if their performance is worse than that of previous trials (Li et al., 2018), but we discovered in our experiments that this algorithm tends to penalize slow learning models, which sometimes ended up giving the best results. We sampled 50 times the search space, with validation

split of 20% and test split of 20%, and the best hyperparameters, used in the remaining sections, are reported in the appendix (Table A1), as well as average runtimes and number of parameters. With our dataset, we provide full details of the training results, with confusion matrices, training history, validation metrics plots, etc.

4 Models’ performance

4.1 Full original dataset

Table 1 shows the performance of each one of the models after training with the original dataset ($N = 28,850$) and optimized parameters. The text-only models, particularly the BERT model, perform best in terms of both macro and weighted F-scores, reaching a weighted average of 0.826 (macro average of 0.746), comparable to the weighted average reported by Haddadan et al. (2019) of 0.843 (or macro average of 0.730) using a LSTM network. As in that paper, the precision and recall of the "other" class is low, but classification of the "argument" class performs much better, with a high recall in both the BERT and Bi-LSTM models. The audio-only model yields a rather low macro averaged F-score of 0.540, as it relies on over-classifying the argument class. The BERT-based multimodal model performs significantly better than the audio-only model and similarly to the text models, with a macro average of 0.737. The Bi-LSTM-based multimodal model performs better than the audio-only model in terms of macro

Model	Class	10% original dataset ($N = 2, 885$)			10% balanced dataset ($N = 1, 376$)

Table 2: Models’ performance for 10% of the datasets. Errors indicate standard deviation after 5 replicates.

averaged F-score, with 0.624. Our models perform slightly better than those of Mancini et al. (2022), who used the same architecture (although with their own hyperparameter optimization) and dataset (although slightly smaller). But, like us, they find that the multimodal models do not significantly (if at all) outperform the text-only models, with macro F-scores of 0.674 in both. Their audio-only model was not better than the random baseline at 0.505.

In both the original work of Mestre et al. (2021) and the replication by Mancini et al. (2022), the authors show a beneficial impact of audio embeddings in argument classification. However, that dataset was significantly smaller ($N = 4, 104$) and heavily imbalanced towards one of the classes. Our dataset is also slightly imbalanced towards the "argument" class (76.15% arguments) and the text-only models seem to be reaching saturation, as per the previous paragraph. Moreover, the low precision and recall of the "other" class leads us to believe that the models overly rely on classifying many instances as "argument". Therefore, we asked ourselves what would happen: 1) when the dataset is small and the performance of the text-only model might suffer; 2) when the dataset is balanced and the models cannot rely on over-classifying the "argument" class. Does the addition of audio improve the performance metrics in those cases?

4.2 Fractional and balanced datasets

The right-hand side of Table 1 shows the results with the same models for a balanced dataset. To obtain a balanced dataset, a random number of "ar-

gument" classes were dropped from the original dataset, until we obtained an equal number of both classes, therefore reducing the total size to 13,758 sentences. This table shows how the overall performance of the BERT and Bi-LSTM models has been reduced, reaching macro averaged F-score values of 0.754 for the BERT model and 0.728 for the Bi-LSTM model. Moreover, the precision and recall of both classes are more balanced: whereas in the original dataset the recall of the "argument" and "other" classes of the BERT model were 0.951 and 0.487, respectively, they are now 0.839 and 0.674. The multimodal model continues to perform significantly better than the audio-only model, but still not better than the BERT model, to which it still achieves similar F-score values. It seems, therefore, that a multimodal model does not provide better results than text-only models when the datasets are balanced, at least as long as the number of annotations continues to be large ($N = 13, 758$). The text-only models still seem to reach saturation of what can be accomplished with the dataset.

Table 2 shows the results for a fractional dataset composed of only 10% of the original and balanced data. We hypothesize that the performance of the text-only models will start to suffer with small amounts of training data and the audio features from the multimodal models will be able to partially recover previous performance. Indeed, it has been shown in some work that BERT models tend to decline in performance with small datasets and can be outperformed by simpler models like Bi-LSTM (Ezen-Can, 2020). Likewise, not only does

the overall performance suffer, but also the stability of the model as discussed by Dodge et al. (2020). In our case, we see that the BERT model shows a large drop in macro average F-score, down to 0.539, and high instability, as can be observed from the large standard error of the "other" class. In this case, the Bi-LSTM model outperforms the BERT model at 0.656, suggesting that the BERT model is more sensitive to smaller datasets. The BERT-based multimodal model also outperforms the BERT model, with a macro average F-score of 0.709, very close to the best scenario with the original dataset at 0.746. Surprisingly, the Bi-LSTM-based multimodal model does not outperform the Bi-LSTM model, but worsens its performance. On 10% of the balanced dataset, results are similar, with the BERT model suffering and the BERT-based multimodal model outperforming all with F-scores of 0.743, close to the original balanced case.

For intermediate sizes, such as 50% and 20% (reported in Section C) the change seems to be gradual. For both 50% and 20% of the original dataset, the performance of the only-text BERT model and the BERT-based multimodal model is practically identical. However, for balanced datasets of 20% (with only $N = 2,751$), the performance of the BERT model starts to decrease and is overcome by the multimodal model. All these results suggest that there is a point at around $N = 3,000$ or below where audio features provide an important added value in the performance of the models. Full details of all the replicates, including the model history with validation losses and accuracy, confusion matrices and a full breakdown of the performance metrics can be found in the repository of the project⁵ and its official release (Mestre et al., 2023).

5 Artificial voices

It is not clear what the audio models are specifically looking at when they undergo training, as the features extracted are not always easy to interpret. One hypothesis is that they learn from the words being uttered, their pronunciation and associations thereof in a similar way to text-based models. However, it is also likely that these audio models are picking up intonation or pitch features that are possibly different when one person is making an argument.

As a first step in investigating what the audio-

⁵<https://github.com/rafamestre/Multimodal-USElecDeb60To16>.

based models are paying attention to, we ran our models using artificial voices, instead of the original voices from the presidential candidates. For this, we used the computer generated voices from the Microsoft Windows Text to Speech (TTS) system. Then, we used the text-to-speech conversion library `pyttsx3` (v 2.9) for Python to run each sentence through the Microsoft TTS system and generate utterances spoken by the so-called Microsoft Mark and Microsoft Zira, the male and female version of US voices. We set the speaking rate at 200 words per minute, but it could be interesting for future studies to observe the accuracy of the models when the speech rate is changed. Likewise, each country package in Microsoft Windows has its own set of unique voices, even if they speak the same language, e.g., UK, India, South Africa, and so on, so it could be interesting to check potential differences in accuracy with different accents.

We then ran our audio-only models as described before and the performance metrics are displayed in Table 3. We only report the F-scores, and not precision and recall, for simplicity.⁶ We can see in this table that, generally, there are no differences in F-score by gender of the artificial voices, although there seems to be a bias towards the female Zira voice. When compared to the audio model run with original voices, it is interesting to see that whereas using artificial voices results in a similar score with the full dataset, with the balanced dataset the results are improved, going from 0.566 as reported in 1 to 0.626 using the Zira voice. This improvement is also found with the 10% dataset, which reported 0.536 and 0.594 for the original and balanced datasets, whereas Table 2 reported 0.572 and 0.585, respectively. In the balanced case, these values are even better than the BERT model at 0.524. A potential explanation is that the artificial audio models lack noise coming from the recording, or remove variation coming from different people having different baseline pitches that might confuse the model. There might be a trade-off between taking advantage of pitch or intonation during arguments (which we were not able to prove produces any effect) and benefiting from the noise-reduced nature of artificial audio. In any case, it seems that audio-only models based on artificial voices can learn features and classify arguments with an accuracy comparable to text-only models, and sometimes

⁶Full information, all the computerized utterances and scripts to reproduce our results can be found in our repository (Mestre et al., 2023).

Voice	Class	F_1			
		Original dataset	Balanced dataset	10% original	10% balanced

Table 3: Audio-only models’ performance with artificial voices. Errors indicate standard deviation after 5 replicates.

even better than those when data is scarce. Models based on the original voices often struggle, and this might be due to the inherent noise of the recordings or differences at the speaker level.

6 Ablation study

Finally, to further understand how the different LLD audio features might play a role in argument detection, we perform an ablation study with the audio model in which we eliminate one of the six features at a time and assess how the performance of the model changes. The results are in Table 4 for the full and balanced datasets (we only report F-score for simplicity). The first column indicates the feature that was eliminated from the feature tensor, which originally had dimensions of $(45, T_{max})$, whereas the second column displays the dimensions of the tensor after elimination. In general, none of the cases deviate much from the full-feature model with macro F-scores of 0.540 and 0.566 for the original and balanced datasets (Table 1). The first four features are spectral features, meaning that they are features extracted from the spectrogram of the sound wave. In particular, the spectral centroid and bandwidth characterize the center of mass of the spectrum (where most of the energy is located) and its weighted standard deviation, respectively (Sandhya et al., 2020). The spectral rolloff also characterizes the energy spectrum by identifying the frequency below which a certain percentage (in our case, 85%) of the energy is located, and can be used to differentiate voices from noise (Syed et al., 2021). These three features are 1-dimensional and only reduce the feature space to $(44, T)$. The spectral contrast feature, however, is 7-dimensional and works by dividing the spectrogram into 6 sub-bands, for which the difference between their peaks and valleys are computed, and is commonly used in music identification (Jiang et al., 2002b). The chromagram, or chroma feature,

is a feature that aggregates all information of a waveform into the 12 different pitch classes, which are separated by an octave. This feature is mostly used for music synchronization and singing voice separation (Yuan et al., 2022). Finally, MFCCs are a variable set of features (in our case, we use 12) which describe the shape of the spectral signal. They are based on human auditive perceptions and are widely used in the literature to capture phonetically relevant features (Mansour and Lachiri, 2017).

From the ablation study, we see that skipping features does not have a strong influence on the performance with the original full dataset. With the balanced dataset, the elimination of the spectral roll-off feature seems to have a strong effect, as it decreases its macro F-score to 0.402. A special mention to the MFCCs is deserved. These are the most common LDDs in the literature. Eliminating this feature but keeping the rest does not affect the performance (F-score of 0.544) in the original dataset, and improves it in the balanced case to 0.612. As MFCCs (and many of the other features) are commonly used to distinguish between voices based on their frequency and pitch, they could bias the model by considering information about the speaker, which is not necessarily relevant to the argument. This would also explain why the artificial voices performed better than the original dataset and why some of the simplest features, like spectral roll-off, have a big influence on performance.

7 Conclusion

In this paper, we explored the possibilities of using audio to detect arguments with multimodal machine learning models in a dataset of US presidential debates that was annotated for arguments. We found that, generally, BERT-based text-only models outperformed all models in the original dataset, but multimodal models can improve performance

Table 4: Results from ablation study. The complete feature space has a dimensions of $(45, T_{max})$, where T_{max} is the 99% percentile length of the utterances.

when the datasets are small and BERT encodings start performing poorly, in both balanced and unbalanced versions of the data. Multimodal models are therefore an alternative that could be used to improve classifications of arguments when data is scarce. To further investigate the reasons for these improvements, we ran audio-only models using artificially generated voices of male and female genders. Although we did not find a significant difference in the performance with the artificial voices (only a slight preference toward female), we find that in the most difficult scenarios (balanced and small datasets), the models with artificial voices outperform those with the original audio from the debates. Moreover, we perform an ablation study and we find that removing certain features like MFCCs can improve the performance of the models. We recognize that these features are commonly used to distinguish between speakers, so irrelevant characteristics of speakers might be influencing the capacity of the models to accurately classify arguments. However, all these features are highly correlated with one another, so further work should investigate which features are more independent of the speakers themselves or if they can be normalized before being fed into the network. These results should be compared with artificially generated voices, which could have different accents or speech rates to understand how those features can influence the classification of arguments.

Limitations

This paper assesses the benefits of audio features in the task of argumentation mining. Although the dataset presented has a large number of annotations ($N = 28, 850$) further research should be aimed at studying its cross-domain adaptability in different scenarios and datasets. The model architectures used in this paper are fairly standard in the literature and thus represent benchmarking results for further research in the field, as the application of multimodal sources of data in argumentation mining is still largely unexplored. Newer architectures, for instance those based on cross-attention mechanisms between the different modalities, should be explored next to check whether these results could be improved. It is still not fully clear what information from the audio embeddings are being picked up by the models. Our study on computerized voices offers an interesting avenue of research, but it should be further expanded to include a larger array of voices, different speech rates and embedding in fully multimodal models to assess their performance. The potential biases of models that use audio, especially how different voice’s characteristics (such as pitch frequency, which is correlated to gender) affect the classification, are not fully studied here, but briefly touched upon in the computerized voice study. This is rather important but unexplored territory and normalization strategies should be investigated to solve these issues. Finally, there are a large number of audio features that could be explored in this domain. Those used in this work are just some of the most common ones, but, as mentioned before, the choice is generally based on the extraction package used by the researcher. There is a need for standardization of these features in the community, so different work can be better compared.

Ethics Statement

We acknowledge that the use of audio features for automatic classification can cause potential privacy issues, as the real voice, and not only the speech, is used for classification. At this stage, we do not foresee any outstanding ethical issues from this research, as we use public domain data that was televised in public national television and is widely available on the web. Ethics approval for this research was received from the University of Southampton’s Faculty of Social Science Ethics and Research Governance committee, Ref: 66226,

Date 16/03/2022. The audio-enhanced dataset of this work along with the codes to reproduce our results are made available under license CC0: Public Domain in the project's [GitHub](#) and is also assigned a DOI to ensure reliable access to this work's supplementary data ([Mestre et al., 2023](#)).

A Hyperparameter tuning

Table A1 shows the hyperparameter bounds, as well as the final values selected for each model. After hyperparameter tuning, BERT-based text-models took approximately 45 minutes to train, whereas Bi-LSTM-based text-models took only 2 minutes (on the full dataset). Audio-only models took 25 min to train (as they would converge very slowly taking more than 50 training epochs), BERT-based multimodal models took an average of 3 hours and Bi-LSTM-based multimodal models took 8 minutes.

B Notes on alignment

As mentioned in the main text, we used the Aeneas package, which is a Python package that uses “forced alignment” to match the text and audio from utterances. Briefly, each sentence is provided as text and the tool uses the *espeak* Windows speech synthesizer to generate a computerized voice uttering that sentence. Then, amplitude waves are contrasted from the real and computer-generated sentences, and they are aligned to extract the timestamps. Two researchers manually checked every debate for major misalignment (and fixed them) until we obtained an almost perfectly aligned text.

We indicated omissions to be ignored during alignment: text between brackets that indicates transcription tags like “applause”, or the interjection “uh”, that appeared (too much) in some of the transcripts and never in others. This tool comes with a handy HTML output that allows the user to click on different parts of the transcript and check the alignment. Two people manually checked every debate for major misalignment (and fixed those cases as described above) until we obtained an almost perfectly aligned text.

Together with the dataset and codes to reproduce the results, we present our code to reproduce the alignment process, as well as an exhaustive list of the problems we encountered during alignment and how we solved them (e.g., modifications to the original transcripts, splitting videos, etc.). We share a folder with all the results from training our models with original and balanced datasets, as well as fractional subsets of 50%, 20% and 10%. We also include the training with artificial voices and from the ablation study. Each subfolder contains the parameters used by the model, confusion matrices of each run (5 runs per model), loss value vs epoch plots, training history with validation met-

rics, and precision/recall/F-score metrics for each run, as well as the average values.

C Results for 50% and 20% datasets

Tables A2 and A3 show the results for all models with 50% and 20% fractional datasets.

Hyper-parameter	Range	Bi-LSTM	BERT	Audio	Multimodal (Bi-LSTM +Audio)	Multimodal (BERT +Audio)

Improving Retrieval Augmented Neural Machine Translation by Controlling Source and Fuzzy-Match Interactions

Abstract

We explore zero-shot adaptation, where a general-domain model has access to customer or domain specific parallel data at inference time, but not during training. We build on the idea of Retrieval Augmented Translation (RAT) where top- k in-domain fuzzy matches are found for the source sentence, and target-language translations of those fuzzy-matched sentences are provided to the translation model at inference time. We propose a novel architecture to control interactions between a source sentence and the top- k fuzzy target-language matches, and compare it to architectures from prior work. We conduct experiments in two language pairs (En-De and En-Fr) by training models on WMT data and testing them with five and seven multi-domain datasets, respectively. Our approach consistently outperforms the alternative architectures, improving BLEU across language pair, domain, and number k of fuzzy matches with almost no trade-off on inference latency.

1 Introduction

Domain adaptation techniques such as fine-tuning (Freitag and Al-Onaizan, 2016; Luong and Manning, 2015) are highly effective at increasing in-domain performance of neural machine translation (NMT) systems, but are impractical in many realistic settings. For example, consider a single machine serving translations to thousands of customers, each with a private Translation Memory (TM). In this case, adapting, storing and loading large adapted models for each customer is computationally infeasible. In this paper we thus consider zero-shot adaptation instead, with a single general-domain model trained from heterogeneous sources that has access to the customer or domain specific TM only at inference time.

Our work builds on Retrieval Augmented Translation (RAT) (Li et al., 2022; Bulte and Tezcan, 2019; Xu et al., 2020; He et al., 2021; Cai et al., 2021), a paradigm which combines a translation model (Vaswani et al., 2017) with an external retriever module that retrieves the top- k most similar source sentences from a TM (i.e. "fuzzy matches") (Farajian et al., 2017; Gu et al., 2017; Bulte and Tezcan, 2019). The encoder encodes the input sentence along with the translations of the top- k fuzzy-matches and passes the resulting encodings to the decoder.

Prior RAT methods for NMT have fallen into two camps: Early work (Bulte and Tezcan, 2019; Zhang et al., 2018) concatenated the source sentence and the top- k fuzzy matches before encoding, relying on the encoder’s self-attention to compare the source sentence to each target sentences and determine which target phrases are relevant for the translation. More recent work (He et al., 2021; Cai et al., 2021) has opted to encode the source sentences and the top- k fuzzy matches *independently*, effectively shifting the entire burden of determining which target phrases are relevant to the decoder. We hypothesize that neither approach is ideal: In the first, the encoder has access to the information that we expect to be important (namely, the source and the fuzzy matches), but the self-attention also has potentially confusing/spurious connections. In the second, the encoder lacks the self-attention connections between the source and the fuzzy matches.

To address these issues, we propose a novel architecture which has self-attention connections between the source sentence and each fuzzy-match, but not between fuzzy-matches. We denote this method **RAT with Selective Interactions (RAT-SI)**. Our method is illustrated in Figure 1, along with two previously discussed approaches.

Experiments in five English-German (En-De) domain-specific test sets (Aharoni and Goldberg, 2020) and seven English-French (En-Fr) domain

*Work done while the authors were at AWS AI Labs.

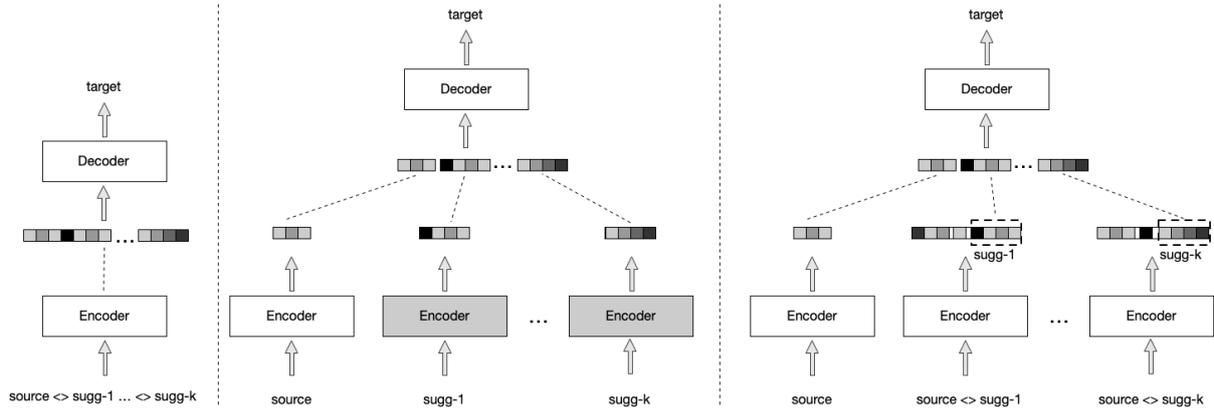

Figure 1: Architectures for retrieval augmented NMT. Left: Plain transformer ingesting source and retrieved fuzzy matches concatenated with a separator symbol (Bulte and Tezcan, 2019), denoted herein as RAT-CAT. Center: Transformer with dual encoder, one for encoding the source and one for encoding each retrieved fuzzy-match, inspired by He et al. (2021), denoted herein as RAT-SEP. Right: Transformer separately encoding the source and each source + fuzzy-match pair (this work), denoted herein as RAT-SI.

specific test sets (Pham et al., 2021), for $k = \{3, 4, 5\}$, demonstrate that our proposed method outperforms both prior approaches in 32 out of 36 cases considered. The proposed method outperforms the closest competitor by +0.82 to +1.75 BLEU for En-De and +1.57 to +1.93 for En-Fr.

2 Method

To isolate the effects of the underlying modeling strategy from the various tricks and implementation details employed in prior papers, we build baseline models which distill the two primary modeling strategies used in prior works:

The first concatenates a source sentence with target-language fuzzy matches and then encodes the entire sequence, as in Bulte and Tezcan (2019) and Xu et al. (2020). In this approach, the cross-attention of the encoder must learn to find the relevant parts of target-language fuzzy-matches by comparing each fuzzy-match to the source sentence, while ignoring potential spurious fuzzy-match to fuzzy-match interactions (see the left diagram in Figure 1). We denote this method **RAT-CAT**.

The second encodes the source and each target-language fuzzy-match separately (with two distinct encoders), and instead concatenates the encoded representations, inspired by He et al. (2021) and Cai et al. (2021). In this approach, the spurious connections between the target-language fuzzy-matches are eliminated, but the connections between the source and each fuzzy-match are also eliminated, forcing the attention in the decoder to

find the relevant portions in the fuzzy-match that are relevant to the source (see the center diagram in Figure 1). We denote this method **RAT-SEP**.

Finally, we propose a third method which attempts to build on the strengths of each of the prior methods. As in RAT-SEP, our method separately encodes (with the same encoder) the source and each target-language fuzzy-match; however, each fuzzy-match is jointly encoded with a copy of the source, as in RAT-CAT, allowing the encoder to find portions of the fuzzy-match which are relevant to the input. Finally, all the encoded inputs are concatenated and exposed to the decoder; However, the encoding of the source is only provided to the encoder once, to avoid potentially spurious interactions between copies of the input (see the right diagram in Figure 1). We denote our proposed method **RAT-SI**.

3 Experimental Setup

Our experiments are in two language directions: English-German (En-De) and English-French (En-Fr). We train models using the public WMT 2014 (Bojar et al., 2014) data set, with 4.5M En-De sentences and 36M En-Fr sentences.

During training, the model sees target-language fuzzy-match sentences from the same dataset it is being trained on (i.e. WMT14), but at inference, models must perform zero-shot adaptation to five En-De domain-specialized TMs¹ and seven En-Fr domain-specialized TMs.² En-De data is taken

¹Medical, Law, IT, Religion and Subtitles.

²News, Medical, Bank, Law, IT, TED and Religion.

from Aharoni and Goldberg (2020), which is a re-split version of the multi-domain data set from Koehn and Knowles (2017) while En-Fr data set is taken from the multi-domain data set of Pham et al. (2021).

To find target-language fuzzy matches for our model from domain specific TMs, we use Okapi BM25 (Robertson and Zaragoza, 2009), a classical retrieval algorithm that performs search by computing lexical matches of the query with all sentences in the evidence, to obtain top-ranked sentences for each input. To enable fast retrieval, we leverage the implementation provided by the ElasticSearch library.³ Specifically, we built an index using source sentences of each TM, and for every input source sentence, we collect top- k similar source side sentences and then use their corresponding target side sentences as inputs to the model.

To explore how each method performs (and how robust they are) under different conditions, we run a full set of experiments for $k = \{3, 4, 5\}$. We train separate models for each language pair and k value, and then apply that model to each of the 5 (En-De) or 7 (En-Fr) domains.

We report translation quality with BLEU scores computed via Sacrebleu (Post, 2018).⁴ We use compare-mt (Neubig et al., 2019) to perform pairwise significance testing with `bootstrap = 1000` and `prob_thresh = 0.05` for all pairs.

All models employed transformers (Vaswani et al., 2017) with 6 encoder and 6 decoder layers. Hidden size was set to 1024 and maximum input length truncated to 1024 tokens. All models employed a joint source-target language subword vocabulary of size $32K$ using Sentencepiece algorithm (Kudo and Richardson, 2018).

We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$; and (ii) increase the learning rate linearly for the first $4K$ training steps and decrease it thereafter; (iii) use batch size of $32K$ source tokens and $32K$ target tokens. Checkpoints are saved after every $10K$ iterations during training. We train models with maximum of $300K$ iterations. We use dropout of 0.1 and label-smoothing of 0.1.

4 Results

Results for En-De are shown in Table 1 and results for En-Fr are shown in Table 2.

We observe several trends in the results. First, our proposed RAT-SI method outperforms both the RAT-CAT and RAT-SEP methods across both language pairs, having the best performance in 32/36 cases considered. In En-De, the proposed RAT-SI method has an average improvement of 1.43 BLEU over RAT-CAT and 2.35 BLEU over RAT-SEP, while in En-Fr we observe an average improvement of 1.73 BLEU over RAT-CAT and 2.98 over RAT-SEP. These results support our hypothesis that attention connections between the source sentences and each fuzzy match are critical to translation quality and the connections between the fuzzy matches are actually harmful.

Second, on average, $k = 5$ produces the best results for the RAT-SI method, but only by a small amount. However, considering individual language pair / domain combinations, there are many cases where $k = 5$ does not produce the best results, sometimes by several BLEU points. We hypothesize that this is due to the different domains containing, on average, different amounts of relevant data. This observation underscores the importance of tuning k , as well as testing new RAT methods under a variety of conditions, including different k values.

Finally, consistent with prior work, we see large improvements for all online domain-adapted methods (RAT-CAT, RAT-SEP, and RAT-SI) over the non-domain-adapted baseline, with improvements of up to +13.85 BLEU. This is not surprising, since the baseline model does not take advantage of any domain-specific data.

4.1 Latency

While not the focus of this work, we did a preliminary study of latency, comparing a baseline transformer to RAT-CAT and RAT-SI models during inference. We follow Domhan et al. (2020) and measure latency values as the 90th percentile of inference time when translating each sentence individually (no batching). We run experiments on an EC2 p3.2xlarge instance with a Tesla V100 GPU and report encoding latency results in Table 3. We use a batch size of 1 and $k=3$ for all experiments.

We observe a small increase of encoding latency by using RAT-SI (i.e. 17.48 ms) compared to of RAT-CAT. We provide a breakdown of the total

Model	Encoding Latency
Transformer	14.80 ms
RAT-CAT	15.23 ms
RAT-SI	17.48 ms

Table 3: Encoding latency in milliseconds of models (lower is better).

encoding latency in Table 4 which shows encoding the inputs in RAT-SI is faster than RAT-CAT but it requires an extra overhead for extracting the encoding of fuzzy matches from the joint encoding of source with fuzzy match. However, the encoding time is a very small fraction of overall latency (see Table 5) and thus this difference appears to be negligible.

We find that RAT-CAT and RAT-SI have nearly identical latencies, and each is only slightly slower than the baseline transformer (see Table 5). This is somewhat surprising since both methods make the input to the decoder significantly longer. We hypothesize that we are under-utilizing the GPU in all cases, and thus the increased computations does not increase latency. Further investigation of this is

RAT-SI Model	Encoding Latency
Encoding input	14.91 ms
Extra overheads	2.57 ms
Total time	17.48 ms

left for future work.

5 Related Work

Bulte and Tezcan (2019) proposed augmenting the input to NMT with target-language fuzzy-match sentences from a TM, concatenating the input and fuzzy-matches together. Their method was simpler than prior works such as (Zhang et al., 2018), which manipulated n-gram probabilities based on their occurrence in the fuzzy-matches. Xu et al. (2020) proposed several enhancements using the same architecture, including fine-tuning models

Model	Translation Latency
Transformer	574.02 ms
RAT-CAT	597.28 ms
RAT-SI	597.41 ms

Table 5: Translation latency in milliseconds of RAT-CAT and our model RAT-SI (lower is better). Batch size was set to one to simulate an on-demand system.

and masking out or marking words not related to the input sentence, and matching arbitrarily large n-grams instead of sentences.

More recent work has explored using separate encoders for input and fuzzy-match (He et al., 2021; Cai et al., 2021). He et al. (2021) also considers the realistic scenario where a TM may include noise, while Cai et al. (2021) explores finding target sentences in monolingual data instead of relying on a TM at inference time.

Xia et al. (2019) and Xu et al. (2020) explore aspects of filtering fuzzy-matches by applying similarity thresholds, leveraging word alignment information (Zhang et al., 2018; Xu et al., 2020; He et al., 2021) or re-ranking with additional score (e.g. word overlapping) (Gu et al., 2018; Zhang et al., 2018).

Our work is related to the use of k -nearest-neighbor for NMT (Khandelwal et al., 2021; Zheng et al., 2021) but it is less expensive and does not require storage and search over a large data store of context representations and corresponding target tokens (Meng et al., 2021).

Other works have considered online adaptation outside the context of RAT, including Vilar (2018), who proposes Learning Hidden Unit Contributions (Swietojanski et al., 2016) as a compact way to store many adaptations of the same general-domain model. For an overview of fuzzy-match augmentation outside of NMT, see Li et al. (2022).

Domain adaptation can also be performed offline, typically via fine tuning (Luong and Manning, 2015). Regularization is often applied during fine tuning to avoid catastrophic forgetting (Khayrallah et al., 2018; Thompson et al., 2019a,b).

TMs are commonly used in the localization industry to provide suggestions to translators in order to boost their productivity (Federico et al., 2012). Enhancing translation quality of MT system by leveraging fuzzy-matches extracted from TMs has been explored widely for statistical MT (Koehn and Senellart, 2010; Mathur et al., 2013) and neural MT

systems (Farajian et al., 2017; Gu et al., 2017; Cao and Xiong, 2018; Bulte and Tezcan, 2019).

6 Conclusion

Previous work in retrieval augmented translation has used architectures which either have full connections between source and all fuzzy matches, or independently encode the source and each fuzzy match. Based on our hypothesis that the attention connections between source and each fuzzy match are helpful, but that the connections between different fuzzy matches are harmful, we propose a new architecture (RAT-SI) with the former connections but not the latter. Experiments on several language pairs, domains, and different numbers of fuzzy matches (k) demonstrate that RAT-SI substantially outperforms the prior architectures.

7 Limitations

Due to the availability of domain specific datasets, we perform experiments on two high-resource languages, both out of English. It is unclear if our conclusions would hold on low-resource language pairs. Furthermore, our domains may or may not match real world use cases where an MT customer has their own TM. Real TMs may be significantly larger/smaller, contain multiple domains, etc.

Abstract

Causal reasoning is a critical component of human cognition and is required across a range of question-answering (QA) tasks (such as abductive reasoning, commonsense QA, and procedural reasoning). Research on causal QA has been underdefined, task-specific, and limited in complexity. Recent advances in foundation language models (such as BERT, ERNIE, and T5) have shown the efficacy of pre-trained models across diverse QA tasks. However, there is limited research exploring the causal reasoning capabilities of those language models and no standard evaluation benchmark. To unify causal QA research, we propose *CALM-Bench*, a multi-task benchmark for evaluating causality-aware language models (CALM). We present a standardized definition of causal QA tasks and show empirically that causal reasoning can be generalized and transferred across different QA tasks. Additionally, we share a strong multi-task baseline model which outperforms single-task fine-tuned models on the *CALM-Bench* tasks.

1 Introduction

Causal reasoning is a crucial aspect of human cognition and is critical to the development of our mental models of reality (Neeleman et al., 2012; Johnson-Laird and Khemlani, 2017; Griffiths, 2017). Theories of causation have been studied extensively across philosophy (Beebe et al., 2009), physics (Dowe, 2009), cognitive science (Waldmann, 2017), and probability and statistics (Pearl, 2009), amongst many other fields. Explorations of causality in the language domain tend to be semantic, linguistic, or logical in nature as access to direct observational data or event probabilities is not assumed nor is required. Descriptions of causality can be linguistically valid but factually incorrect (e.g. butter is the leading cause of factory deaths). Therefore, causal reasoning in language should ideally be logically consistent and grounded

Premise: Air pollution in the city worsened.
Question: What is the CAUSE of this?
Alternative 1: Factories increased their production
Alternative 2: Factories shut down.
1. Identify Causal Concepts Air pollution, factories, and production
2. Causal Knowledge Linking Air pollution is the introduction of toxic substances and poisonous gasses into the air which make it harmful for humans and other living beings to breathe. Industrial factories release chemical byproducts and harmful gasses into the atmosphere during the production process.
3. Reasoning over causal knowledge Factory, cause-effect, pollution Increased production, cause-effect, air pollution

Figure 1: An CQA example from the COPA (Gordon et al., 2012). CQA requires identifying causal concepts, linking those concepts to causal relations, and reasoning over those relations.

in commonsense knowledge. The *counterfactual theory of causation* (Lewis, 1973) provides a useful definition of causation for language applications. It posits that causation is relational (there is a cause and effect), temporal (the cause must precede the effect), and counterfactual (if the causing event had not occurred, the effect would not have occurred). Various natural language processing (NLP) applications require identifying causal relations and reasoning over those relations.

These NLP applications can be split into two general categories: causal relation identification (CRI) and causal question-answering (CQA). CRI tasks aim to identify and extract cause/effect spans from descriptions of causal events. CRI requires linguistic knowledge - relying on lexical triggers (i.e. causative verbs and causal connectives) and grammatical structures (Neeleman et al., 2012; Girju, 2003). Historically, the majority of NLP research on causality has focused on CRI.

In contrast to CRI, CQA tasks require both background causal knowledge and reasoning. Consider the question *Air pollution in the city worsened. What is the cause of this?* (Figure 1). To answer this question, commonsense knowledge about factories, pollution, and the ability to infer both causal and counterfactual relations is required. General

Task	Example	Size	Question Type	Format	Knowledge
aNLI (Bhagavatula et al., 2020)	Context: Jessie wants to save the planet. This summer has been the hottest in all history. Question: Which hypothesis is the most plausible for the provided observations? A: Jessie decides to buy a new truck. B: Jessie decides to sell her truck and use public transportation instead.	174,226 Train: 169,654 Val: 1,532 Test: 3,040	cause prediction	multiple-choice	social, world
COPA (Gordon et al., 2012)	Question: Air pollution in the city worsened. What is the cause of this? A: Factories increased their production. B: Factories shut down.	1,000 Train: 800* Val: 200 Test: 500	cause prediction effect prediction	multiple-choice	world
CosmosQA (Huang et al., 2019)	Context: Two things happened today in Beijing. First off, incoming journalists were amazed to find China had successfully lifted the brown haze in city. Skies were crystal blue and the air felt noticeably lighter. Question: Why did the sky appear clearer? A: None of the above choices. B: The citizens learned to ignore the gloomy skies. C: The citizens made an effort to cut down on pollution. D: A large storm had recently passed.	35,210 Train: 25,262 Val: 2,985 Test: 6,963	cause prediction effect prediction	multiple-choice	social, world
E-Care (Du et al., 2022)	Question: The city is determined to control air pollution. What is the effect? A: They have to reduce the number of automobiles. B: Environmental pollution has been increased.	17,051 Train: 14,929 Val: 2,122 Test: blind	cause prediction effect prediction	multiple-choice	social, world, science
ROPES (Lin et al., 2019)	Context: There are two planets, Glarnak and Bornak, that share the same atmospheric composition. The planets have nearly identical ecosystems and topography. The main difference between the two planets is the level of global warming on each planet. Glarnak is experiencing a strong impact from global warming. Bornak, though, is experiencing practically no effects of global warming. Question: Which planet has more pollutants in the atmosphere? Glarnak	14,322 Train: 10,924 Val: 1,688 Test: 1,710	cause prediction cause comparison effect prediction effect comparison	reading comprehension	science, world
WIQA (Tandon et al., 2019)	Context: 1. A seed is in soil. 2. The seed germinates. 3. The plant grows roots. 4. The plant grows out of the ground. 5. The plant gets bigger. 6. The plant flowers. 7. The flower produces fruit. 8. The fruit releases seeds. 9. The plant dies. Question: Suppose less pollution in the environment happens, how will it affect the population of plants? A: More B: Less C: No Effect	39,705 Train: 29,808 Val: 6,894 Test: 3,003	effect prediction	multiple-choice	science, world

Table 1: CALM-Bench is a multi-task causal question answering benchmark consisting of six diverse QA tasks requiring both causal reasoning and knowledge.

work on CQA is often under-defined and limited based on the task definition. For example, previous work defined CQA as answering variations of *What is the cause/effect of X?* style questions where the model had to select the most plausible cause or effect from a set of candidate options. While this task requires causal knowledge, it could be recast as an information retrieval problem with no further requirement of causal reasoning. A stronger definition of CQA would allow for more principled explorations of causal reasoning (e.g. reasoning over causal chains, abductive inference, counterfactual reasoning, etc) and aid in the development of stronger NLP models.

Recent advances in foundation language models have demonstrated the effectiveness of pre-trained models across a wide range of NLP and general language understanding tasks. The term *foundation model* (Bommasani et al., 2021) describes any monolithic neural model (e.g. BERT (Devlin et al., 2019)) that captures general knowledge through pre-training and is able to transfer that knowledge to a wide range of downstream tasks. Foundation language models exhibit general reasoning capabilities (Clark et al., 2021), factual knowledge recall (Petroni et al., 2019), and superior performance on a wide range of QA tasks (Khashabi et al., 2020; He et al., 2021; Lourie et al., 2021a). Knowledge in foundation language models is usually injected through denoising objectives (e.g. masked token prediction) (Sun et al., 2020). However, interpreting and extracting that knowledge is difficult (requiring specialized probing tasks) and these

models can be susceptible to exploiting superficial (Kavumba et al., 2019). CQA tasks could provide a unique opportunity to develop both explainable models (through producing causal explanation chains) and expand the reasoning capabilities of those models in QA settings. To date, no comprehensive study has explored the causal reasoning capabilities of foundation language models.

We aim to unify research around CQA research by providing a definition for CQA rooted in the cognitive understanding of causal learning and propose *CALM-Bench*, a multi-task causal question-answering benchmark for evaluating causality-aware language models (CALM). *CALM-Bench* (Table 1) consists of six different QA tasks (aNLI (Bhagavatula et al., 2020), COPA (Gordon et al., 2012), CosmosQA (Huang et al., 2019), E-Care (Du et al., 2022), WIQA (Tandon et al., 2019), and ROPES (Lin et al., 2019)) that require both causal knowledge and causal reasoning. We show empirically that causal reasoning can be generalized across the different tasks in *CALM-Bench*. We present a multi-task learning (MTL) setup that outperforms all single-task fine-tuned baselines and demonstrates strong results on the COPA task in a zero-shot setting. Relevant details about the code and model weights can be found on GitHub ¹.

2 Causal question-answering

We define CQA broadly as any QA task which requires both *causal reasoning* and *causal knowl-*

¹<https://github.com/dhairyalal/CALM-Bench>

edge provided a real or hypothetical description of events. Cognitive theories of causal learning provide a framework for understanding and evaluating the process of causal question-answering in NLP applications. The inferential theory of causal learning posits that causal learning is a slow and effortful cognitive process that involves drawing causal conclusions over propositional premises (Boddez et al., 2017).

Propositions represent our causal knowledge and contain both qualified relational information (e.g. increase of greenhouse gasses in the atmosphere causes global warming) and propositional beliefs (I believe that greenhouse gasses cause global warming). Propositions are compositional (given the propositions: factories cause air pollution and pollution leads to global warming, we can infer that factories cause global warming) and directional (i.e. we would not infer that global warming causes factories). A key aspect of causal learning is the ability to generalize specific causal knowledge to new situations which is known as causal mechanism knowledge. (Johnson and Ahn, 2017; Ahn et al., 1995).

Causal mechanism knowledge is the mental representation of a system of physical or abstract parts/processes and the expectation of causal interactions between those components that can be generalized to new situations. For example, an arson investigator relies on their mechanism knowledge of fire catalysts and forensic experience to ascertain human involvement. Causal mechanism knowledge can be succinctly represented as propositional statements. Causal bridging inferences describe the relationship between causal knowledge and reasoning. Singer et al. (1992) found that individuals invoke causal statements to bridge two events and then validate those statements against prior commonsense and causal knowledge. For example, given the events *Anna added butter to the hot pan.* and *The butter melted.*, we implicitly invoke the bridging statement *heat caused the butter to melt* based on our prior knowledge.

Solving CQA tasks can be decomposed into three general steps: *causal concept identification*, *causal knowledge linking*, and *causal reasoning*. Consider Figure 1, the causal concepts of air pollution and factories are identified and then linked to background knowledge in order to produce causal knowledge. Causal knowledge can be expressed as relational triples (e.g. factory, cause-effect, pol-

lution) which are effectively propositional statements. The final step requires reasoning over that knowledge through both inferential and counterfactual reasoning. We infer that the increase in factory production results in worsening air pollution based on causal knowledge that factory production causes pollution. The counterfactual, if factories shut down then air pollution would not increase, allows us to eliminate the second option. Arriving at the correct answer in this example is difficult without any background causal knowledge and reasoning over that knowledge.

An important aspect of causal learning is the ability to generalize causal mechanism knowledge to novel situations and task settings. We can see in Table 1 that while thematically all the examples are about the causal relationship between global warming and air pollution, each question requires different types of reasoning over the same knowledge. With the aNLI example, global warming is not mentioned explicitly but must be inferred from social commonsense knowledge (i.e. through the bridging inferences that *saving the planet* and *the hottest summer* are related to global warming) and then use abductive reasoning to select the most plausible hypothesis. The COPA example requires counterfactual reasoning to eliminate the option that factories shutting down would not contribute to air pollution and inferential reasoning to infer that increased factory production results in more air pollution. The WIQA example requires both understanding the life cycle of a plant as a procedural chain and predicting the magnitude impact of environmental pollution as a downstream effect on the plant population. Finally, the ROPES example involves generalizing mechanism knowledge to a fictional setting in order to identify which planet is more likely to have pollutants in the air.

CALM-bench consists of diverse QA tasks requiring social, world, and science knowledge. Our empirical experiments aim to validate the assumption that causal reasoning is transferable across these QA tasks in *CALM-Bench* and produce strong baselines for future research in this space.

3 Related Work

3.1 Causal question-answering

COPA was one of the first QA benchmark tasks which required both background commonsense knowledge and causal reasoning. It is also included as part of the SuperGlue (Wang et al., 2019) bench-

mark. COPA can be considered solved by modern massive foundation models which achieve near human performance (99% accuracy). However, these models are very large (the top three models having more than 10 billion+ parameters), are trained on multi-terabyte scale corpora, and require significant computing resources. Sharp et al. (2016) constructed the first CQA dataset from the Yahoo! Answers corpus using the templates *What causes ...* and *What is the result of ...* to identify causal questions. Sharp et al. (2016) and Xie and Mu (2019) investigated different strategies for training distributed causal embeddings for re-ranking answer options for those causal questions. Hassanzadeh et al. (2019) and Kayesh et al. (2020) explored binary causal questions (i.e. could X cause y) answering using a mixture of co-occurrence statistics and cosine similarity threshold derived from fixed BERT embeddings. The proposed solutions were specific to the task format (i.e. learning threshold values for predicting the yes option). causalqa introduced CausalQA, a corpus of 1.1 million causality-related questions and answers extracted from various datasets primarily related to open-domain web queries (e.g. GooAQ (Khashabi et al., 2021), MS-Marco (Nguyen et al., 2016)). Causal questions were identified using templates spanning *What*, *How*, and *Why* style questions whose intent is to enquire about causes and effects.

Both the CausalQA and the Yahoo Answers! causal questions focus on causal knowledge retrieval or basic reading comprehension without further requirement of causal reasoning. Causal knowledge retrieval can be generalized to information retrieval where the goal is to ensure the retrieved passage contains causal explanations related to the query. Here linguistic cues (Khoo et al., 1998; Girju et al., 2007; Neeleman et al., 2012) or semantic similarity (Dalal et al., 2021b) can be used to identify relevant passages. Likewise, answering *What*, *How*, and *Why* style questions in the context of reading comprehension (e.g. SQuAD (Rajpurkar et al., 2016)) focus more on the lexical overlap between the question and supporting text and linguistic cues associated with the question typologies. CALM-Bench aims to address this gap by focusing QA tasks that require both causal knowledge and causal reasoning.

Most recently, CQA research has investigated augmenting foundation language models with external knowledge for CQA. Dalal et al. (2021a)

proposes augmentation with external causal knowledge graph embeddings derived from CauseNet (Heindorf et al., 2020) for QA on the COPA and WIQA tasks and Hosseini et al. (2022) explores injecting the commonsense knowledge from the ATOMIC (Sap et al., 2019) commonsense knowledge base using the BERT masked language modeling pretraining objective for the COPA task. Recent interest in question-answering has led to the development of many large-scale and complex QA tasks. *CALM-bench* consists of curated tasks that require causal reasoning and are described in Section 4.

3.2 Commonsense Reasoning

Commonsense reasoning is closely related to CQA and can be considered a broader superset of CQA depending on the task. Several of the *CALM-Bench* tasks (aNLI, COPA, CosmosQA, and E-CARE) require causal reasoning over commonsense knowledge, and the aNLI, COPA, and CosmosQA tasks were first introduced as commonsense QA tasks. Recent work on commonsense reasoning has focused on probing commonsense knowledge found in foundation language models (Zhou et al., 2020), strategies for effective knowledge augmentation (Fan et al., 2020), and the generation of commonsense knowledge (Bosselut et al., 2019). Lourie et al. (2021b) introduced the first multi-task commonsense QA benchmark (RAINBOW) and a universal model (UNICORN) for general commonsense QA. UNICORN is a T5-11b model (Raffel et al., 2020) trained on the RAINBOW multi-set tasks and fine-tuned in a multi-task setting. Our approach and motivation for multi-task CQA benchmark were greatly inspired by (Lourie et al., 2021b). *CALM-bench* shares two of its tasks (aNLI and CosmosQA) with the RAINBOW benchmark and we consider multi-task learning in our experiments.

3.3 Causal Relation Identification

CRI is often the first step for aggregating causal knowledge when building automated CQA systems (Hassanzadeh et al., 2020). Extracted causal relations are often useful for generating causal knowledge graphs (Heindorf et al., 2020) and developing causal knowledge representations (Sharp et al., 2016; Dalal et al., 2021a) which can be used to improve model performance in CQA tasks. CRI tasks have been studied extensively in the computational linguistics and NLP domain (Yang et al., 2022; Drury et al., 2022). Early methods relied on lexical triggers and linguistic cues (Khoo et al.,

1998; Girju et al., 2007; Neeleman et al., 2012). More recent approaches have explored using neural methods with word embedding features (Dasgupta et al., 2018), self-supervision (Zuo et al., 2021), and external knowledge (Liu et al., 2020). Several efforts have been undertaken to unify CRI research. Tan et al. (2022) introduced the UniCausal benchmark which consolidates six annotated CRI corpora across the tasks of causal sequence classification, cause-effect span detection, and causal pair classification. (Hosseini et al., 2021) introduced the CREST schema and toolkit which converts thirteen commonly used CRI datasets into a unified format.

4 CALM-Bench Tasks

CALM-Bench (Table 1) consists of five multiple-choice tasks (aNLI, COPA, Cosmos QA, E-Care, and WIQA) and a reading comprehension task (ROPES). These tasks require diverse causal knowledge which can be broadly summarized as social (sociological norms of human behavior), world (general commonsense knowledge), and science (specific scientific knowledge of natural processes such as the precipitation cycle or plant life cycle). Questions either require predicting the cause or effect (i.e. cause and effect prediction) provided a description of events or comparing entities (i.e. cause and effect comparison) in a causal system.

Abductive Natural Language Inference (aNLI) (Bhagavatula et al., 2020) is an abductive reasoning task over narratives of social situations. Provided a sequential pair of social observations, the model must predict which of the two provided hypotheses best explains the observations.

Choice of Plausible Alternatives (COPA) (Gordon et al., 2012) is a commonsense causal reasoning task. Provided a premise, the goal is to select the most likely cause or effect from a pair of options. (Kavumba et al., 2019) introduced 500 additional training examples in Balanced-COPA to mitigate the corpus-level artifacts that were likely to be exploited by language models during fine-tuning.

COSMOS QA (Huang et al., 2019) is a multiple-choice QA task requiring social commonsense knowledge. Provided a narrative about people in everyday situations, the goal is to identify the most plausible cause or effect about agents in the story.

E-Care (Du et al., 2022) consists of two causal reasoning tasks. The first task, similar to COPA, requires identifying the most likely cause or effect

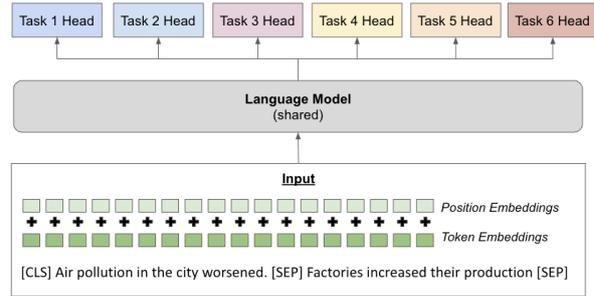

Figure 2: Our MTL model adapts the hard-parameter sharing architecture (Baxter, 2004) where the language model is shared across all the task heads. During training, the task losses are averaged and backpropagated to produce causality-aware contextual embeddings which are effective across all the *CALM-Bench* tasks (Table 4).

of the provided premise. The second task requires generating a causal explanation of the correct answer option. We only consider the first task as part of *CALM-Bench*.

Reasoning over Paragraph Effects (ROPES) (Lin et al., 2019) is a reading comprehension task. Provided a knowledge passage, the model is required to reason over the causal and qualitative relations in the passage and apply them to answering questions about a hypothetical situation. 70% of background passages contain causal relations and 26% contain both causal and qualitative relations.

What If question-answering (WIQA) (Tandon et al., 2019) is a multiple-choice QA task requiring reasoning over procedural descriptions of natural processes. WIQA requires predicting the downstream magnitude (more, less, no effect) effect of a perturbation to an individual step in the procedural chain.

5 Methodology

5.1 Language Models

Our experiments consider two different foundation language models, BERT (Devlin et al., 2019) and ERNIE 2.0 (Sun et al., 2020). BERT and derivative models (e.g. RoBERTa (Liu et al., 2019b), DeBERTa (He et al., 2021), etc) contain unspecified distributional knowledge which is learned through the random masked language modeling pretraining objective. In a contrast, ERNIE 2.0 injects external knowledge through a variety of pretraining objectives including masked knowledge prediction, discourse relation prediction, and the IR relevance task. ERNIE 2.0’s underlying transformer encoder has the same architecture and parameters as the

<i>ROPES</i>	+0.02	-0.06	-0.01	+0.01	+0.02	-

Table 3: This table contains the transfer learning results for the ERNIE 2.0 model. In contrast the BERT model, we observe general consistent positive improvement across nearly all tasks. This suggests that language models with grounded knowledge tend to both do better on CQA tasks and are able to transfer causal reasoning across tasks more effectively.

BERT model and is trained on similar data. ERNIE 2.0 is trained on additional Reddit and Discovery data but the primary difference is in its knowledge-focused pretraining objectives.

We hypothesize that ERNIE 2.0 will outperform BERT across the CQA task as grounded knowledge is a requisite for causal reasoning in our definition. The BERT and ERNIE 2.0 implementations come from the Huggingface Transformers library (Wolf et al., 2020). We use the pretrained base models for both (bert-base-uncased² and

nghuyong/ernie-2.0-base-en respectively³).

5.2 Language Model Training

Single-task fine-tuning and multi-task fine-tuning are used to train our models on the CQA tasks. Sequential fine-tuning (Pratt, 1992) was also investigated but found to be inconsistent and not as effective as the other methods (Appendix A.6.2). Following the task head paradigm introduced in Devlin et al. (2019), we develop separate classification heads for each task (see Appendix A.1 for

ERNIE-base MTL	0.65	0.80	0.65	0.78	0.58	0.77	0.71

Table 4: We present the baselines results for CALM-bench. All the task are evaluated using the accuracy metric with the exception of ROPES which displays exact match. Results are presented for the test sets for COPA and WIQA and on validations sets for aNLI, CosmosQA, E-Care, and ROPES. We find that MTL models outperform the single-task finetuned models consistently with ERNIE-base MTL model having the best results.

more details). The pooled *CLS* embedding from the last layer in the language model is fed into the classification head to map the language model’s contextualized output into the task’s classification space. In the single-task setting, each task is trained independently. The cross-entropy loss is calculated per training batch and back-propagated through all the layers in the language model.

For the multi-task learning (MTL) model, we adapt a hard-parameter sharing model (Baxter, 2004) and train it using the multi-task fine-tuning strategy (Liu et al., 2019a). Our MTL model (Figure 2) consists of a shared base language model and separate task heads for tasks in CALM-Bench. For each train step, a train batch is sampled for each task and the task-specific losses are calculated. The task losses are averaged before backpropagation. The MTL model is trained for 8,000 steps on the aNLI, CosmosQA, E-Care, and WIQA tasks. The ROPES task is not included in training as its format is significantly different from the multiple-choice tasks and resulted in lower performance in our early experiments. COPA was also omitted from the MTL training given its small size (800 training examples) and instead saved for zero-shot evaluation. At evaluation time, we fine-tune the MTL model on each target task for one additional epoch and then evaluate the model on the target evaluation set.

A hyperparameter search is run to identify the optimal random seed and the learning rate for each task (see Appendix A.5.1). Four of the tasks (aNLI, CosmosQA, E-CARE, and ROPES) have private test sets and a public leaderboard. For these tasks, we treat the validation set as the test set during evaluation and generate a new validation split from the training data to be used for training validation. The general intuition is that fine-tuned language models

should have the best task-specific performance. If causal reasoning is transferrable, we should see improvements over the single-task fine-tuned models in both the transfer learning and multi-task learning experiments.

6 Empirical Findings

6.1 Single-task Fine-tuned Baselines

The baseline results for the single-task fine-tuned language models for all tasks can be found in Table 4. We find the ERNIE model on average outperforms the BERT model across most of the CQA tasks with an average improvement of 5.3pp on the aNLI, COPA, and CosmosQA tasks. However, ERNIE does underperform the BERT model on both the ROPES and WIQA tasks and shows no improvement on the E-Care task. These results are used as the baseline for the transfer learning and MTL experiments in Table 4.

6.2 Transferability of Causal Reasoning

We conduct sixty experiments to see if causal reasoning can be generalized and transferred across the QA tasks in CALM-Bench. For each experiment, we select a base task (e.g. aNLI) and a different target evaluation task (e.g. COPA). The language model is first fine-tuned on the base task and then fine-tuned on the target task. That model is then evaluated on the target task. Each transfer learning experiment is independent and the final results are summarized in Table 2 and 3.

Across both BERT and ERNIE 2.0 models, we observe that task-specific causal knowledge and reasoning are transferable. However, the pattern of transference differs across both models.

For the BERT model, the E-Care, WIQA, and ROPES tasks generally see degradation in accuracy

and exact match. However, there is improvement across aNLI, COPA, and CosmosQA tasks with COPA receiving an average of 7pp gain. We hypothesize this may due to two factors. As noted earlier, there is no grounded knowledge in BERT. BERT has to learn both task-specific knowledge and reasoning processes associated with each task. Tasks with similar knowledge requirements (aNLI, COPA, and CosmosQA) benefit from each other and the shared task format (multiple-choice). In contrast, the ROPES and WIQA tasks have different task heads and knowledge requirements. BERT is likely suffering from catastrophic forgetting when fine-tuning on the target task.

In contrast, we find consistent general improvement across all the tasks with the ERNIE 2.0 model. ERNIE 2.0 contains grounded knowledge which allows for better transfer learning across the tasks. This was observed with WIQA and ROPES seeing average improvements of 1.8pp and 1.4pp in contrast to the average losses of -0.08pp and -1.5pp with the BERT model.

To summarize, we provide empirical evidence that causal reasoning and knowledge can be transferred across different CQA tasks. We further find validate our assumptions that CQA requires both reasoning capabilities and grounded knowledge as the knowledge-rich ERNIE demonstrates more consistent improvement across the *CALM-Bench* tasks.

6.3 Multi-Task Learning Results

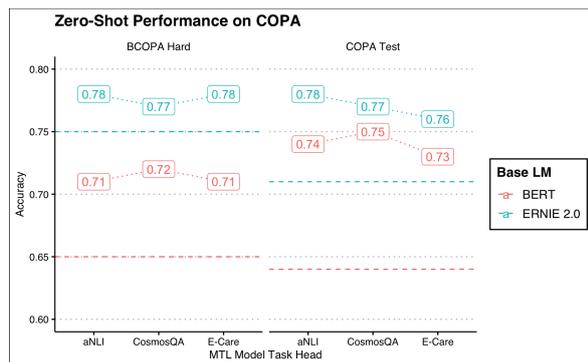

Figure 3: Zero-shot results on the COPA task. We present results for both the primary COPA Test set and the BCOPA Hard (Kavumba et al., 2019) subset. The dashed lines are the single-task fine-tuned baselines. Despite each task head having not seen the COPA examples during the MTL training, they outperform the single-task fine-tuned baselines.

In Table 4, we provide the baseline results for both the single-task fine-tuned and multi-task mod-

els on the CALM-Benchmark. The score column equally averages all metrics to provide a single value for comparing the different approaches. The MTL baselines outperform all the single-task fine-tuned baselines with the ERNIE MTL model providing the best results. These results further corroborate our claim that causal knowledge and reasoning are generalizable across diverse QA tasks. However, we do observe that task format matters. The inclusion of ROPES (a reading comprehension task) during multi-task training resulted in generally lower performance. As a result, our final MTL model was only trained on the subset of multiple-choice tasks (aNLI, CosmosQA, E-Care, and WIQA). Future work may consider alternative ways to weight task-specific losses or different model architectures (e.g. T5 (Raffel et al., 2020)) which can map all tasks to the same text-to-text format.

In the context of multiple-choice CQA, we find consistent and positive improvement across all tasks in both the single-task transfer learning and multi-task learning scenarios. We run an additional zero-shot experiment where is task head in the MTL model is used to evaluate the COPA test and BCOPA hard test examples. Figure 3 shows that both the BERT and ERNIE single-task fine-tuned baselines are outperformed by an average of +10pp and +6.6pp on the test set and see an average of +6.3pp and +1.3pp improvement on the BCOPA hard subset. For comparison, Hosseini et al. (2022) fine-tune a BERT large (345 million parameters) model on 780,000 knowledge triples from the ATOMIC commonsense knowledge base. Their BERT-Large-ATOMIC model achieves 88% accuracy on the COPA test set and 73% accuracy on the BCOPA hard subset. Our smaller ERNIE 2.0 MTL model achieves 80% fine-tuned accuracy on the COPA test set with fewer parameters (110 million) and less training data. Further, our MTL model outperforms the BERT-Large-ATOMIC model on the BCOPA hard subset with the zero-shot MTL heads averaging around 77% accuracy and fine-tuned model achieving 79% accuracy.

7 Conclusion

In this paper, we provide a unified definition of causal question-answering in the context of natural language applications. Drawing from the cognitive science literature, we posit that CQA tasks

require both causal reasoning and causal knowledge. Based on this definition, we introduce the *CALM-bench*, the first multi-task CQA benchmark to evaluate the general causal reasoning capabilities of foundation language models. We provide empirical evidence which validates the intuition that causal reasoning and knowledge are transferable across the CQA tasks. Knowledge-enriched language models like ERNIE are likely to outperform distributional models (i.e. BERT) across all tasks in both the single-task fine-tuning and multi-task fine-tuning settings. Finally, we provide a set of strong baselines for future work exploring causal question-answering and the causal reasoning capabilities of language models.

While our experiments show causal knowledge is transferable, these models are still opaque. CQA provides a unique opportunity for model explainability through causal explanation structures and reasoning chains. The E-Care and WIQA task have annotated explanations that provide a useful starting point. Causal knowledge sources like CauseNet (Heindorf et al., 2020), ConceptNet (Speer et al., 2017), and Wikidata⁴ can also be used to generate causal explanations. We believe the next evolution of foundation language models will have stronger causal reasoning capabilities and implicit structured causal knowledge. CALM-bench provides a starting point for further research on causal question-answering.

Limitations

Our research assumes the English language due to the lack of multi-lingual QA datasets. Future work may consider developing CQA tasks in other languages.

Additionally, we used the base models for BERT and ERNIE 2.0 in our experiments for all experiments. The public leaderboards for most of the tasks in *CALM-Bench* feature larger models with the billion parameter plus models occupying the top spots. Future work can explore scaling our experimental setup to the large and extra-large versions of our language models used as well as considering more modern architectures such DeBERTa (He et al., 2021) and ERNIE 3.0 (Sun et al., 2021). A challenge for multi-task training with large models is that the batch size for each task must be significantly reduced to ensure the model fits in GPU memory. Smaller batch sizes lead to unstable

training and convergence. Tricks like gradient accumulation and modern optimization libraries (e.g. DeepSpeed⁵ and Fairscale⁶) can be explored.

Finally, our multi-task model is not truly universal in the sense that a new task head is required for each additional CQA task. While there is transferability across the multiple-choice formats, the model does struggle to generalize causal reasoning across different formats like reading comprehension. Our encoder-only approach is unable to handle generation tasks. As a result, the E-CARE and aNLI explanation tasks are excluded. Lourie et al. (2021b) found success using encoder-decoder models where all tasks are converted to a text-to-text format. While (Lourie et al., 2021b) only considered multiple-choice tasks, future work could explore including reading comprehension and explanation generation tasks using models like UnifiedQA (Khashabi et al., 2020) and T5.

A Appendix

A.1 Training Details

A.1.1 Training Environment

All models were trained on a single Nvidia A100 GPU and the a2-highgpu-1g Google Cloud Compute (GCP) instance. The GCP instance has 12 virtual CPUs and 85 GB of memory.

Model training was implemented using the Pytorch Lightning library ([Falcon and The PyTorch](#)

Lightning team, 2019). To ensure reproducibility we use the Pytorch Lightning `seed_everything` function which sets the random seed for the pytorch, numpy and the python.random libraries and the seeds used for data sampling.

The AdamW optimizer (Loshchilov and Hutter, 2017) and FP16 precision were used during training. Task specific learning rates were selected through a hyperparameter search (see Appendix A.5.1). For single-task fine-tuning experiments, the model was trained for 5 epochs and the model with the best validation accuracy was selected for evaluation. For the MTL experiment we train the model for 10,000 steps and checkpoint the model every 1,000 steps. The checkpoint (8,000 steps) with best average validation accuracy/exact match was selected for evaluation on the test set.

A.2 Multiple-Choice Tasks

In this section we detail the input format and the classification heads for the multiple-choice tasks in *CALM-Bench*. The aNLI, COPA, CosmosQA, and E-Care tasks all converted to the SWAG data format (Zellers et al., 2018) and we adapt the Huggingface BERTforMultipleChoice task head as the classification head.

The WIQA task is treated as simple multi-class classification problem. Provided a procedural description, question, and the answer options (more, less, and no effect) the input format is as follows: [CLS] procedural description [SEP] question [SEP] more [SEP] less [SEP] no effect[SEP]. The classification head is a single layer feed forward network which maps the pooled CLS token embedding of the language model’s last layer into the label space.

A.3 Reading Comprehension Task

We treat the ROPES task as a SQuAD (Rajpurkar et al., 2016) style reading comprehension task and adapt the XLNET reading comprehension task head (Yang et al., 2019). Provided a question, hypothetical situation, and background passage we format the input as follows: [CLS] question [SEP] hypothetical situation [SEP] background [SEP]

The objective of the task head is to identify the answer span in the provided input text. The pooled CLS embedding of the last layer in the language model is fed to a feed forward network which independently predicts the start and end positions of the answer span in the input text. Beam search is run

to identify the most probable start and end position, after which the answer text is extracted. Unlike SQuAD, the answer span is not always present in the situation description or background passage, but it is guaranteed to specified in the question text. As a result, we do not mask the question token positions during for the task head.

A.4 Sequence Classification Tasks

The causal sequence identification and counterfactual sequence identification tasks (Appendix A.6.1) are treated as binary classification tasks. The pooled CLS embedding of the last layer in the language model is fed to a feed forward network which maps it to a binary classification space.

A.5 Relation Extraction Tasks

We treat causal and counterfactual relation extraction tasks (Appendix A.6.1) as token classification tasks and adopt a custom BIO tagging format (Ramshaw and Marcus, 1995). Causal and counterfactual entities are tagged with the <cause>, <effect>, <antecedent>, and <consequent> begin and inside tags (e.g. <B-cause> and <I-cause>). All other tokens are labelled with the outside tag (<O>). The token embeddings of the last layer in the model are fed into a single layer feed forward network which predicts for each token the most probable tag.

A.5.1 Hyperparameter Details

We run a hyperparameter search for the random seed and learning rate for each task in *CALM-Bench*. We search over the following learning rates: [0, 1, 42, 1988, 2022, 3023] and randomly selected seeds: [1e-5, 3e-5, 2e-5, 5e-5]. The search is conducted in a two-stage process where we first identify the best learning rate and then identify the best random seed. During the search trial, the model is trained for 100 steps with the provided hyperparameter and then evaluated on validation set. The best hyperparameters are summarized in Table 5 and Table 6.

A.6 Additional Experiments

A.6.1 Transfer Learning Across CRI and CALM-Bench

For analyzing the relationship between CRI and CQA in the transfer learning context, we consider the following CRI tasks:

- **Causal sequence identification:** a binary classification task to evaluate if the sentence

Model	Huggingface Alias	Parameters	Task	Seed	Learning Rate	Batch Size
BERT	bert-base-uncased	110 million	aNLI	3023	2e-5	24
BERT	bert-base-uncased	110 million	COPA	1	1e-5	24
BERT	bert-base-uncased	110 million	CosmosQA	3023	2e-5	24
BERT	bert-base-uncased	110 million	E-CARE	42	2e-5	24
BERT	bert-base-uncased	110 million	ROPES	0	5e-5	24
BERT	bert-base-uncased	110 million	WIQA	1988	2e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	aNLI	0	2e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	COPA	42	2e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	CosmosQA	0	3e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	E-CARE	2022	3e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	ROPES	42	3e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	WIQA	1988	2e-5	24

Table 5: This table summarizes the best single-task fine-tuning hyperparameters task in *CALM-Bench*.

contains causal relata (i.e. cause and effect entities and a causal relation)

- **Causal relation tagging:** a sequence tagging task that requires identifying cause and effect spans provided a sequence of a token representing a sentence.
- **Counterfactual sequence identification:** a binary classification task to evaluate if the sentence contains counterfactual relata (i.e. antecedent and consequent entities and a counterfactual relation)
- **Counterfactual relation tagging:** a sequence tagging task requires the identification of consequent and antecedent spans from a sequence of tokens representing a sentence

SemEval 2007 Task 4 (Girju et al., 2007) and 2010 Task 8 (Hendrickx et al., 2010) tasks require classifying the relation given a pairs of entities in a sentence. We combine the SemEval 2007 Task 4 and 2010 Task 8 datasets to generate examples for causal relation identification and tagging. CREST (Hosseini et al., 2022) is used to convert all examples from the 2007 and 2010 tasks into a standardized sequence tagging format. For counterfactual tasks, we use the SemEval 2020 Task 5a and 5b datasets.

Table 8 and Table 9 summarize the results for these additional experiments. We find similar patterns to our CQA transfer learning experiments. With BERT, transfer between CRI and CQA tasks is not consistent. However, the ERNIE 2.0 model shows consistent improvement from CQA tasks to the Causal Id and Causal Relation identification

tasks. Across both models there seems to be no transfer learning improvements on the counterfactual relation identification tasks.

A.6.2 Sequential fine-tuning Results

Table 7 summarizes the results of the sequential fine-tuning experiment with the BERT model. We start with a pretrained BERT model and then sequentially train it on the following multiple-choice tasks: WIQA, aNLI, CosmosQA, and E-Care. The model initially sees improvements over the single-task fine-tuned baseline results. However, as additional tasks are added, performance starts to degrade across several tasks. Due to the unstable results of sequential fine-tuning, we choose instead to pursue multi-task learning.

Model	Huggingface Alias	Parameters	Task	Seed	Learning Rate	Batch Size
BERT	bert-base-uncased	110 million	Causal Sequence Identification	42	5e-5	24
BERT	bert-base-uncased	110 million	Causal Relation Identification	1	5e-5	24
BERT	bert-base-uncased	110 million	Counterfactual Sequence Identification	1	1e-5	24
BERT	bert-base-uncased	110 million	Counterfactual Relation Identification	3023	5e-5	24
ERNIE 2.0	nghuyong/ernie-2.0-base-en	110 million	Causal Sequence Identification	0	2e-5	24

Abstract

Large-scale, high-quality corpora are critical for advancing research in coreference resolution. However, existing datasets vary in their definition of coreferences and have been collected via complex and lengthy guidelines that are curated for linguistic experts. These concerns have sparked a growing interest among researchers to curate a unified set of guidelines suitable for annotators with various backgrounds. In this work, we develop a crowdsourcing-friendly coreference annotation methodology, ezCoref, consisting of an annotation tool and an interactive tutorial. We use ezCoref to re-annotate 240 passages from seven existing English coreference datasets (spanning fiction, news, and multiple other domains) while teaching annotators only cases that are treated similarly across these datasets.¹ Surprisingly, we find that reasonable quality annotations were already achievable (>90% agreement between crowd and experts) even without extensive training. On carefully analyzing the remaining disagreements, we identify the presence of linguistic cases that our annotators unanimously agree upon but lack unified treatments (e.g., generic pronouns, appositives) in existing datasets. We propose the research community should revisit these phenomena when curating future unified annotation guidelines.

1 Introduction

Coreference resolution is the task of identifying and clustering together all textual expressions (*mentions*) that refer to the same discourse entity in a given document. Impressive progress has been made in developing coreference systems (Lee et al., 2017; Moosavi and Strube, 2018; Joshi et al., 2020), enabled by datasets annotated by experts (Hovy et al., 2006; Bamman et al., 2020; Uryupina et al., 2019) and crowdsourcing (Chamberlain et al., 2016). However, these datasets vary widely in

¹Our platform’s code and collected data is available at <https://github.com/gnkitaa/ezCoref>

OntoNotes: Maybe we need a [CIA] version of the Miranda warning: You have the right to conceal your coup intentions, because we may rat on you.

ARRAU: Maybe [we]e1 need [a [CIA] version of [the Miranda warning]]: [You]e4 have [the right to conceal [[your]e5 [coup] intentions]], because [we]e6 may rat on [you]e7.

Crowd (this work): Maybe [we]e1 need [a [CIA] version of [the [Miranda] warning]]: [You]e3 have [the right] to conceal [[your]e3 coup intentions], because [we]e1 may rat on [you]e3.

Figure 1: We visualize a common sentence from news domain annotated by two expert-curated datasets, OntoNotes (Hovy et al., 2006) and ARRAU (Uryupina et al., 2019), along with the crowd annotations collected via our ezCoref platform. OntoNotes does not mark generic pronouns. ARRAU does not consider them as coreferent and annotates them using a special relation “undef-reference” (markables with vague interpretations). On the contrary, our crowdworkers assign all mentions of the generic pronoun “you” to the same coreference chain. The situation is also similar for the generic “we.”

their definitions of coreference (expressed via annotation guidelines), resulting in inconsistent annotations both within and across domains and languages. For instance, as shown in Figure 1, while ARRAU (Uryupina et al., 2019) treats generic pronouns as non-referring, OntoNotes (Hovy et al., 2006) chooses not to mark them at all.

It is thus unclear which guidelines one should employ when collecting coreference annotations in a new domain or language. Traditionally, existing guidelines have leaned towards lengthy explanations of complex linguistic concepts, such as those in the OntoNotes guidelines (Weischedel et al., 2012), which detail what should and should not be coreferent (e.g., how to deal with head-sharing noun phrases, premodifiers, and generic mentions). As a result, coreference datasets have traditionally been annotated by linguists (experts) already familiar with such concepts, which makes the process expensive and time-consuming. Crowd-

sourced coreference data collection has the potential to be significantly cheaper and faster; however, teaching an exhaustive set of linguistic guidelines to non-expert crowd workers remains a formidable challenge. As a result, there has been a growing interest among researchers in curating a unified set of guidelines (Poesio et al., 2021) suitable for annotators with various backgrounds.

More recently, games-with-a-purpose (GWAPs) (von Ahn, 2006; Poesio et al., 2013) were proposed to aid crowdsourcing of large coreference datasets (e.g., Chamberlain et al., 2016; Yu et al., 2022). While GWAPs make it enjoyable for crowdworkers to learn complex guidelines and perform annotations using them (Madge et al., 2019b), they also require significant effort to attract and maintain workers. For instance, Phrase Detectives Corpus 1.0 was collected over a span of six years (Chamberlain et al., 2016; Poesio et al., 2013; Yu et al., 2022), which motivates us to instead study coreference collection on more efficient payment-based platforms.

Specifically, our work investigates the quality of crowdsourced coreference annotations when annotators are taught only simple coreference cases that are treated uniformly across existing datasets (e.g., pronouns). By providing only these simple cases, we are able to teach the annotators the concept of coreference, while allowing them to freely interpret cases treated differently across the existing datasets. This setup allows us to identify cases where our annotators unanimously agree with each other but disagree with the expert, thus suggesting cases that should be revisited by the research community when curating future guidelines.

Our main contributions are:

- We develop a crowdsourcing-friendly coreference annotation methodology—ezCoref—which includes an intuitive, open-sourced annotation tool supported by a short crowd-oriented interactive tutorial.²
- We use ezCoref to re-annotate 240 passages from seven existing English coreference datasets on Amazon Mechanical Turk (AMT), and conduct a comparative analysis of crowd and expert annotations. We find that high-quality annotations are already achievable from non-experts without extensive train-

²Our tutorial received overwhelmingly positive feedback. One annotator commented that it was “*absolutely beautiful, intuitive, and helpful. Legitimately the best one I’ve ever seen in my 2 years on AMT! Awesome job.*” (Table A4 in Appendix)

ing (>90% B3 (Bagga and Baldwin, 1998a) agreement between crowd and experts).

- We further qualitatively analyze remaining disagreements among crowd and expert annotations and identify linguistic cases that crowd unanimously marks as coreferent but lack unified treatment in existing datasets (e.g., generic pronouns as shown in Figure 1). Additionally, analyzing inter-annotator agreement among the crowd reveals that crowd exhibits higher agreement when annotating familiar texts (e.g., childhood stories or fiction) compared to texts rich in cataphoras or those requiring world knowledge. Finally, our qualitative analysis also provides an empirical evidence to support previous findings in literary studies (Szakolczai’s (2016) analysis of Bleak House) and psychology (Orvell et al.’s (2020) claims about generic “you”).

2 Related Work

Existing coreference datasets: Table 1 provides an overview of seven prominent coreference datasets, which differ widely in their annotator population, mention detection, and coreference guidelines.³ Many datasets are annotated by experts heavily trained in linguistic standards, including ARRAU (Uryupina et al., 2019), LitBank (Bamman et al., 2020), GUM (Zeldes, 2017), and OntoNotes (Hovy et al., 2006). Due to its scale and quality, OntoNotes is likely the most widely used for NLP coreference research, including in two CoNLL shared tasks (Pradhan et al., 2011, 2012). QuizBowl (Guha et al., 2015) has been annotated by domain (but not linguistic) experts. Few coreference datasets exist which are annotated by non-experts, including those created by part-time non-native English speakers (PreCo; Chen et al., 2018), and gamified crowdsourcing without financial compensation (Phrase Detectives; Chamberlain et al., 2016; Yu et al., 2022).

Coreference annotation tools: Several coreference annotation tools have been developed (See Table A3 in Appendix for more details). However, these are difficult to port to a crowdsourced workflow, as they require users to install software on their local machine (Widlöcher and Mathet, 2012; Landragin et al., 2012; Kopeć, 2014; Mueller and Strube, 2001; Reiter, 2018), or have complicated

³Many others exist too; for example, see Jonathan Kummerfeld’s spreadsheet list (accessed Jan. 2022).

Dataset	Domains #(doc, ment, tok)	Annotators	Mention Detection	Mention Types		Coreference Links			
				Singletons	Entity Restrictions	Copulae	Appositives	Generics	Ambiguity

Table 1: Summary of seven datasets analyzed in this work, which differ in domain, size, annotator qualifications, mention detection procedures, types of mentions, and types of links considered as coreferences between these mentions. *Allows other types of mention only when this mention is an answer to a question. **We interpret manual identification based on illustrations presented in the original publication (Chen et al., 2018). ***Inaccessible, see Footnote 8.

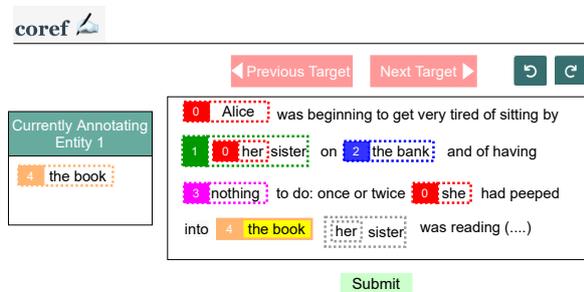

Figure 2: Part of the ezCoref interface (§3)

UI design with multiple drag and drop actions and/or multiple windows (Stenetorp et al., 2012; Widlöcher and Mathet, 2012; Landragin et al., 2012; Yimam et al., 2013; Girardi et al., 2014; Kopeć, 2014; Mueller and Strube, 2001; Oberle, 2018). Closest to ezCoref is CoRefi (Bornstein et al., 2020), a web-based coreference annotation tool that can be embedded into crowdsourcing websites. Subjectively, we found its user interface difficult to use (e.g., users have to memorize multiple key combinations). It also does not allow for nested spans, reducing its usability.

Crowdsourcing linguistic annotations: Several efforts have been made to crowdsource linguistic annotations (Snow et al., 2008; Callison-Burch, 2009; Howe, 2008; Lawson et al., 2010), including on payment-based microtasks via platforms like AMT and GWAPs (von Ahn, 2006). Many GWAPs (Poesio et al., 2013; Kicikoglu et al., 2019; Madge et al., 2019a; Fort et al., 2014) have been used in NLP to collect linguistic annotations including coreferences; with some broader platforms (Venhuizen et al., 2013; Madge et al.,

2019b) aiming to gamify the entire text annotation pipeline. One solution to teaching crowd workers complex guidelines is to incorporate *learning by progression* (Kicikoglu et al., 2020; Madge et al., 2019b; Miller et al., 2019), where annotators start with simpler tasks and gradually move towards more complex problems, but this requires subjective judgments of task difficulty. In contrast to the payment-based microtask setting studied in this work, GWAPs are not open-sourced, need significant development, take longer to collect data, and require continuous efforts to maintain visibility (Poesio et al., 2013).

3 ezCoref: A Crowdsourced Coreference Annotation Platform

The ezCoref user experience consists of (1) a step-by-step interactive tutorial and (2) an annotation interface, which are part of a pipeline including automatic mention detection and AMT Integration.

Annotation structure: Two annotation approaches are prominent in the literature: (1) a local pairwise approach, annotators are shown a pair of mentions and asked whether they refer to the same entity (Hladká et al., 2009; Chamberlain et al., 2016; Li et al., 2020; Ravenscroft et al., 2021), which is time-consuming; or (2) a cluster-based approach (Reiter, 2018; Oberle, 2018; Bornstein et al., 2020), in which annotators group all mentions of the same entity into a single cluster. In ezCoref we use the latter approach, which can be faster but requires the UI to support more complex actions for creating and editing cluster structures.

Example	Phenomena Taught
[John] doesn't like [Fred], but [he] still invited [him] to [the party].	(1) personal pronouns (2) singletons
[This dog] likes to play [catch]. [It]'s better than other [dogs] at [this game]. [Its] owner is really proud.	(1) possessive pronouns (2) semantically similar expression which are not corefering (3) non-person entities (animals)
[Director [Mackenzie]] spent [last two years] working on a ["Young Adam"]. During [this time] [he] often had to make [compromises] but [the movie] turned out to exceed expectations.	(1) nested spans (2) non-person entities (time, item)
[The office] wasn't exactly small either. [I]'m sure that 50, or maybe even 60, [people] could easily fit [there].	(1) non-person entities (place)

Table 2: Simple coreference cases explained in tutorial.

User interface: We spent two years iteratively designing, implementing, and user testing the interface to make it as simple and crowdsourcing-friendly as possible (Figure 2).⁴ Marked mentions are surrounded by color-coded frames with entity IDs. The currently selected mention (“the book”), is highlighted with a flashing yellow cursor-like box. The core annotation action is to select other mentions that corefer with the current mention, and then advance to a later unassigned mention; annotators can also re-assign a previously annotated mention to another cluster. Advanced users can exclusively use keyboard shortcuts, undo and redo actions were added to allow error correction. Finally, ezCoref provides a side panel showing mentions of the entity currently being annotated to spot mentions assigned to the wrong cluster.

Coreference tutorial: To teach crowdworkers the basic definition of coreference and familiarize them with the interface, we develop a tutorial (aimed to take ~ 20 minutes) that introduces them to the mechanics of the annotation tool, and then trains them on simple cases of coreferences. These cases (e.g., personal/possessive pronouns or determinative phrases which corefer with their antecedents as shown in Table 2) are annotated similarly across all existing datasets and are unlikely to be disputed. The tutorial concludes with a quality control example to exclude poor quality annotators.⁵ These training examples, feedback, and annotation guidelines can be easily customized using a simple JSON schema.

Annotation workflow: The annotators are presented with one passage (or “document”) at a time (Figure 2), and all mentions have to be annotated before proceeding to the next passage. There is no limitation to the length or language of the passage.

⁴The interface is implemented in [ReactJS](#).

⁵Examples of the tutorial interface and the quality control example are provided in Appendix.

In this work, we divide an initial document into a sequence of shorter passages of complete sentences, on average 175 tokens, as shorter passages minimize the need to scroll, reducing annotator effort. While this obviously cannot capture longer distance coreference,⁶ a large portion of important coreference phenomena is local: within the OntoNotes written genres, for pronominal mentions, the closest antecedent is contained within the current or previous two sentences more than 95% of the time.

Automatic mention detection: As a first step to collect coreference annotations, we must identify mentions in the documents from each of the seven existing datasets; this process is done in a diverse array of ways (from manually to automatic) in prior work as shown in Table 1. We decided to automatically identify mentions to give all crowdworkers an identical set of mentions, which simplifies the annotation task and also allows us to easily compare and study their coreference annotations via inter-annotator agreement. Specifically, we implement a simple algorithm that yields a high average recall over all seven datasets.⁷

Our algorithm considers all noun phrases (including proper nouns, common nouns, and pronouns) as markables, extracting them using the Stanza dependency parser (version 1.3.0; Qi et al., 2020). We allow for nested mentions and proper noun premodifiers (e.g., [U.S.] in “U.S. policy”). We include all conjuncts with the entire coordinated noun phrase ([Mark], [Mary], as well as [Mark and Mary], are all considered mentions); details in Appendix A.3.

4 Using ezCoref to Re-annotate Existing Coreference Datasets

We deploy ezCoref on the AMT crowdsourcing platform to re-annotate 240 passages from seven existing datasets, covering seven unique domains. In total, we collect annotations for 12,200 mentions and 42,108 tokens. We compare our workers’ an-

⁶We leave this for future work—for example, more sophisticated user interfaces to support longer documents, or merging coreference chains between short passages. As documents get progressively longer, such as book chapters or books, the task takes on aspects of cross-document coreference and entity linking (e.g. Bagga and Baldwin, 1998b; FitzGerald et al., 2021; Logan IV et al., 2021).

⁷We acknowledge that any algorithm can be used as long as its recall across all datasets is high, and ours is only one such algorithm. However, we do not conduct an ablation study to compare crowd annotations for mentions obtained from these potential algorithms as it would be prohibitively expensive. Furthermore, while advanced mention detection methods can improve annotation quality, our goal is not to collect the highest-quality coreference dataset, but to study annotator behavior when a common set of mentions is provided.

notations both quantitatively and qualitatively to each other and to existing expert annotations.

Datasets: We collect coreference annotations for the seven existing datasets described in Table 1: OntoNotes (Hovy et al., 2006), LitBank (Bamman et al., 2020), PreCo⁸ (Chen et al., 2018), ARRAU (Uryupina et al., 2019), GUM (Zeldes, 2017), Phrase Detectives (Chamberlain et al., 2016), and QuizBowl (Guha et al., 2015). The sample covers seven domains: news, opinionated magazines, weblogs, fiction, biographies, Wikipedia articles, and trivia questions from Quiz Bowl. For each dataset with multiple domains, we manually select a broad range of domain(s) for re-annotation. From each domain in each dataset, we then select documents and divide them into shorter passages (on average 175 tokens each), creating 20 such passages per dataset. For datasets with multiple domains, we choose 20 such passages per domain (see Appendix A.1 for detail). Overall, we collect annotations for 240 passages with 5 annotations per passage to measure inter-annotator agreement.

Procedure: We first launch an annotation tutorial and recruit the annotators on the AMT platform.⁹ At the end of the tutorial, each annotator is asked to annotate a short passage (around 150 words). Only annotators with a B3 score (Bagga and Baldwin, 1998a) of 0.90 or higher are then invited to participate in the annotation task.

Training Annotators with Simplified Guidelines using ezCoref: As the goal of our study is to understand what crowdworkers perceive as coreference, we train our annotators with simple guidelines. We carefully draft our training examples to include only cases which are considered as coreference by all the existing datasets. The objective is to

⁸The PreCo dataset is interestingly large but seems difficult to access. In November 2018 and October 2021 we filled out the data request form at the URL provided by the paper, and attempted to contact the PreCo official email directly, but did not receive a response. To enable a precise research comparison, we scraped all documents from PreCo’s public demo in November 2018 (no longer available as of 2021); its statistics match their paper and our experiments use this version of the data. PreCo further suffers from data curation issues (Gebru et al., 2018; Jo and Gebru, 2020); it uses text from English reading comprehension tests collected from several websites, but the original document sources and copyright statuses are undocumented. When reading through PreCo documents, we found many domains including opinion, fiction, biographies, and news (Table A1 in Appendix); we use our manual categories for domain analysis.

⁹We allow only workers with a $\geq 99\%$ approval rate and at least 10,000 approved tasks who are from the US, Canada, Australia, New Zealand, or the UK.

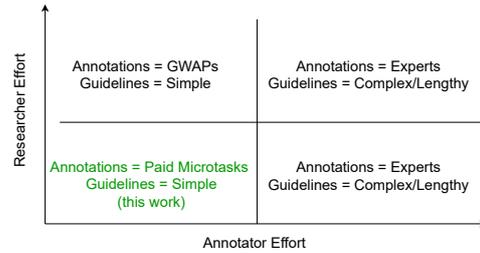

Figure 3: Existing expert annotated datasets entail high annotator effort (e.g., OntoNotes, ARRAU). Existing crowdsourced coreference datasets (e.g., Phrase Detectives) entail significant researcher effort. In this work, we explore the minimum effort scenario for both annotators (by providing them simplified guidelines) and researchers (by open-sourcing ezCoref).

teach crowdworkers the broad definition of coreference while leaving space for different interpretations of ambiguous cases or those resolved differently across the existing datasets. Note that a comparable experiment with more complex guidelines is infeasible since it is unclear which guidelines to choose, and also providing complex linguistic guidelines to crowdworkers remains an open challenge. Overall, ezCoref is aimed to minimize both researcher and annotator effort for new coreference data collection, compared to prior work (Figure 3).

Worker details: Overall, 73 annotators (including 44 males, 20 females, and one non-binary person)¹⁰ completed the tutorial task, which took 19.4 minutes on average (sd=11.2 minutes). They were aged between 21 and 69 years (mean=38.9, sd=11.3) and identified themselves as native English speakers. Most of the annotators had at least a college degree (47 vs 18). 89.0% of annotators, who did the tutorial, received a B3 score of 0.90 or higher for the final screening example, and were invited to the annotation task. 50.7% of the invited annotators returned to participate in the main annotation task, and 29.2% of them annotated five or more passages. Annotation of one passage took, on average, 4.15 minutes, a rate of 2530 tokens per hour. The total cost of the tutorial was \$460.70 (\$4.50 per tutorial). We paid \$1 per passage for the main annotation task, resulting in a total cost of \$1440.¹¹

5 Analysis

In this section, we perform quantitative and qualitative analyses of our crowdsourced coreference annotations. First, we evaluate the performance

¹⁰We did not collect demographic data for the remaining eight individuals, from an earlier pilot experiment.

¹¹All reported costs include 20% AMT fee.

of our mention detection algorithm, comparing it to gold mentions across seven datasets. Next, we measure the quality of our annotations and their agreement with other datasets. Finally, we discuss interesting qualitative results.

5.1 Mention Detector Evaluation

Datasets differ in the way they define their mention boundaries and thus the boundaries for the same mention may differ. To fairly compare our mentions with the gold standards, we employ a headword-based comparison. We find the head of the given phrase by identifying, in the dependency tree, the most-shared ancestor of all tokens within the given mention. Two mentions are considered same if their respective headwords match.

Table 3 compares our mention detector to the gold mentions in existing datasets. Our method obtains high recall across most datasets (>0.90), which shows that most of the mentions annotated in existing datasets are correctly identified and allows a direct comparison of crowd annotations with expert annotations. It has the lowest recall with ARRAU (0.84) and PreCo (0.88), which is to be expected as ARRAU marks all referring premodifiers (identified manually) and PreCo allows common noun modifiers, while we identify only the premodifiers which are proper nouns.¹²

For most datasets, the precision is >0.80 , suggesting that the algorithm identifies most of the relevant mentions. We observe a substantially lower score for OntoNotes, LitBank, and QuizBowl as these datasets restrict their mention types to limited entities (refer to Table 1). However, this does not limit our analysis. In fact, an algorithm with high precision on LitBank or OntoNotes would miss a huge percentage of relevant mentions and entities on other datasets (constraining our analysis) and when annotating new texts and domains. Furthermore, our algorithm identifies more mentions than in the original datasets, which in the best case allows us to discover new entities and, in the worst case, may result in more singletons. Finally, the mention density (number of mentions per token) from our detector remains roughly consistent across all datasets when using our method, allowing us to fairly compare statistics (e.g., agreement rates) across datasets.

¹²We made this decision as identifying automatically all premodifiers would result in many singletons and lead to more arduous annotation effort.

Dataset	Recall	Precision	Mentions / Tokens	
			Gold	This Work
OntoNotes	0.957	0.376	0.112	0.286
LitBank	0.962	0.415	0.121	0.280
QuizBowl	0.956	0.543	0.188	0.318
PD (Gold)	0.953	0.803	0.259	0.273
PD (Silver)	0.938	0.791	0.265	0.274
GUM	0.906	0.848	0.269	0.287
PreCo	0.881	0.883	0.287	0.287
ARRAU	0.840	0.870	0.289	0.279

Table 3: Comparison of mentions identified by our mention detection algorithm with the gold mentions annotated in the respective datasets. We use head-word based comparison to compare mentions of different lengths. Our method obtains high recall across most datasets and the mention-density using our mention-detector remains roughly consistent across datasets, allowing us to do fair analysis (e.g., agreement) across datasets.

5.2 Agreement with Existing Datasets

How well do annotations from ezCoref agree with annotations from existing datasets?

Aggregating annotations: To compare crowd-sourced annotations with gold annotations, we first require an aggregation method that can combine annotations from multiple crowdworkers to infer coreference clusters. We use a simple aggregation method that determines whether a pair of mentions is coreferent by counting the number of annotators who marked the two mentions in the same cluster.¹³ Two mentions are considered as coreferent when the number of annotators linking them together is greater than a threshold (τ). After inferring these pairs of mentions, we construct an undirected graph where nodes are mentions and edges represent coreference links. Finally, we find connected components in the graph to obtain coreference clusters.¹⁴ We compare aggregated annotations from ezCoref with gold annotations across the seven datasets using B3 scores (precision, recall, and F1),¹⁵ as illustrated in Figure 4.

High agreement with OntoNotes, GUM, LitBank, ARRAU: Our annotators achieve the high-

¹³Future data collection efforts interested in creating large resources can utilize more advanced aggregation methods (Poesio et al., 2019).

¹⁴This method resolves to majority voting-based aggregation when the τ is set so that more than half of annotators should agree. For $\tau = N$, this method is very conservative, adding a link between two mentions only when all annotators agree unanimously. Conversely, for $\tau = 1$, only a single vote is required to add a link between two mentions.

¹⁵For a mention in a given document, B3 recall is the fraction of mentions that are correctly predicted by the system as coreferent with it out of all mentions that are actually coreferent with it. B3 precision is the fraction of mentions that are correctly predicted by the system as coreferent with it out of all system-predicted mentions.

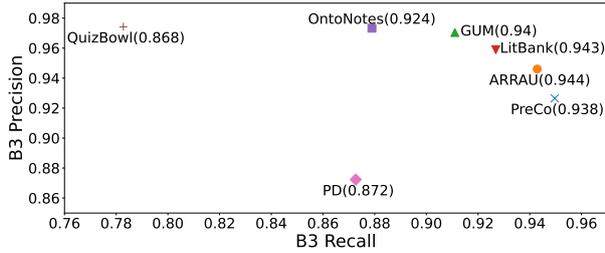

Figure 4: Agreement with gold annotations across datasets. B3 (F1) scores shown in parentheses are computed with singletons included.

est precision with OntoNotes (Figure 4), suggesting that most of the entities identified by crowdworkers are correct for this dataset. In terms of F1 scores, the datasets which are closest to crowd annotations are GUM, LitBank, and ARRAU, all of which are annotated by experts. This result shows that high-quality annotations can be obtained from non-experts using ezCoref without extensive training. We further conducted a qualitative analysis of high agreement cases for each dataset. Overall, we observe that non-experts agree with experts on chains containing pronouns and named entities. However, non-experts also mark noun phrases in appositive constructions as coreferent, consistent with GUM guidelines. Finally, non-experts also assign generic mentions to the same coreference chain, consistent with their treatment by GUM and ARRAU, and leads to higher agreement with these datasets.

Low precision with Phrase Detectives and PreCo, low recall with Quiz Bowl:

We observe that Phrase Detectives has a very low precision compared to all other datasets, implying that crowdworkers add more links compared to gold annotations. Our qualitative analysis reveals that PD annotators miss some valid links, splitting entities which are correctly linked together by our annotators (see Table 4). Another dataset with lower precision is PreCo, which also contains many missing links. In general, we observe more actual mistakes in PreCo and PD than in the other datasets, which is not surprising as they were not annotated by experts.¹⁶ This result is further validated by our agreement analysis of the fiction domain (Table 5), in which ezCoref annotations agree far more closely with expert annotations (GUM, LitBank) than PreCo and PD. Finally, Quiz Bowl has by far the lowest recall with ezCoref annotations, which is ex-

¹⁶That said, both PreCo and PD were additionally validated by multiple non-expert annotators.

PD	Not long after [a suitor] appeared, and as [he] appeared to be very rich and the miller could see nothing in [him] with which to find fault, he betrothed his daughter to [him]. But the girl did not care for [the man] (...). She did not feel that she could trust [him], and she could not look at [him] nor think of [him] without an inward shudder.
PreCo	When I listened to the weather report, I was afraid to see [the advertisements]. [Those colorful advertisements] always made me crazy.

Table 4: Cases of split entities (missing links) in annotations provided with Phrase Detectives and PreCo. Instead, our crowd annotators mark all mentions as referring to the same entity in each of these examples.

pected given the difficulty with cataphora and factual knowledge (examples (c) and (e) in Table 6).

Domain	Dataset	B3		
		Precision	Recall	F1
Fiction	GUM	0.982	0.921	0.950
	LitBank	0.959	0.927	0.943
	PreCo	0.805	0.963	0.877
	Phrase Detectives	0.784	0.775	0.780

Table 5: Agreement with existing datasets for fiction.

Varying the aggregation threshold τ : What is the effect of varying the aggregation threshold (τ) on precision and recall with gold annotations? Figure 5 shows that the Quiz Bowl dataset has the highest drop in recall (36% absolute drop) when increasing τ from 1 to 5.¹⁷ This indicates that the number of unanimous clusters ($\tau = 5$) is considerably lower than the total number of clusters found individually by all annotators ($\tau = 1$); as such, our annotators heavily disagree about gold clusters in the QuizBowl dataset. We observe a similar trend in OntoNotes (26% drop in recall), whereas Phrase Detectives has the lowest drop in recall (0.07) with the increase in the number of annotators, which is expected since Phrase Detectives is crowdsourced.

5.3 What domains are most suitable for crowdsourcing coreference?

We use the B3 metric¹⁸ (Bagga and Baldwin, 1998a) to compute IAA for each domain, excluding singletons¹⁹ (see Table 7). We obtain the highest agreement on fiction (72.6%) and biographies (72.4%). This is because both domains contain a high frequency of pronouns (see examples *a* and

¹⁷We analyze variations in recall which is more interpretable than precision, since the denominator is fixed in recall when varying number of annotators.

¹⁸Krippendorff’s alpha/kappa are other possible measures for IAA. However, prior work (Paun et al., 2022) has raised concerns over using Krippendorff’s alpha/kappa for anaphora resolution. Instead, we found B3 intuitive to understand as a measure of agreement among annotators at the mention level, i.e. fraction of mentions two annotators agree should be coreferent with a given mention.

¹⁹IAA including singletons is much higher (Appendix A.4).

Phenomena	Dataset (Domain)	Example
Pronouns	LitBank (Fiction)	A Wolf had been gorging on an animal [he] had killed, when suddenly a small bone in the meat stuck in [his] throat and [he] could not (a) swallow [it]. [He] soon felt a terrible pain in [his] throat (...) [He] tried to induce everyone [he] met to remove the bone. "[I] would give anything," said [he] , " if [you] would take [it] out. "
	GUM (Biographies)	Despite Daniel's attempts at reconciliation, [his] father carried the grudge until [his] death. Around schooling age, [his] father, Johann, (b) encouraged [him] to study business (...). However, Daniel refused because [he] wanted to study mathematics. [He] later gave in to [his] father's wish and studied business. [His] father then asked [him] to study in medicine.
Cataphora	QuizBowl (Quizzes)	[One character in this work] is forgiven by [magenta] wife for an affair with a governess before beginning one with a ballerina. [Another (c) character in this work] is a sickly, thin man who eventually starts dating a reformed prostitute, Marya Nikolaevna. In addition to [Stiva] and [Nikolai] , [another character in this work] (...) had earlier failed in [his] courtship of Ekaterina Shcherbatskaya.
Factual Knowledge	OntoNotes (News)	(d) The Soviet Union's jobless rate is soaring (...), [Pravda] said. Unemployment has reached 27.6 % in Azerbaijan, (...) and 16.3% in Kirgizia, [the Communist Party newspaper] said.
	QuizBowl (Quizzes)	(e) (...) [another character in this work] (...) had earlier failed in [his] courtship of [Ekaterina Shcherbatskaya]. Another character in this work rejects [Ekaterina] before (...) moving to St. Petersburg. For 10 points name this work in which [Levin] marries [Kitty] , (...) a novel by Leo Tolstoy.

Table 6: Representative examples showing unique phenomena in each dataset (coreferences are color coded).

Fiction	Biographies	Opinion	Web	News	Wikipedia	Quiz
72.6	72.4	69.5	65.9	62.3	61.8	59.7

Table 7: Domain-wise IAA: B3% scores using CoNLL script (Pradhan et al., 2014), excluding singletons.

b in Table 6), which our annotators found easier to annotate. We also observe that the fiction domain contains many well-known children stories (e.g., Little Red Riding Hood) that are likely familiar to our annotators, which may have made them easier to annotate. Annotators have the least agreement on Quiz Bowl coreference (59.73%), as this dataset is rich in challenging cataphoras (example *c* in Table 6) and often require world knowledge about books, characters, and authors to identify coreferences (example *e* in Table 6).

5.4 Qualitative analysis

To better understand the differences in annotation quality, we conduct a manual analysis²⁰ of all 240 passages, comparing our ezCoref annotations to gold annotations from each dataset. Specifically, we look at each link that was annotated by our workers but not in the gold data, or vice versa. For each link, we determine whether crowd or the gold annotations contained a mistake, or whether the discrepancy is reasonable under specific guidelines. We find that ezCoref annotations contain fewer mistakes than non-expert annotated datasets (PreCo and PD), almost twice as many mistakes as those of expert datasets (OntoNotes and GUM), and seven times as many mistakes as those in the esoteric Quiz Bowl dataset (Appendix Table A2).

Disagreements and deviations from expert guidelines: As in Poesio and Artstein (2005), we identify cases of genuine ambiguity, where a mention can refer to two different antecedents. The

²⁰By a linguist who studied guidelines of all datasets.

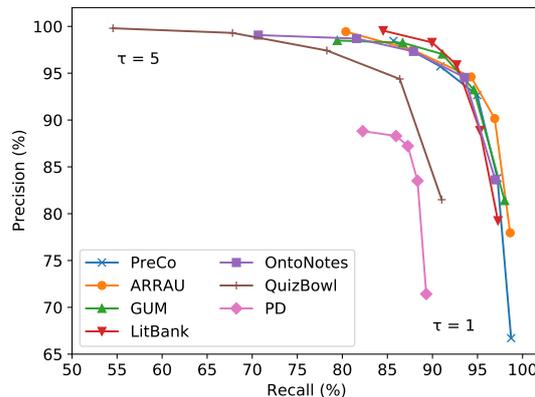

Figure 5: Agreement with gold annotations with varying voting threshold τ . $\tau = 3$ is majority voting (Figure 4). B3 scores computed with singletons included.

first row of Table 8 shows an example from Dickens' *Bleak House*, where the pronoun "it" could reasonably refer to either the "fog" or the "river." Our annotators have high disagreement on this link, which is understandable given the literary analysis of Szokolczai (2016) who interprets the ambiguity of this pronoun as Dickens' way to show indeterminacy attributed to elements in the scene.²¹

We observe that generic mentions, especially generic pronouns, are almost always annotated as coreferring by crowd, while existing datasets lack consensus (Table 1). Table 8 (second row) shows an example where annotators unanimously connected all instances of generic "you." This observation is in line with Orvell et al.'s (2020) study which explains that by using the same linguistic form ("you"), one invites readers (annotators) to consider how the situation refers to them. Finally, while datasets tend to treat copulae and appositive constructions identically and annotate them

²¹In LitBank, the source of this passage, the pronoun "it" is annotated as referring to the "river" as only "river" is a potential markable per entity restriction (ACE entities only).

Ambiguity	[Fog] everywhere. [Fog] up [the river] , where [it] flows among green aits and meadows; [fog] down [the river] , where [it] rolls defiled among the tiers of shipping and the waterside pollutions of a great (and dirty) city. - Charles Dickens, <i>Bleak House</i>
Generic	Please , Ma'am , is this New Zealand or Australia? (and she tried to curtsey as she spoke – fancy CURTSEYING as [you] 're falling through the air! Do [you] think [you] could manage it?) - Lewis Carroll, <i>Alice in Wonderland</i>

Table 8: Examples of genuine ambiguity and generic “you” observed in our data.

in a similar way, our annotators intuitively annotate them differently. While crowdworkers almost always mark noun phrases in appositive constructions as coreferent, the noun phrases in copulae are linked by majority vote only in $\sim 35\%$ of cases.

6 Conclusion

Existing coreference datasets vary in their definition of coreferences and have been collected via complex guidelines. In this work, we investigate the quality of annotations when crowdworkers are taught only few coreference cases that are treated similarly across existing datasets. We develop a crowdsourcing-friendly coreference annotation methodology, ezCoref and use it to re-annotate 240 passages from seven existing English coreference datasets. We observe reasonable quality annotations were already achievable even without extensive training. On analyzing the remaining disagreements, we identify linguistic cases that crowd unanimously agree upon but lack unified treatments in existing datasets, suggesting cases the researchers should revisit when curating future unified annotation guidelines.

7 Limitations

We list some of the limitations of our study which researchers and practitioners would hopefully benefit from when interpreting our analysis. Firstly, our analysis is only applicable to the English language and how native English speakers understand coreferences. In this work, we have taken a step towards building a framework to facilitate the comparison of the crowd and expert annotations, and the variations observed in non-native speakers should be explored in future studies. Secondly, as a result of resource constraints, we limited ourselves to one set of guidelines and compared crowd annotations under these guidelines with expert annotations. Understanding the effects of various guidelines on annotator behavior is left for future research. Thirdly, even the best automatic mention detection algorithm could have errors, especially when tested out-of-domain. Despite this limitation,

we decided to use an automatic method as it allows us to study annotators’ behavior when a “common set of mentions” is provided. Some of the proposed solutions to address this issue are to directly crowdsource mentions or verify the automatically identified mentions via crowdsourcing (Madge et al., 2019b), which can be utilized for future collection of high-quality corpora. Finally, we also acknowledge that the tool cannot handle split-antecedents or separate tags for different relations, which we leave for future work. As a result, our approach focuses on cases of identity coreferences. However, we believe that identity coreference supported by our tool has value as an NLP tool (e.g., studying characters in narratives (Bamman et al., 2013)), allowing the collection of more in-domain annotations, necessary to advance such practical applications.

8 Ethics Statement

The data collection protocol was approved by the coauthors’ institutional review board. All annotators were presented with a consent form (mentioned below) prior to the annotation. They were also informed that only satisfactory performance on the screening example will allow them to take part in the annotation task. All data collected during the tutorial and annotations (including annotators’ feedback and demographics) will be released anonymized. We also ensure that the annotators receive at least \$13.50 per hour. Since base compensation is per unit of work, not by time (the standard practice on Amazon Mechanical Turk), we add bonuses for workers whose speed caused them to fall below that hourly rate.

Consent Before participating in our study, we requested every annotator to provide their consent. The annotators were informed about the purpose of this research study, any risks associated with it, and the qualifications necessary to participate. The consent form also elaborated on task details describing what they will be asked to do and how long it will take. The participants were informed that they could choose as many documents as they would like to annotate (by accepting new Human Intelligence Tasks at AMT) subject to availability, and they may drop out at any time. Annotators were informed that they would be compensated in the standard manner through the Amazon Mechanical Turk crowdsourcing platform, with the amount specified in the Amazon Mechanical Turk interface. As part of this study, we also collected demographic information, including their age, gender,

native language, education level, and proficiency in the English language. We ensured our annotators that the collected personal information would remain confidential in the consent form.

Acknowledgements

We are very grateful to the crowd annotators on AMT for participating in our annotation tasks and providing positive reviews. We are grateful to Abe Handler, Aditya Jain, Anna Rogers, Julian Richardson, Kavya Jeganathan, Neha Kennard, Nishant Yadav, Timothy O’Gorman, and the UMass NLP group for several useful discussions during the course of the project. We also thank Massimo Poesio for sharing the GNOME portion of AR-RAU dataset. This material is based upon work supported by National Science Foundation awards 1925548, 1814955, and 1845576, and a Google PhD Fellowship awarded to KK.

A Appendix

A.1 Details of our crowdsourced data

Table A1 mentions all datasets that we re-annotate in this work with their breakdown based on domains, number of documents, passages, tokens and mentions annotated.

Dataset	Domain	#Docs	#Passages	#Tokens	#Mentions
OntoNotes	News	6	30	4923	1365
	Weblogs	5	20	3452	1001
	Opinion	12	20	3861	1157
LitBank	Fiction	4	30	5455	1494
QuizBowl	Quizzes	20	20	3304	1083
ARRAU	News	3	20	3336	885
GUM	Biographies	4	20	3422	1119
	Fiction	4	20	3299	1008
Phrase	Wikipedia	7	20	3509	1003
Detectives	Fiction	4	20	4007	1063
	Opinion	7	9	1692	495
PreCo	News	4	8	1318	369
	Fiction	2	2	378	105
	Biographies	1	1	152	53
Total	All	83	240	42108	12200

Table A1: All datasets analyzed in this work with their breakdown based on domains, number of documents, passages, tokens and mentions annotated.

A.2 Manual Qualitative Analysis

Dataset	Mistakes (our)	Mistakes (gold)
PD (silver)	22	76
OntoNotes	81	49
PreCo	12	33
GUM	48	25
ARRAU	33	16
LitBank	21	13
QuizBowl	67	10

Table A2: Number of mistakes in our crowd annotations vs. gold datasets, obtained through a manual analysis.

A.3 Detailed Mention Detection Algorithm

- We identify all noun phrases using the Stanza dependency parser (Qi et al., 2020). For each word with a noun-related part-of-speech tag,²² we recursively traverse all of its children in the dependency graph until a dependency relation is found in a whitelist.²³ The maximal span considered as a candidate mention thus covers all words related by relations in the whitelist.
- Possessive nominal modifiers are also considered as candidate mentions. For instance, in the sentence “Mary’s book is on the table,” we consider both “Mary” and “Mary’s book” as mentions.

²²Pronouns, nouns, proper nouns, and numbers.

²³The whitelist includes all multi-word expression relations (i.e., compound, flat, and fixed) and modifier relations (i.e., determiners, adjectival modifiers, numeric modifiers, nominal modifiers, and possessive nominal modifiers).

- Modifiers that are proper nouns in a multi-word expression are considered as mentions. For instance, in “U.S. foreign policy,” the modifier “U.S.” is also considered as a mention.
- All conjuncts, including the headword and other words depending on it via the conjunct relation, are considered mentions in a coordinated noun phrase. For instance, in the sentence, “John, Bob, and Mary went to the party.”, the detected mentions are “John,” “Bob,” “Mary,” and the coordinated noun phrase “John, Bob, and Mary.”
- Finally, we remove mentions if a larger mention with the same headword exists. We allow nested spans (e.g., [[my] hands]) but merge any intersecting spans into one large span (e.g., [western [Canadian] province] is merged into [western Canadian province]).

A.4 Inter-Annotator Agreement Among Our Annotators Across Domains

Figure 6 illustrates agreement among our annotators computed with B3 scores including singletons.

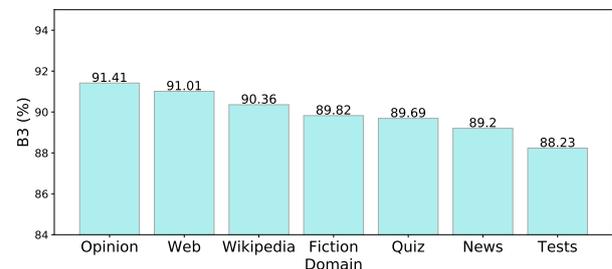

Figure 6: Inter Annotator Agreement across different domains. B3 scores with Singletons included.

A.5 Another illustrative example

An example of a single sentence annotated by two datasets, OntoNotes and ARRAU. These annotations differ widely from each other in kinds of mentions and links between mentions.

OntoNotes: [Lloyd’s, once a pillar of [the world insurance market]e1,]e2 is being shaken to [its]e2 very foundation.

ARRAU: [Lloyd’s, once [a pillar of [the world [insurance]e3 market]e2]eS1]e1, is being shaken to [[its]e1 very foundation]eS2.

Tutorial feedback from our crowd annotators

1. This was a really interesting task. The tutorial was very clear and easy to understand. I think it was very helpful when I completed the final passage.
2. Very great tutorial, I loved how it walked me through each and every step making sure I understood.
3. excellent interface and very precise instructions! out of curiosity, what is the time-frame and scale for this project? several weeks? months? hundreds or thousands of hits? I have a ton of projects during the autumn normally but will definitely make time for this if it's going to be around for more than a day or two. Looking forward to working with you folks if possible!
4. I actually enjoyed this. Thank you for the opportunity.
5. it was interesting a bit difficult but overall gave a lot of feedback necessary to do a good job.
6. I loved the tutorial and the layout. I am still a little bit unsure about a couple of the entities and hope I got it right. For example: would 'legs' be in 'his' because it refers to that person? I wasn't sure and made them separate.
7. I loved how this tutorial was set up. It was easy to use and made me very interested in doing the actual HITs. It would have been nice to be able to print out a quick reference guide or something, so we could refer to the instructions from before while we completed the final task. I don't think it would be needed for very long after starting the real HITs, but it would still be nice to have.
8. On the last test section, there was no place for feedback. There was a section that said ""it was getting dark"" ""It was getting late"" Both of those refer to a time of day, but one is light, one is the hour, so I marked them as different. Not sure of how broad or narrow we need to be when justifying ""same"" entities, as there is an argument either way.
9. I just wanted to say that I really appreciated how efficiently put together and clear this tutorial was.
10. This was a unique task. Thank you.
11. I feel much better with the help and feedback. It was interesting and definitely way different in a good way than the usual survey. I did my best and I hope I did well enough. Keep safe and Happy Holidays no matter what happens.

Table A4: Some of the comments received from our annotators after completing the tutorial. We received overwhelmingly positive feedback; annotators sometimes also mentioned cases they found confusing.

Coreference Tutorial

Welcome!

This is a **paid tutorial** for the "**Large-Scale Coreference Annotation Task.**"

In this tutorial you will learn how to annotate **coreferences**, that is, words and phrases that refer to the same people or things.

Upon completing the tutorial, you will get a **completion code**. You **MUST enter this code** in the textbox below and **submit the HIT** in order to receive the payment.

Depending on your performance, you might be invited to participate in our "Large-Scale Coreference Annotation Task."

Before proceeding to the tutorial, please **fill in the following survey**:

What is your **gender**?

What is your **age**?

What is your **native language**?

How is your **English level**?

- Beginner
- Intermediate
- Advanced (near native)
- Native speaker

What is your **education level**?

- Primary
- Secondary
- College
- Graduate School

[Click this link to begin.](#)

[OPTIONAL] We would love to hear **your feedback** about **this tutorial**.

Submit your code below:

Figure 7: Screenshot of tutorial task invitation on AMT with detailed instructions.

Coreference Tutorial Mode

Welcome to the coreference tutorial mode. Here you will learn how to use the interface efficiently to label text for coreferences.

What are **coreferences**?

A coreference is when **two words** or **spans** (sequence of words) refer to **the same thing**.

In the examples below, the following words are coreferences (they refer to the same "thing"):

- (1) **"John"** and **"He"**
- (2) **"Robert"** and **"He"**
- (3) **"Alice"** and **"Her"**

John is cool. He is nice.

Robert loves Alice. He talks to her everyday.

Let's get started.

Figure 8: Tutorial Interface (Introductory prompt)

Select Spans (Task 1 of 10)

Step 1 of 2

Observe how the border around "Mary" is flashing. This means the span "Mary" is the current target.
Click on all the spans that refer to the target "Mary."

Happy Annotating!

Currently Annotating Entity 0

Mary

Mary is fun.

She jokes a lot.

That's why Mark likes her.

Coreference Annotation Task

Welcome to the coreference annotation task. In this task you will be asked to annotate a short paragraph for coreferences. If you need to review the tutorial, please follow this [link](#).

What are **coreferences**?

A coreference is when **two words** or **spans** (sequence of words) refer to **the same thing**.

In the examples below, the following words are coreferences (they refer to the same “thing”):

- (1) "John" and "He"
- (2) "Robert" and "He"
- (3) "Alice" and "Her"

John is cool. He is nice.

Robert loves Alice. He talks to her everyday.

[Click this link to begin annotation.](#)

[OPTIONAL] We would love to hear **your feedback**. Let us know if anything was unclear or particularly challenging.

Submit your code below:

Abstract

The recent increase in the volume of online meetings necessitates automated tools for organizing the material, especially when an attendee has missed the discussion and needs assistance in quickly exploring it. In this work, we propose a novel end-to-end framework for generating interactive questionnaires for preference-based meeting exploration. As a result, users are supplied with a list of suggested questions reflecting their preferences. Since the task is new, we introduce an automatic evaluation strategy by measuring how much the generated questions via questionnaire are answerable to ensure factual correctness and covers the source meeting for the depth of possible exploration.

1 Introduction

In recent years, video conferencing technology has gained substantial improvements, and thus, online meetings have become easily accessible and more prominent. Primarily due to the pandemic and working from home, the need for video calling has grown significantly. Therefore, the high volume of online meetings necessitates automated tools for managing and organizing essential information for attendees. Especially when an attendee has missed an online meeting, it is critical to access the required information since quickly reading through the transcript is quite time-consuming.

Providing meeting summaries is a promising direction (Wang and Cardie, 2013; Jacquenet et al., 2019; Zhao et al., 2019; Singhal et al., 2020). However, recent studies show that 1) users' needs do not fully align with current approaches to automatic text summarization (ter Hoeve et al., 2020, 2022) and 2) approaches designed for document summarization could not effectively apply to meetings transcripts (Murray et al., 2010; Mehdad et al., 2013; Li et al., 2019) due to the following potential reasons: **(R1) Structure:** standard documents are well structured compared to meeting transcripts;

The following subjects were discussed in the meeting.

Figure 1: An example of exploring one of the meetings from the collection (Carletta et al., 2005) based on user preferences through an interactive questionnaire.

(R2) Language: spoken language used in meetings is less regular than documents; and **(R3) Multiple speakers:** the speaker role is essential. Moreover, there is little meeting data publicly available that can be used for experimentation compared to regular documents such as news or articles. In contrast with document summarization, when summarizing a meeting, different users tend different preferences on what content should be included in the summary. Therefore, there is an increasing calling for alternative ways of summarizing, especially for meetings transcripts. Recently, Zhong et al. (2021) attempted to tackle this problem by proposing a query-based multi-domain meeting summary, where a user provides a query in question form, e.g., ‘*What was the discussion about the jog dial’s function when talking about changes in the current design?*’ to locate the part of the transcript that related to the query and then summarize. However, when attendees have missed the meeting, they cannot formulate such questions due to no prior knowledge about the meeting. To overcome this, we aim to address the following **research challenge:** *How can attendees effectively explore a meeting content without having prior knowledge about it?*

This work is motivated by the fact that asking questions is a more efficient way for humans to ac-

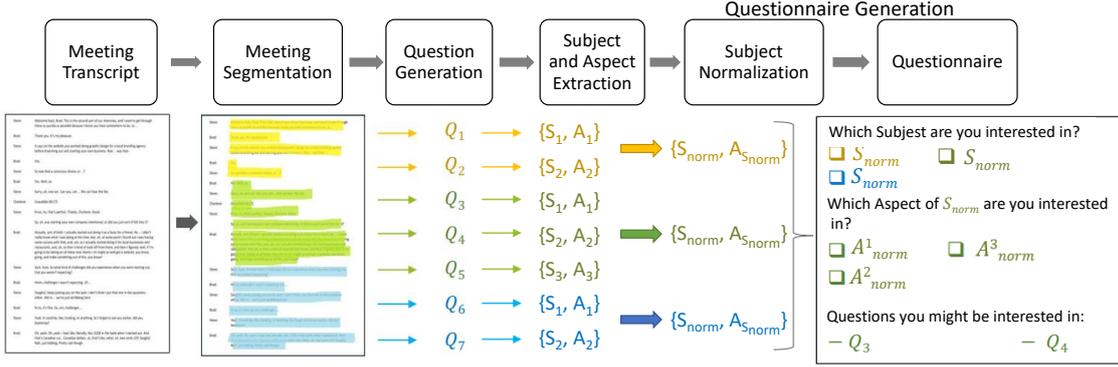

Figure 2: Overview of our framework, Preference-based Meeting Exploration through an Interactive Questionnaire (PREME), where Q is a comprehensive set of questions, and S_i and A_j are extracted pairs of subjects and aspects.

quire information than notes in plain text (Lawson et al., 2007, 2006; Aliannejadi et al., 2021). Thus, we address preference-based meeting exploration by automatically generating a structured interactive questionnaire for a transcript that covers most of the discussed topics and quickly walks users through the discussed content. An example of the desired questionnaire is shown in Fig. 1. First, the user has the ability to express their preferences regarding *subjects* that have been discussed (Solbiati et al., 2021; Huang et al., 2018; Zhang and Zhou, 2019; Sehikh et al., 2017). Next, the questionnaire interactively suggests narrowing down their exploration if possible by displaying a list of possible related *aspects*. As a result, a ranked list of questions reflecting user preferences is generated. Next, the user can pick a question that demonstrates their seeking needs the most and is redirected to the meeting part containing an answer. Interactively asking for preferences in the questionnaire is beneficial because the user oversees what has been covered during the meeting they have missed. In section 4.2 we elaborate on a user study on a number of professionals who find such application useful for their daily job. Hence, the goal of proposed questionnaires is two-fold: **(G1)** to compactly represent the discussed content; **(G2)** to guide users to form questions that express their preference regarding the transcript. We require the generated questionnaire to satisfy the following properties:

- P1 Coverage:** coverage is the amount of the information from the source text that a questionnaire points to. The generated questionnaire must cover the meeting as much as possible;
- P2 Answerable:** a given meeting transcript should contain the answers to the questions generated as a result of the questionnaire.

To address the defined challenge, we propose

a framework, PREME, which consists of several concrete sequential steps highlighted in Fig. 2. We start by enchaining the method to extract meeting segments (Solbiati et al., 2021). Due to the conversational nature of the meeting, topic detection from the segments is challenging (Huang et al., 2018; Zhang and Zhou, 2019; Sehikh et al., 2017). Thus, we indirectly extract the topics as follows. First, we generate questions from each segments (Brown et al., 2020) since extracting topics from the questions is much more well studied. Further, we employ a trained Conditional Random Field (CRF) model to tag subjects and aspects (Fig. 1) from generated questions originated from each segments (Wallach, 2004). Once we got each segment’s topic list, we proposed a strategy to normalize them to reduce the number of options in the questionnaire. Recently, Deutsch et al. (2020) demonstrated that QA-Based evaluation is strongly correlated with human opinion. Thus, to evaluate PREME, we employ a similar QA-based strategy.

To summarize, the main contributions are:

- C1** We propose PREME, a novel framework to enable meetings exploration based on user’s preferences through an interactive questionnaire;
- C2** We propose a new method for subject normalization which returns the most informative subject from a set of phrases and keywords;
- C3** We introduce a new automatic evaluation strategy for measuring the effectiveness of the proposed questionnaire to assess the required properties **P1** and **P2**, which according to (Deutsch et al., 2020) has a strong correlation with human judgments; and
- C4** We open-source a dataset that includes 1000 questions comprehensively annotated with subject to their subjects and aspects at <https://github.com/microsoft/preme>

2 Related Work

2.1 Automatic Textual Summarization

Automatic text summarization task has attracted lots of attention across Natural Language Processing (NLP) community recently. Many systems are proposed to summarize documents in different domains, including news (Rush et al., 2015; Nallapati et al., 2017; See et al., 2017; Celikyilmaz et al., 2018; Liu and Lapata, 2019; Zhang et al., 2020), academic papers (Manakul and Gales, 2021; Huang et al., 2021) and books (Kryściński et al., 2021). Meeting summarization has also emerged as a widespread need recently. Due to the unique discourse structure of dialogues, conventional document summarization systems are facing challenges when summarizing meetings (Li et al., 2019; Zhu et al., 2020). Thus, new models are proposed for tackling this task. Wang and Cardie (2013) employ decisions, and action items in dialogues to generate the summary progressively. Oya et al. (2014) propose a template-based meeting summarization system by learning the relationship between summaries and their source meeting transcripts. Shang et al. (2018) design an unsupervised meeting summarization model with multi-sentence compression techniques. Li et al. (2019) introduce multi-modal information into meeting summarization with a hierarchical attention mechanism. Zhu et al. (2020) propose a hierarchical meeting summarizer that can process both word-level and turn-level information of dialogues. Furthermore, the community noted that due to the lengthy content and distributed information, a general summary of the meetings does not necessarily satisfy what users seek. Thus, Query-based summarization methods have become more prevailing for generating concise and specific summaries. (Litvak and Vanetik, 2017; Nema et al., 2017; Baumel et al., 2018; Ishigaki et al., 2020; Kulkarni et al., 2020, 2021; Pasunuru et al., 2021). Recently, Zhong et al. (2021) proposed a new framework of query-based summarization for meetings, in which they annotate QMSUM, a query-based multi-domain meeting dataset. Each QMSUM meetings come along with a set of queries with different levels of abstractness, i.e., general queries and specific queries. Human annotators write these queries, and the summaries align with these queries after reading the meeting transcripts.

While query-based summarization can be a proper path to provide users with meeting information at different specificity levels, we argue that

issuing such specific queries still requires a certain degree of background knowledge. In real-life scenarios, users might not be equipped with that knowledge and issue informative queries, especially when they did not attend the meeting. Hence, they can not benefit from query-based summarization techniques to explore the meetings. We address the drawbacks of query-based summarizers by providing users with an interactive questionnaire which provides them with potential queries and allows them to explore the meetings more flexibly.

2.2 Evaluation of Summaries Factuality

The summaries often has called out for hallucination issues (Maynez et al., 2020). Thus, Wang et al. (2020) propose a framework to evaluate factual consistency of summaries with the source text. Similarly, Deutsch et al. (2020) propose a Question Answering (QA)-based evaluation approach on summaries' content quality. They measure how much information is contained in a candidate summary by calculating the proportion of questions it can answer. These approaches inspired us for automated end-to-end evaluations of the questionnaires.

2.3 Question Generation and Filtering

Initial works in Question Generation task leveraged crowd-sourcing or rule-based methods to generate pre-defined question templates (Mostow and Chen, 2009; Rus et al., 2010; Lindberg et al., 2013; Fabri et al., 2020; Mazidi and Nielsen, 2014; Labutov et al., 2015). Heilman and Smith (2010) tackled this problem by over-generating candidate questions and then using a learning to rank framework to rank them to filter the low-quality questions. SQUASH (Krishna and Iyyer, 2019) is one of the recent works in which authors used question generation methods to convert a document into a hierarchy of question-answer pairs with the focus on questions' granularity level. They employed a neural encoder-decoder model trained on three reading comprehension data sets, i.e., SQuAD (Rajpurkar et al., 2016), QuAC (Choi et al., 2018), and CoQ (Reddy et al., 2019) to generate the questions, and further, they filtered out the unanswerable questions using some heuristics and question answering models. While question generation using question answering data sets seems a general approach, this method does not work well on meeting-related questions generated due to many reasons, including: (1) Different structure of meetings compared to documents; (2) There are not many ques-

tion-answering datasets available from meetings; (3) Sometimes, the answer to questions generated from meetings could be very long, making it hard to fit the context in neural models. In our work, we introduce an automatic method that can generate questions regarding the meeting to overcome the high price of collecting with annotators.

2.4 Questionnaire Organization

Obtaining users preferences has always shown to be a challenging task (Jiang et al., 2008; Rokach and Kisilevich, 2012; Anava et al., 2015; Christakopoulou et al., 2016; Sepliarskaia et al., 2018). The task becomes more challenging when we aim to minimize the number of interactions with users to get to know their preferences. Sepliarskaia et al. (2018) reformulate this task as an optimization problem. They propose a static questionnaire by choosing a minimal and diverse set of questions. Similarly, in Liu et al. (2019) proposed a dynamic questionnaire generation method for search of clinical trials. Quiz-style question generation has also been explored recently by Lelkes et al. (2021). The authors have formulated the problem as two sequence to sequence tasks, including the question-answer generation step and incorrect answer generation step. We argue that while the former step seems relevant to our work, it could not be adapted to meeting transcripts since their proposed dataset has been trained on factual question answering data sets and cannot be used for meeting purposes. All in all, we can conclude that creating questionnaires are still under exploration in different domain. Hence, our effort in organizing a questionnaire, especially for meetings, is timely and useful for future research.

3 Proposed Framework: PREME

This section explains PREME, our proposed novel methodology to explore meetings based on users' preferences through an interactive questionnaire. An overview of our methodology is shown in Fig. 2 in which we first apply a topic segmentation method (Solbiati et al., 2021) on meeting transcript to retrieve segments with different topics (Section 3.1). Then, we generate a set of all possible questions from each segment (Section 3.2). Further, we extract the most informative part of the questions, i.e., the subject and aspect of each question (Section 3.3). In the last step, we map the normalized subjects and aspects with generated questions and form the questionnaire (Section 3.4).

3.1 Meeting Segmentation

A meeting transcript can be extremely long and contain discussions of various topics. Therefore, our goal is to divide the meeting text into a sequence of topically coherent chunks. Thus, we adopted an unsupervised topic segmentation method based on the contextualized presentation of meeting (Solbiati et al., 2021). In this topic segmentation method, the authors compute the BERT embeddings for every utterance of the meeting transcript. Further, they curated blocks of utterances and performed a block-wise max-pooling operation to generate contextualized embedding for each block. Then, the semantic similarity between two adjacent blocks is captured, and a change in the topic is detected if two adjacent blocks show similarity below a certain threshold. This approach has several advantages, including: (1) It is unsupervised; (2) Since we are just converting the meeting into smaller pieces, and we are not losing any part of the meeting.

3.2 Question Generation

For question generation from a segment, we leveraged the powerful GPT-3 model (Brown et al., 2020). An impressive capability of the GPT-3 is to generate very realistic results from few training samples or even no training sample (few-shot and zero-shot learning). The variety of the generated content can be controlled using a temperature hyper-parameter. To expand the size of generated questions' pool as much as possible, in each segment, the API is called in a zero shot learning model with different temperature values between [0-1] with a 0.05 margin, where the value closer to 1 means more diversified questions. We set the maximum output length to 128 tokens and then we repeat the process for 10 trials for each specific temperature. Given that the maximum context window for the API was 2048 tokens, we truncate and slide by half-a-window size of 2048 tokens whenever a segment includes more than 2048 tokens. As a results, A list of questions is extracted based on random initialization in each API call, meaning different results are achieved even with the same hyper-parameters. We extracted five questions on average per segment in each call. Finally, a union across all runs is used to form our question pool.

3.3 Subject and Aspect Extraction

Every of the generated questions has one or more *subject(s)* that is defined as the principal matter that attendees have discussed, i.e., the main con-

Table 1: Examples of annotated questions with their subjects and aspects. Subjects are highlighted in red and Aspects are highlighted in green.

Q1	What is the arrow symbol on the remote control for?
Q2	What are the main frustrations people have with the remote control ?
Q3	How will the logo and color scheme be incorporated into the product ?
Q4	What are pros and cons of having a remote with a large number of buttons ?
Q5	What is the most difficult part of the project from the industrial engineer's point of view?

cern of the questions. Some questions might point to a specific *aspect(s)* of the subject which is defined as the mentioned details about a given subject. We aim to extract the primary subjects from any question and the detailed aspect if it is mentioned. Table 1 shows examples of annotated *subjects* and *aspects* for a few questions. For instance, in the question “What is the arrow symbol on the remote control for?”, “remote control” is annotated as the subject and the “arrow symbol” is the specific aspect of the subject. To extract the subjects and aspects from the questions, we use CRF (Wallach, 2004). We examined SOTA keyword extraction and contextualized neural embedding-based topic extraction models; however, the CRF model which uses word’s identity, suffix, shape and POS tags as features, seems to work the best among them. To train the CRF model, we were required to have annotated questions with subjects and aspects labels. We designed an annotation study using the UHRS¹ crowd-sourcing platform, where we carefully trained annotators with detailed instructions to label randomly selected 1000 questions generated by GPT3 with their subject and aspects². Each question has been assigned to two annotators, and we report the annotators’ agreement in Section 4. Further, we employ the trained CRF model to extract subjects and aspects from the questions.

3.4 Questionnaire Generation

Given a meeting transcript, for each of its segment T which was initially supposed to coherently point out one subject, we generate Q_T , a set of generated questions from T . In other words, given an ideal meeting segmentation method, each segment

¹<https://prod.uhrs.playmsn.com/uhrs/>

²We invested in having a few well-trained annotators rather than having a high number of annotators who have not been trained well. Thus, annotators were paid hourly and by the quality of their work and they had no intentions for cheating.

is supposed to be pointed to one subject. Thus, we assume that each segment has only one valid topic and as shown in Figure 2, each segment is being represented with one S_{norm} . We create a set S_{Q_T} by extracting the subjects from each question in Q_T . Therefore, for the segment T , we have at least $|Q_T|$ number of subjects. Extracted subjects from a question set with the same origin segment must be normalized so that one comprehensive, general, and informative subject presents a segment. The more the selected subject representative covers other concepts in S_{Q_T} , the better normalization we employed. This subject normalization reduces the number of subjects shown to the user at the first step of the questionnaire and will decrease the user’s effort, causing figuring out users’ preferences by asking them the minimum number of questions. In other words, our goal is to select a single subject S_{norm} from S_{Q_T} which represents S_{Q_T} in the most informative way. To do so, we define the notion of the subject network as follows.

Definition 3.1. Given a segment T , a set of generated questions Q_T , and extracted subjects S_{Q_T} , a subject-network for $G(S_{Q_T})$ is denoted as $G(S_{Q_T}) = (\mathbb{V}, \mathbb{E}, w)$. It is a weighted undirected graph, where $\mathbb{V} = \{s_i \in S_{Q_T}\}$, and $\mathbb{E} = \{e_{s_i, s_j} : \forall s_i, s_j \in \mathbb{V}\}$. The function $w : \mathbb{E} \rightarrow [0, 1]$ is the cosine similarity between the semantic relatedness of the contextualized embedding vectors of two incident subjects of an edge e_{s_i, s_j} , i.e., v_{s_i} and v_{s_j} .

In Def. 3.1, we propose a subject-network where subjects are connected, and edge weights represent the semantic similarity between the two subjects. We hypothesize that the node with highest similarity and connection to others is the most central one. In other words, since it has great similarity to other subjects, there is a high probability that it points to a more generic concept and that covers the other subjects. Hence, the node S_{norm} should have high centrality attribute to represent the main subject of segment S . We employed PageRank (Haveliwala, 2003) value to find the most important and informative node in this network. Similarly, PageRank has shown to have a high correlation with the most important nodes and has been used in tackling different tasks such as quantifying term’s specificity or ranking problems in different information retrieval tasks (Arabzadeh et al., 2020, 2019; Kurland and Lee, 2010). We measure the PageRank score of each node and select the node

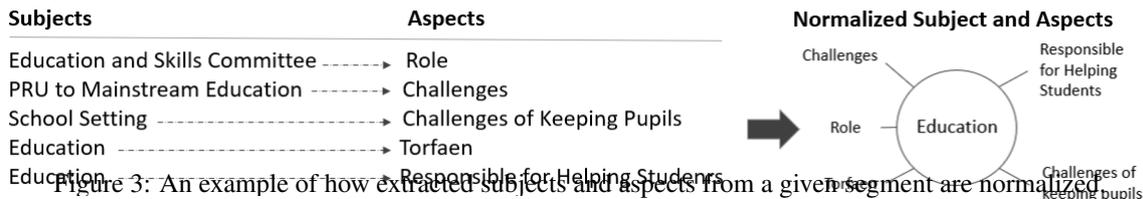

Figure 3: An example of how extracted subjects and aspects from a given segment are normalized

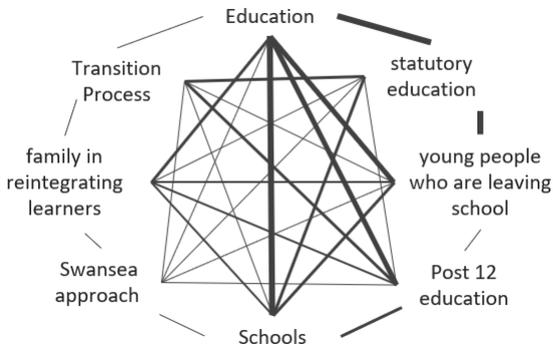

Figure 4: An example of subject-network built for one extracted segments from (Janin et al., 2003). The edge weights represent the semantic similarity between each nodes. Higher weights are shown with higher width.

with the highest PageRank value as the representative subject S_{norm} of the subject set S_{Q_T} for segment T . In other words, we represent each segment T by subject S_{norm} where $PageRank(S_{norm}) > PageRank(s_i)$ for every $s_i \in \mathbb{V}$.

Fig. 4 displays a subject-network generated from extracted subjects from one of the meetings’ segments in the QMSUM dataset. subjects such as “Education”, “Schools,” “Young people who are leaving school” are included in this subject set and represented by nodes in this subject-network. Further, we connect every pair of nodes in this graph, and the edge weight is directly related to their semantic similarity. As presented in Fig. 4, some nodes have higher edge weights which their connected lines are shown with greater width. We measure page rank in this weighted network. Here “Education” got the highest PageRank value in this subject-network. Hence, we present these subjects by one subject, i.e., “Education”. “Education” can be a promising representative for these subjects as it covers more specific concepts such as “schools”, “statutory education,” and “post 12 education.”

Next, the extracted aspects from each question set should be mapped to their representative subject. We remove the redundant and repetitive aspects and subjects by removing those who have highly similar n-grams. Plus, There might be several subjects existing in S_{Q_T} which all point out to S_{norm} , and they might be semantically very similar. In this step, we must be concerned not to lose any aspect because of subject normalization. We aim to

Table 2: Annotators agreement on annotated questions with respect to subjects and aspects using Krippendorff’s score (Krippendorff, 2011)

	Subject	Aspect
Hard [Exact Match]	0.459	0.415
Soft [At least one term matched]	0.490	0.485

map every aspect from S_{norm} and every s_i in S_{Q_T} which is highly similar to S_{norm} to maximize the potential of questions we might want to show at the end of the questionnaire. For instance, in Fig 3 we display a few extracted subjects and aspects from one segment. If we only consider “education” and its related aspect, we will lose many aspects that users might be interested in, and as a result, the questionnaire coverage will drop. On the other hand, if we merge the highly similar representative subjects with, e.g., “school setting” and “Education and Skills Committee,” we will have a broader host of questions to suggest to users. Therefore, we will filter out dissimilar subjects from S_{Q_T} to S_{norm} and map extracted aspects from filtered S_{Q_T} to S_{norm} as it is shown in Fig. 3. As a result, if “education” is the subject of interest for a user, they have the opportunity to select which aspects of education they are more interested in, such as “Role” of education or “challenges” of education. Finally, we will show users the questions in which the selected aspects and normalized subjects have appeared.

4 Evaluation Methodology

For experiments, we use the QMSUM dataset (Zhong et al., 2021), which includes 232 product, academic, and committee meetings (Janin et al., 2003; Carletta et al., 2005). Each meeting comes with a set of general and specific questions; the general ones are out of the scope of this work since they refer to very broad concepts, e.g., “summarize the whole meeting.”. Further evaluations are conducted on the QMSUM test set.

4.1 Evaluating Framework Components

The proposed framework consists of several steps (Fig. 2). The used *meeting segmentation* (Solbiati et al., 2021) method has shown to outperform baselines (Hearst, 1997; Beeferman et al., 1999; Badjatiya et al., 2018). Hence, we refer to original paper for evaluation results.

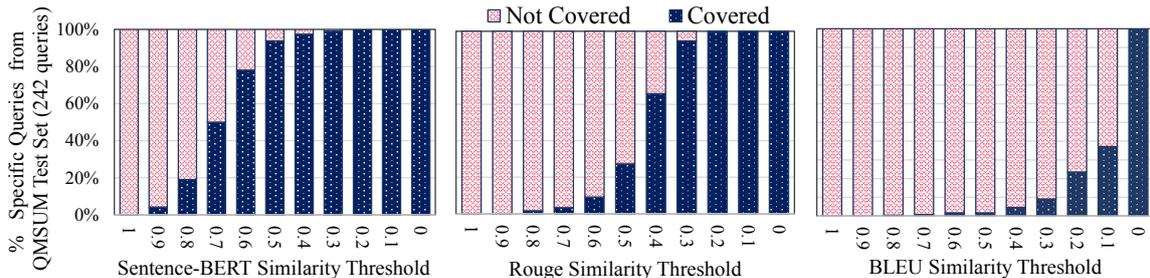

Figure 5: Coverage of PREMEon QMSUM test set considering different similarity metrics and threshold

Table 3: CRF performance on extracting subjects and aspects of questions using 10-fold cross validation

	Precision	Recall	F1-Score
Subject	0.64	0.69	0.67
Aspect	0.89	0.80	0.84
N/A	0.63	0.73	0.68

Evaluating Question Generation: We evaluate the quality of our generated questions by measuring the fraction of generated questions by human annotators in QMSUM that we covered in PREME. We assume the specific queries in the QMSUM dataset enjoy relatively high quality because annotators issued them after comprehensively reading the transcript (gold standard questions). Hence, Fig. 5 reports the similarity between most similar questions generated by PREME and the gold questions by three different similarity metrics i.e., Sentence-BERT similarity (Reimers and Gurevych, 2019), Rouge F-1 score (Lin, 2004), and BLEU-4 score (Papineni et al., 2002). We assume a questions from QMSUM is covered if there is at least a question generated by PREME that has similarity is higher than a certain threshold $t \in [1, 0.9, \dots, 0.1, 0]$. We report the percentage of ‘Covered/Not Covered’ questions based on different similarity matching thresholds. Based on Fig. 5 we conclude while we cover a relatively fair number of specific questions, there is still room for improvement. However, we should note that the questions in QMSUM are very limited, and initially, they were not supposed to cover all possible questions that one could raise from the meeting. Additionally, we observe that questions in QMSUM, which are issued by humans, include more abstractive questions while our generated questions inclined toward more factual ones.

Evaluating Subject and Aspect Extraction: To assess the quality of the collected dataset, we measure Krippendorff’s alpha agreement between annotators (Krippendorff, 2011) for extracted *subject* and *aspect* of the 1000 questions generated from the training set. Tab. 2 shows annotators have

agreement ~ 0.4 , which is interpreted as “Moderate” agreement for such a challenging task. Since different annotators might selected different section of the text, Tab. 2 reports both *hard* and *soft* agreements. we trained the CRF model using *crfsuite* library and evaluated it by 10-fold cross-validation. Given each term in the questions, the model predicts whether the term is considered the subject, aspect, or not applicable for labeling (N/A). Tab. 3 shows the result of the CRF model evaluation in terms of precision, recall, and F1 scores. We notice that the model shows better performance on detecting aspects compared to the subject.

4.2 Evaluating Questionnaires

To the best of our knowledge, we are first to propose a preference-based questionnaire as a way for meeting exploration; thus, no particular gold standard benchmark or evaluation metrics. Since we require users to express their preference, it makes it challenging to simulate ‘enough imaginative context’ among annotators. Thus, we conducted a user study to highlight the usefulness of exploring meetings through an interactive questionnaire. We provided 20 participants who were professional workers and graduate students aged between 24-41 with detailed explanations and examples of results generated by PREME such as in Figure 1. Participants on average had over 5 hours of online meetings per week. Among which, over 80% of them reported that they need to explore the content of a past meeting, at least a couple of times a week. Finally, over 80% of participants agreed on finding PREME useful for meetings exploration. Also, we introduce a new evaluation strategy that satisfies the desired properties on coverage (P1) and the existence of answers in the transcript (P2). The proposed automatic metrics capture if our framework is ready to be tested through a more comprehensive user study in the future, when we can run a pair-wise preference-based comparison between PREME and other meeting exploration methods.

Table 4: Test set statistics and PREME Performance: Average number of generated questions and Coverage.

	#Meetings	Average # Turns	Average # Questions	Coverage (%)
Academic	9	893	1257	83.07%
Committee	6	214	1105	64.04%
Product	20	569	724	86.25%
All	35	591	927	81.62%

Automatic evaluation: We utilize the model SOTA called Locator in (Zhong et al., 2021) in which, given the query, it can extract the relevant spans from the meeting. The Locator employs a hierarchical ranking-based model structure based on CNN (Kim, 2014) and Transformers (Vaswani et al., 2017) architecture. The Locator embeds each utterance of the meeting and feeds it to a CNN network by capturing the local features, and utilize Transformer layers to obtain contextualized turn-level representations. In addition, the speaker’s embedding is also concatenated to the features list. Finally, the model uses MLP to score each turn, and the turns with the highest scores are considered the relevant spans for each question.

To measure the coverage (to satisfy **P1**), we adopt the newly proposed QA-style of evaluation (Deutsch et al., 2020; Wang et al., 2020) which has shown to have substantial correlation with human judgments in terms of questions quality assessments. *Coverage* is defined as the fraction of a meeting that a questionnaire encompasses. To measure the coverage, first, the relevant answer spans for the existing questions in a questionnaire are located. Further, the proportion of utterances that were already located as relevance answer spans w.r.t. the whole meeting transcripts, is measured as the coverage. We believe that that is a promising indicator of questionnaire informativeness. The coverage is basically how much of the original meeting was covered by the questionnaire. We hypothesize that a good questionnaire should ideally include questions from all parts of a meeting. i.e., the questionnaire includes questions related to every part of the meeting so that users are able to explore their section of interest from the meeting. Therefore, the more the questionnaire covers the meeting, the better it is. To do so, we find the answer spans to the generated question in each questionnaire and we report the percentage of utterances that the locator detected as the answer span for all the questions in the questionnaire from the whole meeting. We run our experiments on the QMSUM test set. Tab. 4 shows the details of this test set. We over generate the questions and after

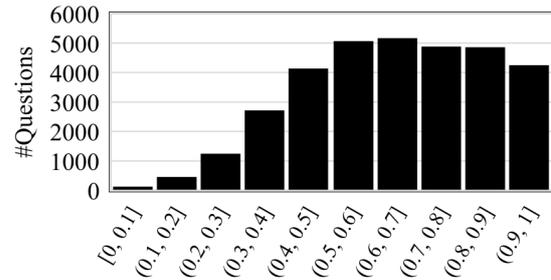

Figure 6: Histogram of Confidence Scores of Question-Answering model on generated questions from PREME.

removing the duplicates, on average, the questionnaire has 1257 unique questions from Academic meetings, 1105 questions from Committee meetings, and 724 questions from Product meetings. Further, Tab. 4 reports the percentage of utterances covered in each meeting. On average, our proposed questionnaire can cover 81% of the meeting. We also compared the coverage on different types of meetings. While our generated questionnaire covered Committee meetings the least (64%), the Product and Academic meetings show higher coverage (over 80%). Further, we evaluate how much the generated questions in PREME are answerable (to satisfy **P2**). Inspired by (Krishna and Iyyer, 2019), we run a pretrained QA model (Sanh et al., 2019) over generated questions and report the confidence score for each QA pair in Fig. 6. We use DistilBERT fine-tuned on SQUAD (Rajpurkar et al., 2016) dataset. We observe that more than 73% of generated questions from PREME on meetings in test set of QMSUM shows confidence score higher than 0.5 and more than 42% of questions shows confidence score greater than 0.7. The results confirm that a promising portion of generated questions are answerable.

5 Conclusions and Future Work

We proposed an end-to-end framework, called PREME, that allows automatically building a questionnaire that will enable users to explore the most of discussed subjects and their aspects if desired. As a result, users are supplied with questions about the meetings that express their information needs, and answers can be found in the transcript. Since simulating actual users’ preferences is challenging and requires hired annotators, we have ran a small user study as well running an automatic end-to-end evaluation strategy to demonstrate the desired properties (**P1** and **P2**) of the generated questionnaires. We publicly release the collected dataset of annotated questions concerning its subjects and aspects, the code for questionnaires generation, and our

evaluation procedure to carry forward the proposed state-of-the-art for the newly formulated problem. In future, and by proposing a new method for questionnaire generation will allow us to run a user study for pair-wise comparison of the methods and reveal the correlation between human and automatic evaluation metrics for the suggested task.

6 Limitations

Generally, there is not much data available for meeting exploration. Thus, all studies on this domain are limited by small training and exploratory data. Therefore, it would be beneficial for the community to collect more labelled meeting data for meeting exploration and organization purposes. Since PREME is made of different SOTA components, its performance is also limited by individual components. In future, novel attempts can be made to address this problem as an end-to-end framework. In addition, the future works should include an extensive human evaluation that will reveal additional requirements for the PREME to satisfy, which will suggest additional evaluation metrics. Plus, since this the first work on to tackle meeting exploration via questionnaire, the preference-based evaluation is not possible.

Sentence Identification with BOS and EOS Label Combinations

IBM Research - Tokyo, Japan

Takuma.Udagawa@ibm.com, {hkana, issei}@jp.ibm.com

Abstract

The sentence is a fundamental unit in many NLP applications. Sentence segmentation is widely used as the first preprocessing task, where an input text is split into consecutive sentences considering the end of the sentence (EOS) as their boundaries. This task formulation relies on a strong assumption that the input text consists only of sentences, or what we call the sentential units (SUs). However, real-world texts often contain non-sentential units (NSUs) such as metadata, sentence fragments, non-linguistic markers, etc. which are unreasonable or undesirable to be treated as a part of an SU. To tackle this issue, we formulate a novel task of sentence identification, where the goal is to identify SUs while excluding NSUs in a given text. To conduct sentence identification, we propose a simple yet effective method which combines the beginning of the sentence (BOS) and EOS labels to determine the most probable SUs and NSUs based on dynamic programming. To evaluate this task, we design an automatic, language-independent procedure to convert the Universal Dependencies corpora into sentence identification benchmarks. Finally, our experiments on the sentence identification task demonstrate that our proposed method generally outperforms sentence segmentation baselines which only utilize EOS labels.

1 Introduction

The sentence, which we refer to as the sentential unit (SU), is a fundamental unit of processing in many NLP applications including syntactic parsing (Dozat and Manning, 2017), semantic parsing (Dozat and Manning, 2018), and machine translation (Liu et al., 2020). Existing works mostly rely on *sentence segmentation* (a.k.a. *sentence boundary detection*) as the first preprocessing task, where we predict the end of the sentence (EOS) to split a text into consecutive SUs (Kiss and Strunk, 2006; Gillick, 2009). This approach relies on a strong

assumption that the text only consists of SUs; however, real-world texts like web contents often contain non-sentential units (NSUs) such as the metadata of attachments embedded in the email body, repetition of symbols for separating texts, irregular series of nouns, etc. (just to name a few). Such NSUs may cause detrimental or unexpected results in the downstream tasks if considered as parts of the SUs and are more desirable to be distinguished from SUs in the first preprocessing step.

To tackle this problem, we formulate a novel task of *sentence identification*, where the goal is to identify SUs while excluding NSUs in a given text (§3). This can be regarded as an SU span extraction task, where each SU span is represented by the beginning of the sentence (BOS) and the EOS labels.¹ We illustrate the difference between sentence segmentation and sentence identification in Table 1. In sentence segmentation, the text fragment of an embedded file (“- TEXT.htm << File: TEXT.htm >>”) needs to be considered as a part of an SU. In contrast, sentence identification can regard it as an NSU and exclude it for downstream applications such as dependency parsing.

To conduct sentence identification, we propose a simple method which effectively combines the BOS and EOS probabilities to determine both SUs and NSUs (§4). To be specific, we first train the BOS and EOS labeling models based on either the sentence identification dataset (with SUs and NSUs) or sentence segmentation dataset (only SUs). Then, we search for the most probable spans of SUs and NSUs using a simple dynamic programming framework. Theoretically, our method can be considered as a natural generalization of existing sentence segmentation algorithms.

To evaluate this task, we design an automatic pro-

¹For simplicity, we assume that the input text can be segmented into consecutive, non-overlapping units of SUs and NSUs. This way, we can also represent and evaluate SU extraction as an equivalent BIO labeling task (§5-§7).

Input Text (from EWT)	Thank you. - TEXT.htm << File: TEXT.htm >> I was thinking of converting it to a hover vehicle. I might just sell the car and get you to drive me around all winter.	
Sentence Segmentation	E	
		Thank you. - TEXT.htm << File: TEXT.htm >> I was thinking of converting it to a hover vehicle. I might just sell the car and get you to drive me around all winter.
Sentence Identification	B E	
		Thank you. - TEXT.htm << File: TEXT.htm >> I was thinking of converting it to a hover vehicle. I might just sell the car and get you to drive me around all winter.

Table 1: Illustration of sentence segmentation and sentence identification. In sentence segmentation, EOS labels (E) are used to segment the input text into consecutive SUs (in blue). In sentence identification, only the spans bracketed by the BOS (B) and EOS labels are extracted as SUs, while the rest can be excluded as NSUs.

cedure to convert the Universal Dependencies (UD) corpora (de Marneffe et al., 2021) into sentence identification benchmarks (§5). To be specific, (i) we use the original sentence boundaries in UD as the unit (SU and NSU) boundaries and (ii) classify each unit as an SU iff it contains at least one clausal predicate with a core/non-core argument. Importantly, our classification rule follows the definition of *lexical sentence* in linguistics (Nunberg, 1990), is easily customizable with language-independent rules, and makes reasonable classification within the scope of our experiments.

To conduct our experiments, we focus on the English Web Treebank (Silveira et al., 2014) as the primary benchmark for sentence identification and train the BOS/EOS labeling models by finetuning RoBERTa (Liu et al., 2019) (§6). We also propose techniques to develop these models using a standard sentence segmentation dataset, i.e. the Wall Street Journal corpus (Marcus et al., 1993), which only contains clean, edited SUs without any NSUs.

Based on our experimental results, we demonstrate that our proposed method generally outperforms sentence segmentation baselines which only utilize EOS labels (§7). These results highlight the importance of combining the BOS labels in addition to the EOS labels for accurate sentence identification under various conditions.

2 Background

Sentence segmentation, a.k.a. sentence boundary detection, is the task of segmenting an input text into the unit of sentences. Despite the long history of study (Riley, 1989) and its importance in the entire NLP pipeline (Walker et al., 2001), this area has received relatively little attention. For one reason, the task has been recognized as “long

solved” (Read et al., 2012) with the most recent approach reporting 99.8% F1 score on the standard English Wall Street Journal (WSJ) dataset (Wicks and Post, 2021). Their state-of-the-art method ER-SATZ combines (i) a regular-expression based detector of candidate sentence boundaries, followed by (ii) a Transformer-based (Vaswani et al., 2017) binary classifier which predicts whether the candidate boundary is EOS based on the local context, i.e. surrounding few words. This modern context-based approach has been shown to outperform competitive, widely used baselines such as SPLITTA (Gillick, 2009), PUNKT (Kiss and Strunk, 2006), and MOSES (Koehn et al., 2007).

However, two important aspects are not fully addressed in the current literature. First is the coverage of *diverse domains, genres, and writing styles*. Existing works (including Wicks and Post, 2021) focus on formal/edited text and assume the existence of sentence ending punctuations (e.g. full stops) at the sentence boundaries. However, social media texts often lack such punctuations and contain various types of non-linguistic noise, which can lead to a substantial degradation in the segmentation performance (Read et al., 2012; Rudrapal et al., 2015). Speech transcription texts also usually contain disfluent, ungrammatical, or fragmented structures and lack both punctuations and casing (Wang et al., 2019; Rehbein et al., 2020). Considering the amount of such informal or non-standard texts in the real world, it is compelling to expand the capability of sentence segmentation beyond formal, standardized text.

The second aspect is the coverage of *multiple languages*. Different languages involve different complexities in sentence segmentation, e.g. Chinese requires the disambiguation of commas as the

sentence ending punctuation (Xue and Yang, 2011) and Thai does not mark EOS with any type of punctuations (Aroonmanakun et al., 2007; Zhou et al., 2016). To advance NLP from a multilingual perspective, it is crucial to develop and evaluate models in multiple languages: Wicks and Post (2021) make an important step in this direction, proposing a language-agnostic, unified sentence segmentation model covering a total of 87 languages.

Based on these observations, we first propose to extend the task of sentence segmentation to *sentence identification*, which expands the capability of sentence segmentation beyond formal, standardized text (§3, §4). Secondly, we propose a cross-lingual method of benchmarking sentence identification based on the UD corpora, considering every word or character as the candidate boundary to cover diverse domains, genres, and languages that lack sentence ending punctuations (§5). Finally, we follow Wicks and Post (2021) to develop modern neural-based models that require no language-specific engineering and can be developed for different languages in a unified manner (§6).

3 Task Formulation

3.1 Sentence Segmentation Task

First, we introduce a precise (re-)formulation of the sentence segmentation task. Let $\mathbf{W} = (w_0, w_1, \dots, w_{N-1})$ represent the input text, where each w_i denotes a word (but can also be a subword or character). We also define the text span $\mathbf{W}[i : j] = (w_i, \dots, w_{j-1})$, their concatenation $\mathbf{W}[i : j] \oplus \mathbf{W}[j : k] = \mathbf{W}[i : k]$, and SU boundary indices $\mathbf{B} = (b_0, b_1, \dots, b_M)$ where $b_0 = 0$, $b_M = N$, and $\bigoplus_{i=1}^M \mathbf{W}[b_{i-1} : b_i] = \mathbf{W}$ (i.e. the concatenation of all SUs recovers the input text).

Next, we introduce the SU probability $p_{\text{SU}}(\mathbf{W}[i : j])$ which corresponds to the probability of the text span $\mathbf{W}[i : j]$ being an SU. Based on this probability, the task of sentence segmentation can be formalized as searching for the boundaries \mathbf{B} which maximize the following probability:²

$$\arg \max_{\mathbf{B}} \prod_{i=1}^M p_{\text{SU}}(\mathbf{W}[b_{i-1} : b_i]) \quad (1)$$

The most standard approach is to define $p_{\text{SU}}(\mathbf{W}[i : j])$ based on a pretrained EOS labeling model, as we describe in §4.1. However, our (re-)formulation

² M is a variable and need not be fixed during the search.

as Eq. (1) is more general and permits other definitions of SU probability as well.

3.2 Sentence Identification Task

In sentence identification, we consider the input text \mathbf{W} can be segmented into consecutive, non-overlapping units of SUs and NSUs. Hence, we regard $\mathbf{B} = (b_0, b_1, \dots, b_M)$ as the unit (SU and NSU) boundaries and define the unit indicators $\mathbf{A} = (a_1, a_2, \dots, a_M)$ for each unit as follows:

$$a_i = \begin{cases} 1 & \text{if } \mathbf{W}[b_{i-1} : b_i] \text{ is an SU} \\ 0 & \text{if } \mathbf{W}[b_{i-1} : b_i] \text{ is an NSU} \end{cases}$$

Next, we introduce the NSU probability $p_{\text{NSU}}(\mathbf{W}[i : j])$ which corresponds to the probability of the text span $\mathbf{W}[i : j]$ being an NSU. Based on p_{SU} and p_{NSU} , we can formalize the task of sentence identification as searching for the unit boundaries \mathbf{B} and unit indicators \mathbf{A} which maximize the following probability:

$$\arg \max_{\mathbf{B}, \mathbf{A}} \prod_{i=1}^M p_{\text{SU}}(\mathbf{W}[b_{i-1} : b_i])^{a_i} p_{\text{NSU}}(\mathbf{W}[b_{i-1} : b_i])^{1-a_i} \quad (2)$$

Note that this strictly generalizes the sentence segmentation task in Eq. (1), which is a special case where $a_i = 1, \forall a_i \in \mathbf{A}$. Based on this task formulation, we discuss how we can define $p_{\text{SU}}(\mathbf{W}[i : j])$ and $p_{\text{NSU}}(\mathbf{W}[i : j])$ to derive our sentence identification algorithm in §4.2.

4 Methods

4.1 Sentence Segmentation Method

In the most standard approach, sentence segmentation employs an EOS labeling model p_{EOS} to define the SU probability p_{SU} in Eq. (1). To be specific, let $p_{\text{EOS}}(w_i | \mathbf{W}; \theta)$ denote the EOS labeling model, which computes the probability of w_i being EOS in \mathbf{W} (θ denotes the model parameters). Typically, it is straightforward to train this model in a *supervised learning* setup using a dataset annotated with gold EOS boundaries (Wicks and Post, 2021). For brevity, we use the notation $p_{\text{EOS}}(w_i)$ as a shorthand for $p_{\text{EOS}}(w_i | \mathbf{W}; \theta)$, i.e. we omit \mathbf{W} and θ (unless required) in the rest of this paper.

Based on the pretrained model p_{EOS} , we can define the SU probability as $p_{\text{SU}}(\mathbf{W}[i : j]) = p_{\text{EOS}}(w_{j-1}) \prod_{i \leq k < j-1} (1 - p_{\text{EOS}}(w_k))$, which requires the last word w_{j-1} to be EOS and all other

words to be non-EOS. By substituting this definition, we can decompose Eq. (1) as follows:

$$\begin{aligned}
(1) &= \arg \max_{\mathbf{B}} \sum_{i=1}^M \log p_{\text{SU}}(\mathbf{W}[b_{i-1}:b_i]) \\
&= \arg \max_{\mathbf{B}} \sum_{i=1}^M \left\{ \log p_{\text{EOS}}(w_{b_{i-1}}) + \sum_{b_{i-1} \leq j < b_i} \log(1 - p_{\text{EOS}}(w_j)) \right\} \\
&= \arg \max_{\mathbf{B}} \sum_{i \in \mathbf{B}_{\text{EOS}}} \log p_{\text{EOS}}(w_i) + \sum_{i \notin \mathbf{B}_{\text{EOS}}} \log(1 - p_{\text{EOS}}(w_i))
\end{aligned} \tag{3}$$

where $\mathbf{B}_{\text{EOS}} = \{b_i - 1 \mid i \in (1, 2, \dots, M)\}$ represents all the EOS indices defined by \mathbf{B} .

This is a trivial optimization problem where we can simply choose $\mathbf{B}_{\text{EOS}} = \{i \in (0, 1, \dots, N - 1) \mid p_{\text{EOS}}(w_i) \geq 0.5\}$ to maximize Eq. (3). This also shows that sentence segmentation can be conducted by predicting the EOS independently for each w_i based on $p_{\text{EOS}}(w_i)$. In contrast, sentence identification involves a more complex optimization problem which we solve using dynamic programming (§4.2).

4.2 Sentence Identification Method

We extend the method of sentence segmentation (§4.1) to conduct sentence identification. To be specific, we employ pretrained BOS and EOS labeling models $p_{\text{BOS}}, p_{\text{EOS}}$ to define the SU and NSU probabilities $p_{\text{SU}}, p_{\text{NSU}}$ in Eq. (2). As a first step, we need to train the BOS and EOS labeling models: this can be conducted in a supervised manner using a dataset containing gold BOS and EOS labels, as we explain in §6.1.

Based on the pretrained BOS and EOS labeling models, we can define the SU and NSU probabilities as follows:

$$\begin{aligned}
p_{\text{SU}}(\mathbf{W}[i:j]) &= p_{\text{BOS}}(w_i) \prod_{i < k \leq j-1} (1 - p_{\text{BOS}}(w_k)) \\
&\quad \times p_{\text{EOS}}(w_{j-1}) \prod_{i \leq k < j-1} (1 - p_{\text{EOS}}(w_k)) \\
p_{\text{NSU}}(\mathbf{W}[i:j]) &= \prod_{i \leq k \leq j-1} (1 - p_{\text{BOS}}(w_k)) \times \prod_{i \leq k \leq j-1} (1 - p_{\text{EOS}}(w_k))
\end{aligned}$$

In the SU probability p_{SU} , the first word w_i is required to be BOS, the last word w_{j-1} to be EOS, and all other words to be neither BOS nor EOS. Note that this definition of p_{SU} is a natural generalization from §4.1 which only relies on the EOS probability p_{EOS} .

In contrast, the NSU probability p_{NSU} requires all words to be neither BOS nor EOS. Notably, this definition does not distinguish contiguous NSUs in the sense that $p_{\text{NSU}}(\mathbf{W}[i:k]) = p_{\text{NSU}}(\mathbf{W}[i:j]) \times p_{\text{NSU}}(\mathbf{W}[j:k])$ if $\mathbf{W}[i:j] \oplus \mathbf{W}[j:k] = \mathbf{W}[i:k]$.

This is convenient as we are only interested in the extraction of SUs and do not need to seek the exact boundaries between consecutive NSUs.

By substituting these definitions of p_{SU} and p_{NSU} , we can decompose Eq. (2) as follows:

$$\begin{aligned}
(2) &= \arg \max_{\mathbf{B}, \mathbf{A}} \sum_{i=1}^M \left\{ a_i \log p_{\text{SU}}(\mathbf{W}[b_{i-1}:b_i]) \right. \\
&\quad \left. + (1 - a_i) \log p_{\text{NSU}}(\mathbf{W}[b_{i-1}:b_i]) \right\} \\
&= \arg \max_{\mathbf{B}, \mathbf{A}} \sum_{i \in \mathbf{B}_{\text{BOS}}^{\mathbf{A}}} \log p_{\text{BOS}}(w_i) + \sum_{i \notin \mathbf{B}_{\text{BOS}}^{\mathbf{A}}} \log(1 - p_{\text{BOS}}(w_i)) \\
&\quad + \sum_{i \in \mathbf{B}_{\text{EOS}}^{\mathbf{A}}} \log p_{\text{EOS}}(w_i) + \sum_{i \notin \mathbf{B}_{\text{EOS}}^{\mathbf{A}}} \log(1 - p_{\text{EOS}}(w_i))
\end{aligned} \tag{4}$$

where $\mathbf{B}_{\text{BOS}}^{\mathbf{A}} = \{b_{i-1} \mid i \in (1, 2, \dots, M), a_i = 1\}$ denotes the BOS indices and $\mathbf{B}_{\text{EOS}}^{\mathbf{A}} = \{b_i - 1 \mid i \in (1, 2, \dots, M), a_i = 1\}$ denotes the EOS indices, both defined by \mathbf{B} and \mathbf{A} .

Therefore, our goal is to choose $\mathbf{B}_{\text{BOS}}^{\mathbf{A}}$ and $\mathbf{B}_{\text{EOS}}^{\mathbf{A}}$ which maximize Eq. (4). To this end, we need to consider the restrictions that (i) the first label should be BOS, (ii) the last label should be EOS, and (iii) BOS and EOS labels need to appear alternately. These restrictions can be incorporated in our dynamic programming framework to find the argmax of Eq. (4). For the precise algorithm, we refer the readers to Appendix A.

5 Evaluation

Due to the novelty of the task, currently there exists no benchmark for evaluating sentence identification. To address this issue, we propose a fully automatic procedure to convert the Universal Dependencies (UD) corpora (de Marneffe et al., 2021) into sentence identification benchmarks.

Concretely speaking, we conduct the following two steps based on the gold UD annotation: (i) the detection of unit (SU and NSU) boundaries and (ii) the classification of each unit into SU or NSU. As for (i), we simply use the original *sentence boundaries* in the UD annotation, where UD uses the term *sentence* in a broader sense including both SUs and NSUs (e.g. sentence fragments). Note that the exact boundaries between consecutive NSUs (which we call NSU–NSU boundaries) do not need to be accurate or consistent, since we are only interested in extracting the spans of SUs. However, we do expect that the original boundaries are generally reliable in all other cases (SU–SU and SU–NSU boundaries), which seems to be the case.

The main problem is (ii), i.e. how to classify

by adding a binary BOS/EOS classifier on top of the encoder.

To enable our models to handle various lengths of the input texts, we concatenate the consecutive L units of gold SUs and NSUs as the input during training, where L is sampled from a geometric distribution with parameter p_{CC} .⁵ However, the RoBERTa encoder has the restriction that the input text size cannot exceed 512 subwords. Therefore, if the input text size is too large, we replace L with the maximum $L' < L$ which satisfies this restriction. Note that this is a common procedure to sample variable (instead of fixed) lengths of concatenated units (Joshi et al., 2020).

Assuming the existence of the in-domain sentence identification dataset (EWT Train/Dev), it is straightforward to train the BOS/EOS labeling models based on our unit concatenation procedure. However, we may not always have the gold annotation of SUs and NSUs for the target domain. To take such cases into account, we also consider a setup where we only have the standard sentence segmentation dataset (WSJ Train/Dev) to train the BOS/EOS labeling models.

When using the sentence segmentation dataset (WSJ), we need to apply the unit concatenation procedure using only clean, edited SUs. Unfortunately, this can yield the following data priors which do not actually hold in a sentence identification dataset (EWT): (i) an SU (almost) always starts with a capitalization and ends with punctuation, (ii) the first word of the input is always BOS and the last word is always EOS, and (iii) BOS always directly follows EOS.

To address (i) and (ii), we propose a simple data augmentation technique to alleviate the discrepancy in the data priors. To address (iii), we propose an ensembling technique with the unidirectional (instead of bidirectional) models which are agnostic to this data prior.

6.1.1 Data Augmentation (+AUG)

To address (i), we conduct a unit-level data augmentation, i.e. we modify each unit based on the following rules with a small probability p_{DA} :

- Convert all words in the unit to lower-case, upper-case, or title-case (e.g. “hello world”,

⁵With parameter $p_{CC} \in (0, 1]$, the probability mass function of the geometric distribution is $p(L = l) = (1 - p_{CC})^{l-1} p_{CC}$ where $l \in \{1, 2, 3, \dots\}$. As p_{CC} decreases, the distribution gets more skewed towards larger L . With $p_{CC} = 0$, we consider $p(L = \infty) = 1$.

Orig.	B	E B
	Joe went to school.	After that he ...
(i) Unit	B	E B
Aug.	Joe went to school	AFTER THAT HE ...
(ii) Unit	B	E B
Trunc.	Joe went to school	AFTER THAT HE ...

Table 4: Illustration of our data augmentation technique. In (i) *unit-level augmentation*, we randomly change the casing or remove the last punctuations of each unit. In (ii) *unit truncation*, we randomly truncate the first and last units of the input (and regard them as NSUs).

“HELLO WORLD”, or “Hello World”).

- Remove sentence ending punctuations based on a regular-expression matcher (following ERSATZ, Wicks and Post, 2021).

After the unit-level augmentation, we can apply the unit concatenation in the exact same manner.

Finally, to address (ii), we randomly apply a unit truncation to the first and last units of the concatenated input. To be specific, we choose a random word in the first (last) unit and remove all words prior (posterior) to it with a small probability p_{TR} . If the truncation is conducted, we regard the unit as an NSU and fix the gold BOS/EOS labels accordingly. See Table 4 for an illustration.

Based on this procedure, we can expect to alleviate the data priors (i) and (ii). For more details, we refer the readers to Appendix D.

6.1.2 Unidirectional Model (+UNI)

Simply concatenating SUs (without NSUs) yields the data prior (iii), i.e. BOS always directly follows EOS. This prior can be easily captured by the bidirectional models $p_{\text{BOS}}(w_i | \mathbf{W})$, $p_{\text{EOS}}(w_i | \mathbf{W})$ conditioned on the whole input \mathbf{W} , including our RoBERTa-based models. For instance, as shown in Figure 1, the model may predict EOS at the end of the first unit ($w_2 = \#$) just because the next word ($w_3 = \text{This}$) is likely predicted as BOS.

To alleviate this issue, we propose to combine the predictions of the unidirectional models for BOS and EOS labeling. To be precise, let $\mathbf{W}^{\leq i} = (w_0, \dots, w_i)$ and $\mathbf{W}^{\geq i} = (w_i, \dots, w_{N-1})$. Then, we can represent the unidirectional BOS model as $p_{\text{BOS}}^{\text{uni}}(w_i | \mathbf{W}^{\geq i})$ (looking the context right-to-left) and EOS model as $p_{\text{EOS}}^{\text{uni}}(w_i | \mathbf{W}^{\leq i})$ (looking left-to-right). As illustrated in Figure 1, these models are agnostic to the data prior (iii). In practice, we can simply use different attention masks and share the

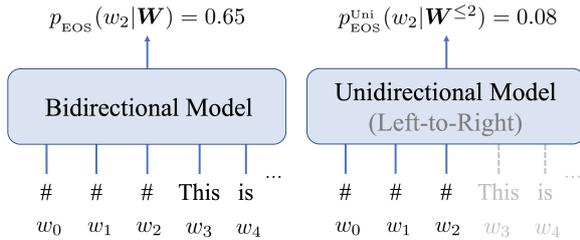

Figure 1: Illustration of the bidirectional EOS model (left) and the unidirectional EOS model (right).

encoder parameters (except the last classifier) for the unidirectional and bidirectional models.

We can utilize these unidirectional models by taking a linear interpolation with the bidirectional models as follows:

$$p_{\text{BOS}}^{+\text{Uni}}(w_i|\mathbf{W}) = \lambda \cdot p_{\text{BOS}}^{\text{Uni}}(w_i|\mathbf{W}^{\geq i}) + (1-\lambda) \cdot p_{\text{BOS}}(w_i|\mathbf{W})$$

$$p_{\text{EOS}}^{+\text{Uni}}(w_i|\mathbf{W}) = \lambda \cdot p_{\text{EOS}}^{\text{Uni}}(w_i|\mathbf{W}^{\leq i}) + (1-\lambda) \cdot p_{\text{EOS}}(w_i|\mathbf{W})$$

Then, we can use $p_{\text{BOS}}^{+\text{Uni}}$ and $p_{\text{EOS}}^{+\text{Uni}}$ in place of p_{BOS} and p_{EOS} (respectively) to conduct sentence identification, as described in §4.2.

Finally, we compare our proposed methods against sentence segmentation baselines which only utilize EOS labels.⁶ As for the baselines, we use the EOS labeling model developed in the same manner to segment the input text based on EOS. Note that we can optionally force the last word in the input to be EOS: in this case, the result will only contain SUs since all segments will end with EOS. By default, we do not force the last EOS: in this case, the segment after the last EOS (if exists) is considered as an NSU.

As a default configuration, we use $p_{CC} = 0.5$, $p_{DA} = 0.3$, $p_{TR} = 0.1$, and $\lambda = 0.5$ in our experiments. To ensure reproducibility, we report more details on the hyperparameters and model setup in Appendix D. For the precise procedure on how we convert between the word-, character-, and subword-level labels (for RoBERTa), we refer the readers to Appendix C.

6.2 Evaluation Setup

In the evaluation phase, we consider three ways of assembling the input texts on which we conduct sentence identification. Firstly, we can apply the same unit concatenation procedure as described in §6.1. To be specific, we use $p_{CC} = 0.5$ (same as the

⁶This EOS-only method is the most reasonable baseline to quantify the precise advantage from combining BOS labels in addition to EOS, which is proposed in our methods.

training phase) and $p_{CC} = 0$ (which concatenates the units up to the maximal length) to simulate both shorter and longer lengths of the input texts.

However, this approach is relatively *synthetic* in the sense that we take the gold unit boundaries for granted. They are usually unavailable at the inference time, so we should consider a more realistic setting for evaluating the methods without relying on the gold unit boundaries.

To this end, we propose to evaluate sentence identification as a *postprocessing* of sentence segmentation. To be specific, we first apply the state-of-the-art method ERSATZ (Wicks and Post, 2021) on the raw text of EWT and then apply sentence identification to each segmented text. Note that ERSATZ has high precision but still predicts false EOS which can fragment a gold SU: in such cases, we consider the fragmented SUs as NSUs and fix the labels accordingly (just as we did in unit truncation, cf. §6.1 and Table 4).

As for the evaluation metrics, we convert the predictions of our methods into word/character-level BIO labels (cf. Appendix C) and compute the F1 score for each label prediction. Then, we summarize the results as the macro average F1 and weighted average F1. We also compute the F1 score of the exact SU span extraction at the word/character-level. Finally, we run each experiment (from model training to testing) five times with different random seeds and report the average and standard deviation as the final results.

7 Results

Table 5 summarizes the word-level evaluation results. The results for the character-level evaluation show similar tendencies, so we put them in Appendix E. The F1 score for each BIO label prediction is also available in Appendix E.

Firstly, we take a look at the results when we have the in-domain sentence identification dataset (EWT Train/Dev) for model development. In this setup, we can verify that our proposed method (BOS&EOS) significantly outperforms the baselines (EOS-Only) in all metrics. For instance, our method achieves consistently high performance of 84~89% F1 for the exact SU span extraction, both at the word- and character-level. This is a very promising result that demonstrates the effectiveness of our method when we can leverage the gold SUs and NSUs from the target domain.

Secondly, we focus on the results where we

only utilize the standard sentence segmentation dataset (WSJ Train/Dev) for model development. In this setup, we also report the results of applying our data augmentation (+AUG) and unidirectional model (+UNI) techniques from §6.1.⁷

Due to the data discrepancy between WSJ and EWT, we find a natural drop in performance compared to the previous setup using in-domain EWT Train/Dev. However, we can verify that our techniques (+AUG, +UNI) generally help to alleviate this issue, and our proposed method performs on par or slightly better than the EOS-only baselines when applying these techniques. It is especially worth noting the improvement in the exact SU span extraction task (reaching 64~72% F1), where the advantage of our method is the most conspicuous and consistent in both word- and character-level evaluation. This improvement can also be explained by the higher performance in the B-label prediction with our method (Appendix E), which is a prerequisite for accurate SU span extraction.

Finally, we note that the EOS-only baseline without forcing the last EOS can be quite competitive with shorter inputs ($p_{CC} = 0.5$ and postprocessing) but performs considerably worse when the input texts are longer ($p_{CC} = 0$). This is because the baseline can only predict the last segment of the input as an NSU, which is less problematic when the input texts are shorter but becomes increasingly problematic with longer inputs (since most NSUs will not be able to be removed). In contrast, our proposed method performs much more robustly under various input lengths.

Through further experiments and analyses, we

⁷We did not observe any improvement from applying these techniques to the in-domain dataset (EWT Train/Dev), which is consistent with our motivation and expectation.

found that (i) the results are stable across different hyperparameter choices, (ii) predictions are reasonable especially when using the in-domain dataset (EWT Train/Dev) for model development, and (iii) our methods do not sacrifice performance on the formal/edited texts of the sentence segmentation dataset (WSJ Test). These detailed evidences can be found in Appendix F.

8 Conclusion

In this paper, we introduced a novel task of sentence identification, where we aim to identify SUs while excluding NSUs in a given text (§3). Through sentence identification, we can clearly distinguish the portions of the text that are appropriate (or not) for the prediction and evaluation of sophisticated linguistic analyses, such as dependency parsing, semantic role labeling, etc.

To conduct sentence identification, we proposed a simple yet effective method of combining the BOS and EOS labeling models to determine the SUs and NSUs (§4). To evaluate sentence identification, we designed an automatic, language-independent procedure to convert the UD corpora into sentence identification benchmarks (§5).

In our experiments, we developed the BOS/EOS labeling models by finetuning pretrained RoBERTa (§6). Based on the experimental results, we showed that our proposed method combining the BOS and EOS labels outperforms sentence segmentation baselines which only utilize EOS labels in all of the considered settings (§7). Overall, we expect sentence identification to be a fundamental framework for the preprocessing of noisy, informal, or non-standard texts in the real world.

Limitations

Firstly, our current experiments are limited to English and cover only five domains of web media texts in EWT. However, our task formulation (§3), method (§4), and evaluation framework (§5) are fully agnostic to the language and domain. Hence it is straightforward to conduct experiments in different languages or domains (as long as they are supported in the UD). While we expect similar results with different languages/domains, we leave further investigation as a future work.

Secondly, while our method performs reliably when the in-domain dataset is available, there is still a huge room left for improvement without relying on such resources (e.g. only using the standard sentence segmentation dataset). To make our method fully practical, we still need to improve on the accuracy and robustness in such cross-domain scenarios. One potential approach is to refine the definitions of SU and NSU probabilities from §4.2 to make sentence identification more robust. For instance, we can incorporate span-level scores instead of only using word-level BOS/EOS probabilities to define the SU/NSU probabilities. We leave further improvement and extension of our approach as an important future work.

Finally, our methods are currently evaluated on the (exact) SU span extraction task. Ideally, we should also evaluate the methods on downstream applications such as POS tagging, syntactic parsing, semantic role labeling, etc. However, we still expect that the (exact) SU span extraction will play a primary role in the evaluation, since accurate (say human-level) identification of SUs/NSUs will likely provide unprecedented benefits on a wide variety of NLP applications dealing with real-world texts. While we leave the precise analyses on downstream applications as future work, our contributions make the first foundational step towards expanding the capability of the long-established sentence segmentation task.

A Dynamic Programming Algorithm

To find the maximum value (and the argmax) of Eq. 4 from §4.2, we rely on a simple dynamic programming framework. To be specific, we consider the partial labeling of BOS and EOS up to $\mathbf{W}^{\leq k} = (w_0, \dots, w_k)$, where $k \leq N - 1$. Then, we aim to compute the maximum log probability of Eq. 4 based on the partial labeling, i.e. using $\mathbf{W}^{\leq k}$ in place of \mathbf{W} .

Since the labeling is partial, $\mathbf{W}^{\leq k}$ may end inside the SU (i.e. the last label is BOS) or outside the SU (i.e. the last label is EOS). Let $\log p_{\text{IS}}(k+1)$ denote the maximum log probability when $\mathbf{W}^{\leq k}$ ends inside the SU and $\log p_{\text{OS}}(k+1)$ the maximum log probability when $\mathbf{W}^{\leq k}$ ends outside the SU. Then, we can initialize $\log p_{\text{IS}}(0) = \log 0 = -\infty$, $\log p_{\text{OS}}(0) = \log 1 = 0$ (since we always start outside the SU) and iteratively update the two values as follows:

$$\begin{aligned} \log p'_{\text{IS}}(i) &= \max \{ \log p_{\text{IS}}(i) + \log(1 - p_{\text{BOS}}(w_i)), \\ &\quad \log p_{\text{OS}}(i) + \log p_{\text{BOS}}(w_i) \} \\ \log p'_{\text{OS}}(i) &= \log p_{\text{OS}}(i) + \log(1 - p_{\text{BOS}}(w_i)) \\ \log p_{\text{IS}}(i+1) &= \log p'_{\text{IS}}(i) + \log(1 - p_{\text{EOS}}(w_i)) \\ \log p_{\text{OS}}(i+1) &= \max \{ \log p'_{\text{IS}}(i) + \log p_{\text{EOS}}(w_i), \\ &\quad \log p'_{\text{OS}}(i) + \log(1 - p_{\text{EOS}}(w_i)) \} \end{aligned} \quad (5)$$

Note that we first update $p_{\text{IS}}(i) \rightarrow p'_{\text{IS}}(i)$ and $p_{\text{OS}}(i) \rightarrow p'_{\text{OS}}(i)$ based on the BOS probability $p_{\text{BOS}}(w_i)$. Then, we update $p'_{\text{IS}}(i) \rightarrow p_{\text{IS}}(i+1)$ and $p'_{\text{OS}}(i) \rightarrow p_{\text{OS}}(i+1)$ based on the EOS probability $p_{\text{EOS}}(w_i)$.⁸ The iterative procedure is illustrated in Figure 2.

Finally, we can compute the log probability $\log p_{\text{OS}}(N)$ (since we always end outside the SU), which corresponds to the maximum value of Eq. 4. To obtain the argmax, we can simply incorporate backtracking during the iterative updates of Eq. 5. Through this dynamic programming framework, we can ensure that the restrictions from §4.2 are satisfied: namely, (i) the first label should be BOS, (ii) the last label should be EOS, and (iii) BOS and EOS labels need to appear alternately.

In practice, we can limit the candidates of BOS indices to the subset where $p_{\text{BOS}}(w_i)$ is higher than a certain threshold c . This can be efficiently implemented by simply skipping the updates of $p'_{\text{IS}}(i)$ and $p'_{\text{OS}}(i)$, i.e. using $p'_{\text{IS}}(i) = p_{\text{IS}}(i)$ and $p'_{\text{OS}}(i) = p_{\text{OS}}(i)$, if $p_{\text{BOS}}(w_i) < c$.⁹ Likewise, we

⁸Note that if a single word w_i is labeled as both BOS and EOS at the same time, we can extract it as a single SU.

⁹This is equivalent to forcing w_i to be non-BOS, i.e. setting

can limit the candidates of EOS indices by skipping the updates of $p_{\text{IS}}(i+1)$ and $p_{\text{OS}}(i+1)$ if $p_{\text{EOS}}(w_i) < c$. Generally speaking, this leads to a more efficient algorithm: therefore, we use the candidate threshold of $c = 0.1$ for restricting both BOS and EOS indices throughout our experiments.

B SU and NSU Examples

In Table 6, we provide more examples of SUs and NSUs identified based on our procedure described in §5. As for the SUs, we can verify that EWT contains clean, formal SUs with appropriate capitalization and punctuation. We can also verify that EWT contains various types of *informal* SUs, e.g. that lack capitalization/punctuation, use non-standard casing, end with emoticons, include spelling errors, concatenate consecutive SUs without a space, etc.

C Label Assignment and Conversion

In this section, we explain the precise procedure on how we (i) assign the gold character-level labels, (ii) convert the character-level labels to word/subword-level labels, and (iii) convert the subword-level labels to character/word-level labels. We limit our explanation to BIO labels, since it is straightforward to convert them to the combination of BOS and EOS labels (and vice versa).

Firstly, we can assign the gold character-level labels from the UD annotation by taking the character-level alignment, which determines the exact spans of SUs and NSUs. From the character-level labels, we can assign the word- or subword-level labels based on the following rule:

- If the word (or subword) contains a character with the B-label, assign it the B-label.
- Else if it contains a character with the I-label, assign the I-label.
- Otherwise assign the O-label.

For instance, this procedure is used to create the subword-level labels for training our BOS/EOS labeling models.

To evaluate our methods, we need to convert the subword-level labels produced by our methods into the character-level labels, which can then be converted into the word-level labels (based on the previous procedure). To convert a subword-level label into a sequence of character-level labels, we

$p_{\text{BOS}}(w_i) = 0$ in Eq. 5.

D Details on the Model Setup

As discussed in §6.1, we finetune the pretrained RoBERTa_{BASE} publicly available on the Hugging-Face model hub¹⁰. We add a binary BOS/EOS classifier on top of the encoder, which is a single-layer MLP with a hidden size of 768. We share the encoder parameters and use different classifiers for the BOS/EOS predictions. The BOS/EOS models are trained jointly by summing their losses.

¹⁰<https://huggingface.co/models>

When we combine the unidirectional models (+UNI), we take the same approach and use different classifiers for the unidirectional/bidirectional models. Again, the encoder parameters are shared and all models are trained jointly.

As for the training data preparation, we apply the unit concatenation and data augmentation (+AUG) *on the fly*, i.e. we see different concatenation and augmentation of the units in each iteration. The same procedure is applied on the validation set.

During data augmentation, we remove the last sentence ending punctuation based on the following regular-expression, similar to the candidate boundary detector in ERSATZ (Wicks and Post, 2021):

- $(.*P_eP^*)$ where P denotes the set of punctuations and $P_e \subset P$ denotes the sentence ending punctuations.

Since our experiments are conducted on English, we use $P = \{ . ? ! " ' \}$ and $P_e = \{ . ? ! \}$.

Finally, all models are implemented in Pytorch and trained on a single Tesla V100-SXM2-32GB

GPU. We use a batch size of 8, accumulate the gradients for 32 batches, and apply the gradient clipping at 1.0 before updating the model weights. As for the optimizer, we use Adam with the initial learning rate of 0.0001 and exponentially decay the learning rate by $\gamma = 0.95$ after each epoch. We check the validation loss every 200 batches and stop the training early if there is no improvement for 5 consecutive evaluations.

E The Full Experimental Results

In this section, we report the full results of our experiments which did not fit in §7. Table 7 shows the word-level F1 scores for each B-, I-, and O-label prediction. Table 8 shows the overall results for the character-level evaluation.

Generally speaking, we can confirm the same results as observed in §7. Firstly, our proposed method significantly outperforms the baselines when we use the EWT Train/Dev dataset for model development. Secondly, our method performs slightly better than (or at least on par with) the baselines when developed on the WSJ Train/Dev dataset. Finally, the baseline without forcing the last EOS is competitive with shorter inputs ($p_{CC} = 0.5$ and postprocessing) but performs considerably worse when the input texts are longer ($p_{CC} = 0$).

F Further Experiments and Analyses

In this section, we provide further experiments and analyses to complement our study. To be specific, we provide discussions on the effect of the choice of hyperparameters (F.1), qualitative analyses based on example model outputs (F.2), and evaluation of sentence identification based on the sentence segmentation dataset (F.3).

F.1 Effect of Hyperparameters

As a default configuration, we used $p_{DA} = 0.3$, $p_{TR} = 0.1$ for the data augmentation (+AUG) and $\lambda = 0.5$ for the unidirectional model ensembling (+UNI). To examine the effect of the choice of these hyperparameters, we conducted further experiments by changing these default hyperparameters. Note that all evaluation results in this subsection are based on BOS&EOS (+UNI +AUG) developed on WSJ Train/Dev.

Firstly, we focus on the data augmentation and report the results of our method trained with different sets of p_{DA} and p_{TR} (with λ fixed at 0.5). Since increasing p_{DA} leads to higher recall (and

lower precision) of SU extraction and increasing p_{TR} leads to higher precision (and lower recall), we used a fixed ratio of $p_{DA} : p_{TR} = 3 : 1$ which seemed to make a good trade-off. As shown in Table 9, the results are generally stable with the different choices of the hyperparameters. However, more data augmentation (with larger values of p_{DA} and p_{TR}) tends to slightly improve the performance, especially for the exact SU span extraction.

Secondly, we focus on the unidirectional model ensembling and report the results of changing the linear interpolation rate $\lambda \in [0, 1]$, where $\lambda = 0$ is equivalent to using only the bidirectional models and $\lambda = 1$ only the unidirectional models. We fix $p_{DA} = 0.3$ and $p_{TR} = 0.1$ and only change λ at the inference time without retraining the unidirectional or bidirectional models. As shown in Figure 3, we found that unidirectional and bidirectional models generally have complementary benefits, and choosing the intermediate value of λ leads to the best performance. The results also indicate that we may be able to obtain further improvement by tuning λ on the validation set, although we simply fixed $\lambda = 0.5$ throughout our experiments.

F.2 Qualitative Analyses

In Table 10 and 11, we show the actual predictions made by our proposed method developed on EWT Train/Dev and WSJ Train/Dev. For the latter, we applied +UNI and +AUG with the default hyperparameters.

In the first example (Table 10), we can verify that both models identify the correct SU span while removing the non-sentential header as the NSU. This is a relatively easy example, since the start of the SU is capitalized and less ambiguous.

In the second example (Table 11), we can observe that our method using in-domain data (EWT Train/Dev) extracts the correct SU span, while our method developed on out-of-domain data (WSJ Train/Dev) incorrectly excludes a part of an SU. This seems to be a relatively difficult example, since the start of the SU is not capitalized and more ambiguous. It is worth noting that such SUs can be reliably extracted when we can leverage the in-domain annotation of gold SUs and NSUs.

F.3 Evaluation on the Sentence Segmentation Dataset

Finally, we report the results of sentence identification on the standard sentence segmentation dataset (WSJ Test).

Train/Dev Datasets	Model	EWT Test ($p_{CC} = 0.5$)			EWT Test ($p_{CC} = 0.0$)			EWT Test (Postprocess)

	BOS&EOS (+UNI +AUG)	72.2±1.3	86.1±0.6	66.5±0.3	72.8±1.8	86.5±0.9	63.6±1.0	73.2±1.9	85.7±0.9	71.8±1.5

Table 8: **Overall Results** (Character-Level). We report the macro/weighted average F1 of the BIO labeling task and the F1 score of the exact SU span extraction task.

In Table 12, we summarize the WSJ dataset statistics. Note that WSJ only contains SUs and do not contain any NSUs (O-labels). However, we can still evaluate the performance using the same metrics, i.e. the macro/weighted average F1 of the BIO labeling task and the F1 of the exact SU span extraction task.¹¹

Table 13 summarizes the word-level evaluation results. Since we are evaluating on WSJ Test, the performance is naturally better when the models are trained on WSJ Train/Dev rather than EWT Train/Dev (which is now out-of-domain).

When the models are trained on EWT, we found that the baseline (EOS-Only) forcing the last EOS performs the best. This is natural, since this baseline better reflects the nature of the sentence segmentation dataset where all units are SUs. However, our method (BOS&EOS) is still comparable to this baseline and do not (or minimally) sacrifice performance on such datasets.

When the models are trained on WSJ, we found that our method without +UNI or +AUG performs

the best. This is most likely because we can leverage the knowledge of BOS to predict EOS. When we apply the data augmentation (+AUG) and uni-directional model ensembling (+UNI), we observe a slight decrease in performance compared to our vanilla method. However, the results are still comparable and even outperforms the baselines in some metrics (e.g. the exact SU span extraction task).

Overall, we can conclude that our methods do not sacrifice the performance on the the clean, edited texts of the sentence segmentation dataset.

¹¹Since the O-label does not exist, we report the macro average F1 as the average F1 scores of the B-label and I-label predictions.

Gauging the Gap Between Human and Machine Text Simplification Through Analytical Evaluation of Simplification Strategies and Errors

Daichi Yamaguchi Rei Miyata Sayuka Shimada Satoshi Sato

Abstract

This study presents an analytical evaluation of neural text simplification (TS) systems. Because recent TS models are trained in an end-to-end fashion, it is difficult to grasp their abilities to perform particular simplification operations. For the advancement of TS research and development, we should understand in detail what current TS systems can and cannot perform in comparison with human performance. To that end, we first developed an analytical evaluation framework consisting of fine-grained taxonomies of simplification strategies (at both the surface and content levels) and errors. Using this framework, we annotated TS instances produced by professional human editors and multiple neural TS systems and compared the results. Our analyses concretely and quantitatively revealed a wide gap between humans and systems, specifically indicating that systems tend to perform deletions and local substitutions while excessively omitting important information, and that the systems can hardly perform information addition operations. Based on our analyses, we also provide detailed directions to address these limitations.

1 Introduction

Text simplification (TS) is the task of reducing the content and structural complexity of text while retaining the core part of the original meaning (Alva-Manchego et al., 2020). TS can not only facilitate the text reading by children or language learners, but also improve the performance of downstream NLP applications, including machine translation and summarization (Siddharthan et al., 2004; Štajner and Popovic, 2016).

Early studies on TS have separately dealt with lexical simplification (Glavaš and Štajner, 2015) and syntactic simplification (Scarton et al., 2017), and developed simplification techniques specialized for particular linguistic phenomena. In contrast, recent studies have tackled TS as a task of

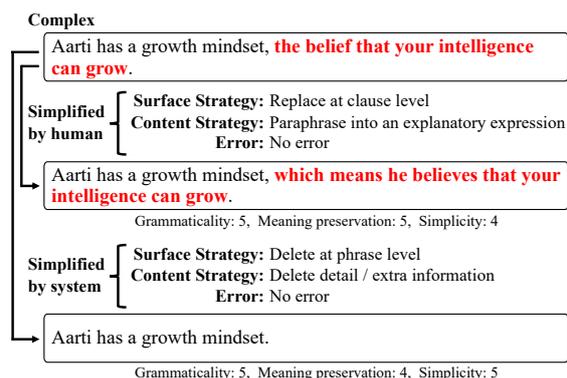

Figure 1: Example of an analytical evaluation in terms of editing strategies and errors.

monolingual translation from a complex to a simplified language using deep neural networks. While neural TS has demonstrated steady improvement, few studies have attempted to assess what kind of editing operations are performed by the systems in concrete terms. To further advance TS research and development, we should understand the potential and limitations of current TS technologies and precisely grasp the gap between human and machine TS. To do so, we need analytical frameworks that can be applied to both human and machine TS. In contrast to (machine) translation research and practice, where several frameworks have been developed for analyzing translation strategies (Chesterman, 2016) and errors (Lommel et al., 2014), no well-established framework tailored for TS tasks is available.

Therefore, in this study, we first propose an analytical evaluation framework consisting of taxonomies of editing strategies (both at the surface and content levels) and errors. We then report an experiment in which we apply our framework to instances of human and machine TS in various settings, and concretely describe the gap between them. Figure 1 shows an example of the evaluation using our framework, illustrating the detailed differences in editing operations between humans and

TS systems. Our results revealed that current neural TS systems can frequently replace local spans, while excessively deleting important parts. Moreover, TS systems cannot perform operations related to content addition, such as the addition of detail information. These findings enable us to understand the fundamental challenges of current technologies and pursue a promising avenue to fill the gap between humans and machines.

2 Related Work

To evaluate TS systems, automatic evaluation metrics such as SARI (Xu et al., 2016), BLEU (Papineni et al., 2002), and Flesch–Kincaid Grade Level (FKGL) (Kincaid et al., 1975) are widely used. SARI and BLEU use n-gram overlap between target sentences and human-created references, whereas FKGL uses the number of syllables and words in the output sentences. These metrics can be easily calculated if references are available and are indispensable for the rapid cycle of system development and evaluation. However, their limitations and pitfalls have been acknowledged. Sulem et al. (2018a), for example, reported that BLEU is negatively correlated with human evaluation scores, such as simplicity and grammaticality. Tanprasert and Kauchak (2021) also showed that the FKGL score can easily be manipulated by minor modifications, such as adding periods randomly.

Subjective human evaluation has also been implemented (Štajner and Nisioi, 2018; Sulem et al., 2018b; Al-Thanyyan and Azmi, 2021). In many cases, certain aspects of TS quality, namely grammaticality/fluency, meaning preservation/adequacy, and simplicity, are rated on a three- to five-point Likert scale based on the evaluation criteria.

Importantly, all the abovementioned evaluation methods only provide summative numerical scores. These scores are useful for comparing the general performances of different systems, but do not necessarily provide a guidepost for achieving higher system performance. To gain a detailed understanding of what TS systems can/cannot do vis-à-vis editing operations by humans, analytical evaluation methods are required.

The analytical evaluation of TS can be broadly divided into strategy and error analyses. The former concerns the type of editing operation (strategy) performed to produce the simplified text. Previous studies have acknowledged general strategies, such as paraphrasing, deletion, and splitting (Shard-

low, 2014), and document-level strategies, such as sentence reordering and sentence-joining operations (Alva-Manchego et al., 2019b). However, these roughly typify superficial textual changes rather than detailed content-level changes that capture editing operations peculiar to TS. The latter concerns the type of error in the resulting simplified text. In contrast to automatic and human evaluations, fewer attempts have been made to conduct an error analysis (Maddela et al., 2021).¹

Proper implementation of analytical evaluation requires well-formulated frameworks to classify textual phenomena observed in the outputs. The general editing strategies mentioned above and some guidelines for human writers (Mitkov and Štajner, 2014) are not sufficiently concrete for fine-grained analysis. Although several typologies of simplification operations (e.g., Amancio and Specia, 2014; Brunato et al., 2014; Koptient et al., 2019) and editing guidelines for human writers (Mitkov and Štajner, 2014) have been proposed, the following limitations can be generally acknowledged: (1) content-level operations are not fully covered; (2) their applicability to outputs of automatic TS systems has not been verified. In the field of translation studies, a wide variety of translation strategies have been proposed to describe the differences between source and target texts (e.g., Vinay and Darbelnet, 1958; Molina and Hurtado Albir, 2002). Chesterman (2016), for example, developed a comprehensive taxonomy of translation strategies that consists of syntactic, semantic, and pragmatic categories, and each includes ten strategies. Taxonomies of translation errors have also been developed and are widely used in practice, such as Multidimensional Quality Metrics (MQM) (Lommel et al., 2014). Although these existing frameworks may be useful as points of departure, detailed ones dedicated to TS tasks are still lacking.

3 Framework of Analytical Evaluation

We developed taxonomies of simplification strategies and errors as the analytical evaluation framework for TS. Simplification strategies consist of two independent components: **surface strategies**, which capture superficial operations for grammatical or textual elements, and **content strategies**, which capture semantic or content changes from the viewpoint of simplification. In this framework,

¹The under-reporting of error analysis is a general problem in NLG literature (van Miltenburg et al., 2021).

each TS instance (i.e., a minimally decomposed editing operation) is first judged as an error category listed in the error taxonomy. If it is not, the instance is then independently labeled a surface and content strategy (see also Figure 1). Our framework includes guidelines for annotating surface and content strategies in the form of a decision tree.²

3.1 Taxonomy Construction

Specifically referring to Alva-Manchego et al. (2019b), Chesterman (2016), and Shardlow (2014), we created taxonomies of the simplification strategies and errors through an analysis of human and machine TS instances. As manual simplification data, we used original and simplified news articles from Newsela,³ which were produced by professional editors and are expected to include various types of editing operations, including creative ones. We selected four articles from Newsela’s Popular category. Each article has four simplified versions with different degrees of simplicity, from Lv0 (the original document) to Lv4 (the simplest document). We manually aligned sentences from all adjacent-level documents (e.g., Lv0–Lv1, Lv1–Lv2) and acquired 551 complex–simplified pairs that exhibited any sort of rewriting.⁴ Next, we decomposed the rewriting from complex to simplified sentences into minimum edits (see Figure 2).⁵ Consequently, we acquired 1,133 minimum editing instances of human simplification.

First, using these instances, we created prototype taxonomies of the simplification strategies in the bottom-up procedures: (i) for each instance, we devised labels for describing surface and content strategies; and (ii) we aggregated and revised the labels to form systematic taxonomies. Edit (3) in Figure 2 is an example of a minimum edit instance: “hard work will help you reach your goals” → “hard work is important”. The same editing operation is annotated differently with the surface strategy (“Replace at sentence level”) and content strategy (“Paraphrase into a direct expression”).

Second, using simplified instances generated by TS systems, we expanded and modified the proto-

²The decision trees are shown in Appendix A.2.

³<https://newsela.com/data>

⁴These pairs included the sentences that were not aligned because we considered such sentences as instances of addition or deletion of a sentence.

⁵Following Miyata and Fujita (2021), we defined a minimum edit as “a small edit that is difficult to be further decomposed into more than one independent edit” and that does not induce “ungrammaticality in the edited sentence” (p. 1541).

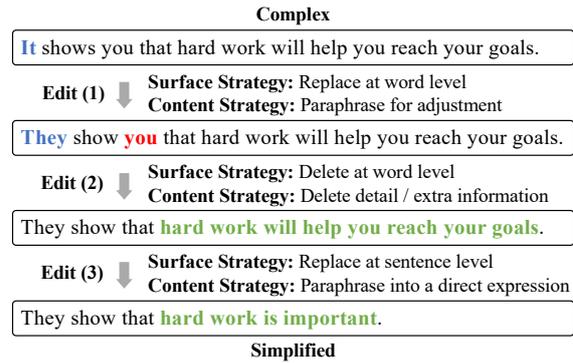

Figure 2: Example of the decomposition of rewriting instances and labeling of strategies.

type taxonomies to improve their applicability. At this stage, we created an error taxonomy by analyzing the system errors.⁶ We used three neural TS models, Transformer (Jiang et al., 2020), DRESS (Zhang and Lapata, 2017), and SUC (Sun et al., 2020) that were trained on Newsela data.⁷ From the same Newsela’s articles, we selected 166, 38, and 38 sentences for Transformer, DRESS, and SUC, respectively, to generate their simplified versions.⁸ We decomposed 125 outputs that exhibited any sort of rewriting to acquire 217 minimum edits. We then separated the non-error and error instances. Using the prototype taxonomies of the surface and content strategies, we classified non-error instances and, if necessary, modified the taxonomies to properly cover all instances. We also created an error taxonomy by analyzing the error instances.

3.2 Taxonomy of Surface Strategies

We defined 22 surface strategies, S1–S22, under the seven general categories: **Replacement**, **Deletion**, **Addition**, **Integration**, **Splitting**, **Move**, and **No change**.⁹ **Replacement**, **Deletion**, and **Addition** have the same set of linguistic focuses, i.e., punctuations, words, phrases, clauses, and sentences.

Note that, if the head of a phrase changes (e.g., “playing the video games” → “the video games), it is classified into the **Replacement** category. If the head of a phrase is retained (e.g., “the video games” → “the games”), it is classified into the **Deletion** rather than **Replacement** category.

⁶In principle, simplification instances by professional human editors seldom include errors.

⁷We explain the detailed implementation in §4.1.

⁸We first used the same set of 38 sentences, but we found out that the outputs of DRESS and SUC consisted of many error instances. To collect a wide range of non-error instances, we added another 128 sentences only for Transformer.

⁹See Table 2 for the detailed surface strategies and Appendix B for the example sentences.

3.3 Taxonomy of Content Strategies

We defined 30 content strategies, C1–C30, under five general categories: **No content change**, **Content deletion**, **Content addition**, **Content change**, and **Document-level adjustment**.¹⁰

Note that while the content strategies in **No content change**, except for (C5) **Remain unchanged**, change the surface structure or textual element, they do not change the propositional meaning of the sentence. **Document-level adjustment** includes the change of the sentence order in a document and the secondary edits that need to be performed due to changes made to a different sentence; for example, some lexical changes might entail changing the pronouns in the later sentences.

3.4 Error Taxonomy

We defined four error categories: **Inappropriate deletion**, **Inappropriate addition**, **Inappropriate paraphrase**, and **Non-sentence**.¹¹ The first three categories roughly correspond to **Deletion**, **Addition**, and **Replacement** in the surface strategies. **Non-sentence** covers other error types that make the sentence ungrammatical or unintelligible.

4 Experimental Setup

To clarify the potential and limitations of current TS systems in comparison with human performance, we designed an experiment to annotate TS instances produced by human editors and recent neural TS systems using our taxonomies of simplification strategies and errors described in §3. We also conducted a human evaluation to better understand the general tendencies of how strategies and errors affect the TS quality.

4.1 Neural Text Simplification Systems

We implemented six systems, that is, three neural models below trained separately with Newsela (in-domain setting) or Wikipedia (out-of-domain setting).¹² It should be noted that the training data size and pre-processing methods differed depending on the models, as we aimed to replicate the models described in the original papers as much as possible.

¹⁰See Table 4 for the detailed content strategies and Appendix B for the example sentences.

¹¹See Appendix B for the example sentences.

¹²We calculated scores of automatic evaluation metrics and verified that we had appropriately reproduced the implementations reported in the original papers. See Appendix C.1 for details on the automatic evaluation.

Transformer (Jiang et al., 2020)¹³ This BERT-initialized Transformer model is a state-of-the-art model. We used the Newsela and Wikipedia models distributed by the authors.

DRESS (Zhang and Lapata, 2017)¹⁴ This model exploits reinforcement learning, which rewards rewriting. Many studies have used this as a baseline (e.g., Vu et al., 2018; Nassar et al., 2019; Omelianchuk et al., 2021). To train the Newsela model, we used newsela_data_share-20150302 from the Newsela corpus, excluding Lv0–Lv1, Lv1–Lv2, and Lv2–Lv3 pairs, following the original paper. We also excluded sentences that were more than 85 words per sentence or included “/” because the original code could not process them. The remaining 94,635 sentences¹⁵ were used for training after the named entities were tagged with Stanford CoreNLP (Manning et al., 2014).¹⁶ We used processed Wikilarge to train the Wikipedia model.

SUC (Sun et al., 2020)¹⁷ This model uses one target sentence and two preceding and following sentences as input. Only this model exploits the context among these three models. Because Sun et al. (2020) did not provide a Newsela model, we trained it using Newsela-Auto, the same dataset used in the Transformer model above. Excluding Lv0–Lv1, Lv1–Lv2, and Lv2–Lv3 pairs following Zhang and Lapata (2017), we used the 640,867 sentences with context and 173,105 sentences without context. To train the Wikipedia model, we used the first 116,020 sentences with context and all of the 40,893 sentences without context from the distributed dataset. We created the vocabularies for Newsela and Wikipedia models, respectively, from the training data using spaCy (Honnibal and Montani, 2017).¹⁸

4.2 Annotation of Strategies and Errors

As evaluation data, from three original Newsela articles (Lv0) in the Popular category, we respectively extracted 13, 11, and 22 sequential sentences while retaining the textual cohesion. For these 46

¹³<https://github.com/chaojiang06/wiki-auto>

¹⁴<https://github.com/XingxingZhang/dress>

¹⁵Zhang and Lapata (2017) reported using 94,208 sentences. Although we processed the corpus in the same manner, we could not obtain the same number of sentences.

¹⁶<https://github.com/stanfordnlp/CoreNLP>

¹⁷<https://github.com/RLSNLP/Document-Context-to-Sentence-Simplification>

¹⁸<https://github.com/explosion/spaCy>

Score	Grammaticality (G)	Meaning preservation (M)	Simplicity (S)
5	Native speaker level fluent	Adequately preserved	Much simpler
4	Non-native speaker level fluent	Mostly preserved	Simpler
3	Understandable	Partially preserved	The same simplicity
2	Partially understandable	Completely different	More difficult
1	Completely unintelligible	Unintelligible	Unintelligible

Table 1: Abridged guidelines for human evaluations. The full version is shown in Appendix A.1.

complex sentences, we extracted 54 corresponding simplified sentences from Newsela’s articles (Lv1) as human references¹⁹ and generated 276 simplified sentences (46 sentences \times 6 systems) as system outputs. We decomposed 39 and 191 sentences that exhibited any sort of rewriting to acquire 105 and 389 minimum edits, respectively, for human references and system outputs.²⁰

Each editing instance was annotated with strategies and error categories based on the classification procedures explained in §3. We counted the sentences that were not rewritten as instances of strategy. The annotation was carried out independently by the first and third authors, who can adequately understand the English text and have a good command of the analytical evaluation framework, i.e., the taxonomies and guidelines. The inter-annotator agreement scores (Cohen’s unweighted kappa) for the surface strategies, content strategies, and errors were 0.806, 0.745, and 0.851, respectively, indicating substantial agreement (Landis and Koch, 1977).²¹ After the independent annotation, the annotators resolved any disagreement in judgments through discussions to obtain the final labels.

4.3 Human Evaluation

Using the sentence data used in §4.2, we also conducted a subjective human evaluation to assess the grammaticality (G), meaning preservation (M), and simplicity (S) of the simplified sentences generated by the six systems.

The annotators were two professional translators who were familiar with Japanese–English translation, English proofreading, and native language checking. They assigned a score to each sentence using a five-point Likert scale by referring to the

¹⁹Because human references include the instances of sentence addition and splitting, the number of simplified sentences is larger than that of complex sentences.

²⁰This means that the average rewriting rate for human editors was 2.69 times per sentence and that of systems was 2.03 times.

²¹When calculating the agreement scores for the strategies, we aggregated the annotations for the errors into one class and vice versa. The detailed distributions of annotations are presented in Appendix D.

evaluation guidelines, an abridged version of which is shown in Table 1.²² Before commencement of the formal evaluation, they evaluated another 29 sentences as a practice to properly understand the task. They evaluated the same set of sentences that exhibited any sort of rewriting. We consistently gave scores of 5, 5, and 3 for G, M, and S, respectively, to the non-rewritten sentences. The inter-annotator agreement scores (Cohen’s quadratic weighted kappa) for G, M, and S were 0.541, 0.257, and 0.628, respectively.²³

5 Results and Discussions

5.1 Surface Strategies

Table 2 lists the annotation results for the surface strategies with human evaluation scores for the system outputs.²⁴ Note that for each strategy, the human evaluation score was calculated using *sentences that exhibit the strategy*. As single sentences may include multiple strategies, the scores may be influenced by other strategies. Nevertheless, the general impact of each strategy can be inferred.

All the systems performed **Replacement** less frequently than humans did. The systems chiefly performed (S2) **Replace at word level** and could not perform (S4) **Replace at clause level** or (S5) **Replace at sentence level**, whereas humans performed **Replacement** strategies at various linguistic levels. This indicates the incapability of current models to learn replacement operations for linguistic units larger than phrases.

Deletion was the dominant strategy for the systems; the Transformer systems and in-domain DRESS system performed **Deletion** more frequently than humans. Human evaluation scores suggest the trade-off between meaning preservation and simplicity according to the size of the linguistic unit that is deleted; the deletion of a larger

²²The detailed guidelines are presented in Appendix A.1.

²³When calculating the inter-annotator agreement scores, we excluded the non-rewritten sentences. If we include them, the scores for G, M, and S rise to 0.618, 0.433, and 0.725, respectively.

²⁴The overall results of the human evaluation are presented in Appendix C.2.

Surface strategy	Human ref.	Number of annotated instances						Human evaluation		
		Transformer		DRESS		SUC		G	M	S
		IND	OOD	IND	OOD	IND	OOD			
Replacement	29	20	12	19	12	12	0			
(S1) Replace at punctuation level	(3)	(3)	(0)	(1)	(0)	(0)	(0)	4.63	3.25	3.88
(S2) Replace at word level	(4)	(10)	(5)	(13)	(11)	(10)	(0)	3.80	3.72	3.14
(S3) Replace at phrase level	(11)	(7)	(6)	(5)	(1)	(2)	(0)	4.26	3.81	3.76
(S4) Replace at clause level	(4)	(0)	(0)	(0)	(0)	(0)	(0)	-	-	-

No transformation	15	4	16	8	23	16	18			
(S22) Use an identical sentence	(15)	(4)	(16)	(8)	(23)	(16)	(18)	5.00	5.00	3.00
Total	105	64	64	59	52	46	18			
Precision		0.313	0.297	0.288	0.327	0.283	0.278			
Recall		0.190	0.181	0.162	0.162	0.124	0.048			

Table 2: Number of annotated instances for the surface strategies. Three TS systems are trained with in-domain Newsela data (IND) and out-of-domain Wikipedia data (OOD). Human evaluation scores are the averaged scores for system outputs that involve each strategy (G: grammaticality; M: meaning preservation; S: simplicity).

unit can increase the simplicity score, but decrease the meaning preservation score. It is also notable that the number of **(S9) Delete at clause level** performed by the systems was much larger than that performed by humans. This is attributable to the structure of the training data, which are aligned at the single-sentence level. Consider the case in which the complex sentence “I bought an apple and ate it” is split into two sentences, “I bought an apple” and “I ate it”. In the current research practices for preparing training data, the two simplified sentences are separately aligned with the complex sentence. This would induce the systems to excessively learn large deletions, such as Examples 1 in Table 3. It is also important to note that none of the systems performed **(S10) Delete at sentence level**. This may be because the training data did not include instances of sentence deletion, as the alignment of such cases is difficult.

The systems seldom performed **Addition**, whereas humans performed this 20 times at var-

ious linguistic levels. Although instances of addition were included in the training data, even word- and phrase-level addition strategies were hardly observed. This implies the fundamental difficulties of addition operations for the current models and training data.

The systems used in this study cannot learn **Integration (S16 and S17)**²⁵, **Splitting (S18 and S19)**, and **(S21) Move a sentence** because of the aforementioned data structure problem. Although some end-to-end systems can perform **Splitting** and **Integration** (Scarton and Specia, 2018), these suprasentential operations remain to be fully achieved in the neural TS research. To address the **Splitting** operation, we can refer to the rich accumulation of linguistically motivated studies on syntactic simplification (Scarton et al., 2017).

The final two rows in Table 2 show the overall

²⁵Neither did the humans perform Integration in the evaluation dataset. We observed six instances of Integration in the 1,133 instances used for taxonomy creation.

#	Model	Text
1	Input	But when schools start later, teens get to class on time and find it easier to stay awake, a new study finds.
	Transformer (IND)	but when schools start later , teens get to class on time .
	DRESS (IND)	But when schools start later , teens get to class on time .
	Human reference	A new study finds that when schools start later, teens get to class on time. They also find it easier to stay awake.
2	Input	Not everyone can become a genius or a star athlete, but they can improve the skills they have and develop new ones.
	Transformer (IND)	not everyone can be a genius or a star athlete .
3	Input	Knowing this, schools in several districts have begun to shift their start times.
	Human reference	Knowing this about teens, schools in several districts have begun to shift their start times.
4	Input	Information from millions of cones reaches our brains as electrical signals that communicate all the types of light reflected by what we see, which is then interpreted as different shades of color.
	Human reference	The cones then send information to our brains, which interprets the light we see as different colors.

Table 3: Examples of system outputs and references.

precision and recall of adopted strategies by the systems in comparison with humans’ strategies for the same sentences. The precision scores are about 0.2–0.3 and the recall scores are all below 0.2, which means that humans and systems tend to adopt different strategies even for the same sentence. Although further investigations are needed to draw insights from these results, we should be aware of the substantial differences between humans and machines in terms of simplification operations.²⁶

5.2 Content Strategies

Table 4 lists the annotation results for the content strategies. While humans performed **(C1) Transform syntactic structure** nine times, the systems rarely did. Most **C1** cases by humans involved sentence splitting, and as previously mentioned, the systems could not learn this operation from the current training data.

The systems generally performed various **Content deletion** strategies. It is worth noting that **(C10) Delete important information**, a large deletion corresponding to **(S9) Delete at clause level** in surface strategies, was performed frequently. Example 2 in Table 3 illustrates the deletion of the latter clause. Although the output can be regarded as a simplified version of the input at the sentence level, this deletion might be inappropriate in terms of logical flow in the entire document. In this sense, these categories might be regarded as **(E1) Inappropriate deletion** in the error taxonomy. Indeed, humans did not adopt this strategy.

The systems did not perform any **Content addition**, which corresponds to the lack of **Addition** of the surface strategies. These strategies require contextual information in many cases like “this” →

“this about teens” (See Example 3 in Table 3). However, even the context-aware SUC models cannot perform these addition operations.

As for **Content change**, the Transformer and DRESS performed **(C20) Paraphrase into a similar phrase** more than humans. The neural systems generally have abilities to perform local rewriting like “become” → “be” (see Example 2 in Table 3). Similarly, **(C25) Paraphrase into an essential point**, which substantially concerns deleting or altering local elements like “color production” → “color”, was performed well by the in-domain systems. By contrast, the systems cannot perform **(C21) Paraphrase into an explanatory expression** and **(C24) Paraphrase into a concrete expression**. The former requires external or contextual knowledge to add information, such as “the belief that your intelligence can grow” → “which means he believes that your intelligence can grow”. The latter requires word sense disambiguation or anaphora resolution to explicitly indicate the hidden meaning, such as “ones” → “friendships”. In general, current systems have limitations in performing these sophisticated **Content change** operations, such as Example 4 in Table 3.

The systems hardly performed **Document-level adjustment**. **(C27) Change information flow** corresponds to **(S21) Move a sentence** at surface level, which is architecturally impossible for the systems used in this study. The other strategies, C28–C30, depend on the results of other operations in the document, and are fundamentally difficult for current systems that do not exploit the output-side context.

5.3 Errors

Table 5 lists the annotation results for the simplification errors. As mentioned in §5.2, the number of **(E1) Inappropriate deletion** can increase if we consider **(C10) Delete important information** as an error. The instances of **(E2) Inappropriate**

²⁶These differences might be attributed not only to the inability of systems to replicate human performance, but also to the nature of TS tasks. Examining the differences between human editors would be an important future task.

Content strategy	Number of annotated instances								Human evaluation		
	Human	Transformer		DRESS		SUC		G	M	S	
	ref.	IND	OOD	IND	OOD	IND	OOD				
No content change	31	7	24	11	24	17	18

Table 4: Number of annotated instances for the content strategies.

addition were also observed. In particular, SUC produced many such instances. Considering the observation that almost no instance was annotated as **Addition** in Table 2, what the systems added to output sentences were not judged as (successful) strategies but as errors. **(E3) Inappropriate paraphrase** is the most frequent error type for most systems, which includes, for example, “intelligence” (being intellectual) → “spy” and “cells called neurons” → “DNA”. These errors are problematic because incorrect information can be conveyed to readers without being noticed as errors.

For Transformer and DRESS, the in-domain systems trained on Newsela generally produced more errors than the out-of-domain systems trained on Wikipedia. Considering the fewer number of **No transformation** cases of in-domain systems (see Table 2), in-domain systems tended to be more aggressive but erroneous than out-of-domain systems.

For all the human evaluation scores, except for

the meaning preservation score for **(E2) Inappropriate addition**, the averaged scores are below 3. This indicates that inclusion of any error can lead to an unacceptable output sentence.

6 Conclusions and Outlook

To better advance TS research and practice, in this study, we conducted an analytical evaluation of current neural TS systems and showed their potential and limitations in comparison with human performance. Using our proposed evaluation framework consisting of taxonomies of surface strategies, content strategies, and errors, we annotated both the human references and outputs of six systems (three models trained on in-domain and out-of-domain datasets). The results demonstrated that, while current TS systems can perform deletions and local substitutions, their performance is far behind human parity, owing to the following limitations:

Error category	Number of annotated instances						Human evaluation		
	Transformer		DRESS		SUC		G	M	S
	IND	OOD	IND	OOD	IND	OOD			
(E1) Inappropriate deletion	6	2	7	0	9	1	2.62	2.82	2.80
(E2) Inappropriate addition	6	2	4	4	12	51	2.68	3.86	2.11
(E3) Inappropriate paraphrase	17	5	28	14	15	0	2.83	2.53	2.76
(E4) Non-sentence	0	0	0	1	3	0	1.00	1.25	1.00
Total	29	9	39	19	39	52			

Table 5: Number of annotated instances for the error categories.

- The systems have difficulties in substituting a linguistic unit larger than a phrase, including sentence splitting.
- Excessive deletion of clause-level important information has occurred frequently.
- The systems tried to perform addition operations; however, they always failed to produce correct results.

Our analytical evaluation also suggests detailed paths to overcome these issues. For example, in addition to improving the capacity of end-to-end neural models, utilizing technologies tailored to particular operations such as sentence splitting and explanation generation can be helpful. To mitigate the excessive deletion, it would be effective to refine the alignment methods. Exploiting document-level contexts on both input and output sides and/or document-external knowledge is a necessary task for successful content addition.

Limitations

Applicability. The primary limitation in our study is that we chiefly used the Newsela dataset to build the annotation framework, i.e., the taxonomies and decision trees, and conduct the analytical evaluation. While we assume that the Newsela dataset includes diverse simplification operations as mentioned in §3.1, the applicability of our framework to other domains or datasets, such as Simple Wikipedia, needs to be investigated.²⁷

The diversity of adopted TS systems is also limited. As the aim of this pilot study is to demonstrate the usefulness of analytical evaluation, we mainly selected orthodox baseline models. To further improve the applicability, it is important to examine other types of TS models, such as controllable models (e.g., Maddela et al., 2021; Nishihara et al., 2019; Scarton and Specia, 2018) and edit-based models (e.g., Dong et al., 2019; Stahlberg and Kumar, 2020). Further investigation of various

²⁷The characteristics of Simple Wikipedia as a TS data resource have been extensively discussed (Xu et al., 2015).

document-level models other than SUC used in this study will also be needed (Sun et al., 2021).

Although our taxonomies are mostly language independent, the forms of decision trees for strategy annotation may need to be changed depending on the language because the decision order was defined based on the degree of difficulty in identifying the strategies, which might be language dependent.²⁸

Feasibility. The annotation of simplification strategies and errors was conducted by the authors, who were involved in the development of the annotation framework. Although the authors independently conducted the annotation task and substantial inter-annotator agreement was achieved, the feasibility of annotation by those outside this study has not been examined. To improve the feasibility, more detailed instructions and a sufficient training session may be needed. Although sharing the annotated data would be beneficial for the feasibility, it is difficult due to copyright issues.

Acknowledgments

We are grateful to Newsela for sharing the data. This work was supported by JSPS KAKENHI Grant Number 19H05660 and by the Research Grant Program of KDDI Foundation, Japan.

Score	Grammaticality/Fluency (G)	Meaning preservation/Adequacy (M)	Simplicity (S)
5	The target sentence is fluent (native speaker level) and grammatically correct.	The target sentence adequately conveys the core meaning of the original sentence.	The target sentence is much simpler than the original sentence.
4	The target sentence is almost fluent (non-native speaker level) and grammatically correct	The target sentence mostly conveys the core meaning of the original sentence.	The target sentence is simpler than the original sentence.
3	The target sentence is less fluent with some ungrammatical parts, but understandable	The core meaning of the original text is not conveyed, but the information of the the original text is partially preserved.	The target sentence is as simple/difficult as the original sentence.
2	The target sentence is ungrammatical, but partially understandable.	The meaning of the target sentence is completely different from that of the original sentence.	The target sentence is more difficult than the original sentence.
1	The target sentence is completely unintelligible.	It is impossible to assess the meaning of the target sentence because of its unintelligibility.	It is impossible to assess the simplicity of the target sentence because of its unintelligibility.

Table 6: Guidelines for human evaluation.

A Guidelines

A.1 Guidelines for Human Evaluation

Table 6 lists the guidelines for human evaluations. We instructed annotators to consider document-level coherence when evaluating each sentence. Additionally, we instructed them to give an S score of 1 to the sentence that was given an M score of 1 or 2.

A.2 Annotation Guidelines for Simplification Strategies

Figures 3 and 4 show the guidelines, i.e., decision trees, for the annotation of simplification strategies. The procedures to build a decision tree were as follows: (1) through the classification of sample instances by trial and error, the first author created the prototype decision tree in a way that easier decisions can be made in earlier stages; (2) the third author validated the prototype by classifying sample instances using it; (3) based on the feedback from the third author, the first author refined the prototype.

L1 represents the category of strategy, and L2 represents the strategy. Note that S# and C# in the figures do not indicate the strategy numbers. In the annotation task described in §4.2, we used the Japanese versions.

B Examples of Strategies and Errors

Tables 7 and 8 list examples of the surface and content strategies. Table 9 lists examples of errors. These sentences were extracted from the in-

stances of human simplification,²⁹ which are based on Newsela articles (see §3.1 for detail).

C Additional Evaluation Results

C.1 Automatic Evaluation Scores

Table 10 shows the overall results of the automatic evaluation in terms of SARI, BLEU, and FKGL, all of which were measured by using EASSE (Alva-Manchego et al., 2019a)³⁰ at the corpus level.

For preparing the evaluation data, we manually aligned complex–simplest sentences for five Newsela articles. To properly implement SUC, we excluded sentences that do not have two preceding or following sentences and that consist of less than four words. We finally used 1,010 sentences for the automatic evaluation.

C.2 Overall Human Evaluation Scores

Table 11 shows the overall results of the human evaluation. The evaluation guidelines are presented in Appendix A.1.

²⁹An exception is (C10) Delete important information in Table 8, the example of which was extracted from the outputs of Transformer.

³⁰<https://github.com/feralvam/easse>

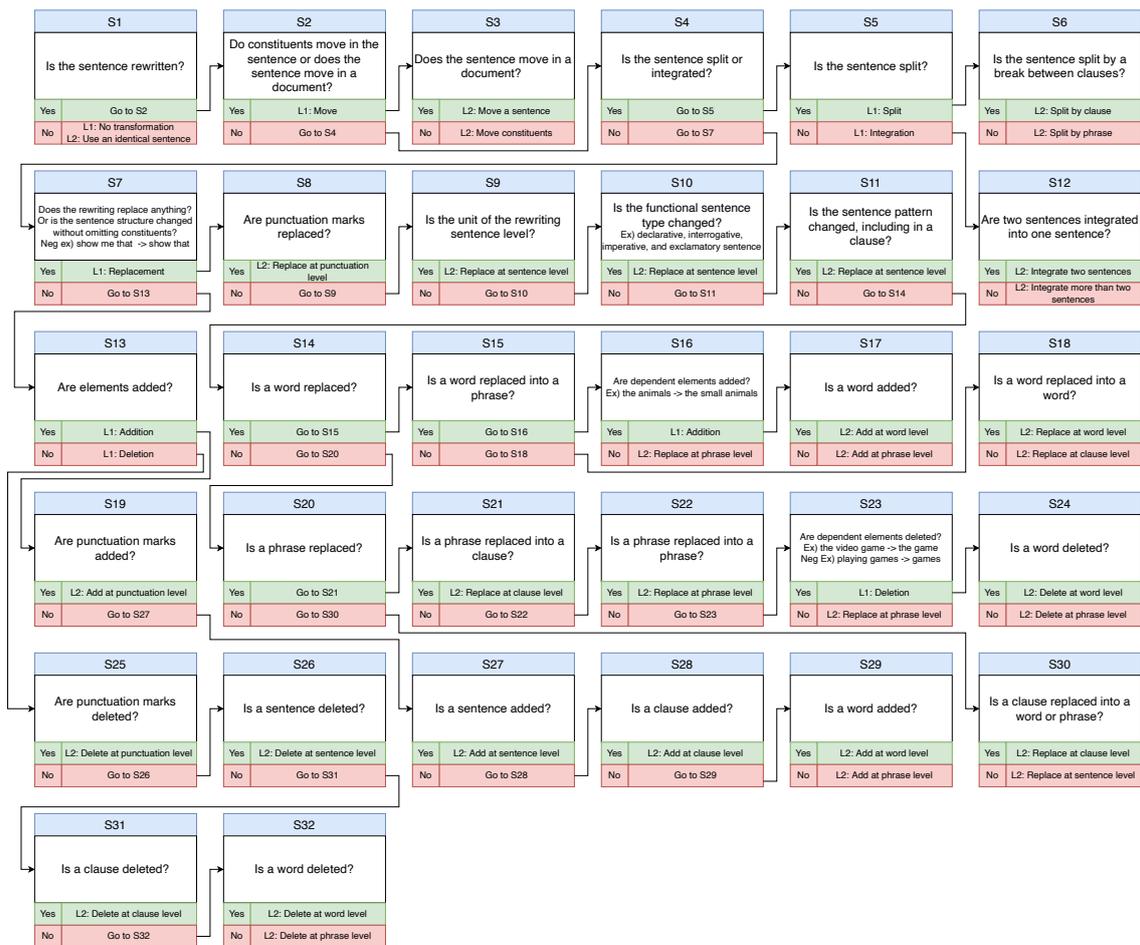

Figure 3: Annotation guidelines for surface strategies.

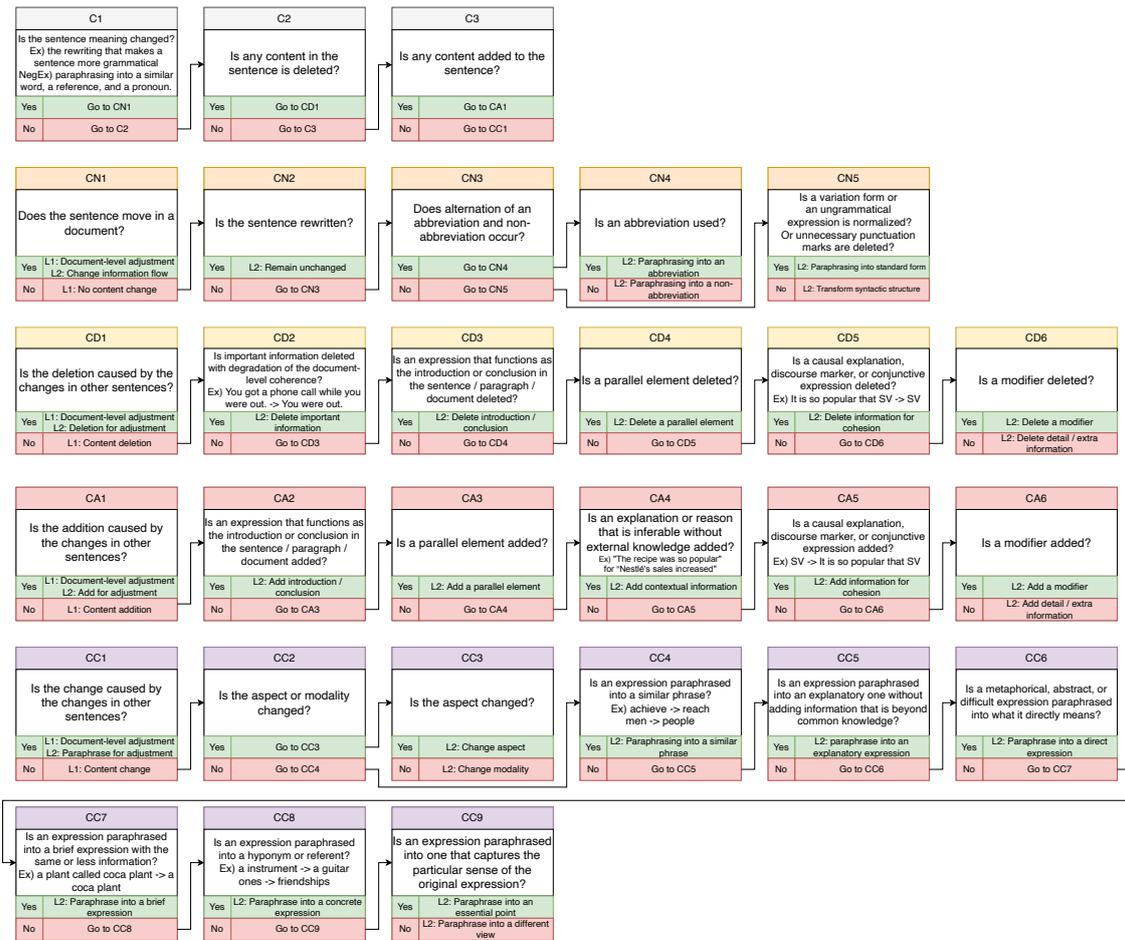

Figure 4: Annotation guidelines for content strategies.

Strategy	Example
Replacement	
(S1) Replace at punctuation level	Comp. ... 10,000 other neurons! Simp. ... 10,000 other neurons.
(S2) Replace at word level	Comp. ... make better surgeons. Simp. ... make good surgeons.
(S3) Replace at phrase level	Comp. ... about playing video games is friendship. Simp. ... about video games is friendship.
(S4) Replace at clause level	Comp. The persistence you use in games Simp. The persistence in games
(S5) Replace at sentence level	Comp. People who tried the syrup liked the taste. Simp. People liked the taste of the syrup.
Deletion	
(S6) Delete at punctuation level	Comp. ... “Toll House Chocolate Crunch Cookies.” Simp. ... Toll House Chocolate Crunch Cookies.
(S7) Delete at word level	Comp. ... inside and outside the video game. Simp. ... inside and outside the game.
(S8) Delete at phrase level	Comp. Beating the final boss or another really good player Simp. Beating another really good player
(S9) Delete at clause level	Comp. He licked the ice that was stuck around it. Simp. He licked the ice.
(S10) Delete at sentence level	Comp. So does saving a teammate when they’re down. Simp. ϕ
Addition	
(S11) Add at punctuation level	<i>This strategy does not exist in our collected instances.</i>
(S12) Add at word level	Comp. Remember games are Simp. Remember that games are
(S13) Add at phrase level	Comp. You have to be smart. Simp. In video games , you have to be smart.
(S14) Add at clause level	Comp. ... — the monkeys, apes, and gorillas — Simp. ... — the monkeys, apes, and gorillas that are most like human —
(S15) Add at sentence level	Comp. ϕ Simp. Scientists have studied video games.
Integration	
(S16) Integrate two sentences	Comp. Epperson pulled the stick. He licked the frozen juice. Simp. Epperson pulled the stick and licked the frozen juice.
(S17) Integrate more than two sentences	Comp. We got masks. We got gloves. We got all those hand wipes. They’re everywhere. Simp. Now masks, gloves, hand wipes, and other material are everywhere
Splitting	
(S18) Split by phrase	Comp. Think about how boring it can be to play an easy game Simp. Think about playing an easy game. It can get boring.
(S19) Split by clause	Comp. Ruth Wakefield was an expert chef, and the inn became famous for its desserts. Simp. Ruth Wakefield was an expert chef. The inn became famous for its desserts.
Move	
(S20) Move constituents	Comp. It can also help fix broken ones. Simp. It also can help fix broken ones.
(S21) Move a sentence	<i>The complex and simplified sentences are identical.</i>
No transformation	
(S22) Use an identical sentence	<i>The complex and simplified sentences are identical.</i>

Table 7: Examples of surface strategies (Comp.: Complex sentence; Simp.: Simplified sentence).

Strategy	Example
No content change	
(C1) Transform syntactic structure	Comp. Some people think ... are waste of time or bad for you. Simp. Some people think ... are a waste of time. Some people think they are bad for you.
(C2) Paraphrase into an abbreviated form	Comp. ... seem like they've been around forever. Simp. ... seem like they have been around forever.
(C3) Paraphrase into a non-abbreviated form	Comp. Helping build Simp. Helping to build
(C4) Paraphrase into a standard form	Comp. But Simp. However,
(C5) Paraphrase into an identical sentence	<i>The complex and simplified sentences are identical.</i>
Content deletion	
(C6) Delete introduction / conclusion	Comp. Think about your favorite games. Simp. ϕ
(C7) Delete a parallel element	Comp. ... feel strong and popular. Simp. ... feel strong.
(C8) Delete information for cohesion	Comp. The treats were so popular that Epperson started Simp. Epperson started
(C9) Delete a modifier	Comp. He licked the ice that was stuck around it. Simp. He licked the ice.
(C10) Delete important information	Comp. Winkler teamed up with another scientist named Greg Bryant, a professor Simp. He is a professor [Transformer IND]
(C11) Delete detail / extra information	Comp. ... created the semi-sweet morsel, or chocolate chip. Simp. ... created chocolate chip.
Content Addition	
(C12) Add introduction / conclusion	Comp. ϕ Simp. Chocolate chip cookies seem like they've been around forever.
(C13) Add a parallel element	Comp. ... a different culture. Simp. ... a different culture or speak a different language.
(C14) Add contextual information	Comp. ϕ Simp. The company was selling more and more chocolate bars.
(C15) Add information for cohesion	Comp. People can recognize it, even if Simp. Laughter is so important to humans that people can recognize it, even if
(C16) Add a modifier	Comp. It can help fix broken ones. Simp. It can also help fix broken ones.
(C17) Add detail / extra information	Comp. ... to connect and bond. Simp. ... to connect and bond with others.
Content change	
(C18) Change aspect	Comp. You might do Simp. You might start doing
(C19) Change modality	Comp. They can teach Simp. They teach
(C20) Paraphrase into a similar phrase	Comp. ... Nestlé's sales soared. Simp. ... Nestlé's sales increased.
(C21) Paraphrase into an explanatory expression	Comp. ... to make a headache medicine. Simp. ... to make a medicine to fix headaches.
(C22) Paraphrase into a direct expression	Comp. ... to shred a guitar in real life. Simp. ... to play a guitar in real life.
(C23) Paraphrase into a brief expression	Comp. ... parts of a plant called the coca plant. Simp. ... parts of the coca plant.
(C24) Paraphrase into a concrete expression	Comp. It also can fix broken ones. Simp. It also can fix broken friendships.
(C25) Paraphrase into an essential point	Comp. It is one of many benefits Simp. It is one of many good things
(C26) Paraphrase into a different view	Comp. The cookies became so popular Simp. The recipe became so popular
Documet-level adjustment	
(C27) Change information flow	<i>The complex and simplified sentences are identical.</i>
(C28) Delete for adjustment	Comp. This makes you see that solving problems can be fun. Simp. Solving problems can be fun.
(C29) Add for adjustment	Comp. You also have to be smart. Simp. In video games, you also have to be smart.
(C30) Paraphrase for adjustment	Comp. It shows you that Simp. They shows you that

Table 8: Examples of content strategies (Comp.: Complex sentence; Simp.: Simplified sentence).

Error		Example
(E1) Inappropriate deletion	Input	When you think, feel, move, or use your senses, signals travel through this network.
	Output	When you think , feel , move , or use your senses . [DRESS IND]
(E2) Inappropriate addition	Input	It's how we tell friends that we find their joke funny, ...
	Output	it's how we tell friends that we find their joke funny funny , ... [Transformer IND]
(E3) Inappropriate paraphrase	Input	... but rats can make a very high-pitched trill.
	Output	... but rats can make a very high-pitched noise. [Transformer IND]
(E4) Non-sentence	Input	The animals that laugh the most include primates like monkeys, rats, and mammals that live in the ocean like dolphins.
	Output	humans, on the other hand, like monkeys, rats and mammals that live in the ocean like dolphins. [Transformer IND]

Table 9: Examples of errors.

	Transformer		DRESS		SUC	
	IND	OOD	IND	OOD	IND	OOD
SARI \uparrow	37.57	30.89	37.08	31.83	31.09	22.24
BLEU \uparrow	32.20	38.22	37.11	39.29	31.92	24.12
FKGL \downarrow	3.00	4.40	3.27	4.02	4.20	2.61

Bridging the Gap between Pre-Training and Fine-Tuning for Commonsense Generation *

Abstract

Commonsense generation aims to generate a plausible sentence containing all given unordered concept words. Previous methods focusing on this task usually directly concatenate these words as the input of a pre-trained language model (PLM). However, in PLMs' pre-training process, the inputs are often corrupted sentences with correct word order. This input distribution discrepancy between pre-training and fine-tuning makes the model difficult to fully utilize the knowledge of PLMs. In this paper, we propose a two-stage framework to alleviate this issue. Firstly, in pre-training stage, we design a new format of input to endow PLMs the ability to deal with masked sentences with incorrect word order. Secondly, during fine-tuning, we insert the special token [MASK] between two consecutive concept words to make the input distribution more similar to the input distribution in pre-training. We conduct extensive experiments and provide a thorough analysis to demonstrate the effectiveness of our proposed method. The code is available at <https://github.com/LHRYANG/CommonGen>.

1 Introduction

To investigate machines' ability of generating logical sentences, Lin et al. (2020) propose the Commonsense Generation task. Given a set of concept words, this task is designed to generate a sentence which not only contains the given concepts but also can correctly describe the relations between concepts. An example is shown in Table 1.

Existing methods employ the Pre-trained Language Models (PLMs) such as BART (Lewis et al., 2020), GPT-2 (Radford et al., 2019) as the backbone to solve this problem. They (Liu et al., 2021; Fan et al., 2020; Wang et al., 2021; Li et al., 2021) usually take the concatenated concepts words as the inputs. However, such processing of inputs

concept words	{wear, player, field, jersey}
references	The player will wear a jersey while on the field. A soccer player wears a jersey on the field. ...
output of our model	football player wears a jersey on the field.

Table 1: An example of Commonsense Generation task

causes a huge gap between pre-training and fine-tuning. Specifically, these concept words are unordered which means the order of the input words is inconsistent with the order of these words in the references. It seems incompatible to PLMs pre-trained with ordered words (For BART (Lewis et al., 2020), sentence permutation is adopted, nevertheless, the word order within a sentence remains correct.). As studied by Zhao et al. (2022) and Ou et al. (2022), the word order of inputs can hinder the exploitation of knowledge existing in PLMs. Moreover, even if the word order of inputs is correct, for some LMs (e.g., BART (Lewis et al., 2020), T5 (Raffel et al., 2020)), the inputs are masked sentences during pre-training, while in commonsense generation task, the inputs are unconnected word sequences. This kind of discrepancy also degrades the models' performance.

In this paper, we propose a two-stage framework to bridge the gap between pre-training and fine-tuning for this task. Specifically, we firstly propose to introduce a domain-specific pre-training stage using the tasks' training dataset. The pre-training objective is designed to recover original sentences given the *masked* and *shuffled* sentences. Therefore, the PLMs' ability of reasoning out new concepts or relations (mask operation) and processing order-agnostic inputs (shuffle operation) is enhanced. Secondly, in downstream task fine-tuning, we insert the special token [MASK] between two consecutive concept words. This makes the input distribution more similar to the distribution in pre-training. The experimental results shows

This work was done during an internship at Tencent.

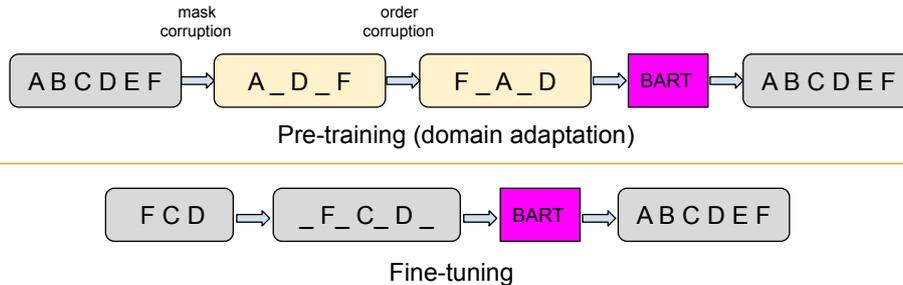

Figure 1: An overview of our model. _ represents the [MASK] token.

that our proposed model can significantly improve the performance of the commonsense generation task. We also conduct experiments to show that our model is superior than baselines in terms of continual learning and few-shot scenarios.

2 Model

We propose a two-stage training framework as shown in Figure 1. We firstly continually pre-train the BART with a newly designed input format. Secondly, we fine-tune the model whose inputs are inserted with the special token [MASK].

Formally, given a concept word set $\mathbf{x} = \{x_1, x_2, \dots, x_n\} \in X$ (n can be different for different inputs), the task aims to generate a fluent, plausible and grammatically correct sentence $\mathbf{y} = (y_1, y_2, \dots, y_m) \in Y$ containing all the words in \mathbf{x} .

2.1 Domain-Specific Pre-training

Continually pre-training the PLMs on the target domain is beneficial to improving the performance of the target task consistently (Gururangan et al., 2020). We adopt this idea and moreover, we design a new sentence corruption strategy considering that the input words order in target task is shuffled. Below is the procedure for constructing the corrupted inputs for each sentence $\mathbf{y} \in Y$ in training dataset:

1. Randomly select a subset of words in \mathbf{y} and each word is selected with a probability p which is also called the mask probability.
2. Replace the selected words with the special token [MASK]. It should be noted that multiple consecutive [MASK] tokens are merged to one [MASK] token. This allows the PLMs to predict a span (multiple words) based on one [MASK] token, which is more similar to the commonsense generation task as we will see below.

3. The unmasked words are shuffled while the positions of the [MASK] tokens remain unchanged. The corrupted input is denoted by $\tilde{\mathbf{y}}$.

An example of the above process is shown in the upper part of Figure 1. We usually choose a large value for the probability p instead of 15% used by BERT (Devlin et al., 2019). We will study the effect of p (0.5 in our experiment) in Section 3.2. Since a part of concept words and non-concept words are masked, this pre-training process can also enhance PLMs’ ability of reasoning out unseen concepts and relations between concepts.

Finally, the pre-training loss function is:

$$\mathcal{L}(\theta) = -\frac{1}{|Y|} \sum_{\mathbf{y} \in Y} \log\left(\prod_{i=1}^m P(y_i | y_{<i}, \tilde{\mathbf{y}}; \theta)\right) \quad (1)$$

2.2 Fine-tuning

Although the domain-specific pre-training can adapt the PLMs to the target domain and alleviate the problem related to word order, the inputs during fine-tuning are still a list of words while in pre-training for many LMs, the inputs are corrupted sentences with [MASK] tokens. Chada and Natarajan (2021) have shown that aligning the input distribution between pre-training and fine-tuning can boost the few-shot performance on QA tasks. Armed with such finding, we transform the inputs by inserting [MASK] tokens. Formally, given an input $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$, we transform \mathbf{x} to ¹:

$$[\text{MASK}], x_1, \dots, [\text{MASK}], x_i, [\text{MASK}], \dots, x_n, [\text{MASK}]$$

Then, we input the transformed \mathbf{x} to the PLM to predict the target \mathbf{y} . Through this way, the input distribution is more similar to that in pre-training (especially domain-specific pre-training). This input format is similar to the text infilling task (Donahue et al., 2020), the main differences are that

¹We send the transformed \mathbf{x} to the tokenizer so that [CLS] and [EOS] will also be added.

Model \ Metrics	ROUGE-2/L		BLEU-3/4		METEOR	CIDEr	SPICE
GPT-2	17.18	39.28	30.70	21.10	26.20	12.15	25.90

Table 2: Automatic Evaluation Results.

the words in commonsense generation task are unordered and masked words also account for a large proportion of sentences.

3 Experiments

3.1 Experimental Settings

Dataset We use the CommonGen dataset collected by Lin et al. (2020). The dataset contains 67389/4018/6042 training/development/testing samples with 32651/993/1497 different concept sets (one concept set has multiple references.). For evaluation metrics, we use BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). We also report human evaluation score and coverage score. However, due to the space constraint, regarding these two scores, please refer to Appendix ?? for more details.

Baselines We compare our model with several baselines. For PLMs, we choose GPT-2 (Radford et al., 2019), UniLM (Dong et al., 2019), T5 (Rafael et al., 2020), BART (Lewis et al., 2020). We also compare our model with (1) KG-BART (Liu et al., 2021) which incorporates the knowledge graph to BART. (2) NeuroLogic (Lu et al., 2021) which controls the decoding stage to enforce the satisfaction of the given lexical constraints. (3) CALM (Zhou et al., 2021) which designs several self-supervised tasks to obtain a concept-aware language model. (4) EKI-out (Fan et al., 2020) which augments inputs with retrieved sentences from *out-of-domain* corpus. Generally, EKI-out is stronger than other baselines due to the high informativeness of Wikipedia.

Implementation Details We adopt BART-large as the generation model. The max length of x and

y are set to 48 and 128 respectively. The batch size is set to 32. For Domain-Specific Pre-training, the mask probability p is set to 0.5. The number of training epochs is 10. We use AdamW (Loshchilov and Hutter, 2019) with learning rate $1e-7$ to optimize the model. For fine-tuning, the model is optimized using AdamW with an initial learning rate of $2e-5$. We also employ linear warmup with steps 10000. We save the model with the highest Rouge-L score on development set for testing.

3.2 Results

Main Results As summarized in Table 2, Ours can generally achieve better performance than all the baselines on BLEU, METEOR, CIDEr. On ROUGE, Ours outperforms most of the baselines except EKI-out which facilitates the Wikipedia as the external corpus. On SPICE, Ours is superior than most of the baselines except CALM.

Ablative Results We conduct ablation study with three variants. The results are shown in Table 4. We can see that the performance of -mask (Ours without adding [MASK] during fine-tuning) and -pretraining (Ours without pretraining) are inferior than Ours. -both (Ours with neither) obtains the worst performance. We can also observe that adding mask and adding pretraining have similar degree of improvement compared to -both. Moreover, since there are numerous ways to insert [MASK] to inputs (different positions or different numbers), we compare our model with Random Mask: during pre-training and fine-tuning, *one* mask token is randomly inserted into the corrupted inputs. We can see from Table 4 that Ours outperforms Random Mask. Moreover, we provide some generated examples in Appendix B.

Model	Training on	Evaluation on	ROUGE-L	BLEU-4	METEOR	CIDEr	SPICE
Ours	Size = 3	Size = 3	45.25	18.74	24.06	14.64	34.92

		Size = 4	44.29	31.53	30.98	16.24	32.04
	Size = 5	Size = 3	45.36(-0.16)	17.75(+0.29)	24.77(+0.06)	14.69(+0.11)	35.88(+0.50)
		Size = 4	44.49(+0.20)	30.99(-0.54)	30.88(-0.10)	16.09(-0.15)	31.17(-0.87)
		Size = 5	42.69	29.16	29.63	15.11	30.05

Table 3: Continual Learning Results. The rows with the same color represents the same domain we evaluate the model on. The red number in parentheses is the improvement compared with the previous time step on the same domain. For example, (+1.06) = 46.31 − 45.25, (-0.69) = 45.62 − 46.31, (+0.30) = 45.27 − 44.97.

Model	ROUGE-L	BLEU-4	METEOR	CIDEr	SPICE
Ours	44.89	32.49	32.50	17.10	32.81
-mask	44.67	31.66	32.09	16.51	32.11
-pretraining	44.35	31.60	31.87	16.57	32.33
-both	43.56	29.61	30.87	15.61	30.93
Random Mask	44.43	31.64	32.23	16.69	32.36

Table 4: Variant Analysis Results.

Effects of Hyperparameter p We investigate the effects of the mask probability p . As presented in Table 6, the performance is the best when p equals 0.5. The reason may be that if p is too large, it is hardly possible to recover corrupted sentences during pre-training. However, if p is too small, most of the masked tokens are not concept words, thus the pre-trained model cannot learn the relations between concepts.

Human Evaluation & Coverage To provide more perspective of the generation quality, we report the human evaluation score and coverage score. For human evaluation, we randomly select 30 sentences and each sentence is given a score ranging from one to five to assess the holistic quality. We report the average value of two annotators. The concept coverage score is the average percentage of input concepts that are present in lemmatized outputs. The results are shown in Table 5. We can see that Ours achieves the highest human evaluation score and coverage score and Ours-w/o-pretraining achieves a slightly better performance than Ours-w/o-mask, indicating that inserting [MASK] to the input is more important than adding the pretraining stage.

3.3 Few-Shot Scenario

We investigate the performance of our model under few-shot scenario. We randomly select $n \in$

Model	Ours	Ours-w/o-mask	Ours-w/o-pretraining	Ours-w/o-both
human score	4.534	4.367	4.467	4.084
coverage	97.48	96.03	96.07	93.05

Table 5: Human Evaluation Score and Coverage Score

p	ROUGE-L	BLEU-4	METEOR	CIDEr	SPICE
0.2	44.36	31.21	31.16	16.48	32.33
0.4	44.32	30.99	32.05	16.64	32.48
0.5	44.89	32.49	32.50	17.10	32.81
0.6	44.37	31.95	32.64	16.91	32.72
0.8	44.58	32.25	32.38	16.83	31.90

Table 6: Effects of p .

{16, 32, 64} samples from original training dataset as the new training dataset and the testing dataset remains unchanged. The learning rate is set to $2e-5$. Table 7 shows the results. We can see that inserting [MASK] to the inputs can significantly boost the performance on all the metrics. Combined with the result in Table 2, we can conclude that inserting [MASK] to the inputs is beneficial to the performance on both full-data and few-shot settings.

3.4 Continual Learning Scenario

We investigate the performance of our model under continual learning scenario (Biesialska et al., 2020). We regard concept sets with the same length as a domain. The details of the dataset are described in Appendix A. The model is trained sequentially from the domain with length 3 to the domain with length 5. After the model is trained on a new domain, we also evaluate it on previous domains to measure the backward transfer degree. Backward transfer means that learning a new task may hurt (negative backward transfer) or improve (positive backward transfer) the performance of previously

n	model	ROUGE-L	BLEU-4	METEOR	CIDEr	SPICE
16	Ours	35.04	16.22	21.98	9.02	21.93
	-pretraining	33.49	12.25	19.29	7.46	20.42
	-mask	32.33	7.5	19.23	6.16	17.24
	-both	31.74	6.75	19.83	6.18	16.30
32	Ours	35.66	19.72	23.20	10.00	21.43
	-pretraining	35.92	16.21	21.35	8.88	20.78
	-mask	33.98	15.17	21.34	8.63	18.36
	-both	33.15	11.73	19.36	7.51	19.13
64	Ours	38.94	22.15	25.96	12.31	26.64
	-pretraining	38.17	21.17	25.48	11.6	26.27
	-mask	35.75	18.79	24.73	10.73	24.00
	-both	35.04	15.43	22.58	9.18	21.23

Table 7: Few-Shot Setting.

learned tasks (Lopez-Paz and Ranzato, 2017). The results are shown in Table 3. We can see that Ours generally obtains better performance than -mask. Also, we can see that our model achieves a larger positive backward transfer and a smaller negative backward transfer (forget less) than -mask. For example, ROUGE-L of the domain with concept set size 3 is changed from 45.25 to 46.31 (improved by 1.06) after the model is trained on the domain with concept size 4 for our model. While for -mask, the improvement is only 0.72. Therefore, we can conclude that bridging such a gap is effective under continual learning setting.

4 Conclusion

We study the gap issue between pre-training and fine-tuning for commonsense generation task. We propose a two-stage training framework which is composed of a domain-specific pre-training stage and a fine-tuning stage. Pre-training stage aims to recover the masked and shuffled sentences which could enhance the models’ ability of processing unordered inputs and reasoning out the relations and concepts. Inserting [MASK] to the inputs during fine-tuning have also been demonstrated very useful. Experimental results show that our model is superior than many baselines, especially under few-shot setting.

Limitations

In this work, we study the gap between pre-training and fine-tuning for commonsense generation task. Despite the promising experimental results, there are still several limitations of our work:

1. The order issue is still not fully solved since the original pre-training stage uses ordered sentences. Our proposed domain-specific training stage can only alleviate this issue instead of completely solving it.
2. During fine-tuning, the optimal positions and an optimal number of the [MASK] tokens are not well solved.

A Continual Learning

We introduce how to construct the dataset used for continual learning. Table 8 shows the distribution of the original dataset. Since there is no testing instances whose concept set size is 3. We randomly sample a number of instances with concept size 3 from the training dataset. Also, since the dataset is unbalanced (the number of instances belonging to the domain with concept size 3 is far larger than that in other domains.) We re-sample the instances to make the dataset more balanced. The statistic of the continual learning setting dataset is shown in Table 9.

Statistics	Train	Dev	Test
Sentences	67,389	4,018	6,042
Concept-Sets	32,651	993	1,497
-Size = 3	25,020	493	-
-Size = 4	4,240	250	747
-Size = 5	3,391	250	750

Table 8: Statistics of Original Dataset.

Statistics	Train	Dev	Test
-Size = 3	5,867	1,819	2,170
-Size = 4	5,352	1,137	2,993
-Size = 5	3,436	1,062	3,049

B Generated Examples

We list some examples generated by our proposed model and ablative models, which are shown in Table 10.

concept words	<i>{sheep, wool, shave, hold}</i>
Ours	<i>A man is holding a sheep and shaving its wool.</i>
Ours-w/o-pretraining	<i>A woman holds a sheep and shaves its wool.</i>
Our-w/o-mask	<i>A man is holding a sheep and shaving it with wool.</i>
Our-w/o-both	<i>sheep holding their wool in their beaks as they shave.</i>
concept words	<i>{stand, fence, feed, goat}</i>
Ours	<i>A goat stands at the fence to be fed.</i>
Ours-w/o-pretraining	<i>goats standing next to a fence to feed.</i>
Our-w/o-mask	<i>A goat standing next to a fence to feed.</i>
Our-w/o-both	<i>A goat stands at the fence to feed a goat.</i>
concept words	<i>{hold, bag, popsicle, eat, chip}</i>
Ours	<i>A boy is eating a popsicle while holding a bag of chips.</i>
Ours-w/o-pretraining	<i>A girl is holding a bag of chips and eating a popsicle.</i>
Our-w/o-mask	<i>A man holding a bag of chips and a popsicle to eat.</i>
Our-w/o-both	<i>A man holding a bag of chips and a popsicle eats a chip.</i>

Abstract

Lifelogging has gained more attention due to its wide applications, such as personalized recommendations or memory assistance. The issues of collecting and extracting personal life events have emerged. People often share their life experiences with others through conversations. However, extracting life events from conversations is rarely explored. In this paper, we present Life Event Dialog, a dataset containing fine-grained life event annotations on conversational data. In addition, we initiate a novel conversational life event extraction task and differentiate the task from the public event extraction or the life event extraction from other sources like microblogs. We explore three information extraction (IE) frameworks to address the conversational life event extraction task: OpenIE, relation extraction, and event extraction. A comprehensive empirical analysis of the three baselines is established. The results suggest that the current event extraction model still struggles with extracting life events from human daily conversations. Our proposed life event dialog dataset and in-depth analysis of IE frameworks will facilitate future research on life event extraction from conversations.

1 Introduction

Daily conversation, as a means of communication and switching information, is full of personal information, including personal background, interests and hobbies, connections to other people, and various life events. Mining life events lets us better understand a person. The extracted life events can be used to construct the personal knowledge base and benefit a variety of downstream tasks, such as lifestyle understanding (Doherty et al., 2011) and memory assistance (Rahman et al., 2018).

Previous research on life event extraction mainly focuses on life events from microblogs or social

media platforms such as Twitter (Li et al., 2014; Yen et al., 2018, 2019). However, these events from a given fixed passage are static. In contrast, an event mentioned in a conversation might change its status dynamically throughout the chat. Besides, conversations allow participants to interact with each other and gather the information which stimulates participants' interests, revealing people's general interests in different aspects of information about a life event and expanding additional event information. For example, when a person talks about a travel event only with the destination mentioned, the other interlocutor might ask additional information about who they are traveling with, how much the trip cost, and the period and timing of the travel. Nevertheless, life event extraction from conversations is rarely explored and existing works only detect course or ambiguous event types (Eisenberg and Sheriff, 2020; Kao et al., 2021). The participants and status of events are not recognized, preventing more fine-grained life events analysis and limiting the applications.

We present Life Event Dialog (LED), a dataset with refined life event annotations in English.¹ We define life events as activities in a person's daily life. Following previous works, our life event definition is verb-centered. For each event, we annotate three levels of event type from fine-grained to coarse: *Verb*, *Class*, and *Frame*. Unlike formal writing and social network posts, dialogue is usually in a more flexible and more abstruse style, where the event type is often omitted. For example, "S1: Can I get you some coffee? S2: De-caff." indicates an "order" event, where the verb "order" does not appear in the dialogue. Therefore, we also introduce *Explicitness* of an event. When the event type cannot be extracted from the dialogue, we manually

¹<https://github.com/ntunlp/LifeEventDialog>

assign a verb to denote the activity and label the event as an implicit event. Besides event types, we annotate *Subject* and *Object* of each event as event participants. Furthermore, based on the interactive nature of a conversation, more detailed event information is likely to be revealed as the conversation continues. People might ask follow-up questions or clarifications in a response that specify the status or attributes of a known event. We consider the new supplemental information as the event status change instead of a new event. To be more specific, we record three aspects of event status: *Polarity*, *Modality*, and *Time*. These detailed annotations provide more comprehensive information about life events and allow us to track the dynamic event status changes throughout the conversation.

Moving forward from previous research on classifying the types of life events, we introduce the Conversational Life Event Extraction task, which classifies the event type and identifies event participants simultaneously from conversations. Classifying the event type of a life event is much harder than conventional public event extraction because of the high diversity of life events. The form of conversation further adds up to the difficulty of this task. For instance, event participants are challenging to identify because they are often in free form, and mentions of the same entity are easily changed throughout the dialogue. Due to the uniqueness of conversational life event extraction, there has not been a model that specifically tackles this problem.

In this paper, we examine multiple information extraction (IE) frameworks, including OpenIE, event extraction (EE), and end-to-end relation extraction (RE) models, for this task. Experimental results show that the existing information extraction models, even the recent models on top of their tasks, still perform poorly in extracting life events from conversations. We analyze the strengths and limitations of each model, and urge the development of a better model for Conversational Life Event Extraction. The contributions of this work are threefold as follows:

- We introduce Life Event Dialog (LED) dataset, the first dataset annotated with fine-grained life events in conversations.
- We propose a novel task of Conversational Life Event Extraction, stepping forward the event type classification task from previous works.

- We explore several IE frameworks on the conversational life event extraction task and offer a thorough analysis of the baselines.

2 Related Work

2.1 Life Event Extraction

With the rise of social media platforms, people increasingly document their lives online. A large amount of personal data is beneficial for applying to lifelogging tasks. Most life event research collects data from Twitter and contains limited event types. [Li et al. \(2014\)](#) gathered tweets with congratulations or condolences replies and proposed a pipeline system to extract 42 major life events like “getting a job”, “graduation”, or “marriage”. [Yen et al. \(2018\)](#) constructed a multi-labeled Chinese tweets dataset with 12 life event types and proposed multiple LSTM models for life events extraction. [Yen et al. \(2019\)](#) built a life event corpus on Chinese tweets focusing on general life events such as dining or visiting a local place, transforming the extracted events into personal knowledge-based facts. Other than social media posts, the NTCIR14 Lifelog dataset ([Gurrin et al., 2019](#)) consists of multimodal lifelogs of images and their metadata. They assorted daily activities into 16 categories, but targeted visual lifelog retrieval instead of life event extraction. Although all concentrate on life events, Conversational Life Event Extraction is distinct from social media or multimodal sources.

2.2 Conversational Event Extraction

[Li et al. \(2021\)](#) designed a task-oriented dialogue system especially for the event extraction task, which differs from our goal of extracting life events from an existing open-domain conversation. [Imani \(2014\)](#) studied the performance of OpenIE systems on conversations collected from reviews, emails, meetings, blogs, forums, and Twitter. Besides the small data size of only a hundred sentences and the dataset not being publically available, their dataset lacks of auxiliary event information such as the event status.

2.3 Life Event Extraction from Conversation

Works by [Eisenberg and Sheriff \(2020\)](#) and [Kao et al. \(2021\)](#) are the most related works to ours. [Eisenberg and Sheriff \(2020\)](#) collected conversations from a podcast and classified event features by SVM. Their event annotations only include the event tokens and lack other event information. [Kao](#)

D	Dialogue	i	Event Types	Participants	P	M	T
1	S1: Bill, I must tell <u>you</u> the truth. <u>You</u> failed the English exam again.	1	[Explicit] Verb: failed Class: fail Frame: Success Act	[S] You [O] English exam	+	○	before
	S2: Ah? Really? That stinks!						
	S1: Haha. April Fool’s! Did <u>you</u> forget what day it is today?				-	○	before
2	S1: Excuse me. I would like to <u>purchase</u> some travelers’ checks.	1	[Explicit] Verb: purchase Class: purchase Frame: Buy	[S] I [O] some travelers’ checks	+	△	now
	S2: Sure. How much do <u>you</u> want?						
	S1: \$5000 and I want them all in fifties.	2	[Explicit] Verb: purchase Class: purchase Frame: Buy	[S] you [O] \$5000	+	○	now
	S2: OK, here you are. Please <u>sign</u> <u>your</u> name here.	3	[Implicit] Verb: give Class: give Frame: Giving	[S] S2 [O] S1 [O] \$5000	+	○	now
	S1: Thank <u>you</u> .	4	[Explicit] Verb: sign Class: sign Frame: Text Creation	[S] S1 [O] your name	+	△	after

Table 1: Two example dialogues with 1 and 4 events, respectively. D: Dialogue ID, i: Event ID. We display the coreference cluster in red for S1 and in blue for S2. *Verb* of explicit events (extractive) are underlined. For each event, we show the event types, participants, and status (*Polarity* (P), *Modality* (M), and *Time* (T)). +: positive event, -: negative event, ○: actual event, △: hypothetical event.

et al. (2021) also constructed a dataset from Daily-Dialog (Li et al., 2017), but they only annotated the frame name for each event. Both works also aimed at extracting personal life events from conversations, yet their proposed datasets only contain plain event annotations. In contrast, our LED dataset has more comprehensive annotations, including participants, status, event category, and the coreference clusters of participants.

3 Life Event Dialog

In this paper, we define life events as daily life activities, personal habits, life experiences, or personal information of the interlocutors or related people. On the other hand, personal feelings or preference, public issues, and general knowledge are not considered life events in our dataset.

3.1 Event Schema

Event Type: We define three granularities of event type: *Verb*, *Class*, and *Frame*. We also labeled the *Explicitness* based on whether *Verb* can be extracted from the dialogue.

- *Explicitness* (E) is determined by whether a verb exists in the dialogue that triggers an event. If no explicit verb exists in the dialogue, but an event is recognized and labeled

by annotators, we consider it as an implicit event. See Dialogue 2 Event 3 in Table 1 for an example.

- *Verb* is a verb event trigger, which might be a span extracted from the dialogue (explicit event) or abstractly written by annotators (implicit event).
- *Class* is the fine-grained event type determined by the lemma of *Verb*.
- *Frame* is the coarse event type selected from FrameNet (Fillmore et al., 2002) by annotators. This event type is also used in previous works (Yen et al., 2019; Eisenberg and Sheriff, 2020; Kao et al., 2021; Wang et al., 2020).

Note that *Frame* and *Class* are not one-to-one mappings. For example, *Class* “get” could belong to *Frame* “Possession”, “Receiving”, or “Giving”. In LED, each *Class* belongs to 1.25 *Frame* on average. **Participant:** We label the span for *Subject* (S) and *Object* (O). In a conversation, the same S/O entity might appear recurrently in different mentions, therefore, we also include the coreference cluster ID for S/O as their entity ID.

Status: Three event properties that might change dynamically throughout the dialogue are recorded,

	# Dialogs	U	Evt	Unique Evt
Train	858	3,823	5,529	1,856
Valid	75	349	593	179
Test	70	313	426	151
Total	1,003	4,485	6,548	2,186

Table 2: Dataset Statistics. The number of utterances (U) is the number of training instances (a training instance is an utterance with its dialogue history), and the number of events (Evt) is the cumulative number of events of a training instance. Also, we consider events with same event types and participants as the same event (Unique Evt), which might have different event status.

including *Polarity*, *Modality*, and *Time*.

- *Polarity* (P) is a binary class of whether an event happens (positive) or does not happen (negative). In some conversations, a life event is specifically expressed in a negative form. Given an utterance, “You did not invite me to the party.” We consider the negativity in this sentence as a strong indication of a particular event rather than a random event that doesn’t happen. Moreover, an event might change its *Polarity* as the conversation continues. As shown in Dialogue 1 Event 1 in Table 1, (You, failed, English exam again) is a positive event in the first two utterances, but after the speaker S1 says it’s an April Fool’s joke, *Polarity* becomes negative. Therefore, we especially mark the negative event status to keep track of the polarity changes of a life event in the conversation.
- *Modality* (M) refers to whether an event has happened/is happening (actual), or is mentioned in the dialogue that it will happen in the future (hypothetical), as illustrated in Dialogue 2 Event 1. Note that an event is hypothetical only when indicated in an affirmative sentence and not in a question. For example, (We, have, meeting) in “We will have a meeting at 9 a.m. tomorrow.” is a hypothetical event, but (she, call, you) in “Can she call you back?” is not.
- *Time* (T) is labeled as one of “before”, “now”, “after”, “continuously”, or a specified time span if the time information is explicitly mentioned in the dialogue. *Time* might be related to *Modality*. For instance, one hypothetical

event might have *Time* “after”, waiting for confirmation. After the next utterance reply, the event status would become an actual event with time labeled “now”. Dialogue 2 Event 4 is an example that changes its status after the last turn is given.

The default event status is positive, actual, and happens at now.

3.2 Annotation Details

We recruited three annotators with a linguistic degree to annotate the data. The dialogue is augmented by one turn at each time, and annotators are asked to label life events for the whole conversation up to the given turns. To calculate the agreement, we sampled 40 dialogues and asked all annotators to annotate them. We calculate the agreement on the *Frame* of all positive and actual events in the last turn of each dialogue (the accumulated events in one dialogue). The total number of annotated events are 550. The annotation agreement is 0.81, measured by Krippendorff’s alpha (Krippendorff, 2011). For the disagreed cases, we conducted the majority vote or discussed with annotators to re-annotate the event. The annotation guideline and more annotation details are provided in Appendix A.

3.3 Dataset Construction

We sample 1,003 dialogues from the DailyDialog dataset (Li et al., 2017) as the material for life event annotation. DailyDialog is a multi-turn English dialogue dataset, which contains daily life conversations from various English learning websites. The conversations usually focus on a certain topic and under a certain situation, such as a customer finding some goods in a shop. We take the five most frequent topics, including Relationship (35%), Ordinary Life (28%), Work (20%), Tourism (9%), and Attitude & Emotion (8%), and annotate four to six utterances of each conversation. We include conversations with (73.5%) and without (26.5%) events to reflect the real world scenario that not all conversations contain life events. Overall, we annotate 2,186 unique life events (Unique Evt) from 4,485 utterances. Note that one training instance is an utterance (U) with its dialogue history, and the events of an instance (Evt) would be the cumulative events from the utterance and its dialogue history. The statistics of our dataset is shown in Table 2.

For every unique event, the event status might

Unique Event Types			Status Change		
<i>Verb</i>	<i>Class</i>	<i>Frame</i>	P	M	T
695	371	175	26	58	117

Table 3: The number of unique categories in each event type and the number of times when an event changes one of its status.

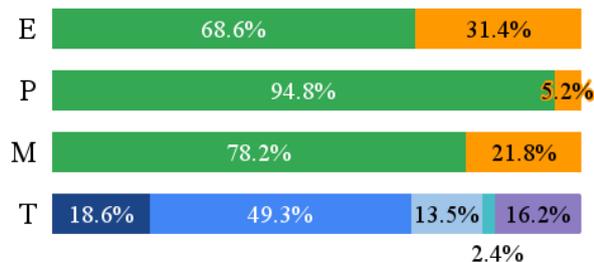

Figure 1: Statistics of *Explicitness* (E) and event status. Green and orange colors stand for explicit/implicit, positive/negative, and actual/hypothetical, for E, P, and M, respectively. Colors of T from left to right are “before”, “now”, “after”, “continuously”, and the specified time.

change throughout the conversation. We list the number of event status change for P, M, and T, as well as the number of unique event types for *Verb*, *Class*, and *Frame* in Table 3. The ratio of explicit vs. implicit, positive vs. negative, actual vs. hypothetical events, and the distribution of the T labels are shown in Figure 1.

4 Dataset Analysis

4.1 Life Events Distribution

We list the top five most frequent *Class* and *Frame* among 371 classes and 175 frames in Table 4, from which we can see that either *Class* or *Frame* is sparsely distributed. Even the most frequent *Class* accounts for only 3.9% of all, and the dominant *Frame* makes up only 6.1%. The majority event status change is the change of *Time*, which usually happens when people specify the event time. The top five implicit event classes are: “receive”, “hear”, “give”, “invite”, and “pay”. In contrast, the top explicit event classes are: “have”, “tell”, “go”, “see”, and “be”. Three classes (“go”, “hear”, and “bring”) are overlapped in top 10 explicit and implicit events classes.

4.2 Comparison with Event Extraction and Relation Extraction Benchmarks

Both event extraction (EE) and relation extraction (RE) aim to predict the event type and participant

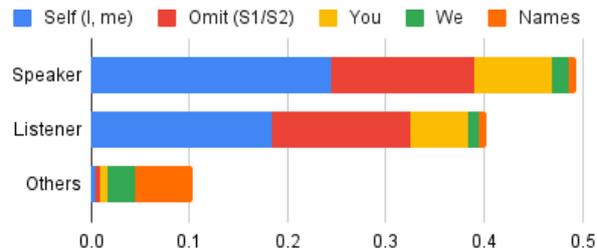

Figure 2: Subject analysis. When S is the speaker, the listener, or others, the mention of S usually belongs to one of the five categories: Self, We, You, Omit, Names.

information. For EE, each event has a event type (subtype) and argument roles. We regard *Frame* and *Class* in LED as the type and sub-types and map *S*, *O*, and event status (*Polarity*, *Modality*, and *Time*) as the argument roles. The RE output is a (head, relation, tail) triple. We consider (S, event type, O) in LED as the mapping of a RE triple. The major difference between the life events from our LED dataset and the public events from EE/RE benchmarks is the event domain and the distribution of event types. Life events in LED belong to a wide variety of categories that are sparsely distributed. In contrast, current EE and RE benchmarks are often from news reports and focus on certain limited event types. We compare two EE benchmarks (ACE2005 (Walker et al., 2006) and MAVEN (Wang et al., 2020)) and one RE benchmark (CONLL04 (Roth and Yih, 2004)) in Table 4, demonstrating the distinguishable event type discrepancy on domain and distribution.

Further, the arguments in EE benchmarks are often a single entity or the head word of a noun phrase, but we often want to keep the informative descriptions of life events, especially for objects. The average object length in LED is 2.95, which is 2.5 times of argument length in ACE2005. In addition, a quarter of life events are implicit events, which means 25% of the event trigger (*Verb*) cannot be found in the text input, whereas all event triggers and arguments are extractable from the given text in EE benchmarks.

4.3 Comparison with Life Event Datasets

LiveKB (Yen et al., 2019) is a large-scale life event dataset crawled from Chinese Twitter with an event schema similar to ours. The major difference between LiveKB and Life Event Dialog derives from the characteristics of a single-person narrative versus interactions between two people. In a tweet, the event subject is almost always the author of

LED (Frame)	%	LED (Class)	%	ACE2005	%	MAVEN	%	CONLL04	LiveKB
Statement	6.1	have	3.9	Attack	28.8	Action	46.9	kill	Perception
Perception	5.3	go	3.8	Transport	13.5	Change	27.5	work for	Presence
Motion	3.8	tell	3.5	Die	11.2	Scenario	13.4	organization based on	Using
Request	3.2	hear	2.8	Meet	5.2	Sentiment	6.4	live in	Motion
Ingestion	3.2	see	2.8	End-Position	4.0	Possession	5.7	located in	Ingestion

Table 4: Top 5 event types of our LED dataset compared to other datasets.

Dataset	Task	Source	# Docs	# Events	# Types (Subtypes)	# Arg Roles	Coref
ACE2005 (2006)	EE	News	599	5,349	8 (33)	35	
CONLL04 (2004)	RE	News	1,437	2,041	5	4	
LiveKB (2019)	Life EE	Twitter	25,344	15,525	137	6	
PEDC (2020)	Life EE	Podcast	1,038	3,664	278	0	
DiaLog (2021)	Life EE	DailyDialog	600	780	21	0	
Life Event Dialog	Life EE	DailyDialog	1,003	2,186	175 (371)	5	✓

Table 5: Datasets comparison. EE: Event Extraction, RE: Relation Extraction.

Framework	Original Output	LED Output
OpenIE	(head, relation, tail)	(S, <i>Verb</i> (explicit), O)
RE	(head, relation, tail)	(S, <i>Verb/Class/Frame</i> , O)
EE	[T span, T type, A ₁ span, A ₁ type, A ₂ span, A ₂ type, ...]	[<i>Verb</i> (explicit), <i>Class/Frame</i> , S/O, “subject”/“object”]

Table 6: Outputs from OpenIE, RE, and EE frameworks and their mapping to LED output. For EE framework, original output is the span and type of event trigger (T) and the span and type of arguments (A). The T span maps to the span of *Verb* of explicit events; T type maps to *Class* or *Frame* of that event; A span maps to the span of S or O with corresponding “subject” or “object” string as their A type.

the tweet if not mentioned. In contrast, the event subject in a dialogue is half time the speaker, 40% the listener, and 10% the others, as shown in Fig. 2. The case of the subject being the listener happens when the event of the listener is told by the speaker, such as “You are hired by our compan”, “You get high marks in the exam”, or “I’m Jame, your neighbor when you lived here last year (indicating the event of the listener living here last year)”. Also, besides the case when the speaker themselves being the subject (when the mention is self-referred), the mention of the subject is often omitted (and annotated as S1/S2) or being “you”. It usually happens when the speaker is confirming an event. For example, S1: “Could you please sign this memo?” S2: “No problem.” The event (S2, sign, memo) becomes positive after S2’s confirmation. These kinds of events that happen after user interactions only appear in our Life Event Dialog data. There is sometimes an ambiguity regarding the event subject, e.g., S mention “we” might refer to only the speaker or

both participants in the dialogue. Further, comparing the top 10 *Frame* in LED and LiveKB, we find that LED has more interactive activities, such as “Statement”, “Request”, and “Acquaintance”. In contrast, LiveKB activities are more self-centered, like “Presence”, “Create”, and “Buy”.

Both conversational event extraction datasets, PEDC (Eisenberg and Sheriff, 2020) and DiaLog (Kao et al., 2021), only annotate event type labels. The former is collected from podcast transcripts and focuses on event from life stories told by first-person narrators. The latter classifies events by FrameNet and is also from the DailyDialog. Our LED has more data, more event types, and additional annotations of argument roles, event status, and coreference clusters, compared with them.

5 Conversational Life Event Extraction

We define Conversational Life Event Extraction as the combination of two subtasks: (1) Event Type Classification and (2) Participants Identification.

Given a dialogue $D_u = \{T_1, T_2, \dots, T_u\}$ of u turns utterances, we extract i events $E_u^i = \{e_u^1, \dots, e_u^i\}$ from D_u , where an event e comprises an event type from either *Verb*, *Class*, or *Frame* and spans of participants (S and O). We consider an input instance as the concatenation of turns T_1 to T_u .

5.1 Frameworks

We aim to identify the event type and participants simultaneously. By contrast, previous works on life event extraction only dealt with event type prediction. Hence no model specifically tackles our proposed task of conversational life event extraction. As a result, we examine different information extraction frameworks, including (1) OpenIE, (2) Event Extraction (EE), and (3) Relation Extraction (RE), for this task. We transform our data schema to fit the original schema of each framework, as shown in Table 6. Both OpenIE and RE output (head, relation, tail) triples. We consider the head and tail to be S and O and relation to be an event type. EE outputs the span and type of an event trigger, as well as the span and type of arguments. When converting to our LED schema, the event trigger can be seen as the event type and arguments as participants. Due to limitations of each framework, the output from each framework is slightly different when adapting to our dataset. The major constraint is that OpenIE and EE frameworks can only predict explicit events because both output spans from the input dialogue.

OpenIE: OpenIE requires each element in the triplet to be a span from the input, therefore, it is not able to predict event types of *Class* and *Frame*, nor the implicit event which *Verb* is written by annotators. Also, OpenIE always outputs the whole event triplet, so it can never correctly predict the events without object. We use Stanford Open IE system (Angeli et al., 2015) as the OpenIE baseline to extract life event triples.

Relation Extraction: RE framework also generates triples as output. REBEL (Huguet Cabot and Navigli, 2021) is selected as the relation extraction baseline, which is based on an autoregressive model BART-large (Lewis et al., 2019). Since REBEL is a generation model, it can generate tokens not in the given dialogue and avoid the limitations of OpenIE framework.

Event Extraction: Event Extraction framework predicts both spans and their type; thus, the implicit events without trigger span can never be pre-

dicted. We choose DyGIE++ (Wadden et al., 2019) as our event extraction baseline. DyGIE++ is a span-based model with RoBERTa-base (Liu et al., 2019) backbone, which can perform multi-tasks training on entity recognition, relation extraction, event extraction, and coreference resolution.

5.2 Evaluation

Evaluation metrics vary between frameworks. We evaluate the output triples from OpenIE and RE using precision (P), recall (R), and micro-F1, following previous works (Huguet Cabot and Navigli, 2021). We adapt the strict evaluation (Taillé et al., 2020), that is, a triple is considered as correct only if the whole triple is exactly the same as the ground truth triplet. EE results are evaluated by P, R, and F1 of span identification and type classification. An event trigger is correctly identified if the span is correct and is correctly classified if the event type is correct. An event argument is correctly identified if both the event type and the argument span are correct, and is correctly classified if the argument type is correct.

We unite evaluation metrics for all frameworks using a lenient evaluation metric. For each life event, we first evaluate the event type classification (ET-C) by P, R, and F1. Then, for those events with correct event type, we evaluate the participants identification by P, R, and F1 of S (S-ID) and O (O-ID F1). We also compute BERT Score (Zhang et al., 2020) for the object (O-ID BS), because O in LED are often longer than a single token, unlike in EE/RE datasets (as discussed in Sec 4.2).

5.3 Analysis

Table 7 presents the result of employing each framework on explicit life event extraction, suggesting that the EE framework works the best on event type classification (ET-C) and subject identification (S-ID) over different granularities of event type. We think the graph-based EE model (DyGIE++) can better capture critical entities and their interactions for event type and S. The other thing we can benefit from DyGIE++ is that it is compatible with the coreference training, so we can make use of our annotations on participants’ coreference clusters. However, we are surprised to find that the additional coreference training does not help. We suspect that a large amount of examples of the same mention referring to different entities in a dialogue confuse the coreference training. For example, the

Event Type Granularity	Framework	ET-C			S-ID			O-ID			
		P	R	F1	P	R	F1	P	R	F1	BS
<i>Verb</i>	OpenIE	18.5	29.1	22.6	17.3	27.2	21.1	6.5	10.2	7.9	33.5
	RE	28.5	49.8	36.2	23.6	41.3	30.1	15.4	26.9	19.6	66.2
	EE	79.0	30.0	43.5	64.2	24.4	35.4	28.4	10.8	15.6	42.0
	EE + coref	84.1	24.9	38.4	63.5	18.8	29.0	30.2	8.9	13.8	19.7
<i>Class</i>	RE	27.6	49.3	35.4	22.9	40.8	29.3	14.7	26.3	18.9	64.4
	EE	67.8	27.7	39.3	55.2	22.5	32.0	26.4	10.8	15.3	42.0
	EE+coref	59.2	19.7	29.6	40.8	13.6	20.4	26.8	8.9	13.4	19.7
<i>Frame</i>	RE	23.4	40.4	29.6	16.3	28.2	20.7	12.0	20.7	15.1	61.1
	EE	58.6	23.9	34.0	46.0	18.8	26.7	26.4	10.8	15.3	40.2
	EE+coref	57.4	12.7	20.8	57.4	12.7	20.8	21.3	4.7	7.7	64.0

Table 7: Result on explicit events across different frameworks evaluated by our lenient evaluation. ET-C: Event Type Classification, S-ID: Subject Identification, O-ID: Object Identification, BS: BERT Score.

Event Type Granularity	Data	ET-C		S-ID		O-ID	
		(F1)	(Δ)	(F1)	(Δ)	(F1)	(BS)
<i>Verb</i>	E	36.2		30.1		19.6	66.2
	E+I	29.9	-6.3	20.7	-9.4	13.9	57.7
<i>Class</i>	E	35.4		29.3		18.9	64.4
	E+I	28.4	-7.0	20.9	-8.4	12.0	57.9
<i>Frame</i>	E	29.6		20.7		15.1	61.1
	E+I	24.3	-5.3	16.4	-4.3	12.4	58.3

Table 8: Event extraction with (E+I) and without (E) implicit events by RE framework.

same subject mention ‘‘I’’ might refer to S1 or S2 in different events.

As for object identification (O-ID), the RE framework gets the top. We can see from Table 7 that the bottleneck of Conversational Life Event Extraction is on O-ID, whose F1 score is much lower than the ET-C and S-ID. The reason might be the high variance of object mentions. We think the best performing RE model (REBEL), an autoregressive model based on a large pretrained language model, is better at copying a sequence of input for O, therefore, can get the best result on O-ID. We also found that REBEL often generates repeated output and has higher recall (R) than precision (P), in contrast to DyGIE++, which gets a higher P than R.

For the three event type granularities, *Verb* is the easiest to predict, and *Frame* is the most challenging. The result in Table 7 shows a consistent decreasing trend from *Verb*, *Class*, to *Frame* across all frameworks. For ET-C, the gap from *Verb* to *Class* (RE: -0.8, EE: -4.2) is smaller than from *Class* to *Frame* (RE: -5.8, EE: -5.3). This is intuitive because *Verb* and *Class* are more similar. The drastic drop on *Frame* demonstrates the difficulty of inferring the frame name from the dialogue.

RE is the only framework among the three that

Event Type Granularity	Framework	ET-C	S-ID	O-ID	
		(F1)	(F1)	(F1)	(BS)
<i>Verb</i>	OpenIE	37.6	37.6	12.5	36.8
	RE	25.6	22.8	15.9	50.0
	EE	21.7	21.7	0.0	8.0
<i>Class</i>	RE	22.5	22.5	12.5	44.3
	EE	21.7	21.7	0.0	8.0
<i>Frame</i>	RE	0.0	0.0	0.0	51.6
	EE	0.0	0.0	0.0	0.0

Table 9: Zero-shot result on explicit events across different frameworks.

can deal with implicit events. The implicit events account for 31.4% of all events; hence, we further analyze their impact. Table 8 shows the results from the RE framework with and without implicit events. Despite event type granularities, the results drop after adding implicit events. Particularly, when the event type is of *Verb* or *Class*, the negative effect of implicit events is significant (see the Δ column). The results with implicit events are almost the same as the result of explicit events’ frame name prediction. In other words, predicting an event type that is not in the input dialogue is extremely difficult, and current models cannot achieve promising results.

We examine the zero-shot result over the three frameworks, when the testing event types are not seen in training time. The result is shown in Table 9. OpenIE performs the best for ET-C and S-ID on the setting of *Verb* zero-shot. Since OpenIE is a rule-based model and does not need any training, it is better than the models required training for unseen event types. In addition, for the trained models of RE and EE frameworks, they cannot infer any unseen frame name. Since life events are broad and not fully covered in our dataset, developing

models that can extract unseen event types remains an essential research question.

6 Conclusion

This work presents Life Event Dialog: a comprehensive life event dataset annotated on DailyDialog conversations. The main differences between our dataset and previous datasets on personal life event extraction are: (1) Life Event Dialog is built on top of conversations instead of microblogs like Twitter. The interaction between speakers adds dynamics to events, such as information expansion or status modification, and indicates people’s general interests in multiple aspects of other’s life events. (2) Life Event Dialog contains more data, more types, and more fine-grained event annotations compared to other conversational life event datasets.

We propose the Conversational Life Event Extraction task, extending life event extraction tasks from social media to the conversation domain and from event type detection to predicting both event type and participants simultaneously. We then carefully examine three information extraction frameworks: OpenIE, relation extraction (RE), and event extraction (EE), for the pilot study on this task. The result suggests that current top models on three closely related fields cannot perform well in the Conversational Life Event Extraction task. Improving object identification and implicit event extraction, detecting unseen life events, and keeping track of event status, constitute our future work.

Limitations

Our LED dataset is annotated on DailyDialog. While annotating on another dataset brings some benefits, it also constrains our dataset. For instance, our dataset is limited to the top five frequent topics in DailyDialog, which might not be enough to cover all life events in various scenarios. Also, DailyDialog only contains conversations between two interlocutors. For a multi-party conversation, the conversational life events extraction would be much more complicated and interesting.

The other limitation of LED is the size of the dataset. Although with more comprehensive annotations of life events, the number of events in our dataset might not be enough for today’s data-hungry models. There is always room for larger datasets and more annotations. Compared to the entity types in RE like “person”, “organization”, “location”, to name a few. We do not label such so-

phisticated argument roles but only “subject” and “object”. We leave this part to our future work. Besides, we only consider up to 6 turn utterances, yet a dialogue might be much longer in real life.

Lastly, the definition of life events varies from individual to individual, and our definition of life events might not suit everyone’s needs. However, our exploration of the zero-shot experiment shows that it is still possible to find unseen events, and a better model for zero-shot life extraction is needed.

Ethics Statement

Our Life Event Dialogs dataset is an extension of an existing public dataset DailyDialog, with all speakers being anonymized in the original release. In other words, our dataset does not contain any personally identifiable information that would infringe on someone’s privacy. In this work, we will only release the life event annotations for research purposes. The dialogues in DailyDialog will not be included in LED, but one can access the full DailyDialog dataset from the author’s website.²

Our dataset is constructed upon a considerable amount of human annotation. We recruited three annotators and paid them a local hourly wage for the time they spent. The annotation period spanned 1.5 months and resulted in 1,003 annotated conversations (including conversations without events).

A Annotation Guideline

A.1 Goal

We want to extract personal life events related to the speaker according to their dialogue, so that we can construct a personal life knowledge base and benefit other downstream tasks.

A.2 What **are** personal life events?

1. The event happens or might happen in the future to the interlocutor themselves or their relatives and friends.
 - Example: “I went to Salt Lake City on business with Mr. Wang.”
2. The event must occur before the dialog or before the dialog ends.
3. When expressing personal thoughts or feelings, the context implies life events.
 - Example: “These cookies taste delicious.” may imply an event that the speaker has eaten cookies.
4. The life history or personal information of the interlocutor.
 - Example: summer vacation, school start, graduation, “I skipped fourth grade.”, etc, all belong to life experiences.
 - Example: “I live in Taiwan.”, “I was born in 1980.” are personal information.
5. Interlocutor’s personal habits.
 - Example: “I usually look at English language websites every day and go to my local English Corner twice a week.”
6. If there is no clear sentence describing an event in the conversation, use the context to see if a life event occurred before the conversation completes.
 - Example: “S1: What’s for supper? S2: Red cooked carp and rape with fresh mushrooms.” When the dialogue is completed, it can be deduced that the event

“S2 cooked Red cooked carp and rape with fresh mushrooms for dinner” occurred.

- Example: “S1: I ran a red light? S2: Yes, you did.”, S1 was originally a question, and the answer of S2 affirmed the occurrence of S1 running a red light.

A.3 What **are not** personal life events?

1. Public issues or general knowledge
 - Examples: news, knowledge, company business related events.
 - Examples: “We run a spotless and cockroach-less hotel.” Events that represent the company’s position are not counted.
2. Only expressing personal feelings and preferences (related to emotions)
 - Examples: “I feel tired,” “I think you are cute,” “I like Chinese food,” “I’m worried about his condition,” “I’m tired of going to school,” etc.
3. Expressing personal abilities
 - Example: “I can type 80 words a minute.”
4. Things that are not guaranteed to happen don’t need to be marked as possible future events
 - Examples: “Can you wait a little while?” “You should go to school tomorrow.”
5. “Ask questions” and “express opinions” are not considered life events of themselves (unless there is an answer response to judge that an event has occurred)
 - Example: “S1: Did you go to school yesterday? S2: No, I didn’t.” Only need to mark the event “S2 did not go to school yesterday”, and do not need to mark the event “S1 asked S2 a question”.
6. A simple description of the environment, people, things, and things is not considered a life event (unless there is an implied life event)
 - Example: “That girl standing there is pretty.”

A.4 Event Explicitness

Events can be classified into *Explicit* or *Implicit* events, depending on whether there is a clear action in the sentence to indicate the occurrence of the event.

Explicit Event: There exists an explicit action describing a life event.

- As long as the Predicate appears in the dialogue that clearly represents the action of the event, it belongs to the *Explicit* event. If there is a verb but it is not clear, please deduce the explicit verb and mark it as *Implicit*.
 - Example: “S1: I ran a red light? S2: Yes.” → Explicit Event: (Subject= S1, Predicate= ran, Object= red light, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
- Object can be missing, for example: “We’ll wait.” with a clear action (wait).
- If the life event has been explicitly described, it is not necessary to extend the label to other possible events.
 - Example: “Today I played basketball.” There is no need to mark the event of “I went to the basketball court.”

Implicit Event: Contexts and situations are required to infer a life event. (As long as the Predicate needs to be deduced, it is considered *Implicit*).

- Please infer the action most relevant to your life experience based on the dialogue context.
- A sentence with an ambiguous verb.
 - Example: “I want a fillet steak, medium.” In the context of ordering food, please deduce that the Predicate is “order”, and mark the event as *Implicit*. → Implicit Event: (Subject= I, Predicate= order, Object= fillet steak, medium, Time= NOW, Polarity= POS, Modality= ACTUAL)
- Events implicit in the dialogue.
 - Example: “S1 : Can I get you some coffee? S2 : De-caff.” → Implicit Event: (Subject= S2, Predicate= order, Object= De-caff, Time= NOW, Polarity= POS, Modality= ACTUAL)

- Implicit event in a sentence.
 - “S1 : You must be exhausted after your long trip from Canada.” → Implicit Event: (Subject= You, Predicate= travel from, Object= Canada, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
- The situations of the dialogue, such as order meals, make phone calls, send things, job interviews, etc.
 - Example: “S1 : This is John speaking. S2 : Hi, this is Mary.” → Implicit Event: (Subject= S2(Mary), Predicate= call, Object= S1(John))
- Note: Except for the Predicate of Implicit Event, please use the vocabulary in the sentence for Subject, Predicate, Object, and Time of Explicit Event, and do not create your own vocabulary.

A.5 Format Description

The annotation for an event includes the following fields: Subject, Predicate, Object, Time, Polarity, Modality.

Subject: The subject is the word that performs the action. Most subjects are nouns, pronouns, noun phrases or noun clauses. Subjects are mainly the two interlocutors, but may also be people or things related to life events.

Predicate: The action of a life event, expressing what the subject did or what happened. Usually a verb, but may also be a preposition (please refer to the example label below).

- Predicate needs to indicate a clear action.
 - Example: “I’d like to take the apartment I looked at yesterday.”, take means accept, but we know from the above that the interlocutor wants to rent a house, so please mark the more specific action rent as a Predicate.
 - Example: “I need a double and three triples.”, need means need, but it can be inferred in the dialogue that the interlocutor wants to book a room, so please mark the action book as Predicate.
 - Example: “I’ll be right there.” This sentence means that I will go to a certain store immediately, please do not directly mark (I, be, there), please deduce a more precise action go to from the predicate

- When Predicate is a preposition, please mark it according to the following example:
 - "with" means "and", which means an event involving more than two people.
 - * Example: "I went shopping with her." or "I went shopping ... with her."
 - Explicit Event 1: (Subject= I, Predicate= went , Object= shopping, Time= BEFORE, Polarity= POS, Modality=ACTUAL,)
 - Explicit Event 2: (Subject= I, Predicate= went with / with , Object= her, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
 - Modifies verbs, such as prepositions denoting the destination and means of movement.
 - * Example: "I went to San Francisco by plane."
 - Event 1: (Subject= I, Predicate= went to , Object= San Francisco, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
 - Event 2: (Subject= I, Predicate= went by , Object= plane, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
 - * Example: "He is on the school volleyball team."
 - Event: (Subject= He, Predicate= is on , Object= school volleyball team, Time= CONTINUOUSLY, Polarity= POS, Modality= ACTUAL)
 - * Example: "S1 : Did you hear it on the radio? S2 : Yes."
 - Event 1: (Subject= S2, Predicate= hear , Object= it, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
 - Event 2: (Subject= S2, Predicate= hear on , Object= radio, Time= BEFORE, Polarity= POS, Modality= ACTUAL)
 - If the preposition refers to the time, please mark the time directly in the field of Time.
 - * Example: "We ate dinner at 8 pm"
 - Event: (Subject= We, Predicate= ate, Object= dinner, Time= 8 pm, Polarity= POS, Modality= ACTUAL)
 - Nested events.
 - Example: "I'm planning to sing a song in front of everybody."
 - Event 1: (Subject= I , Predicate= 'm planning to , Object= sing a song in front of everybody , Time= NOW, Polarity= POS, Modality= ACTUAL)
 - Event 2: (Subject= I , Predicate= sing , Object= song , Time= AFTER, Polarity= POS, Modality= HYPOTHETICAL)
 - Event 3: (Subject= I , Predicate= in front of , Object= everybody , Time= AFTER, Polarity= POS, Modality= HYPOTHETICAL)
 - Sentences that describe situations where no event occurred.
 - Example: "John didn't go to the party tonight." Predicate does not need to mark negative words (didn't), please mark positive or negative marks in Polarity.
 - Sentences describe possible future events.
 - Example: "We will have a meeting at 9 am tomorrow." Predicate does not need to mark auxiliary verbs that indicate future occurrences (for example: will, is going to), please mark the form of event occurrence in Modality.
 - Not a predicate of personal life events: think, know, need, want, hope, trust, like, feel.
- Object:** The object may be a person, thing, or object, expressing the relationship with the Subject through the Predicate. Most are nouns, pronouns, noun phrases or noun clauses.
- Please use words that appear in the dialogue as much as possible, and only mark words that are meaningful to the event.
- Example: "I have a hat." Do not need to annotate articles (such as "a", "the").
 - Example: "I made this delicious dinner." Do not need to annotate the adjective.
 - Example: "I have a problem with my room." Supplemental words such as "with my room" need to be annotated.

Time: Express the time information of the life event, such as the time or frequency of the event.

If there is a clear description of the time information in the dialogue, for example: yesterday, last week, directly fill in the time information in the sentence.

If there is no clear description, the default time mark can be filled in as follows:

- **BEFORE** : Indicates that the event occurs before the dialog occurs.
- **NOW** : Indicates that the event occurred during the period from the beginning of the conversation to the end of the conversation
- **CONTINUOUSLY** : Indicates that the event has continued to occur from the past to the present (longer duration).
- **AFTER** : Indicates that the event (possibly) happens after the conversation ends.

Please infer which label is suitable for filling in according to the dialogue.

If there is a vague description in the sentence, please fill in the mark that matches the meaning of the adverb of time.

- Example: “I just finished my homework.”
Please fill in NOW for Time.

If people use “after...” or “before...” to describe the occurrence time in the sentence, you can fill in it directly.

Polarity: Indicates that the life event is positive or negative. The default is POS for positive and NEG for negative.

- Example: “You did not invite me to the party.”
→ Event 1: (Subject=You, Predicate=invite, Object=me, Time=BEFORE, Polarity= NEG , Modality=ACTUAL)
→ Event 2: (Subject=You, Predicate=invite to, Object=party, Time=BEFORE, Polarity= NEG , Modality=ACTUAL)
- Example: “I have no money with me.”
→ Event: (Subject=I, Predicate=have, Object=money, Time=NOW, Polarity= NEG , Modality=ACTUAL)

Modality: Indicates the form of life events, with the following symbols:

- **ACTUAL:** Indicates that the event has occurred before or at the moment when the sentence is spoken.
- **HYPOTHETICAL:** Indicates that the event may happen in the future, but only if there is a clear sentence in the dialogue to affirm or deny that the future will do. Even if the next moment of speaking may happen but has not happened yet, please mark it as HYPOTHETICAL. After adding the next sentence of dialogue, the situation can be deduced that it has happened, and then changed to ACTUAL.

A.6 Coreference Annotation

Mark all words in the dialogue that point to pronouns in the Event. Mark all the words representing the same thing into the same mention.

- Example: “S1 : Did you eat the cake on the table? S2 : Yes, I ate that.”
→ Explicit Event: (Subject= I, Predicate= ate, Object= that, ...)
→ Coref tag: (Subject: (I, S2), Object: (that, cake on the table))

B Annotation Interface

Figure 3 shows the annotation interface. The annotator was first shown the topic of the conversation, the number of turns to annotate, and the full dialogue. Then, the utterances of the dialogue are displayed turn by turn cumulatively. The example in Fig 3 is the second instance of the dialogue. The annotators should decide whether the cumulative turns contain life events of the speakers. If answering “Yes”, they will add the index of “Subject”, “Predicate” (if it’s an explicit event), and “Object”, and select the event status.

Annotate Life Events

Topic : Work

Turns : 4

S1 : May I help you ?
 S2 : Yes , I 'm looking for Bob .
 S1 : He 's in a meeting with Phil .
 S2 : No problem , I can wait .

Please annotate life events according to the order of the utterances

S1 : May I help you ?
 (0) (1) (2) (3) (4) (5) (6)
 S2 : Yes , I 'm looking for Bob .
 (7) (8) (9) (10) (11) (12) (13) (14) (15) (16)

Does the conversation contain life events of "S1" or "S2"? No Yes

Explicitness	Subject	Predicate	Object	Time	Polarity	Modality
<input checked="" type="radio"/> Explicit <input type="radio"/> Implicit	7 Paste 11 Paste + Coreference	12-14 Paste	15 Paste + Coreference	<input checked="" type="radio"/> NOW <input type="radio"/> BEFORE <input type="radio"/> AFTER <input type="radio"/> CONTINUOUSLY <input type="radio"/> <input type="text"/> Paste	<input checked="" type="radio"/> POS <input type="radio"/> NEG	<input checked="" type="radio"/> Actual <input type="radio"/> Hypothetical

Reading and Reasoning over Chart Images for Evidence-based Automated Fact-Checking

Mubashara Akhtar, Oana Cocarascu and Elena Simperl

Department of Informatics, King’s College London

{mubashara.akhtar,oana.cocarascu,elena.simperl}@kcl.ac.uk

Abstract

Evidence data for automated fact-checking (AFC) can be in multiple modalities such as text, tables, images, audio, or video. While there is increasing interest in using images for AFC, previous works mostly focus on detecting manipulated or fake images. We propose a novel task, chart-based fact-checking, and introduce ChartBERT as the first model for AFC against chart evidence. ChartBERT leverages textual, structural and visual information of charts to determine the veracity of textual claims. For evaluation, we create ChartFC, a new dataset of 15,886 charts. We systematically evaluate 75 different vision-language (VL) baselines and show that ChartBERT outperforms VL models, achieving 63.8% accuracy. Our results suggest that the task is complex yet feasible, with many challenges ahead.

1 Introduction

Charts are often used to present data in news articles, reports, scientific publications, and across social media posts (Lo et al., 2022; Zhang et al., 2021). For example, in recent years, charts have been widely used to guide policymakers in deciding health policies and to communicate COVID information with the general public; a popular example is the coronavirus dashboard by Johns Hopkins University,¹ which was integrated in several websites (Perkel, 2020).

Misinformation can spread through charts in various ways. Previous works in data visualization have discussed how misleading chart design can cause misinformation (Lo et al., 2022). However, a more subtle form of misinformation occurs during chart interpretation (e.g. through invalid comparisons, framing correlation as causation, or spreading of misleading claims). To identify these misinformation types not only the stand-alone chart but the chart together with its message need to be

¹<https://coronavirus.jhu.edu/map.html>

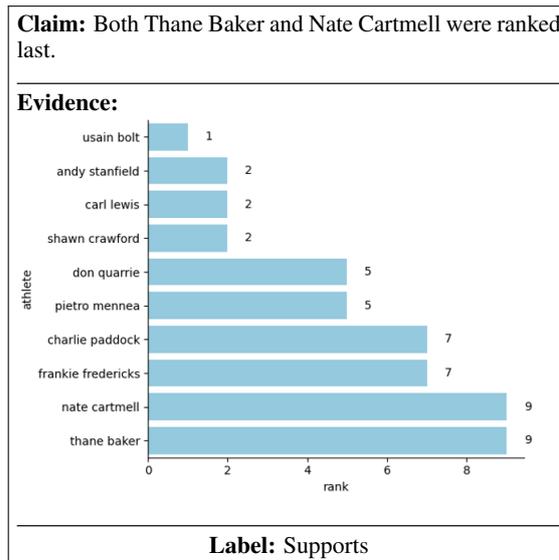

Figure 1: An example from the ChartFC dataset where the claim is supported by the evidence chart.

considered jointly (Lo et al., 2022). In this work, we focus on verifying whether charts support or refute claims about them.

There has been substantial progress in automated fact-checking (AFC) in recent years, with a focus on verifying claims against text (Wang, 2017; Thorne et al., 2018; Schuster et al., 2021; Thorne et al., 2021; Diggelmann et al., 2020), table (Aly et al., 2021; Diggelmann et al., 2020; Chen et al., 2020a; Akhtar et al., 2022), and image (Yao et al., 2022; Zlatkova et al., 2019; Qu et al., 2022) evidence. Previous work has widely ignored claim verification against chart images. There are several challenges related to chart fact-checking as opposed to other evidence modalities: the structural information, text in charts, and location of text need to be considered jointly for chart understanding. Text plays a key role and is used, for example, as bar labels, chart titles, or in legends to explain the use of colors. Moreover, verifying claims against charts requires different reasoning

types, e.g. retrieving values, finding extremes, or calculating a sum.

To address these challenges, we propose the chart fact-checking task where, given a text claim and a chart, the goal is to classify if it *supports* or *refutes* the claim. We introduce ChartBERT as the first model for AFC against chart evidence comprising (i) an OCR-based reading component to extract text and structural information from chart images; (ii) a sequence generation component to process the extracted information; and (iii) an encoding component that extends the BERT architecture (Devlin et al., 2019) with three additional structural embeddings to jointly learn textual and structural representations of chart images.

Moreover, we release ChartFC as the first benchmark for chart-based AFC, created using TabFact (Chen et al., 2020a) as a seed dataset. Our dataset contains 15.9k human-written claims and bars of different colors, orientations, and backgrounds (see Figure 1 for an example). Our highest-performing ChartBERT model achieves 63.8% accuracy on ChartFC. We compare ChartBERT to 75 vision-language (VL) baselines, combining five vision encoders, three language encoders, and five fusion methods. The best-performing VL model is a transformer-based (Vaswani et al., 2017), dual encoder architecture that uses a simple, yet effective fusion block: concatenation and gated recurrent units (GRUs) (Bahdanau et al., 2015). Our results suggest that state-of-the-art VL approaches struggle with the proposed task, calling for more research.

Our **contributions** are as follows: 1) we propose the chart fact-checking task and build ChartBERT as the first chart fact-checking model; 2) we introduce ChartFC, the first dataset for AFC with chart evidence; 3) we systematically evaluate state-of-the-art language/vision encoders and fusion methods on the proposed task, highlighting challenges and providing an analysis of common reasoning types that contribute to failures.²

2 Related Work

2.1 Verifying Claims against Evidence

Evidence-based fact-checking aims to predict claims’ veracity given evidence data. While many datasets focus on text (Thorne et al., 2018; Kotonya and Toni, 2020; Schuster et al., 2021; Wang, 2017)

²The ChartFC dataset and our code are available at https://github.com/mubasharaak/ChartFC_chartBERT.

and table evidence (Chen et al., 2020a; Gupta et al., 2020; Aly et al., 2021; Wang et al., 2021a; Akhtar et al., 2022), human fact-checkers use a wider range of modalities for verification (Nakov et al., 2021b; Alam et al., 2021). They consult experts and extract information from databases, text, tables, graphics, and audio/video material from numerous sources.³

Charts influence how messages are perceived (Pandey et al., 2014). For example, Lee et al. (2021) use the term “counter-visualization” to describe data visualizations by the anti-vaccination communities in the US who created charts from publicly available data and interpreted them in a way that challenged the narrative of the pandemic, leading to disinformation.

2.2 Automated Fact-Checking with Images

Given that claims and evidence can be conveyed through different modalities, interest in AFC with images has increased recently (Nakov et al., 2021a; Cao et al., 2020; Alam et al., 2021; Yao et al., 2022; Sharma et al., 2022). Previous tasks focus mainly on detecting manipulated or fake images rather than on evidence-based claim verification (Blaier et al., 2021; Kiela et al., 2020; Alam et al., 2021; Sharma et al., 2022; Abdali, 2022). Whilst manipulated or fake images can be detected using the image only, claim verification requires understanding the claim and evidence jointly.

2.3 Chart Images in other NLP Tasks

Two tasks related to chart fact-checking are chart question answering and chart summarization. Given a chart image, the summarization task requires to generate a summary of the chart in natural language text (Kantharaj et al., 2022; Tan et al., 2022). For question answering (chartQA) the answer to natural language questions is extracted from chart images. However, different to claim verification, questions typically provide strong indicators for the correct answers. Existing chartQA datasets are either small (Kim et al., 2020) or comprise automatically-generated, template-based questions (Chaudhry et al., 2020; Kahou et al., 2018; Kaffle et al., 2018).

3 ChartBERT Model

We introduce ChartBERT, a first BERT-based chart fact-checking model. Our model consists of (i) a

³https://ballotpedia.org/The_methodologies_of_fact-checking

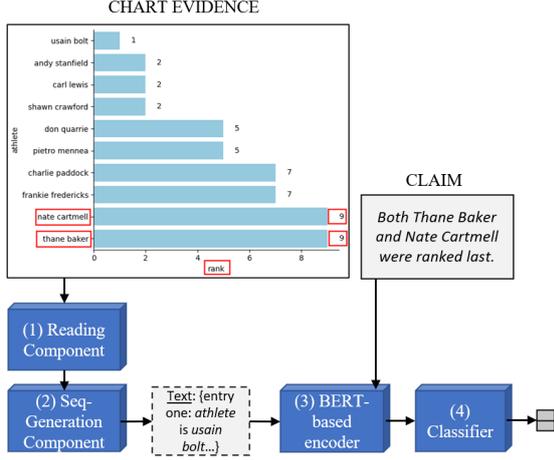

Figure 2: The ChartBERT architecture.

reading component which extracts text and structural information from charts (Section 3.2); (ii) a component for generating textual sequences from the information previously extracted (Section 3.3); and (iii) a BERT-based encoder with additional structural embeddings for the text extracted from charts (Section 3.4). The model architecture is shown in Figure 2.

3.1 Task Formulation

Following previous AFC work (Chen et al., 2020a; Aly et al., 2021; Thorne et al., 2018; Wang et al., 2021b), we view chart fact-checking as a classification task where, given a natural language claim and a piece of evidence (i.e. the chart image), the goal is to decide if the evidence *supports* or *refutes* the claim. We use support/refute as labels for claim classification instead of true/false as we only assess the claim veracity given the provided evidence rather than claiming universal statements.

Each ChartFC sample $i = (c_i, img_i, y_i)$ comprises a natural language claim c_i , a chart image img_i (see Figure 1 for an example), and a label $y_i \in \{supports, refutes\}$.

3.2 Reading Text from Chart Images

Given an image img_i , the reading component extracts text and structural information. First, we detect text regions in the chart using a Tesseract OCR model (Kay, 2007). Specifically, for each image, the model extracts n text regions $T_i = \{t_1, t_2, \dots, t_n\}_{j=1}^n$, where each region t_j consists of $text_j$, a sequence of m tokens, and a rectangular bounding box b_j that surrounds the text region in the chart. The bounding box is a tuple $b_j = (x_j, y_j, w_j, h_j)$ where x_j and y_j are the pixel

coordinates of the top left point of the box, and w_j and h_j represent the width and height of the box in pixels. Thus, for each image img_i we obtain the following output o_i :

$$o_i = f_R(img_i) = \{(text_j, x_j, y_j, w_j, h_j)\}_{j=1}^n$$

3.3 Text Sequence Generation

Next, we process the reading component’s output into a text sequence s_i consisting of m tokens:

$$s_i = f_{SeqGen}(o_i) = [s_1, s_2, \dots, s_m]$$

We compare two approaches as follows.

Concatenation: The concatenation method processes the text regions (i.e. $t_j \in T_i$) based on their coordinates x_j and y_j so that texts that are close in the chart are also close in the generated sequence. The chart text is concatenated into one sequence and tokens that belong to different text regions are separated using a $[\ ;]$ token. Thus, for the chart Figure 1 we obtain a text sequence starting with “usain bolt ; 1 ; andy stanfield ; 2 ; [...]”

Template: We use the structural information (i.e. x, y, w_j, h_j) to fill templates and generate text sequences. We evaluate three templates (an example for each template, extracted from Figure 1, is provided in brackets):

tmp_1 : entry $[num]$: $[l_x]$ is $[text_x]$; $[l_y]$ is $[text_y]$ (entry one: athlete is usain bolt ; rank is 1);
 tmp_2 : “row $[num]$: $[l_x]$ is $[text_x]$; $[l_y]$ is $[text_y]$ ” (“row 0: athlete is usain bolt ; rank is 1”);
 tmp_3 : “[l_x] is $[text_x]$ when $[l_y]$ is $[text_y]$ ” (“athlete is usain bolt when rank is 1”).

The placeholder $[l_x]$ is replaced with the x-axis label from the chart (e.g. “rank” in Figure 1). Similarly, the y-axis label (e.g. “athlete”) replaces $[l_y]$. Based on the coordinates, we classify a bounding boxes that contain axes labels (i.e. the boxes with the largest y coordinates).

A counter starting from *one* replaces $[num]$ and numbers the bars in the chart. We fill $[text_y]$ and $[text_x]$ with text regions detected as bar labels and axis ticks given their positions.

3.4 Encoding and Classification

ChartBERT captures the structure of charts through three learned embeddings: the x coordinate embedding which captures the horizontal location of the text in the chart, the y coordinate embedding which captures the vertical location, and the label embedding which takes value 1 if the text region is part

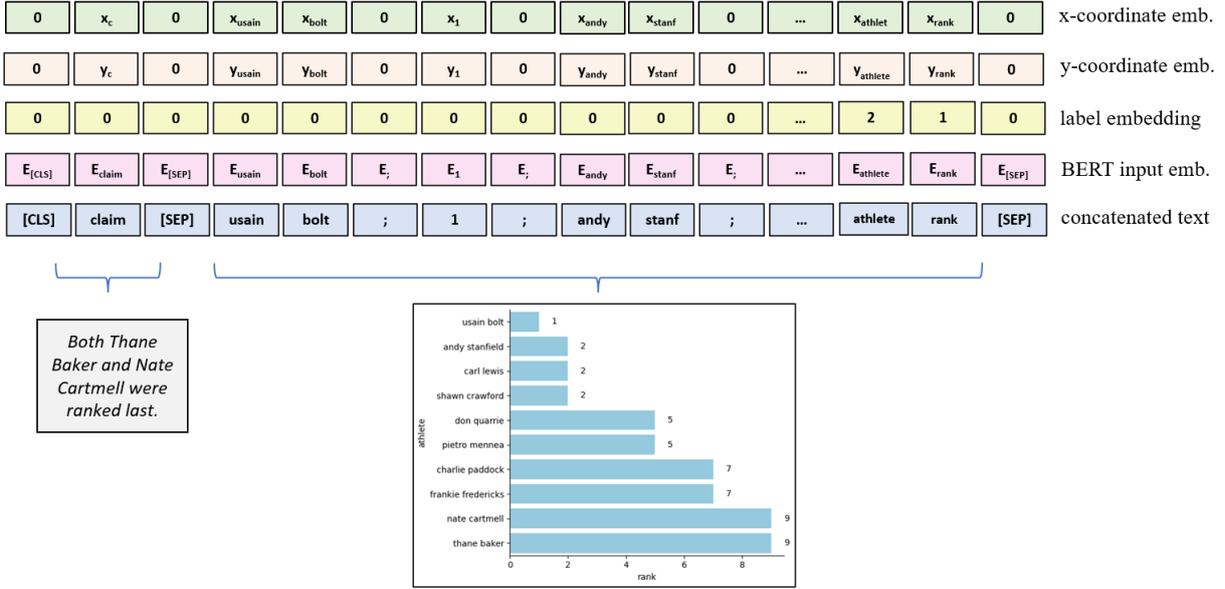

Figure 3: ChartBERT input representation with the text extracted from the chart and concatenated following the approach in Section 3.3. We include additional structural embeddings (i.e. x and y coordinates and label embeddings) to the BERT input embeddings (i.e. token, segment and position embeddings).

of the x -axis label (l_x), 2 if the text region is part of the for y -axis label (l_y) and 0 otherwise.

Figure 3 shows an example of the encoder with the structural embeddings. We concatenate claim c_i and sequence s_i , separate them with a $[SEP]$ token, add $[CLS]$ as the first input token, and feed the resulting vector as input to ChartBERT which generates 768-dimensional representations $h_i \in \mathbb{R}_{768}$. Finally, we pass h_i through a fully connected layer and determine the predicted label using sigmoid. ChartBERT uses binary cross entropy to minimize loss on the training set.

$$inp_i = (c_i, s_i, \{x_j, y_j, l_j^x, l_j^y\}_{j=1}^n)$$

$$h_i = f_{Encoder}(inp_i)$$

$$p_i = \sigma(f_{FC}(h_i))$$

4 Evaluation

For evaluation, we first create a new dataset, ChartFC. We compare ChartBERT with several VL baselines, each comprising three components: a vision encoder, a language encoder, and a fusion block to obtain joint representations. We evaluate the dataset size and potential biases, discuss results obtained with ChartBERT and the baselines, and analyse reasoning types the models fail on.

4.1 ChartFC Dataset

This section provides an overview of the ChartFC dataset and its creation process. Each dataset entry comprises a natural language claim, a chart image, and a label $\in \{supports, refutes\}$.

4.1.1 The TabFact Dataset

We use TabFact (Chen et al., 2020a) as a seed dataset. TabFact is a table fact-checking dataset of natural language claims and tables extracted from Wikipedia as evidence, where the veracity of the claim is decided based on the accompanying table. Claims were written and evaluated by human crowdworkers with at least 95% approval rates for prior tasks and more than 500 accepted HITs on Amazon Mechanical Turk. The inter-annotator agreement for the claim verification task is *Fleiss* $\kappa = 0.75$.

4.1.2 Creation Pipeline

Figure 4 shows the dataset creation process.⁴ Starting with 117,784 claims and 16,000 Wikipedia tables from TabFact, we first generate sub-tables. To link the claim text to table columns, we (i) lemmatize and tokenize the claim and the table content, (ii) link claim tokens to column headers and cells using string matching and heuristic rules, and (iii) decide if a claim token is linked to multiple columns using the minimum *Levenshtein distance*

⁴Figure 8 in the Appendix A illustrates the pipeline.

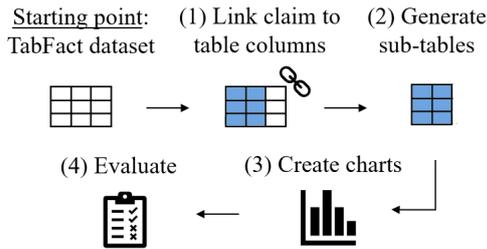

Figure 4: Dataset creation process.

	Train	Valid	Test	Sum
Support	7,048	896	885	8,829
Refute	5,654	697	706	7,057
Sum	12,702	1,593	1,591	15,886

Table 1: Class distribution across dataset split.

(Levenshtein, 1966), and finally, (iv) filter sub-tables with a maximum of twenty rows and two linked columns. This results in a total of 15,886 pairs of claims and sub-tables.

Finally, we generate charts using the Python libraries *seaborn* and *matplotlib*. The charts vary across the dimensions (i) orientation (horizontal, vertical); (ii) bar colors (green, blue, pink); and (iii) background (no/white grid lines, white/gray background color). We show an example in Figure 1. We partition the dataset into training, validation, and test sets using 8:1:1 ratio and show statistics in Table 1.

4.1.3 Dataset Evaluation

To assess the data quality, we apply human and automated evaluation. We evaluate the sub-table generation step (step 2 in Figure 4) by checking the verifiability of claims against the extracted sub-tables with TableBERT (Chen et al., 2020a). We obtain 69.3% accuracy on our test set, comparable to 65.1% accuracy reported by Chen et al. (2020a) on their test set.

For human validation, we extract 100 random dataset entries and manually evaluate the claims against sub-tables and charts. Of the 100 claims, 92 were successfully verifiable against their sub-tables and chart images, six claims were not verifiable because a relevant column was missing in the sub-table, and two claims were already mislabelled in the TabFact dataset.

4.1.4 Chart Reasoning Types

We label 100 random test samples with *chart reasoning types*, using a taxonomy of common reasoning types humans apply while interacting with data

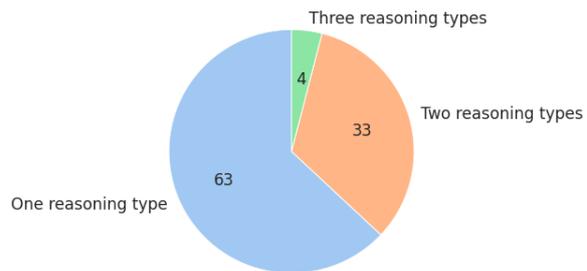

Figure 5: Number of chart reasoning types found in 100 dataset entries.

visualisations (Amar et al., 2005). We find seven reasoning types present in our data: *retrieve value*, *filter*, *comparison*, *compute derived value*, *find extremum*, *determine range*, and *find anomalies*.⁵ On average, we find 1.4 different types per claim with most claims including either one or two different reasoning types (see Figure 5). The reasoning type *retrieve value*, which requires extracting a value from the chart image given certain criteria, occurs most frequently (51%), followed by *find extremum*, i.e. highest or lowest values in the chart, and *filter*, which occur in approximately a quarter of all labelled claims. More complex types such as *compute derived value* or extracting all values in a given *range* are less frequent.

4.2 Vision-Language Baselines

We evaluate our task with several VL baselines, which jointly use claim text and visual information from images for claim verification. We also assess the top-3 VL baselines with OCR-extracted chart text as additional input. Each baseline consists of a language encoder, a vision encoder, and a fusion component to obtain joint representations. We systematically evaluate various state-of-the-art encoders and fusion techniques: we use shallow (e.g. BERT Embedder (Chen et al., 2020b)) and deep encoders (e.g. DenseNet (Huang et al., 2017)), as well as model-agnostic (e.g. concatenation) and model-based (e.g. transformer layers) fusion methods.

Language encoders: Given a claim c_i , we use a language encoder to obtain a feature vector:

$$h_i^{\text{text}} = f_{\text{LangEncoder}}(c_i)$$

We experiment with three language encoders:

BERT Embedder: Following Chen et al. (2020b),

⁵We describe the chart reasoning types in detail and give examples in Appendix B.

we tokenize the claim text into sub-words. For each token, we add the word and position embeddings to obtain the text representation which we then pass through a normalization (Ba et al., 2016) layer.

LSTM: We encode the text with 32-dimensional word embeddings and pass them through two LSTMs (Hochreiter and Schmidhuber, 1997) with 768-dimensional hidden states in each layer. We use the hidden states of the second layer as text representations.

BERT: We use a twelve-layer BERT encoder, initialized with weights from a pretrained BERT-base model.

Vision encoders: We use a vision encoder to extract representations for the chart images:

$$h_i^{\text{img}} = f_{VisEncoder}(img_i)$$

We evaluate five vision encoders:

Fully connected layer: We use a fully connected layer to extract 768-dimensional representations per image $h_i^{\text{img}} \in \mathbb{R}_{768}$.

AlexNet: Using AlexNet (Krizhevsky et al., 2012), for each image, we obtain a representation vector $h_i^{\text{img}} \in \mathbb{R}_{1024}$ by extracting the model output after the third max pooling layer.

ResNet: We use ResNet-152 (He et al., 2016) to obtain 2048-dimensional image representations by extracting the model output before the two final layers of ResNet-152, i.e. before the average pooling layer.

DenseNet: We use a DenseNet (DN) (Huang et al., 2017) comprising three dense blocks, with 6, 12, and 24 layers, respectively. We extract and concatenate the output of the first and third dense block as low- and high-level feature vectors: $h_i^{\text{img}} = f_{concat}(f_{DN[block1]}(img_i); f_{DN[block3]}(img_i))$.

Vision Transformer (ViT): We split images into sequences of n 16x16 patches before using them as input to a pretrained base-ViT model (Dosovitskiy et al., 2021).⁶ We extract the hidden states from the model’s final layer and use them as image representations, resulting in 768-dimensional vectors for each patch: $h_i^{\text{img}} = [h \in \mathbb{R}_{768}]_n$.

Fusion methods: We then fuse the text and image representations:

$$h_i^{\text{joint}} = f_{Fusion}(h_i^{\text{img}}; h_i^{\text{text}})$$

We experiment with five fusion methods:

Concatenation and multiplication: Concatena-

⁶<https://huggingface.co/google/vit-base-patch16-224>

tion and multiplication are common baseline approaches for multimodal fusion (Baltrušaitis et al., 2018). We reshape the text and image representations and either (i) concatenate both vectors, or (ii) perform element-wise multiplication.

Concatenation with GRUs: Inspired by Kafle et al. (2020), we concatenate the text and image representations and pass the resulting vector through m 1x1 convolutional layers and two GRUs. The first GRU takes the input in a forward direction, while the second GRU processes the input vector in a backwards direction to incorporate contextual information:

$$h_i^{\text{concat}} = f_{conv}(f_{concat}\{h_i^{\text{img}}; h_i^{\text{text}}\})$$

$$h_i^{\text{joint}} = f_{concat}\{f_{GRU}(h_i^{\text{concat}}); f_{GRU}(h_i^{\text{concat}})\}$$

Multimodal Compact Bilinear Pooling (MCB):

MCB is an efficient and popular baseline for multimodal fusion (Fukui et al., 2016). The text and image representations are each projected to a higher dimensional space using the projection function Count Sketch (Charikar et al., 2004). The outer product of the projected vectors is then calculated in Fast Fourier Transform space to obtain a joint representation for both modalities and thus reduce the amount of learnable parameters during model training.

Transformer layers: Given the recent popularity of transformer layers used for joining text and visual representations (Tan and Bansal, 2019; Chen et al., 2020b; Yang et al., 2021), we use a three-layer transformer to get cross-modal embeddings.

The representation h_i^{joint} is passed through two fully-connected layers and sigmoid to obtain the classification. We use binary cross entropy loss and stratified sampling in each training batch to minimize the loss on the training set.

4.3 Experimental Setup

We perform hyper-parameter search on the validation set and select the best-performing combination from the following values: $\{8, 16, 32\}$ for batch size, $\{1e^{-3}, 7e^{-4}, 5e^{-5}, 5e^{-6}, 5e^{-7}\}$ for learning rate, $\{1, \dots, 50\}$ for training epochs with early stopping. We also experimented with different learning rates for the language and vision encoders. Ultimately, we used one learning rate for the entire VL model as the modality-specific learning rates did

SeqGen	Val Acc	Val F ₁	Test Acc	Test F ₁
concat.	59.2	55.1	60.6	57.0
temp. <i>tmp</i> ₁	62.4	59.1	63.3	61.0
temp. <i>tmp</i> ₂	62.0	59.4	61.9	58.7
temp. <i>tmp</i> ₃	62.1	59.7	63.8	61.1

Table 2: Results for ChartBERT with different sequence generation (SeqGen) approaches: **concatenation** and **template**.

V-Encoder	Fusion	no OCR	text concat
ViT	concat GRU	59.8	60.5

not provide any performance gains.⁷

We run all experiments on a single NVIDIA Tesla V100 GPU with 32GB RAM. We measure model performance with prediction accuracy and (macro) F_1 on the test dataset.

4.4 Results & Discussion

How does ChartBERT perform on the task? How do different approaches for sequence generation influence model performance?

Table 2 gives an overview of the results obtained by ChartBERT. The best ChartBERT variant yields 63.8% test accuracy and processes chart text into text sequences using the template *tmp*₃. Compared to the concatenation approach, using *tmp*₃ increases the accuracy by +3.2%.

Interestingly, the choice of template design impacts the model performance only slightly. While template *tmp*₃ might seem more “natural” to humans, it does not yield much higher performance compared to *tmp*₂.

How do VL baselines perform on ChartFC? How does the selection of encoder or fusion method impact model performance?

In contrast to many state-of-the-art VL approaches that use simple vision encoders and attention-based fusion (Chen et al., 2020b; Kim et al., 2021; Xia et al., 2021), the three best-performing VL models on ChartFC use BERT as language encoder, ViT or ResNet to obtain image representations, and either concatenation, multiplication, or concatenation with GRUs as a fusion method. Using only the claim and chart as input

⁷The hyper-parameters for each VL baseline can be found in our GitHub repo.

(i.e. without the OCR-extracted chart text), the highest test accuracy we obtain is 60.1% with the model consisting of BERT, ResNet, and multiplication fusion (see Table 3).

Regarding the language encoder,⁸ models that use BERT perform best, irrespectively of the vision encoder and fusion method: the best LSTM-based model achieves 56.1% test accuracy and the best model with BERT embedder yields 56.5% accuracy, both lower than the best BERT-based VL model with 60.1% accuracy. In contrast, we obtain similar accuracy scores across different vision encoder: for example, replacing ResNet in Table 3 row two with a fully connected layer reduces the accuracy slightly by 0.6% to 59.7%. The choice of fusion method does not impact performance strongly: while using multiplication mostly outperforms other methods by a small margin, no fusion method stands out across all vision and language encoders. We also evaluate the chartQA model PReFIL (Kafle et al., 2020), which uses LSTM as language encoder, DenseNet for image representations, and concatenation with GRUs for fusion, and obtain on ChartFC a low test accuracy of 55.6%.

How does OCR-extracted chart text influence performance of VL models?

In addition to claim text and chart images used in VL baselines, we also include the text extracted from the charts through OCR as input (see Sections 3.2 and 3.3 for details). Table 3 shows that using the concatenated chart text as input improves accuracy compared to the models that do not use the chart text (e.g. from 59.8% to 62.7%). The highest accuracy 62.7% is obtained with the BERT-ResNet-concatenation baseline.

Do models fail on particular chart reasoning types?

We evaluate the best VL baseline, consisting of BERT, ViT, and concatenation with GRUs, on the chart reasoning types present in ChartFC and described in Section 4.1.4. We find that the model performs best on the reasoning types *retrieve value*, *filter*, and *finding extremum*, while struggling particularly with *compute derived values*. Figure 6 shows that the model classifies correctly 65% (i.e. 33 out of 51) of claims that require *retrieval* and 61% of claims that require *filtering*. However, only 50% of *comparison* claims and 38% of claims required to *compute derived values* are correctly predicted.

⁸The complete set of results obtained with different encoders and fusion methods can be found in Tables 5, 6, and 7 in the Appendix.

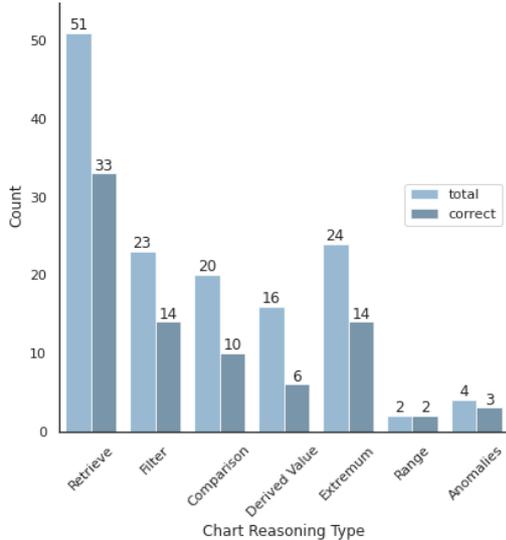

Figure 6: Chart reasoning types: total count and correct predictions of manually annotated test samples.

These results are in line with previous works that discuss limitations of state-of-the-art models in tasks requiring numerical reasoning capabilities (Thawani et al., 2021).

Is the dataset size sufficient for our proposed task? Do ChartFC claims contain biases?

We evaluate the size of the dataset by training our VL baseline (i.e. using BERT, ViT, and concatenation with GRUs) on various subsets of the training data as shown in Table 4 and report the accuracy on the test set. The performance on the test set improves as the number of training samples increases. While the performance gain is high when increasing the training set from 1% to 25% (51.6% accuracy compared to 57%), the difference in accuracy between the baseline trained on half of the training data and the entire training data is only 2.6%, indicating that our training set has a reasonable size.

We also train a claim-only BERT model to determine whether claims contain biases that allow the model to correctly predict the label while ignoring the evidence charts. Trained on the claim text only, the model achieves 52% accuracy on the test set, compared to ChartBERT’s accuracy of (63.8%). We conclude that the claim text itself is not sufficient for correct classification.

What are the dis-/advantages of an automated dataset pipeline for chart fact-checking?

We automatically create ChartFC using a table fact-checking dataset as seed by identifying subtables relevant to the claims and then building the

Training Samples	Test Accuracy
127 (1%)	51.6
3,175 (25%)	57.0
6,351 (50%)	57.1
9,526 (75%)	58.0
12,702 (100%)	59.8

Table 4: Performance of VL baseline (BERT, ViT, and concatenation with GRUs) with different training set sizes.

charts. ChartFC includes common stylistic variations: bars of different colors, horizontal/vertical orientations, different backgrounds (light/dark, grid lines/no grid lines). While natural charts come with large stylistic variation, using them results in reduced control over task complexity and dataset. In future work, we plan to explore two alternative dataset creation pipelines: first, automated pipelines for other charts types to extend the current dataset, and second, a pipeline with natural charts where we would create claims for charts.

Using natural charts would require a multi-step annotation process: selecting and separating charts from other images (Vougiouklis et al., 2020); writing claims which support/refute them; evaluating the claims to check for correctness, typos, etc. We would require annotators with proficiency in interpreting charts, and with basic mathematical and language skills to create claims with different reasoning types (see Figure 5).

5 Conclusion and Future work

We propose the chart fact-checking task and introduce ChartBERT, a novel model for fact-checking claims against chart images comprising three main components: a reading component, a sequence generation component, and an encoder that extends BERT’s encoder with structural embeddings. We also introduce ChartFC as the first dataset for fact-checking against chart images, consisting of 15, 886 claims and chart images.

ChartBERT achieves 63.8% accuracy on ChartFC. We systematically evaluate 75 different VL baselines, using various language encoders, vision encoders, and fusion methods. The highest-performing VL baseline uses BERT as language encoder, ResNet to extract image representations, and concatenation to obtain joint representations for both modalities. The model achieves 62.7% test accuracy. Our results indicate that chart fact-checking, which requires extracting and reasoning over text and structural information from charts, is

a challenging task for future research on AFC and VL methods.

Limitations

The TabFact dataset (Chen et al., 2020a) has been a valuable resource for creating ChartFC. However, using it as (the sole) seed dataset has limitations.

ChartFC consists of bar charts only; indeed, given the claims and tables found in TabFact, the bar chart was deemed the most appropriate chart type. Various types of charts exist (e.g. pie charts, line charts) and their effectiveness in different data contexts and tasks has been investigated in the literature. For example, Saket et al. (2019) evaluated the effectiveness of chart types using crowdsourcing experiments across the chart reasoning types we discussed in Section 4.1.4. In the context of small datasets, i.e. up to 34 rows and two columns which is similar to our setting, Saket et al. (2019) found bar charts to be the most accurate visualization type for the given chart reasoning types. In addition to bar charts, other types of charts used as evidence for fact-checking tasks ought to be investigated. Behrisch et al. (2018) studied visualization methods for different data types (i.e. multi- and high-dimensional data, relational data, geo-spatial data, sequential and temporal data, and text data). For example, they found that scatter plots were appropriate visualization types for queries regarding data distribution (e.g. correlations and clusters), while line charts were more appropriate for queries about temporal aspects of data. To extend ChartFC with other chart types, we require more diverse data types (e.g. sequential and temporal data) and appropriate claims.

Moreover, ChartFC claims are restricted to English, whereas misinformation is commonly spread in different languages. Future work is necessary to address the limited availability of non-English fact-checking datasets and to contribute to the efforts done in this space (Gupta and Srikumar, 2021).

A Dataset Pipeline

ChartFC charts vary across the dimensions (*i*) orientation (horizontal, vertical); (*ii*) bar colors (green, blue, pink); and (*iii*) background (no/white grid lines, white/gray background color). Figure 7 shows multiple chart examples.

In Figure 8, we give an example of the dataset creation pipeline. Starting with the claim and initial TabFact table, we first filter columns required to decide the claims veracity label: “age at appointment” and “prior occupation”. This sub-table is used to create the evidence chart (bottom right).

B Chart Reasoning Types

We label 100 random test set samples with chart reasoning types. Next, we briefly describe each type, for more details we refer to the taxonomy by [Amar et al. \(2005\)](#):

- Retrieve Value: Given some conditions, retrieve a single value from the chart image.
- Filter: Find all data points in the chart that fulfill some specified conditions.
- Compute Derived Value: Calculate an aggregated value (e.g. average or count) using data points extracted from the chart.
- Find Extremum: Extract the top- n data points given some conditions.
- Determine Range: Based on some conditions, find a span of values such that all extracted data points fulfil the conditions.
- Find Anomalies: Find any anomalies in a specified set of data points.
- Compare: Compare the values of different data points to each other.

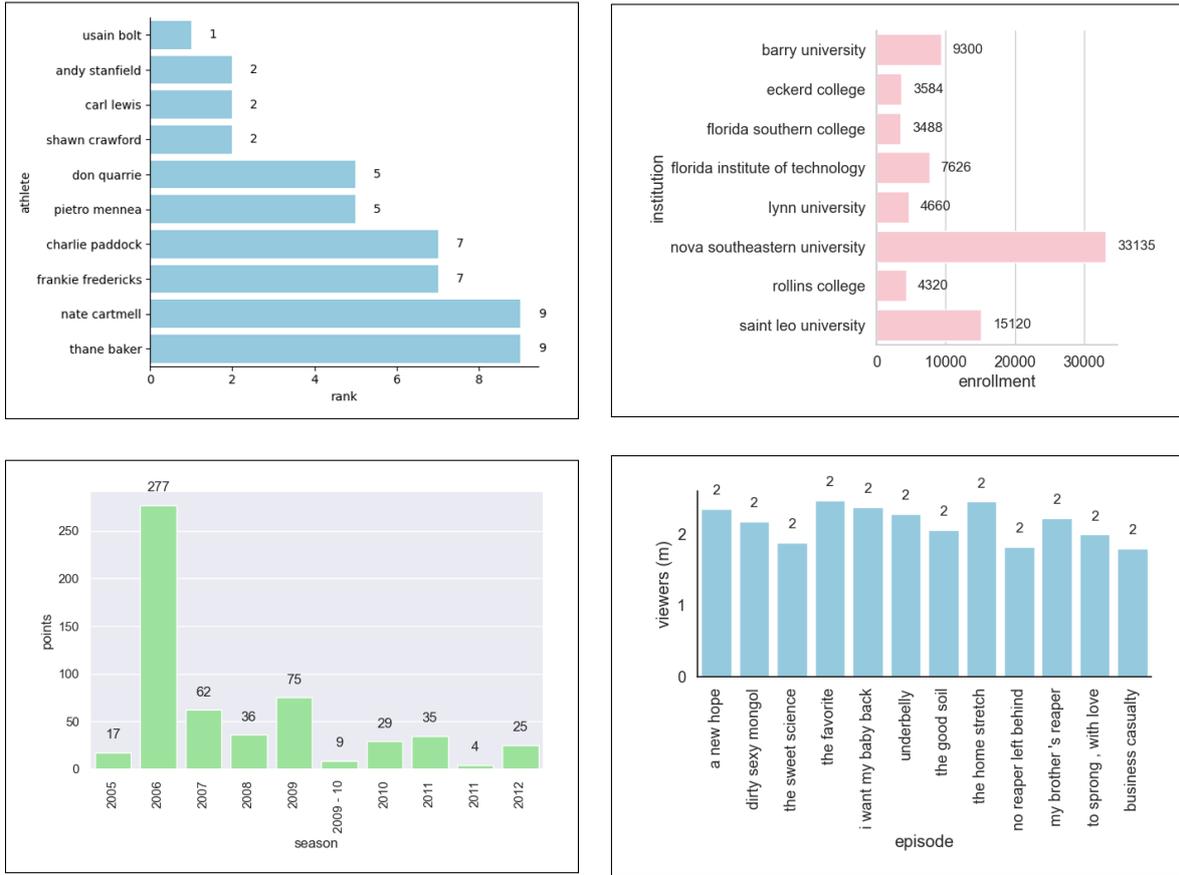

Figure 7: Examples from the ChartFC dataset.

Claim: There are four people who were appointed at secretary at the age of 50.

1. Initial table

	romanised name	chinese name	age at appointment	portfolio	prior occupation
0	donald tsang yam - kuen	曾蔭權	58	chief secretary for administration (cs)	chief secretary for administration (cs)
1	anthony leung kam - chung	梁錦松	50	financial secretary (fs)	financial secretary (fs)
2	elsie leung oi - see	梁愛詩	63	secretary for justice (sj)	secretary for justice (sj)
3	joseph wong wing - ping	王永平	54	secretary for civil service	secretary for civil service
4	henry tang ying - yen	唐英年	50	secretary for commerce , industry and technology	chairman , federation of hong kong industries

2. Subtable

	age at appointment	prior occupation
0	58	chief secretary for administration (cs)
1	50	financial secretary (fs)
2	63	secretary for justice (sj)
3	54	secretary for civil service
4	50	chairman , federation of hong kong industries

3. Chart

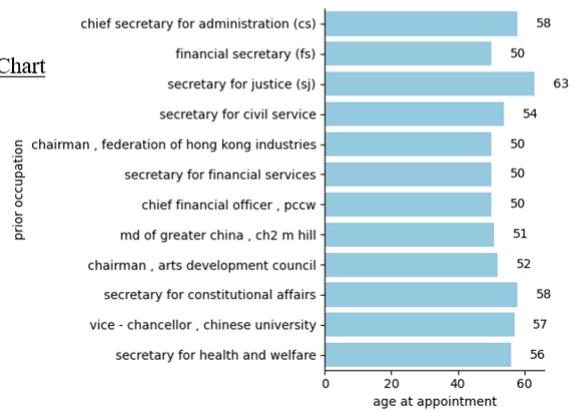

Figure 8: Example for dataset creation process.

Abstract

Entities and events are crucial to natural language reasoning and common in procedural texts. Existing work has focused either exclusively on entity state tracking (e.g., *whether a pan is hot*) or on event reasoning (e.g., *whether one would burn themselves by touching the pan*), while these two tasks are often causally related. We propose CREPE, the first benchmark on causal reasoning of event plausibility and entity states. We show that most language models, including GPT-3, perform close to chance at .35 F1, lagging far behind human at .87 F1. We boost model performance to .59 F1 by creatively representing events as programming languages while prompting language models pretrained on code. By injecting the causal relations between entities and events as intermediate reasoning steps in our representation, we further boost the performance to .67 F1. Our findings indicate not only the challenge that CREPE brings for language models, but also the efficacy of code-like prompting combined with chain-of-thought prompting for multihop event reasoning.¹

1 Introduction

Event-centric natural language processing (Chen et al., 2021b) is one of the leading paradigms in machine understanding of texts. This line of work focuses on first extracting entities and events from texts (Yang et al., 2019; Du and Cardie, 2020) and then making inferences about them (Li et al., 2020; Du et al., 2021). Even with the recent advances of large language models (LLMs), reasoning about events remains challenging as it requires highly contextual information and ample common-sense knowledge. For example, the event “*adding water to a pan containing hot oil*” causes the event “*there is a sizzling sound*” to happen, while “*heat up an*

^{*}Equal contribution.

¹Data and code can be found at https://github.com/zharry29/causal_reasoning_of_entities_and_events.

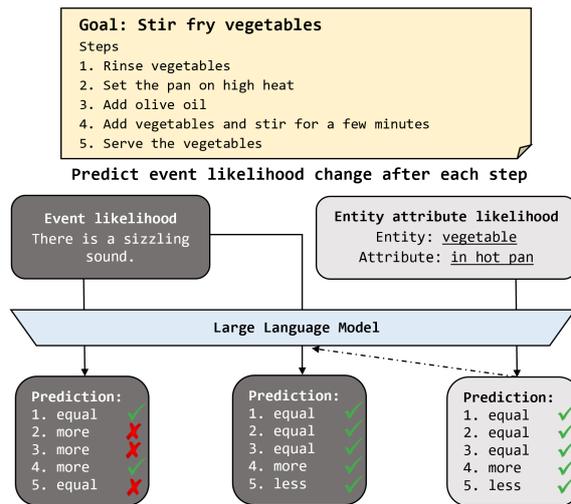

Figure 1: Example of our task CREPE. A procedure including a goal and some steps are provided. A model needs to predict the change in the likelihood of an event throughout the procedure. We show that predicting entity states as an intermediate step improves performance.

empty pan” does not. Any model that can draw the correct conclusion given these contexts is expected to have access to some implicit knowledge about these entities and events.

One type of text which demonstrates these challenges is procedural text, namely sequences of events, such as how-to instructions, recipes, natural processes, scientific protocols, etc. Procedural texts describe an environment that changes dynamically through a sequence of steps. Therefore, the exact environment configuration is often implicit. In the previous cooking example, whether “*there is a sizzling sound*” depends on what steps have taken place. With these interesting challenges coupled with the added benefit of application to robotics (Brohan et al., 2022) and household smart assistants such as Alexa (Panagopoulou et al., 2022), reasoning about procedures attracts great attention from the NLP community (Zhang, 2022).

Most work on reasoning about procedural texts has focused solely on either predicting the proper-

ties of events (e.g., which event is more likely to happen) (Zhang et al., 2020c; Yang et al., 2021b; Tandon et al., 2019) or tracking entity states (e.g., what is some property of an entity after some step) (Dalvi et al., 2018; Tandon et al., 2020), while the causal relation between events and entities is largely underexplored – for example, whether “*there is a sizzling sound*” is determined by the state of “*water*” and “*oil*.” Therefore, we claim that many event prediction tasks are multihop reasoning tasks that require the knowledge of intermediate entity states. Causal reasoning about events and entities differs from existing multihop reasoning tasks, such as Yang et al. (2018); Dua et al. (2019) whose reasoning process is explicitly formulated by a direct question (e.g., *how old is the previous US president*); and Geva et al. (2021) whose supporting evidence is factual and static. In contrast, causal reasoning in procedures requires models to first figure out the relevant entity attributes, then infer their states based on the current context, and finally predict the event.

To this end, we propose the task of **Causal Reasoning of Entities and Events in Procedural Texts (CREPE)**, with an overview in Figure 1. Given a procedure consisting of a goal (“*stir fry vegetables*”) and some steps (“*rinse vegetable*”...), a model is to predict the likelihood of some unobserved events (“*there is a sizzling sound*”) after the execution of each step. We provide a handcrafted, high-quality benchmark containing 183 procedures, 1219 steps, and 324 changes in the likelihood of events along with the corresponding underlying entity state changes. In an in-context learning setting, we show that most LLMs including GPT-3 (Brown et al., 2020) perform no better (.350 F1) than chance (.297 F1), greatly underperforming the human performance of .868 F1, on the development set. Providing ground-truth entity state changes to the prompt of GPT-3 shows no performance gain, indicating that it cannot leverage this causal signal. Instead, we draw inspiration from Madaan et al. (2022) who represented texts as programming languages as the prompt to code language model Codex (Chen et al., 2021a) to perform event reasoning. We propose a novel Python code representation of procedures that achieves .585 F1. Furthermore, our code-like representation allows us to effectively encode and leverage predicted or labeled entity state changes by generating them as an intermediate reasoning step (namely, chain-of-

thought), boosting the performance to .667 using predicted entity state changes and .715 F1 using labeled entity state changes.

Our contributions are summarized as follows:

- We propose a novel task, a dataset, and several strong baselines for causal reasoning about events and entities in procedural texts.
- We devise an effective code-like representation of procedures, leading to superior performance and allowing the injection of structured knowledge for reasoning.
- We are among the first to show that code language models can apply chain-of-thought to tackle multihop reasoning.

2 Task and Hypothesis

A procedure P of length n consists of a goal G and some steps $s_1 \dots s_n \in S$, each represented as a short sentence. Each procedure is associated with a set of hypothetical events $e_1 \dots e_m \in E$ whose likelihood of happening changes throughout the procedure. The task is to predict the change of likelihood of a hypothetical event e_j from step s_{i-1} (the previous step) to step s_i (the current step):

$$\delta_i = p(e_j | s_i, \dots, s_1, G) - p(e_j | s_{i-1}, \dots, s_1, G)$$

The likelihood change δ_i is positive if the label is “more likely”, negative if “less likely”, or zero if “equally likely”.

Predicting the likelihood of hypothetical events, also known as counterfactual reasoning, is extremely important for machine reasoning (Pearl and Mackenzie, 2018) (see more in Section 7). In our work, we hypothesize that **the causal relation between entity changes and events** can be leveraged by LLMs to better perform counterfactual reasoning. In other words, any change of the likelihood of a hypothetical event is given rise to by changes of some entity attributes $a_1 \dots a_m \in A$.

$$\delta_i = p(a_j | s_i, \dots, s_1, G) - p(a_j | s_{i-1}, \dots, s_1, G)$$

3 Dataset

Our CREPE benchmark dataset has two portions. The first is handcrafted and cross-validated by six authors of this paper. The annotation happens in 3 phases: (1) we first write down or acquire a procedure from the web; (2) we then annotate some hypothetical events whose likelihood of happening changes throughout the procedure, and how their likelihood change after each step; (3) for each

Data Statistics

Table 1: Statistics of the CREPE dataset.

event, we annotate a tuple of entity, attribute, and change that causes the event likelihood change. To obtain interesting and challenging data, we require annotators to write procedures covering a diverse range of topics and to prioritize events that undergo multiple likelihood changes, and those that involve information implicit from the steps. In our work, we strictly use this portion as the development set to inform all our experimental designs.

The second portion, designed to be drawn from a different distribution to minimize bias, was annotated by students in an Artificial Intelligence class at the University of Pennsylvania who participated in an extra-credit assignment. The students were given an overview of the project and some guidelines to annotate data with the aforementioned criteria. We carefully validated all resulting annotations by discarding or editing erroneous and inappropriate examples. In our work, we strictly use this portion as the test set to evaluate the generalization ability of our final models. The complete dataset and annotation instructions can be found in our public repository containing no personally identifiable information of any annotator.

The statistics of CREPE are in Table 1. In this work, we consciously focus on few-shot and in-context settings because our data annotation inevitably contains bias and limitation, and thus cannot be truly representative of counterfactual reasoning in every scenario. In such cases, we believe having a sizeable training set aggravates such biases and induces spurious artifacts.

4 Event Likelihood Prediction

The task of CREPE is essentially ternary classification, where the likelihood change of each event after each step is labeled as one of “more likely”, “less likely”, or “equally likely”. In this section, all models have no access to the annotated entity state changes until later sections.

4.1 Baselines

To show the challenge CREPE brings to existing models, we first introduce some naive baselines.

- The **chance** baseline assigns random labels.
- The **majority** baseline always assigns the majority label “equally likely”.

Next, we consider the following state-of-the-art LLMs as strong baselines, where all models are given exactly three examples in their prompt:

- **T5** (Raffel et al., 2020) is one of the state-of-the-art LLMs. Given the goal, steps, and question formatted by a prompt template, we compare the probability of generating “the answer is no|yes.” We use T0-3B² with 3 billion parameters.
- **T0** (Sanh et al., 2022) is a variant of T5, finetuned on a large set of downstream tasks with natural language prompts. We adopt the same inference process as T5 described above. We use T0pp³ with 11 billion parameters.
- **GPT-3** (Brown et al., 2020) is a series of LLMs that excels at few-shot learning using the prompting mechanism. We consider text-curie-001 (7B parameters), text-davinci-002, text-davinci-003, and ChatGPT (all 175B parameters). We use default parameters with a temperature of 0 for deterministic predictions. An example of the prompt is shown in Figure 2.
- **GPT-3 finetuned on StrategyQA** is a GPT-3 curie model finetuned with StrategyQA (Geva et al., 2021), a dataset of factual multihop questions and their decomposition. StrategyQA is similar to our task in that estimating the change of event likelihood can also be decomposed into sub-tasks of estimating the change of state of related entities (Section 5.1).

Table 2 shows that all state-of-the-art LLMs we have attempted achieve close-to-chance performance on CREPE around 0.350 F1, whereas text-davinci-003 and ChatGPT which are

Goal: Wash sneakers
 Context: I remove shoelaces. I rinse.
 Question: What is the likelihood that my feet get wet by wearing the sneakers?
 Answer: likely

Figure 2: Our GPT-3 prompt, which is typical for a QA task. Each likelihood label is compared with the previous one to get the label for the change.

known to be stronger at reasoning perform better. Details about prompt formulation and experimental results on prompt sensitivity are shown in Appendix B and A.

4.2 Representing Procedures as Python Code

Codex (Chen et al., 2021a) is a variation of GPT-3 that was designed to be prompted with and to generate code, in addition to natural language texts. Recently, Madaan et al. (2022) found that prompting Codex with some structured representation such as Python code. Inspired by this observation, we propose novel code representations of procedures and hypothetical events. Among many possibilities we experimented with, the representation with the best empirical performance is described below, later shown to greatly outperform all baseline models. The representation is exemplified in Figure 3.

The procedure is represented as a class where the goal G is the class name, followed by the steps s_i as comments. Then, each step is defined as a member function, in which the hypothetical events e_j are represented as objects with comments. Each event object has an attribute “change” whose value describes the change of the likelihood. During inference, Codex is provided with the prompt including three in-context examples and the current procedure up to the definition of the “init” function and predicts the definition of all step functions. Finally, we extract the assigned value of the “change” attribute as the event likelihood change δ_i .

This prompt design effectively leverages the semantic similarity between procedures with entity states and functions with variables, by representing texts as function identifiers and comments. We use code-davinci-002⁴ with 175B parameters and default hyperparameters with a temperature of 0.

⁴While OpenAI announced that text-davinci-002 is based on code-davinci-002 (<https://platform.openai.com/docs/model-index-for-researchers>), we empirically find the former to perform worse with our code prompt and thus only consider the latter with code prompt.

```
class Wash_Sneakers:
    # Init
    # Remove shoelaces
    # Rinse
    def __init__(self, event0):
        self.event0 = event0 # My feet get
            wet by wearing the sneakers.
    def remove_shoelaces(self):
        self.event0.change = "equally likely
            " # My feet get wet by wearing
                the sneakers.
    def rinse(self):
        self.event0.change = "more likely" #
            My feet get wet by wearing the
                sneakers.
```

Figure 3: Our best-performing Python code representation of a procedure and hypothetical events, for Codex.

4.3 Results

As CREPE is a ternary classification task, we report the macro F1 score across the three classes. As shown in Table 2, T5 and T0 perform only slightly better (.343 and .336 F1) than chance (.297 F1). GPT-3, one of the most dominant models across a variety of NLP tasks, is no better (.336 F1), whereas finetuning it on another multihop reasoning dataset StrategyQA does not bring about any improvement (.341 F1). The latest GPT-3 models, text-davinci-003 (.424 F1) and ChatGPT (.470 F1) which were released contemporarily with this paper, greatly outperform their predecessors.

On the other hand, our code-representation of events as the prompt to Codex greatly outperforms all other models with .585 F1. As Codex is trained on public Github code in addition to the internet texts that GPT-3 is trained on, it is noteworthy that Codex can effectively reason about texts with code-like structures, for a procedure has many analogies to a class in object-oriented programming.

4.4 Ablation Studies

To understand why the representation in our Codex prompt is effective, we perform an ablation study with various changes of the format to the representation, including:

- Remove steps comments in the beginning
- Remove event comments in step functions
- Use nested functions instead of a class
- Use flat variables to encode goals, steps, and events (no hierarchical class functions)

Examples of these empirically inferior representations are shown in Appendix B. As seen in Table 3, the hierarchical representation of procedures, steps,

Params	Naive		Large Language Models								Human

Test	.251	.296	.343	.337	.356	.346	.533	.423	.462	.591	-

Table 2: Macro F1 of baseline models on the CREPE dataset. Human performance is not benchmarked on the test set as we strictly hold out its labels during all experiments. GPT3C represents the text-curie-001 model. GPT3D2 represents the text-davinci-002 model with an abnormal performance on the test set that we have confirmed but regrettably cannot explain. GPT3D3 represents the text-davinci-003 model. GPT3C+S represents the GPT-3 curie model finetuned on StrategyQA. All of the above models work with textual prompts. Codex represents the code-davinci-002 model and works with our proposed code-like prompts.

	Dev	Test
Codex	.585	.591
no step comments	.377	.352
no event comments	.576	.555
nested function	.568	.572
flat variables	.338	.341

Table 3: Macro F1 of the ablations of our Codex prompt.

and events as classes or nested functions is critical. Besides, listing all the steps as comments helps, mimicking a programmer’s textual explanation of a class or a function.

5 Causal Reasoning with Entities

When a human tries to predict whether the event “one would get burnt by touching a pan” is likely, their reasoning process would first focus on some entities in the question (e.g., “the pan”), then attend to some attributes and states of that entity (e.g., the temperature of the pan is hot), and finally draw a logical conclusion (e.g., “the pan being hot means one would get burnt by touching it.”) CREPE is constructed precisely with this thought process in mind. An entity-attribute-change tuple is annotated along with each event likelihood change. In this section, we study how to explicitly leverage the intermediate information to assist the prediction of event likelihood prediction.

5.1 Predicted Entity States as CoT

In CREPE, the task of predicting event likelihood change can be seen as a case of multihop reasoning, where a model first decomposes the question into some open-ended sub-questions, answer these sub-questions, and aggregate them as a final answer. LLMs can be prompted to perform chain-of-thought (CoT) style reasoning (Nye et al., 2021; Wei et al., 2022). Thus, we ask the question:

Q1. Can LLMs benefit from first **predict-**

Goal: Wash sneakers
Context: I remove shoelaces. I rinse.
Question: What is the likelihood that my feet get wet by wearing the sneakers?
Answer: To get feet wet by wearing the sneakers, the sneakers must be wet. In the given context, the sneakers are wet. Therefore, comparing to the previous step, the likelihood change is “more likely”.

Goal: Wash sneakers
Context: I remove shoelaces. I rinse.
Question: What is the likelihood that my feet get wet by wearing the sneakers?
Follow up: Are the sneakers wet?
Intermediate answer: Yes
Follow up: Will my feet get wet by wearing wet sneakers?
Intermediate answer: Yes
Answer: likely

Figure 4: Our GPT-3 prompt with intermediate questions, mimicking the CoT prompt (top) and the Self-Ask prompt (bottom).

ing entity state changes, as a CoT, before predicting event likelihood changes?

CoT with GPT-3. First, we prompt GPT-3 with Wei et al. (2022)’s CoT paradigm and Press et al. (2022)’s self-ask paradigm, both of which are shown in Figure 4. While self-ask relies on search engines for fact retrieval, we use LM generation instead as most of our entity state tracking questions are heavily context-dependent and unanswerable by any search engine. When writing demonstrations for few-shot learning, we impose the following logic progression for the follow-up questions: (1) initial followups shall ask questions on the state of entities that are directly related to the event; (2) followups following the entity state questions shall ask for the logical relationship between the entity states and the original event.

	Naive	LLMs		CoT Large Language Models				Human
	Majority	GPT-3	Codex	GPT-3 + CoT	GPT-3+self-ask	Codex soft (ours)	Codex hard (ours)	
Dev	.297	.346	.585	0.359	.342	.624	.667	.868
Test	.296	.356	.591	0.379	.345	.626	.609	-

Table 4: Macro F1 of chain-of-thought models on the CREPE dataset. GPT-3 + CoT|self-ask represents the text-davinci-002 model prompted with the CoT or self-ask style prompt.

CoT Codex with Soft Entity Representation.

We modify our Codex prompt in Figure 3, so that a sub-event is represented as a string variable whose declaration and value assignments are right before those of the hypothetical event. We refer to this as a *soft representation* of entities (Figure 5). During inference, Codex is provided with the code up to the step function header and predicts the entity and event changes for every step function. Our Codex model achieves the new best performance of .624 F1, outperforming the same model without predicted entities as CoT by .039 F1.

```
class Wash_Sneakers():
    # Init
    # Remove shoelaces
    # Rinse
    def init(self, event0, subevent0):
        self.event0 = event0 # My feet get
            wet by wearing the sneakers.
        self.event0.subevent = subevent0 #
            The sneakers are wet
    def remove_shoelaces(self):
        self.event0.subevent.change =
            "equally likely" # The sneakers
                are wet
        self.event0.change = "equally likely
            " # My feet get wet by wearing
                the sneakers.
    def rinse(self):
        self.event0.subevent.change =
            "more likely" # The sneakers are
                wet
        self.event0.change = "more likely" #
            My feet get wet by wearing the
                sneakers.
```

Figure 5: Our Codex prompt with a soft representation of entity state changes as strings.

CoT Codex with Hard Entity Representation.

The two approaches above both *softly* represent the intermediate entity state changes as texts, either questions or statements. Here, LLMs are not enforced to generate intermediate reasoning steps that contain entities and attributes. To answer Q1 more precisely, we experiment with a *hard entity representation* where the entity-attribute-change tuple is explicitly baked into the Codex prompt as shown in Figure 6. Here, each entity is represented as an

	Dev	Test
Majority	.297	.296
GPT-3 CoT	.342	.345
w/ gold entity changes	.351	.380
Codex CoT	.667	.609
w/ gold entity changes	.715	.722
Human	.868	-

Table 5: Macro F1 of GPT-3 and Codex with chain-of-thought provided with gold entity state changes.

object with an attribute and assigned value. The hard entity representation leads to a far superior performance of .667 F1 on the development set but generalizes worse on the test set with .609 F1.

```
class Wash_Sneakers():
    # Init
    # Remove shoelaces
    # Rinse
    def init(self, event0):
        self.sneakers = Sneakers()
        self.event0 = event0 # My feet get
            wet by wearing the sneakers.
    def remove_shoelaces(self):
        self.event0.change = "equally likely
            " # My feet get wet by wearing
                the sneakers.
    def rinse(self):
        self.sneakers.wet = True
        self.event0.change = "more likely" #
            My feet get wet by wearing the
                sneakers.
```

Figure 6: Our Codex prompt with a hard representation of entity states as variables, attributes, and values.

To recap, we have shown that LLMs can be prompted to exhibit a CoT that first predicts entity state changes and then event likelihood changes. Hence, our answer to Q1 raised at the beginning of this subsection is ‘yes.’

5.2 Annotated Entity States as CoT

In the above section, we have shown how event likelihood prediction can be improved by first having the LLMs predict entity states as a CoT. These experiments mimic a realistic setting where infor-

mation about entities is unavailable. However, in some scenarios, the entity states may be provided. For example, an embodied agent or a robot might have a reliable component that tracks entities; some practitioners might care about a small set of procedures in a narrow domain with annotated entity changes; or, some event schemata containing entity information could be used to predict unseen events. Here, we try to answer the following question:

Q2. Can LLMs effectively leverage **annotated** entity state changes to better predict event likelihood changes?

Instead of having LLMs predict entity state changes, we provide the annotated entity state changes in the CREPE dataset to GPT-3 and Codex. Doing so has the additional benefit of verifying that entity state changes indeed causally benefit LLMs in predicting events.

As shown in Table 5, our Codex representation with access to gold entity changes leads to improved performance of .715 F1 on the development set. In contrast, GPT-3 does not see any gain. Hence, the answer to **Q2** is ‘yes’ for the code-trained LLMs but ‘no’ for standard LLMs.

5.3 Externally Predicted Entity States

As we will discuss further in Section 7, entity state tracking is an established task in NLP with existing datasets and models. We have now predicted entity state changes using LLMs in a few-shot learning setting. It is then natural to pose the question:

Q3. Do existing entity state tracking models make predictions that lead to better performance on CREPE?

Our definition of causal reasoning of events is directional since we consider entity state changes as the cause of the change in event likelihoods. To this extent, we incorporate OpenPI (Tandon et al., 2020), the only open-domain entity state tracking dataset in procedural texts, as a part of the pipeline. In OpenPI, the input is a goal, a step, and the output is tuples of an entity, a feature, and two attributes before and after the execution of the step. For example, after “heat the pan [step]”, “the temperature [feature] of the pan [entity] is cool [attribute] before and hot [attribute] afterward.” While the original paper proposed a GPT2 model (Radford et al., 2019), we opt to finetune the superior GPT-3 Curie model on its data. After the model makes a prediction, we post-process it into the format of CREPE

by discarding the feature and producing two entity-attribute-change pairs (e.g., pan-hot-“more likely” and pan-cold-“less likely”). We provide Codex with only the entity changes when the entity is mentioned in the event. Further, to fit our prompt in the context window of Codex, we provide Codex with 5 entity state changes uniformly drawn from a pool of candidate choices at every step. The resulting OpenPI-prompted Codex gives a degraded macro F1 score of 0.553 on the development set and 0.496 on the testing set. Hence, our answer to **Q3** is ‘no,’ suggesting that existing entity state tracking datasets may be insufficient for our causal reasoning task.

6 Performance Analysis

In this section, we analyze potential factors that play a role in our Codex model’s performance. We investigate three factors: (1) the number of steps in a procedure; (2) explicit mentions of event-related entity-of-interest (EoI) in a given step; and (3) the logical relation (entailment or contradiction) between the event likelihood change and its related entity state change. To study factor (1), we dichotomize procedures from the development set by the average length of the procedure. To investigate factors (2) and (3), we manually labeled the ground truth EoI mentioning and logical relation for the development dataset. Intuitively, estimating event likelihood in lengthy procedures and in steps where EoI is not explicitly mentioned would be difficult. Rather surprisingly, Codex shows no significant performance discrepancy under factors (2) and (3), and only a slight performance difference in factor (1) (see Appendix C).

Further, the task of CREPE can be divided into two sub-tasks, first to identify whether an event likelihood change occurred at all, and then to classify the change as either more or less likely. We observe that CoT Codex outperforms Codex on both sub-tasks. For the classification task, in particular, CoT Codex obtained a .149 increase in macro F1 score from .805 to .954. This shows not only that CoT Codex is effective, but also that its bottleneck is identifying event likelihood change.

7 Related Work

Event & Entity Extraction and Representation
Event-centric NLP has been a dominant strand of approaches to machine reasoning. Myriad work has focused on extracting events from the news

or web data (Liu et al., 2018; Yang et al., 2019; Du and Cardie, 2020). The effort of structurally representing scripts, groups of events in certain scenarios including procedures, started decades ago (Abelson and Schank, 1977) and is receiving revived attention in present years (Li et al., 2020; Wang et al., 2022a). While this line of work mostly focuses on the representation as relations (e.g., temporal, hierarchical) among events, we recognize entities as a cause of event relations and thus propose a more granular representation. Furthermore, structured representations of events typically cannot take advantage of the power of textual LLMs for challenging downstream tasks. In contrast, we advance towards the best of two worlds by working with code language models.

Besides, existing work on jointly extracting and representing events and entities (Lee et al., 2012; Wadden et al., 2019; Barhom et al., 2019) neglects the causal relation therein and treats entities and events simply as two related tasks to be tackled simultaneously. We causally bridge the two.

Entity State Tracking Prior work on entity state tracking spans various disciplines of AI. For instance, object tracking, a sub-task of entity state tracking, has led to much work in both robotics (Wang et al., 2007) and computer vision (Comaniciu et al., 2003). In NLP, early efforts focus on synthetic, closed-domain data (Weston et al., 2015; Long et al., 2016) and more recent ones shift attention to real-world procedures (Bosselut et al., 2017; Dalvi et al., 2018; Gupta and Durrett, 2019; Du et al., 2019; Mysore et al., 2019) with a closed set of entities and attributes or an open-ended set (Tandon et al. (2020)). In all prior work, entity state track is treated as an end-task, whereas we treat it as a critical intermediate step for event reasoning, a more practical application.

Counterfactual Reasoning In this work, we hope to provide evidence that signals of entities effectively help models reason about events. We specifically focus on hypothetical event reasoning because it is a high-level cognitive ability beyond pattern recognition and a manifestation of complex reasoning ability (Pearl and Mackenzie, 2018; Pearl, 2019). Counterfactual reasoning has a long history with formal methods (Forbus, 1984; Lewis, 2013). Less modern work exists in commonsense (Feng et al., 2021), procedural texts (Tandon et al., 2019), and even computer vision (Yue et al., 2021).

Multihop Reasoning Prior studies on multihop reasoning mainly focus on question answering from a passage (Welbl et al., 2018; Talmor and Berant, 2018; Yang et al., 2018; Kočiský et al., 2018; Mihaylov et al., 2018; Khot et al., 2020) and representing and utilizing multihop information in the form of structured data (De Cao et al., 2019; Ding et al., 2019; Qiu et al., 2019; Cao et al., 2019; Fang et al., 2020; Thayaparan et al., 2019; Zhang et al., 2020d, 2021; Huang and Yang, 2021).

There are also efforts such as Decomprc, StrategyQA, and CGDe-FGIn that attempt to conduct multihop reasoning by decomposing the original task to a series of logically related sub-tasks (Min et al., 2019; Geva et al., 2021; Cao and Liu, 2022). Such an approach has recently seen great success with the Chain-of-Thought (CoT) prompting of GPT-3, which significantly improves numerous multihop reasoning tasks (Nye et al., 2021; Kojima et al., 2022; Wei et al., 2022; Wang et al., 2022c). Following CoT prompting, Self-Ask further elicits CoT by demanding GPT-3 to explicitly generate the reasoning questions raised during its chain-of-thought process (Press et al., 2022).

Code-Based Language Models and Prompts Recent work has shown that LLMs trained on programs or code (PLMs) have an augmented ability of reasoning over natural language texts. Notably, Suzgun et al. (2022); Liang et al. (2022) showed that PLMs outperforms only-text-trained LMs on certain reasoning tasks even though the prompts are purely natural language and contain no code. Moreover, there has been speculation that multihop reasoning is an emergent ability exclusive to PLMs and absent in their only-text-trained predecessors (Fu and Khot, 2022).

Even more interestingly, a line of contemporary work found that, for some reasoning tasks, prompting PLMs with certain structured programs (e.g., Python code, JSON, PDDL) that represent the originally textual data outperforms doing so simply with natural language prompts. These tasks include math questions (Chen et al., 2022; Lyu et al., 2023; Mishra et al., 2022) and event reasoning (Madaan et al., 2022; Wang et al., 2022b) like our work.

Procedural Texts Procedural texts are an attractive data source to reason about events and entities which undergo frequent changes. There has been steady efforts in computer vision (Miech et al., 2019), robotics (Ahn et al., 2022), and language (Mujtaba and Mahapatra, 2019; Zhang, 2022). In

NLP specifically, work on procedures includes extracting them from instructional texts (Paris et al., 2002; Delpech and Saint-Dizier, 2008; Zhang et al., 2012), reasoning about events (Takechi et al., 2003; Tandon et al., 2019; Rajagopal et al., 2020; Zhang et al., 2020c), knowledge-base construction (Jung et al., 2010; Chu et al., 2017; Park and Motahari Nezhad, 2018), or applying them to downstream applications (Yang et al., 2021b,a; Zhang et al., 2020a; Lyu et al., 2021; Dalvi et al., 2019; Zhang et al., 2020b; Chen et al., 2020). Our work is scoped in procedural texts due to the outstanding causal relations between entities and events in a dynamic environment.

8 Conclusion and Future Work

We present CREPE, a benchmark for causal reasoning about events and entities in procedural texts. We show that mainstream LLMs such as GPT-3 perform close to chance on CREPE, while using code-like event representation as a prompt to code language model Codex greatly improves the performance. Further, we experiment with various ways to encode entity information into this representation and find that eliciting chain-of-thought reasoning from Codex further improves performance while existing CoT approaches with GPT-3 are ineffective. We clearly show that LLMs benefit from lower-level entity information when making predictions about higher-level events. Future work should explore related tasks such as next-event prediction, event temporal ordering, etc., by injecting relevant information about entities into our representation. Our code-representation of events allows more powerful expressions than simply entailment and negation considered in this work. Future work may explore other forms of code chain-of-thought such as first-order logic. These expressions generated by LLMs can be computed objectively, thus ameliorating LLMs’ hallucinations and improving the interpretability and faithfulness of predictions.

9 Limitations

Despite our best efforts, our CREPE dataset has inherent limitations. First, the choice of studying procedure texts, despite many discussed advantages, limits the domain, writing style, and other semantic features of the texts. As a result, porting our methods and findings to other text styles such as stories or news might require domain adaptation. Second, we prioritize quality over quantity when creating

this benchmark, which suffers from small size and contains biases from the annotators, even though we address the latter by having different annotators label a test set.

When annotating the hypothetical events, our intention is that they represent a wild variety that doers of the procedures, humans or machines, would care about. However, we also have to ensure these events are unambiguously bound to some entities in order to challenge models for their causal reasoning ability. While we do our utmost to balance these two conflicting objectives, the issue might still persist.

In CREPE, each event likelihood change is caused by exactly one entity state change. This is an over-simplification made to facilitate evaluation. In real life, many complex events require many entity states to be reasoned about, which in turn may have complex logical relations among them. We leave this for future work.

While we intend our representation of events and entities to be a general and effective one, we have only shown that it works well empirically using Codex, which is one of the only code language models at present. Whether the idea of our structured representation applies to other models remains to be explored.

10 Acknowledgements

A Prompt Sensitivity

In addition to the results reported in Table 2, we also investigated the effect of the number and choice of in-context examples.

Number of in-context examples The context window of text-davinci-002 maximally fits 3 shots. We experiment with 1-shot (0.245 f1), 2-shots (0.348 f1), and 3-shots (0.359 f1) learning using text-002 with CoT prompting. We see that having more context provides limited improvements in model performance.

Prompt sensitivity with random examples We tested the text-davinci-002 model with CoT prompt on the dev set using randomly chosen examples from our example bank. The F1 scores for 5 runs with randomly chosen in-context examples are 0.333, 0.327, 0.359, 0.336, and 0.331. The mean score is 0.337, and the standard deviation is 0.011, implying low sensitivity of in-context example selection.

B Prompt Engineering

B.1 Code Prompts for Codex

In Section 4 and 5, we have discussed our best-performing prompts for GPT-3 and Codex. Here, we elaborate on inferior Codex prompts and shed light on why they do not work well empirically.

Best prompt As discussed, our best-performing prompt represents procedures as classes and steps as functions.

```
class Wash_Sneakers:
    # Init
    # Remove shoelaces
    # Rinse
    def __init__(self, event0):
        self.event0 = event0 # My feet get wet by
        wearing the sneakers.
    def remove_shoelaces(self):
        self.event0.change = "equally likely" # My
        feet get wet by wearing the sneakers.
    def rinse(self):
        self.event0.change = "more likely" # My
        feet get wet by wearing the sneakers.
```

Nested functions Instead of representing procedures as classes as in our best-performing prompt, we can also represent them as nested functions.

```
def wash_sneakers(event0):
    # Init
    # Remove shoelaces
    # Rinse
    event0 = event0 # My feet get wet by
    wearing the sneakers.
    def remove_shoelaces(self):
        event0.change = "equally likely" # My
        feet get wet by wearing the sneakers.
    def rinse(self):
        event0.change = "more likely" # My
        feet get wet by wearing the sneakers.
```

No step comments The comments displaying the steps immediately after the class declaration are removed.

```
class Wash_Sneakers:
    def __init__(self, event0):
        self.event0 = event0 # My feet get wet by
        wearing the sneakers.
    def remove_shoelaces(self):
        self.event0.change = "equally likely" # My
        feet get wet by wearing the sneakers.
    def rinse(self):
        self.event0.change = "more likely" # My
        feet get wet by wearing the sneakers.
```

No event comments The comments displaying the events in step functions except init are removed.

```
class Wash_Sneakers:
    def __init__(self, event0):
        self.event0 = event0 # My feet get wet by
        wearing the sneakers.
    def remove_shoelaces(self):
        self.event0.change = "equally likely"
    def rinse(self):
        self.event0.change = "more likely"
```

Two-step In this approach, we hypothesize that providing entity state change at every step is helpful. To do this, we first prompt Codex to generate entity states corresponding to a specific event:

```
class Wash_Sneakers:
    def remove_shoelaces(self):
        event = "My feet get wet by wearing
        the sneakers."
        event.precondition = \
            ("sneakers", "wet")
    def rinse(self):
        event = "My feet get wet by wearing
        the sneakers."
        event.precondition = \
            ("sneakers", "wet")
```

We select event-related entities by majority vote. The resulting entity state bank is used to prompt Codex to first deduce entity state at every step and then answer the likelihood of the event.

Flat variables Instead of defining functions using def or creating class with class, we use only

variables to define relevant information.

```
Goal = "Wash Sneakers"

Context = "Remove shoelaces. After this,
the shoelaces are removed"
Question = "What is the likelihood that my feet
get wet by wearing the sneakers?"
Options = [
    "more likely",
    "less likely",
    "equally likely",
]
Answer = Options[2]

Context = "Rinse the sneakers. After this,
the sneakers are damp."
Question = "What is the likelihood that my feet
get wet by wearing the sneakers?"
Options = [
    "more likely",
    "less likely",
    "equally likely",
]
Answer = Options[0]
```

B.2 Textual Prompts for GPT-3

For GPT-3, we attempted a dozen of prompt formulations in our preliminary experiments which we found to differ minimally in performance. Here, we show one example:

```
"Wash hands" involves the followings steps:
1. Turn on the tap water.
2. Put hands under running water.
3. Apply soap and rub hands.
4. Turn off the tap water.
5. Dry my hands using a towel.

For every step, find out how likely it is that
water streaming sound can be heard. Answer as
(A) very likely (B) likely (C) not very likely
(D) unlikely.

Step 1: (A) very likely
Step 2: (A) very likely
Step 3: (A) very likely
Step 4: (D) unlikely
Step 5: (D) unlikely
```

For GPT-3 finetuned with StrategyQA, we ask two questions regarding the likelihood of the events, namely whether it is more/less likely that some event occurs. After obtaining the result, we conduct a consistency check. For consistent likelihood estimates, where only one of the two questions gives a positive answer, or both questions give negative answers, we assign the corresponding label to the event state change. For inconsistent estimates, where both questions give positive answers, we assign the event change likelihood to the majority label, which is "equally likely". An example of

a finetuning prompt-completion pair is shown as follows

```
Prompt:
Context: Julius Caesar had three children.
Genghis Khan had sixteen children.
Modern geneticists have determined
that out of every 200 men today
has DNA that can be traced to
Genghis Khan.
Question: Are more people today
related to Genghis Khan than Julius Caesar?
Take it step by step:

Completion:
#1 How many kids did Julius Caesar have?
two
#2 How many kids did Genghis Khan have?
fourth
#3 Is fourth greater than two?
no
Therefore, the answer to the original
question is True
```

An example of our StrategyQA GPT-3 prompt on the CREPE task is as follows:

```
Context: Remove shoelaces. Rinse. Scrub the
shoes with cleaning solution. Rinse the shoes
again. Air dry the shoes and put the shoelaces
back on.
Question: Is it more likely that my feet get
wet by wearing the sneakers?
Take it step by step:

Completion:
#1 Is the sneaker wet?
Yes
#2 Will my feet get wet by wearing wet shoes?
Yes
Therefore, the answer to the original question
is True.
```

B.3 Textual Prompts for ChatGPT

As of the time of camera-ready submission of this paper (February 1, 2023), OpenAI has not released the API for ChatGPT. Thus, we use an unofficial API⁵ which is believed to behave the same as the official web playground. Because ChatGPT is designed to only work with a zero-shot and multi-turn dialog setting, we tweak our prompt as follows:

⁵<https://github.com/acheong08/ChatGPT>

I'm trying to wash hands.
 First, I turn on the tap water.
 At this point, is it likely that
 water streaming sound can be heard?
 Answer with yes or no.
 [answer]
 Then, I put hands under running water.
 At this point, is it likely that
 water streaming sound can be heard?
 Answer with yes or no.
 [answer]
 ...

B.4 Textual Prompts for T5/T0

We design the following prompt for T5 and T0 to perform our task:

Goal: [The name of the goal]
 Step: [The list of steps]
 Question: Is that okay that [question]?
 Answer: [yes or no, generated by the model]

C Error Analysis

In Section 6, we conclude that the performance of Codex is not influenced by (1) the number of steps in a procedure; (2) explicit mentions of event-related entity-of-interest (EoI) in a given step; and (3) the logical relation (entailment or contradiction) between the event likelihood change and its related entity state change.

Factors	Dev
Procedure Length > 7	.629
Procedure Length ≤ 7	.700
EoI Mentioned	.481
EoI NOT Mentioned	.496
Entailment	.482
Contradiction	.461

Table 6: Macro F1 Score of error analysis. The scores for EoI and Logical relation are lower since we do not consider the majority label, "equally likely", in the error analysis.

Few-Shot Structured Policy Learning for Multi-Domain and Multi-Task Dialogues

Abstract

Reinforcement learning has been widely adopted to model *dialogue managers* in task-oriented dialogues. However, the user simulator provided by state-of-the-art dialogue frameworks are only rough approximations of human behaviour. The ability to learn from a small number of human interactions is hence crucial, especially on multi-domain and multi-task environments where the action space is large. We therefore propose to use *structured policies* to improve sample efficiency when learning on these kinds of environments. We also evaluate the impact of *learning from human vs simulated experts*. Among the different levels of structure that we tested, the graph neural networks (GNNs) show a remarkable superiority by reaching a success rate above 80% with only 50 dialogues, when learning from simulated experts. They also show superiority when learning from human experts, although a performance drop was observed, indicating a possible difficulty in capturing the variability of human strategies. We therefore suggest to concentrate future research efforts on bridging the gap between human data, simulators and automatic evaluators in dialogue frameworks.

1 Introduction

Multi-domain multi-task dialogue systems are designed to complete specific *tasks* in distinct *domains* such as finding and booking a hotel or a restaurant (Zhu et al., 2020). A domain is formally defined as a list of *slots* with their valid values. The most common task, the information-seeking task, is usually modelled as a slot-filling data-query problem in which the system requests constraints to the user and proposes items that fulfil those constraints.

The design of a *dialogue manager* (DMs) is costly: *hand-crafted* policies require a lot of engineering, pure *supervised learning* (or *behaviour cloning*) requires a lot of expert demonstrations, and pure *reinforcement learning* requires a lot of

user interactions to converge. The simulators provided with frameworks, such as PYDIAL (Ultes et al., 2017) or CONVLAB (Zhu et al., 2020), are only rough approximations of human behaviour and the ability to learn from a small number of human interactions remains crucial. This is especially true on multi-domain and multi-task environments where the action space is large (Gao et al., 2018).

A popular approach to reduce these costs is to wire some knowledge about the problem into the policy model, namely: *few shot learning* (Wang et al., 2020). In particular, structured policies like *graph neural networks* (GNNs) are known to be well suited to handle a variable number of slots and domains for the information-seeking task (Chen et al. 2018; Chen et al. 2020). In this paper, we explore structured policies based on GNN. A graph in a GNN is *fully connected* and *directed*. Each *node* represents a sub-policy associated with a slot, while a directed *edge* between two nodes represents a message passing.

For studying sample efficiency, we analyse the dialogue success rate of structured policies once trained in a supervised way from expert demonstrations. We consider two types of demonstrations: *human experts* extracted from the MULTIWOZ dataset (Budzianowski et al., 2018), and *simulated experts* generated by letting the CONVLAB’s *hand-crafted* policy interact with a simulated user.

We perform large scale experiments. We study the impact of different levels of structure (see them in Figure 2) on policy success rate after a limited number of dialogue demonstrations. For each level of structure, we also compare two sources of demonstrations: simulated and human dialogues. We show a notable result: our structured policies are able to reach a success rate above 80% with only 50 when following a simulated expert in CONVLAB. To the best of our knowledge there are not previous works that studied the impact of structure for dialogue policy in a few-shot setting.

Another important finding is that few-shot learning from human demonstrations is harder, producing a lower success rate. This can be explained first by the large variability of human strategies that is not covered by simulated users which stick to more repetitive – easy to learn – dialogue patterns. Another explanation could be an evaluation bias, simulated dialogues are more in line with artificial evaluators.

The remainder of this paper is structured as follows. We present the related work in Section 2. Section 3 presents the proposed GNNs from demonstrations. The experiments and evaluation are described in Sections 4 and 5 respectively. Finally, we conclude in Section 6.

2 Related Work

Few shot learning takes advantage of prior knowledge to avoid overloading the empirical risk minimiser when the number of available examples is small. In particular, prior knowledge can be used to constrain hypothesis space (i.e. model parameters) with parameter sharing or tying in order to reduce reliance on data acquisition and on data annotation (Wang et al., 2020).

Prior knowledge can be built into dialogue systems by imposing a structure in the neural network architecture. A first approach is to use *hierarchical reinforcement learning* that divides a main problem into several simpler sub-problems. We refer to Sutton et al. (1999) that introduces *semi-Markov decision process* using temporal abstraction and to Wen et al. (2020) that introduces *sub-Markov decision process* using state partition. In the scope of the paper, a *hierarchical policy* corresponds to a meta-controller that chooses to activate a domain and we have one sub-policy per domain (Budzianowski et al., 2017; Casanueva et al., 2018; Le et al., 2018).

In the same vein, *graph neural networks* (GNNs) have been explored in a wide range of domains because of their empirical success and their theoretical properties which explains its efficiency: the abilities of generalisation, stability and expressiveness (Garcia and Bruna, 2018). GNNs are suitable for applications where the data have a graph structure i.e where the graph outputs are supposed to be permutation-invariant or equivariant to the input features (Zhou et al., 2020; Wu et al., 2020).

In single-domain dialogue environments, this architecture has been adapted to model the DM in Chen et al. (2018) and Chen et al. (2020). They

have shown that GNNs generalise between similar dialogue slots, manage a variable number of slots and transfer to different domains that perform similar tasks. We thus adopt in this work the *domain independent parametrisation* (DIP) (Wang et al., 2015), which standardises the slots representation into a common feature space.

In this work, as in Chen et al. (2018) and Chen et al. (2020), we propose to improve multi-domain covering by learning a generic policy based on GNN. But unlike them, (i) we use a multi-domain multi-task setting, in which several domains and tasks can be evoked in a dialogue; (ii) the *dialogue state tracker* (DST) output is not discarded when activating the domain; and (iii) we adapt the GNN structure to each domain by keeping the relevant nodes while sharing the edge’s weights.

3 Structured Policies with Expert Demonstrations

In order to investigate the impact of structured policies with behaviour cloning in improving sample efficiency in multi-domain multi-task dialogue environments, we introduce the dialogue state and action spaces for structured policies and we present the different policies and the experts’ nature.

3.1 Dialogue State / Action Representations

In multi-domain multi-task dialogues, the *domain* refers to the set of concepts and values speakers can talk about. Examples of domains are restaurants, attractions, hotels, trains, etc. A *dialogue act* is a predicate that refers to the performative actions of speakers in conversations (Austin, 1975). These actions are formalised as predicates like INFORM (i.e., affirm) or REQUEST with slots or slot-values pairs as arguments. Examples of system actions are: REQUEST(food), or INFORM(address). These structured actions are used to frame a message to the user. We adopt here the multi-task setting as presented in CONVLAB (Zhu et al., 2020), in which a single dialogue can have the following tasks: (i) *find*, in which the system requests information in order to query a database and make an offer; (ii) *book*, in which the system requests information in order to book the item.

We adopt the DIP state and action representations, which are not reduced to a flat vector but to a set of sub-vectors: one corresponding to the domain parametrisation (or *slot-independent representation*), the others to the slots parametrisation

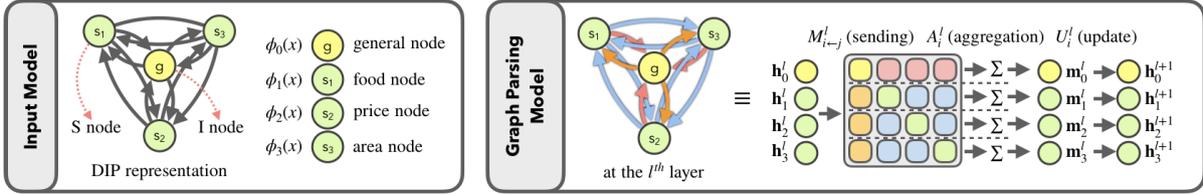

Figure 1: Structure of the input and graph parsing model in restaurant domain example. The input is a fully-connected graph with two kinds of nodes and three kinds of edges. The I-NODE are depicted in yellow; the S-NODE in green. The structured policy is described by successive graph convolutions composed of the shared weights $\mathbf{W}_{i,j}^l$.

(or *slot-dependent representations*). For any active domain, the input to the *slot-independent representation* is the concatenation of the previous *slot-independent* user and system actions (see examples of the output below, and a formal definition in Section 3.2), the number of entities fulfilling the user’s constraints in the database, the booleans indicating if the dialogue is terminated and whether an offer has been found / booked. The output corresponds to action scores such as REQMORE, OFFER, BOOK, GREAT, etc. Regarding the *slot-dependent representation*, its input is composed of the previous *slot-dependent* user and system actions (see output below), the booleans indicating if a value is known and whether the slot is needed for the *find / book* tasks. Its output are actions scores such as INFORM, REQUEST and SELECT. The parameterisation used in CONVLAB does not depend on the probabilistic representation of the states, *i.e.* does not consider the uncertainty in the predictions made by the *natural language understanding* (NLU) module.

3.2 Graph Neural Network

Prior knowledge can be integrated in our models by constraining the layer structure imposing symmetries in the neural dialogue policies. Without prior knowledge, the standard structure used is the *feed-forward neural network* layer (FNN). This unconstrained structure does not assume any symmetry in the network.

Assuming that sub-policies associated with the slots are the same, a better alternative is to use the *graph neural network* layer (GNN). This structure assumes that the state and action representations have a graph structure that are identically parameterised by DIP. The GNN structure is a fully connected and directed graph, in which each *node* represents a sub-policy associated with a slot and a directed *edge* between two sub-policies represents a message passing. We identify two roles for sub-policies: the general node as I-NODE associated

to the *slot-independent representation* and the slot nodes denoted as S-NODE associated to the *slot-dependent representations*. Both representations were introduced in Section 3.1. We also identify the relations: I2S for I-NODE to S-NODE, S2I and S2S respectively¹ (as presented in Figure 1).

We formally define the GNN structure as follows. Let n be the number of slots and L the number of layers. Let be x the dialogue state, $\mathbf{x}_0 = \phi_0(x)$, $\mathbf{h}_0^l \forall l \in [0, L - 1]$ and \mathbf{y}_0 be respectively the input, hidden and output I-NODE representations. Let the input, hidden and output S-NODES representations be respectively $\forall i \in [1, n]$, $\mathbf{x}_i = \phi_i(x)$, $\mathbf{h}_i^l \forall l \in [0, L - 1]$ and \mathbf{y}_i . First, the GNN transforms inputs:

$$\forall i \in [0, n], \quad \mathbf{h}_i^0 = \sigma^0(\mathbf{W}_i^0 \phi_i(\mathbf{x}) + \mathbf{b}_i^0) \quad (1)$$

Then, at the l -th layer, it computes the hidden nodes representations by following message sending² (Eq. 2), message aggregation (Eq. 3) and representation update (Eq. 4). $\forall i, j \in [0, n]$ ²:

$$\mathbf{m}_{i \leftarrow j}^l = M_{i \leftarrow j}^l(\mathbf{h}_j^{l-1}) = \mathbf{W}_{i,j}^l \mathbf{h}_j^{l-1} + \mathbf{b}_{i,j}^l \quad (2)$$

$$\mathbf{m}_i^l = A_i^l(\mathbf{m}_{i \leftarrow *}) = \frac{1}{n} \sum_{j=0}^n \mathbf{m}_{i \leftarrow j}^l \quad (3)$$

$$\mathbf{h}_i^l = U_i^l(\mathbf{m}_i^l) = \sigma^l(\mathbf{m}_i^l) \quad (4)$$

The message sending function $M_{i \leftarrow j}^l$ is a linear transformation with bias. The message aggregation function A_i^l is the average pooling function. The representation update function U_i^l compute the new hidden representation with RELU activation function and dropout technique during learning stage. Finally, the GNN concatenates (\oplus symbol) all final nodes representations and computes the policy function with the Softmax activation function.

$$\mathbf{y} = \sigma^L(\bigoplus_{i=0}^n \mathbf{W}_i^L \mathbf{h}_i^{L-1} + \mathbf{b}_i^L) \quad (5)$$

¹We omit the I2I relation because there is only one I-node.

²The notation $i \leftarrow j$ denotes a message sending from slot j to slot i . It also corresponds to the directed relation between the slots j and i . The notation $i \leftarrow *$ denotes all messages sending to slot i .

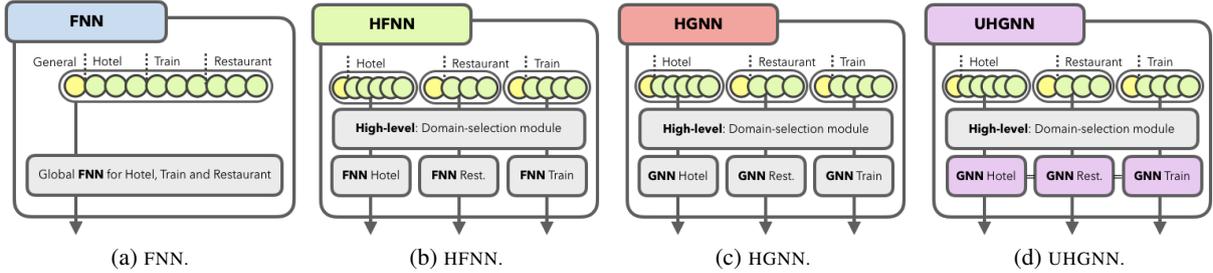

Figure 2: Policy and input data structures. Different levels of structure are presented from classical *feed-forward neural network* (FNN) to *graph neural network* (GNN). The prefix H- corresponds to a hierarchical policy and UH- corresponds to a unique sub-policy for all domains. For a FNN layer, the input data is the concatenation of all DIP slot representations. For a GNN layer, the input keeps its structure.

3.3 Structured Policies

We propose a wide range of dialogue policies to study the impact of the structure in sample efficiency. An ablation study progressively adds some notion of hierarchy to FNNs to approximate the structure of GNNs. Similarly, we analyse the advantage of sharing a generic GNN among several domains versus specialising a GNN to each domain. Therefore, we propose from the least to the most constrained:

- **Feed-forward Neural Network (FNN)** that is a classical feed-forward neural network with DIP parametrisation (Figure 2a).
- **Hierarchy of Feed-forward Neural Networks (HFNN)** that is a hierarchical policy with hand-crafted domain-selection and FNNs for each domain. Each domain has one corresponding FNN model (Figure 2b).
- **Hierarchy of Graph Neural Networks (HGNN)** that is a hierarchical policy with hand-crafted domain-selection and GNNs. Each domain has one corresponding GNN model (Figure 2c).
- **Hierarchy with Unique Graph Neural Network (UHGNN)** that is a HGNN with a unique GNN for all domains. Each domain shares the same GNN model (Figure 2d).

3.4 The Expert’s Nature

Since our goal is to learn on observed demonstrations delivered by an expert, we propose to focus on policies that learn from both simulated and human experts. For this purpose, we use the dataset MULTIWOZ (Budzianowski et al., 2018) to follow

human experts and the hand-crafted policy of CONVLAB (Zhu et al., 2020) as the simulated expert.

Human expert The MULTIWOZ dataset is a large annotated and open-sourced collection of human-human chats that covers multiple domains and tasks. Nearly 10k dialogues have been collected by a *Wizard-of-Oz* set-up at relatively low cost and with a small time effort. However, different versions of this dataset corrected and improved the annotations (Eric et al., 2020; Zang et al., 2020; Han et al., 2021; Ye et al., 2021). In this work, we use the MULTIWOZ dataset integrated in CONVLAB with extended user dialogue act annotations.

Simulated expert The CONVLAB framework has been proposed to automatically build, train and evaluate multi-domain multi-task oriented dialogue systems based on MULTIWOZ features. It implements both hand-crafted simulated user and policy. The latter has been shown to be nearly the optimal policy according to the CONVLAB evaluation setup of (Takanobu et al., 2020). Therefore we use it as the simulated expert.

4 Experiments

In this section we explain the experimental setup, the proposed models and the evaluation metrics.

4.1 Experiment Setup

We performed an ablation study by gradually adding different levels of structure from a baseline FNN to the proposed GNN (Subsection 4.2). On the one hand, we analyse the learning efficiency of our models in small training steps. On the other hand, we compare their generalisation ability in few shot learning.

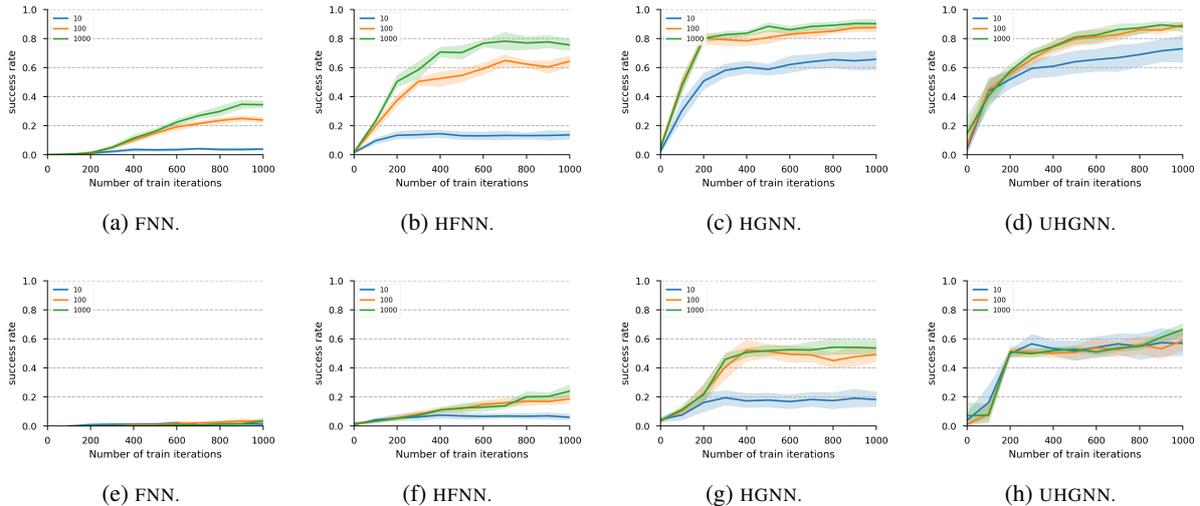

Figure 3: Dialogue manager evaluation with simulated users. We present the success rate on 10 / 100 / 1 000 training dialogues as a function of the number of gradient descent steps in a short training scenario. Learning is based on simulated experts (Figures (a) up to (d)) or on human experts (Figures (e) up to (h)). The line plot represents the mean and the coloured area represents the 95% confidence interval over a sample of 10 runs.

To analyse the learning efficiency, we measure performance with respect to the number of gradient descent steps up to 1 000 iterations with a step size of 100 iterations. We compare learning curves based on randomly chosen 10, 100 and 1 000 training dialogues³. We also measure performance as a function of the number of training dialogues available (randomly chosen) namely 10, 50, 100, 500 and 1000 when each training is performed up to 10 000 gradient descent steps. All the experiments were run on CONVLAB, restarted 10 times with random initialisation and the results estimated on 500 new dialogues.

4.2 Models

The FNN models have two hidden layers, both with 128 neurons. The GNN models have one first hidden layer with 64 neurons for both nodes (S-NODE and I-NODE). Then the second hidden layer is composed of 64 neurons for each relation (S2S, S2I and I2S). For training stage, we use the ADAM optimiser with a learning rate $lr = 0.001$, a dropout rate $dr = 0.1$ and a batch size $bs = 64$.

4.3 Metrics

We evaluate the performance of the policies for all tasks as in CONVLAB. Precision, recall and F-score, namely the **inform rates**, are used for the

³These values were chosen arbitrarily to give us an insight into the impact of the number of dialogues on the performance.

find task. Inform recall evaluates whether all the requested information has been informed while inform precision evaluates whether only the requested information has been informed. For the *book* task, the accuracy, namely the **book rate**, is used. It assesses whether the offered entity meets all the constraints specified in the user goal. The dialogue is marked as **successful** if and only if both inform recall and book rate are equal to 1. The dialogue is considered **completed** if it is successful from the user’s point of view⁴.

5 Evaluation

First, we evaluate the dialogue manager performance when talking to a simulated user. Second, we evaluate the learned policies within the entire dialogue system both with simulated and with real users. The evaluations have been done within CONVLAB.

5.1 Dialogue Manager Evaluation

We analyse our models on the learning efficiency in small training steps and on the ability to generalise in a few-shot setting.

Efficiency We report in Figure 3 the results of the ablation study showing the ability of the models to succeed in a short training stage. First, when

⁴A dialogue can be completed without being successful if the information provided is not the one objectively expected by the simulator.

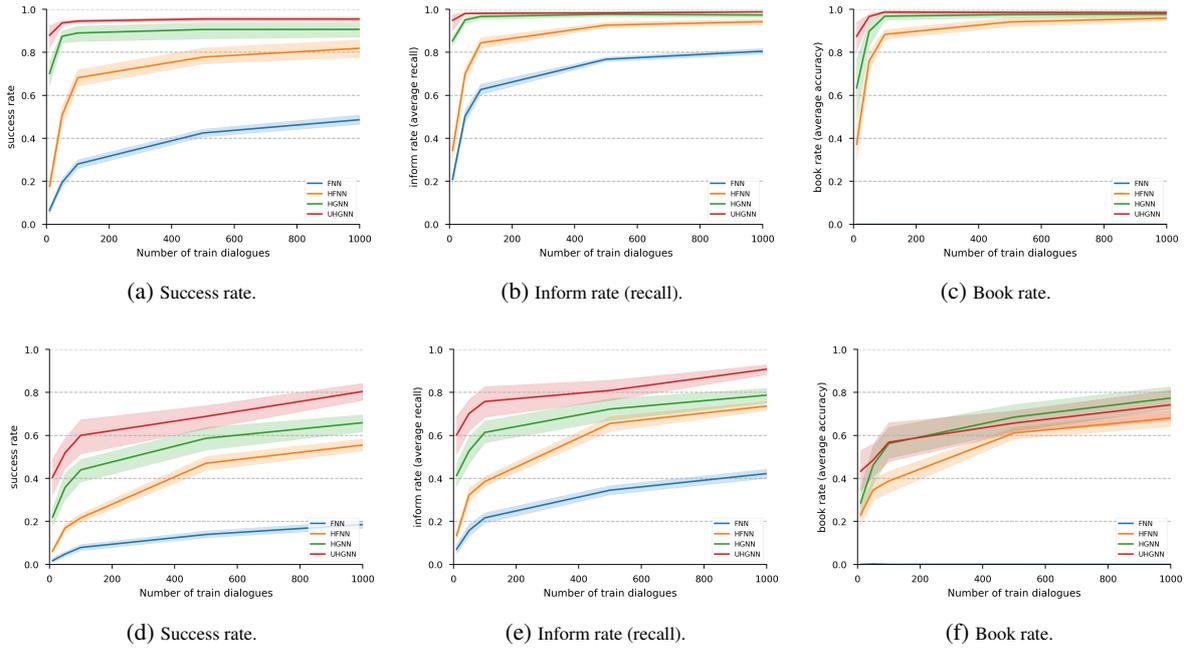

Figure 4: Dialogue manager evaluation with simulated user presenting the success rate based on 10 000 training iterations as a function of the number of training dialogues in a long learning scenario. Learning is based on a simulated expert (Figures (a), (b) and (c)) or human experts (Figures (d), (e) and (f)). The line plot represents the mean and the coloured area represents the 95% confidence interval over a sample of 10 runs.

learning from simulated demonstrations we notice in Figure 3a that the baseline (FNN) needs a large number of training dialogues (more than 100) to achieve a moderate performance (less than 40%). We show then in Figure 3b that hierarchical networks (HFNN) do improve learning efficiency up to 60% with 100 dialogues, up to 80% with 1 000 dialogues. Finally we show that graph neural network (HGNN in Figure 3c) and generic policy (UHGNN in Figure 3d) drastically improve the efficiency with few dialogues, more than 60% with 10 dialogues, and achieve remarkable performance above 80% with only 100 dialogues in 1 000 training steps. These observations confirm that hierarchical and generic GNNs allow efficient learning and collaborative gradient update in a short training stage.

Although standard or hierarchical policies (FNN in Figure 3e and HFNN in Figure 3f) are less efficient when learning from human demonstrations, they are still above baselines. It is worth noting that structured or generic GNN policies HGNN in Figure 3g and UHGNN in Figure 3h are able to reach more than 50% success rate.

Few-Shot We extended the ablation study in a few-shot scenario focusing on the ability of the

models to succeed on specific dialogue tasks as reported in Figure 4. In particular, we show the success rate in Figure 4a, the inform rate (recall) in Figure 4b and the book rate in Figure 4c when using simulated demonstrations and respectively in Figure 4d, Figure 4e and Figure 4f when using human demonstrations. The more structured the model, the greater the learning efficiency and the greater the data efficiency. Likewise, we notice that learning is more data-intensive when imitating human strategies. It appears that the booking task is more difficult to perform according to human demonstrations (when comparing Figure 4c and Figure 4f) or using a flat architecture (FNN gets null results). We therefore foresee that more high quality data is needed to learn on human dialogues.

5.2 Dialogue System Evaluation

We continue our analysis on the robustness of the studied models with the entire dialogue system facing both simulated and human users. The dialogue system utilises a BERT NLU (Devlin et al., 2019) and a hand-crafted NLG.

Simulated User Evaluation As in the previous subsection, we study the robustness of the models in a few-shot scenario as presented in Figure 5.

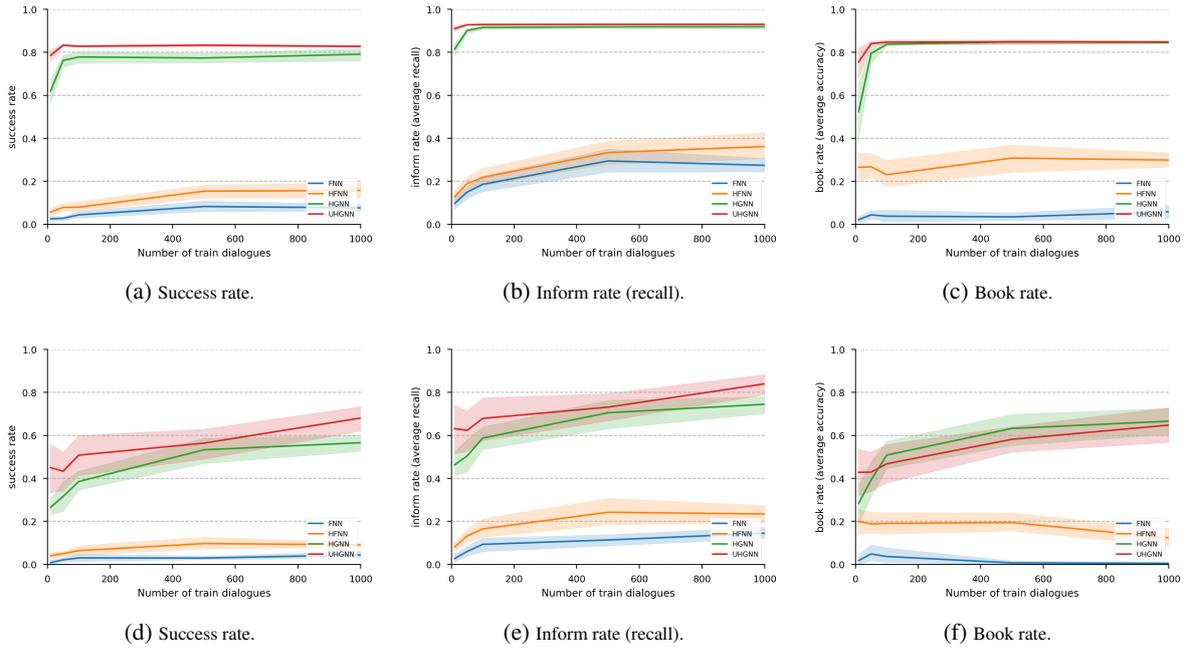

Figure 5: Dialogue system performance with simulated user based on 10 000 training iterations as a function of the number of training dialogues in a long training scenario. The supervised DM is based on simulated demonstrations (Figures (a),(b),(c)) or on human demonstrations (Figures (d),(e),(f)). The line plot represents the mean and the coloured area represents the 95% confidence interval over a sample of 10 runs.

We observe that FNN (in blue) and HFNN (in orange) learning is collapsing when using simulated dialogues (see Figures 5a, 5b and 5c). On the opposite, HGNN (in green) and UHGNN (in red) performance appears more stable in the entire dialogue system even when using real dialogues (see Figures 5d, 5e and 5f). Therefore, these results confirm that behaviour cloning is easier from simulated than human experts. As observed before in Subsection 5.2, this can be explained by a large variability of human strategies (hence the need for more data to improve performance). Another explanation is that simulated dialogues are more in line with the artificial evaluator provided in the CONVLAB. In addition, it is important not to neglect the side effects of cascading errors due to successive NLU, DST, DM and NLG modules. In particular, the NLU BERT proposed by CONVLAB was pre-trained and evaluated on 7 372 user utterances with 14% of errors (F1 86.4%, precision 85.1%, recall 87.8%). This problem can therefore be exacerbated by cascading human errors, as confirmed in the next paragraph.

Finally, we present a detailed comparison table with the best structured policies UHGNN trained on simulated dialogues of CONVLAB noted MLE-

UHGNN-HDC (HDC for *hand-crafted policy*) and trained on real dialogues of MULTIWOZ noted MLE-UHGNN-MW and the baselines of CONVLAB (see Table 1). In particular, the *maximum likelihood estimator* (MLE) proposed by CONVLAB is an implementation of FNN model trained on MULTIWOZ corpus in a very long training scenario (multiple passes on all 10k dialogues)⁵. Our models show competitive results against CONVLAB’s baselines, confirming that the structured with supervised learning in few-shot settings is adapted to address the difficulties in multi-task multi-domain dialogues.

Human Evaluation We organised preliminary evaluation sessions, in which volunteers were invited to chat on-line with three dialogue systems that were randomly assigned⁶. Subjects do not know which system they are evaluating. Each sys-

⁵Another difference is that our models returns one unique action per turn instead of a group of actions.

⁶Crowdsourcing was not used because of ethical concerns regarding the work conditions of collaborators. Volunteers from our research institution were invited to participate and they were aware of the scientific motivations behind the evaluation. In this sense, they were motivated to participate without any economic reward implying no pressure and without knowing the nature of the models they were evaluating, avoiding in this way any evaluation bias.

Configuration	Avg Turn (succ/all)	Inform rate (%) Prec. / Rec. / F1	Book Rate (%)	Complete Rate (%)	Success Rate (%)		
Dialogue Management							
HDC	10.6/10.6	87.2 / 98.6 / 90.9	98.6	97.9	-	97.3	-
MLE-UHGNN-HDC (ours)	12.8/13.0	95.3 / 98.8 / 96.4	98.5	97.3	(-0.6)	95.4	(-1.9)

MLE-UHGNN-MW (ours)	17.0/23.0	84.0 / 87.6 / 84.5	64.8	72.1	(-20.6)	68.1	(-15.7)

Table 1: Dialogue manager and system evaluations with simulated users. When evaluating the dialogue manager, the simulated user passes directly dialogue acts and vice-versa. Our tested configurations are evaluated and averaged on 10 run each with 250 dialogues. Configurations with [†] are taken from the [GitHub of CONVLAB](#).

Dialogue System (BERT NLU + Rule NLG)	Avg Turn	Satisfaction Rate (%)	Nb of Dial.
HDC	22.6	92.6 ± 9.87	27
MLE-UHGNN-HDC	25.6	50.0 ± 14.8	44
MLE-UHGNN-MW	17.3	36.7 ± 17.2	30

Table 2: Dialogue system evaluation with real users with a 95% confidence level for satisfaction rate.

tem has a different DM model: HDC (*hand-crafted policy*), MLE-UHGNN-HDC (based on simulated demonstrations with HDC policy) and MLE-UHGNN-MW (based on MULTIWOZ demonstrations) combined with the BERT NLU and the hand-crafted NLG provided by CONVLAB. At the end of the chat, evaluators were asked whether or not they reach the goal and were satisfied with the performance of the system. The **satisfaction rate** is then the proportion of dialogues in which the system solved the task at the end of the dialogue according to the human evaluator. We reported results on roughly 30 dialogues for each method. The results of this experimentation are presented in Table 2. Although test is small-sized and not highly statistically significant, these preliminary results are disconcerting with respect to the simulated ones. The HDC does very well whereas MLE-UHGNN-HDC gets by in half the cases, MLE-UHGNN-MW fails in most cases.

These results can be explained by the limitations of the NLU facing impatient evaluators, short and ambiguous sentences where the active domain is

unclear (as in this example of the user saying "What is the name?") or typographical errors. Moreover, it is important to underline that CONVLAB does not natively propose the management of uncertainties in the state representation which can strongly restrict the performance of the learning methods in noisy environments. Another limitation is that the HDC is more adapted to conventional dialogues whereas MLE-UHGNNs were trained only on winning dialogues. This implies that learning methods are more sensitive to dialogues that break out of the learned patterns. Similarly, the strategies of simulated and real users do not seem to be well aligned with each other and even more strongly with the expectations of human evaluators.

6 Conclusion

We investigated in this work the impact of policy structure and experts on success rate in few-shot learning for multi-domain multi-task dialogues. Promising results were obtained: hierarchical and generic GNN policies are able to achieve remarkable performance with few dialogues and few training iterations when following a simulated expert. This confirms the growing interest for these neural structures. We also present an important finding: the policy performance degrades in few-shot learning when using human demonstrations. This fact questions the alignment between dialogue evaluators and human strategies in state-of-the-art dialogue frameworks.

Limitations

The reduced performance when learning from human experts suggests that we shall concentrate the efforts in bridging the gap between automatic evaluators and high-quality human-human datasets. We also devise the use of *curriculum learning* (Bengio et al., 2009) strategies: starting from simple – simulated – dialogues then adding progressively more complex, human dialogues demonstrations.

It is also necessary to analyse the impact of GNN policies with neural NLU/NLG modules to study how to integrate such structures in end-to-end architectures.

We point out some limitations of CONVLAB. The detection of the active domain is sensitive to the output of the NLU and thus sensitive to ambiguous statements. Data representation restricts the DST to a deterministic view and must be adapted to a probabilistic representation to capture the uncertainties in the user’s input. Similarly, it may be worthwhile to improve the action space by adding more possibilities for human users, for instance to CONFIRM or DENY in a more flexible way.

Finally, the human evaluation was performed on a small scale and on models trained in a context with few training iterations. A more in-depth or supervised study could shed more light on the raised issues.

Transfer Knowledge from Natural Language to Electrocardiography: Can We Detect Cardiovascular Disease Through Language Models?

Abstract

Recent advancements in Large Language Models (LLMs) have drawn increasing attention since the learned embeddings pretrained on large-scale datasets have shown powerful ability in various downstream applications. However, whether the learned knowledge by LLMs can be transferred to clinical cardiology remains unknown. In this work, we aim to bridge this gap by transferring the knowledge of LLMs to clinical Electrocardiography (ECG). To address this problem, we propose an approach for cardiovascular disease diagnosis and automatic ECG diagnosis report generation. We also introduce an additional loss function by Optimal Transport (OT) to align the distribution between ECG and language embeddings. The learned embeddings are evaluated on two downstream tasks: (1) automatic ECG diagnosis report generation, and (2) zero-shot cardiovascular disease detection. Our approach is able to generate high-quality cardiac diagnosis reports and also achieves competitive zero-shot classification performance even compared with supervised baselines, which proves the feasibility of transferring knowledge from LLMs to the cardiac domain.

1 Introduction

Heart and cardiovascular diseases are the leading global cause of death, with 80% of cardiovascular disease-related deaths due to heart attacks and strokes. The clinical 12-lead ECG, when correctly interpreted, is the primary tool to detect cardiac abnormalities and heart-related issues. ECG provides unique information about the structure and electrical activity of the heart and systemic conditions through changes in the timing and morphology of the recorded waveforms. Achievements of ECG interpretation, such that critical and timely ECG interpretations of cardiac conditions, will lead to efficient and cost-effective intervention.

* marked as equal contribution

LLM starts from the Transformer model (Vaswani et al., 2017) and grows quickly with a wide range of applications (Devlin et al., 2019; Liu et al., 2019b; Brown et al., 2020). Recently, LLM has shown great potential for accelerating learning in many other domains since the learned embeddings can provide meaningful representation for downstream tasks. Examples include transferring the knowledge of LLM to, i.e., robotics control (Liang et al., 2022; Ahn et al., 2022), multimodal reasoning and interaction (Zeng et al., 2022; Zellers et al., 2021), robotics planning (Shah et al., 2022; Kant et al., 2022; Jain et al., 2022), decision-making (Li et al., 2022; Huang et al., 2022), robotics manipulation (Shridhar et al., 2022; Ren et al., 2022; Cui et al., 2022; Tam et al., 2022; Khandelwal et al., 2022), code generation (Fried et al., 2022), laws (Kaplan et al., 2020), computer vision (Radford et al., 2021), and so on.

Some previous works explored LLM and biological protein (Rives et al., 2021), or health records (Yang et al., 2022). However, the medical or health-care domains contain so much domain knowledge that different sources preserve unique data characteristics without a unified paradigm. To the best of our knowledge, no previous work explores the knowledge transfer from LLM to cardiovascular disease with ECG signals.

In this work, we bridge the gap between LLM and clinical ECG by investigating the feasibility of transferring knowledge of LLM to the cardiology domain. Our contributions are listed as follows:

- To the best of our knowledge, our work is the first attempt to bridge the gap between LLM and clinical cardiovascular ECG by leveraging the knowledge from pretrained LLM.
- We propose a cardiovascular disease diagnosis and automatic ECG diagnosis report generation approach by transferring the knowledge from LLM to the cardiac ECG domain.
- We introduce an additional learning objective

based on Optimal Transport distance, which empowers the model to learn the distribution between ECG and language embedding.

- Our method can generate high-quality cardiac diagnosis reports and achieve competitive zero-shot classification performance even compared with supervised baselines, proving the feasibility of using LLM to enhance research and applications in the cardiac domain.

2 Related Work

Cardiovascular diagnosis via ECG The 12-lead ECG is derived from 10 electrodes placed on the surface of the skin (Cadogan, 2020). An ECG works by recording electrical activity corresponding to the heartbeat muscle contractions (Bonow et al., 2011). Although computerized interpretations of ECGs are widely used, automated approaches have not yet matched the quality of expert cardiologists, leading to poor patient outcomes or even fatality (Breen et al., 2019).

Deep learning in ECG Deep learning approaches have been rapidly adopted in many fields for their accuracy and flexibility, including ECG domain (Kiranyaz et al., 2015; Nonaka and Seita, 2021; Khurshid et al., 2021; Raghunath et al., 2021; Giudicessi et al., 2021; Strodthoff et al., 2021; Al-Zaiti et al., 2020; Acharya et al., 2017; Shanmugam et al., 2019; Śmigiel et al., 2021). Transformer (Vaswani et al., 2017) has recently been adopted in several ECG applications, i.e., arrhythmia classification, abnormalities detection, stress detection, etc (Yan et al., 2019; Che et al., 2021; Natarajan et al., 2020; Behinaein et al., 2021; Song et al., 2021; Weimann and Conrad, 2021).

LLM in healthcare Zhou et al. (2021) reviewed existing studies concerning NLP for smart healthcare. Yang et al. (2022) developed a large pre-trained clinical language model using transformer architecture. Steinberg et al. (2021) showed that using patient representation schemes inspired by techniques in LLM can increase the accuracy of clinical prediction models. More related work can be found in Appendix B.

3 Methods

Problem Formulation We formulate the problem as generating cardiovascular diagnosis reports through pretrained LLMs. Given ECG signals $x = [x_1, x_2, \dots, x_t]$, our goal is to take advantage

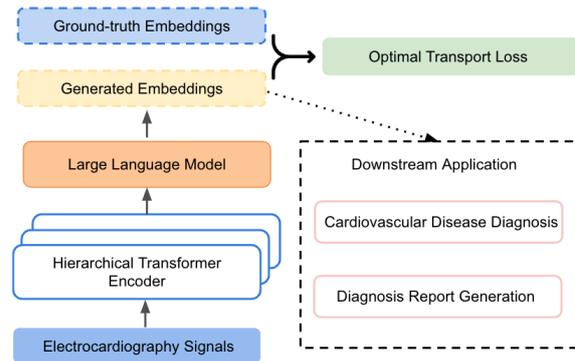

Figure 1: The architecture of our model. The Transformer encoder takes input ECG to generate ECG features as the input to LLM, where LLM transforms it into generated embeddings. An optimal transport based loss objective is formulated on generated embeddings and ground-truth embeddings for the model update.

of the knowledge from LLM and learn a generated text embedding $L = [L_1, L_2, \dots, L_m]$, which can then be decoded into natural language as reports or directly used for disease classification.

Model Architecture The model architecture is shown in Fig. 1, The ECG inputs are processed by hierarchical transformer encoders (Vaswani et al., 2017) to obtain transformed ECG embeddings $X = [X_1, X_2, \dots, X_n]$. Then we adopt a pretrained LLM to transform the ECG embeddings into language embeddings $L = [L_1, L_2, \dots, L_m]$. For the learning objective, we use expert reports to formalize the learning loss, which includes a new loss based on Optimal Transport (OT) in addition to the traditional cross-entropy loss. The learning objective is to update the transformer encoders, which can be interpreted as a sequence-to-sequence mapping from ECG embeddings X to sentence embeddings L . After the learning process, the learned embedding L should be capable of conducting downstream applications.

Downstream Applications For the downstream applications, we first consider a classification problem that uses the embeddings L for cardiovascular disease diagnosis. In addition, we consider a text generation task by decoding the output embeddings L into a cardiovascular report.

Transformer Encoders The transformer is based on the attention mechanism (Vaswani et al., 2017). The original transformer model is composed of an encoder and a decoder. The encoder maps an input sequence into a latent representation, and the

decoder uses the representation with other inputs to generate a target sequence. Our model only adopts the encoder since the target is to learn the representations of ECG features. More details can be found in Appendix D.

Optimal Transport Loss OT is the problem of transporting mass between two discrete distributions supported on latent feature space \mathcal{X} . Let $\boldsymbol{\mu} = \{\mathbf{x}_i, \mu_i\}_{i=1}^n$ and $\boldsymbol{v} = \{\mathbf{y}_j, v_j\}_{j=1}^m$ be the distributions of generated embeddings and ground-truth embeddings, where $\mathbf{x}_i, \mathbf{y}_j \in \mathcal{X}$ denotes the spatial locations and μ_i, v_j , respectively, denoting the non-negative masses. Without loss of generality, we assume $\sum_i \mu_i = \sum_j v_j = 1$. $\pi \in \mathbb{R}_+^{n \times m}$ is a valid transport plan if its row and column marginals match $\boldsymbol{\mu}$ and \boldsymbol{v} , respectively, which is $\sum_i \pi_{ij} = v_j$ and $\sum_j \pi_{ij} = \mu_i$. Intuitively, π transports π_{ij} units of mass at location \mathbf{x}_i to new location \mathbf{y}_j . Such transport plans are not unique, and one often seeks a solution $\pi^* \in \Pi(\boldsymbol{\mu}, \boldsymbol{v})$ that is most preferable in other ways, where $\Pi(\boldsymbol{\mu}, \boldsymbol{v})$ denotes the set of all viable transport plans. OT finds a solution that is most cost-effective w.r.t. cost function $C(\mathbf{x}, \mathbf{y})$:

$$\mathcal{D}(\boldsymbol{\mu}, \boldsymbol{v}) = \sum_{ij} \pi_{ij}^* C(\mathbf{x}_i, \mathbf{y}_j) = \inf_{\pi \in \Pi(\boldsymbol{\mu}, \boldsymbol{v})} \sum_{ij} \pi_{ij} C(\mathbf{x}_i, \mathbf{y}_j) \quad (1)$$

where $\mathcal{D}(\boldsymbol{\mu}, \boldsymbol{v})$ is known as OT distance. $\mathcal{D}(\boldsymbol{\mu}, \boldsymbol{v})$ minimizes the transport cost from $\boldsymbol{\mu}$ to \boldsymbol{v} w.r.t. $C(\mathbf{x}, \mathbf{y})$. When $C(\mathbf{x}, \mathbf{y})$ defines a distance metric on \mathcal{X} , and $\mathcal{D}(\boldsymbol{\mu}, \boldsymbol{v})$ induces a distance metric on the space of probability distributions supported on \mathcal{X} , it becomes the Wasserstein Distance (WD). We use WD as one loss objective, in addition to the standard cross-entropy loss, for the model update.

4 Dataset and Preprocessing

Dataset We conducted the experiments on the PTB-XL dataset (Wagner et al., 2020), which contains clinical 12-lead ECG signals of 10-second length. There are five conditions in total, including Normal ECG (NORM), Myocardial Infarction (MI), ST/T Change (STTC), Conduction Disturbance (CD), and Hypertrophy (HYP). The waveform files are stored in WaveForm DataBase (WFDB) format with 16-bit precision at a resolution of $1\mu\text{V}/\text{LSB}$ and a sampling frequency of 100Hz. The ECG statements conform to the SCP-ECG standard and cover diagnostic, form, and rhythm statements.

Preprocessing The raw ECG signals are first processed by the WFDB library (Xie et al., 2022) and Fast Fourier transform (FFT) to process the time series data into the spectrum, which is shown in Fig. 2. Then we perform n-points window filtering to filter the noise within the original ECG signals and adopt notch processing to filter power frequency interference (noise frequency: 50Hz, quality factor: 30). The ECG signals are segmented by dividing the 10-second ECG signals into individual ECG beats. We first detect the R peaks of each signal by ECG detectors (Porr et al., 2022), and then slice the signal at a fixed-sized interval on both sides of the R peaks to obtain individual beats. More details can be found in Appendix C.

Feature Extraction Instead of directly using the time-series signals, we extract time domain and frequency domain features to better represent ECG signals. The time-domain features include: maximum, minimum, range, mean, median, mode, standard deviation, root mean square, mean square, k-order moment and skewness, kurtosis, kurtosis factor, waveform factor, pulse factor, and margin factor. The frequency-domain features include: FFT mean, FFT variance, FFT entropy, FFT energy, FFT skew, FFT kurt, FFT shape mean, FFT shape std, FFT shape skew, FFT kurt. More details can be found in Appendix C. An analysis of the statistics of the processed ECG data can also be found in Table 1.

Table 1: Statistics of the processed ECG data.

Category	Patients	Percentage	Beats	Percentage
NORM	9528	34.2%	28419	36.6%

5 Experiments

5.1 Experimental Settings

Data and Model The dimension of the processed ECG is 864, including 600 ECG signals and 264 time & frequency domain features. Experiments are conducted on two NVIDIA A6000 GPUs. All the models’ parameters are listed in Appendix A.

Tasks To evaluate the learned embeddings from ECG signals, we tested the performance on two downstream applications: automatic cardiac report generation as a text generation (TG) task, and

Table 2: Comparisons of different backbones on Text generation (TG) and Disease detection (DD). (BERT as LLM)

Different backbones + BERT as LLM	Text generation (TG)						Disease detection (DD)		
	BLEU-1(%)	ROUGE-1(%)			Meteor(%)	BertScore(%)	Acc	AUCROC	F-1

BioDischargeSummary BERT (Alsentzer et al., 2019)	26.81	25.32	35.66	28.10	21.19	88.90	0.73	0.85	0.66

Table 4: Comparisons with supervised baselines (DD).

Supervised learning baselines	Acc	AUROC	F-1
Transformer (Zhu et al., 2022)	0.75	0.843	0.575
CNN (Śmigiel et al., 2021)	0.72	0.877	0.611
SincNet (Ravanelli and Bengio, 2018)	0.73	0.84	0.6
Contrastive Learning (Lan et al., 2022)	–	0.722	–
CNN + Entropy (Śmigiel et al., 2021)	0.76	0.910	0.68
Ours _{BERT}	0.77	0.92	0.68

zero-shot cardiac disease detection (DD) as a multi-class classification task.

Evaluation For text generation evaluation, we adopted the BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), Meteor (Banerjee and Lavie, 2005), and BertScore (Zhang et al., 2020) as evaluation metrics. We report the standard classification evaluation metrics for zero-shot cardiac disease detection: accuracy, AUCROC, and F-1 score.

5.2 Results

In Table 2, we showed the performance of both text generation and disease detection tasks with different backbone models as baselines. We found that the Transformer encoder outperforms other backbones, i.e., MLP, LSTM, and ResNet, showing Transformer encoder could be a good selection as the feature extractor.

In Table 4, we showed the performance of our zero-shot disease detection approach, compared with supervised baselines. Even though our method is in the zero-shot setting, we can already achieve the same performance with state-of-the-art supervised learning methods, demonstrating that the transferred ECG representation from LLM is al-

Table 5: Examples of comparison on generated reports (marked as Predicted-X) and ground-truth reports (marked as GT-X).

Backbone	Reports
GT-1	“sinus rhythm left type peripheral low voltage”
Predicted-1	“ventricular arrhythmia flatfar arrhythmia”
GT-2	“sinus rhythm incomplete right block otherwise normal ekg”
Predicted-2	“ventricularrear extrasystole block sinus rhythm or normal.”

ready good for practical usage. We also showed some examples of generated reports compared with ground-truth reports in Table 5.

5.3 Ablation Study

Different LLM To further analyze the components, we conduct ablation studies on different LLMs and the number of transformer layers (with BERT as LLM). Table 3 shows the results of different LLMs for the text generation and disease detection tasks. We found that all LLMs showed good performance in both tasks, demonstrating that knowledge can be transferred from the language domain to the cardiac domain without constraints. BART shows good performance in the text generation task, while BioClinical BERT shows better performance in the disease detection task, though the variation between different LLMs is not large.

Transformer Layers To evaluate the impact of the number of transformer layers, we conducted additional experiments with different transformer layers, and the results are shown in Table 6. We

Table 6: Ablation study of different transformer layers.

Layers	Text generation (TG)					Disease detection (DD)			
	BLEU-1(%)	ROUGE-1(%)			Meteor(%)	BertScore(%)	Acc	AUCROC	F-1
		P	R	F					
1	25.81	20.36	30.72	23.12	21.38	83.58	0.69	0.83	0.59
2	24.77	19.22	28.55	24.51	20.44	82.89	0.72	0.81	0.61
3	25.44	20.44	27.21	24.81	19.99	84.63	0.75	0.80	0.62
4	25.12	21.36	30.88	25.76	22.68	86.35	0.74	0.80	0.64
5	26.93	25.35	35.67	28.08	21.23	88.90	0.77	0.92	0.68

Table 7: Comparisons with different backbones on the text generation task, where BERT is used as LLM.

Backbone	BLEU-1(%)	ROUGE-1(%)			Meteor(%)	BertScore
		P	R	F		
MLP	18.16	16.19	13.71	14.48	12.11	80.77
LSTM	19.72	19.67	18.83	17.99	19.54	84.73
Resnet	21.15	20.35	20.67	24.08	19.55	85.22
Transformer	24.51	23.22	30.81	26.19	20.02	85.44

Table 8: Comparisons with different backbones on the disease detection task, where BERT is used as LLM.

Backbone	Acc	AUCROC	F-1
MLP	0.69	0.77	0.49
LSTM	0.71	0.82	0.59
Resnet	0.70	0.83	0.55
Transformer	0.75	0.81	0.60

found that more layers could lead to better representations, achieving better performance for downstream applications.

ECG Time Series Signals Only For the results above, we used ECG signals along with ECG time & frequency domain features as inputs. To compare the performance, we also conducted the experiments by only using ECG signals as inputs, with no time & frequency domain features. This set of experiments can be considered an additional ablation study for the inputs. The results are shown in Tables 7, 8, 9, 10.

Compare Table 7 & 8 with Table 2, we can find that the performance of only using ECG signals as inputs is lower than combining time & frequency features as inputs in both text generation and disease detection tasks, which demonstrates that incorporating time & frequency features is useful for capturing the characteristics of ECG and can lead to better representations through LLM.

In Tables 9, 10, the transformer backbone performs the best compared to others in both disease detection and text generation tasks, which is in consistent with the findings in the paper, showing that more layers could lead to better representations,

Table 9: Comparisons of different number of transformer layers on the text generation task, where BERT is used as LLM.

LLM	BLEU-1(%)	ROUGE-1(%)			Meteor(%)	BertScore(%)
		P	R	F		
1	25.52	19.10	27.65	21.43	20.11	86.52
2	24.21	20.00	28.75	23.90	20.32	84.66
3	23.44	20.44	27.21	24.81	19.99	84.63
4	23.17	20.99	28.01	24.44	20.18	87.65
5	25.69	24.75	34.81	27.59	21.03	87.33

Table 10: Comparisons of different numbers of transformer layers on the disease detection task, where BERT is used as LLM.

Num of Layers	Acc	AUCROC	F-1
1	0.62	0.79	0.51
2	0.74	0.80	0.60
3	0.71	0.82	0.59
4	0.72	0.83	0.61
5	0.75	0.88	0.64

achieving better performance for downstream applications. In addition, compared with Table 6 in the paper, we can find that the performance in Tables 9 and 10 are lower than the ones in Table 6, which also proved the same findings that adding time & frequency features is useful for learning the cardiac ECGs.

6 Conclusion

In this paper, we bridge the gap between LLMs and cardiovascular ECG by transferring knowledge of LLMs into the cardiovascular domain. The transferred knowledge embeddings can be used for downstream applications, including cardiovascular disease diagnosis and automatic ECG diagnosis report generation. Our results demonstrate the effectiveness of knowledge transfer, as the proposed method shows excellent performance in both downstream tasks, where our zero-shot classification approach even achieved competitive performance with supervised learning baselines, showing the feasibility of using LLM to enhance applications in the cardiovascular domain.

7 Acknowledgements

The research is partially supported by the DARPA ADAPTER program, and partially supported by the Allegheny Health Network and Mario Lemieux Center for Innovation and Research in EP.

8 Limitations

Due to the constrain of the available datasets, we only conducted experiments on the PTB-XL dataset, which is the current largest ECG dataset that contains high-quality clinical ECG signals and cardiac reports by experienced cardiologists.

We understand that collecting high-quality clinical data is much more complicated and time-consuming than collecting other data from online resources, like images, since it requires expert domain knowledge and is limited by many privacy regulations. We are working with cardiologists, hospitals, and clinical research labs, hope we can release a new dataset to provide additional materials for this research direction.

9 Ethics Statement

In this work, the data used as experimental materials are from publicly available databases, where the patients' information is anonymized. To the best of our knowledge, we do not foresee any harmful uses of this study.

A Experiment Parameters

We provide the experimental parameters of the models in the paper in Table 11 and Table 12.

B More Related Work

Cardiovascular Disease in Current Practice

Patients presenting with chest pain to the emergency department (ED) constitute a diagnostic and logistic challenge as chest pain can be caused by an extensive variety of disorders (Amsterdam et al., 2010). Diagnostic tests and decision algorithms play a critical role in speeding up the appropriate triage of chest pain patients in the ED, facilitating further (often more invasive) testing if warranted, and preventing unnecessary hospitalization of patients with non-critical disorders. In current practice, about half of the patients presenting with chest pain can be discharged from the ED, and only 5.5 percent of all ED visits lead to serious diagnoses (Hsia et al., 2016). However, research suggests the diagnosis of chest pain in the ED now costs an estimated \$10 to \$12 billion per year in the U.S. So a automatic cardiovascular disease diagnosis system is essential to provide cost-efficient patient care.

Deep learning in ECG Deep learning approaches have been rapidly adopted across a wide range of fields due to their accuracy and flexibility but require large labeled training sets. With the development in machine learning, many models have been applied to ECG disease detection (Kiranyaz et al., 2015; Nonaka and Seita, 2021; Khurshid et al., 2021; Raghunath et al., 2021; Giudicessi et al., 2021; Strodthoff et al., 2021; Qiu et al., 2022b; Zhu et al., 2022). Al-Zaiti et al. (2020) predicted acute myocardial ischemia in patients with chest pain with a fusion voting method. Acharya et al. (2017); Moody and Mark (2001) proposed a nine-layer deep convolutional neural network (CNN) to classify heartbeats in the MIT-BIH Arrhythmia database. Shanmugam et al. (2019) estimate a patient’s risk of cardiovascular death after an acute coronary syndrome by a multiple instance learning framework. Recently, Śmigiel et al. (2021) proposed models based on SincNet (Ravanelli and Bengio, 2018) and used entropy-based features for cardiovascular diseases classification. The transformer model has also recently been adopted in several ECG applications, i.e., arrhythmia classification, abnormalities detection, stress detection, etc (Yan et al., 2019; Che et al., 2021; Natarajan

et al., 2020; Behinaein et al., 2021; Song et al., 2021; Weimann and Conrad, 2021).

Multimodal Learning Formalized multimodal learning research dates back to 1989, when Yuhua et al. (1989) conducted an experiment that built off the McGurk Effect for audio-visual speech recognition using neural networks (Tiippana, 2014; McGurk and MacDonald, 1976). Aligning representations from different modalities is an important step in multimodal learning. With the recent advancement in computer vision and natural language processing, multimodal learning, which aims to explore the explicit relationship between vision and language, has drawn significant attention (Wang et al., 2020). There are many methods proposed for exploring the multimodal alignment objective. Torabi et al. (2016); Yu et al. (2017) adopted attention mechanisms, Dong et al. (2021); Qiu et al. (2022a,d,c) composed pairwise joint representation, Chen et al. (2020); Wray et al. (2019); Zhang et al. (2018) learned fine-grained or hierarchical alignment, Lee et al. (2018); Wu et al. (2019) decomposed the images and texts into sub-tokens, Velickovic et al. (2018); Yao et al. (2018) adopted graph attention for reasoning, and Yang et al. (2021) applied contrastive learning algorithms for video-text alignment.

Multimodal Learning in Healthcare Applications

Many previous works have explored multimodal learning to boost performance in clinical healthcare applications, i.e., affective computing for depression disease detection and so on (Liu et al., 2021; Qiu et al., 2018a; Liu et al., 2019a; Qiu and Zhao, 2018; Qiu et al., 2018b, 2019; Han et al., 2022). Liu et al. (2021); Qiu et al. (2018a); Liu et al. (2019a); Qiu and Zhao (2018); Qiu et al. (2018b) explored the inner correlation between different modalities. Bao et al. (2019) investigated the demographics, showing that the subject’s individual characteristics can also be involved in robustness and personalized design. Qiu et al. (2019) investigated the relationship between computational vision models and computational neuroscience. Holenstein et al. (2021); Han et al. (2022) explored the connectivity between natural language and EEG signals.

C Preprocessing

The raw ECG signals are first processed by the WFDB library (Xie et al., 2022) and Fast Fourier

transform (FFT) to process the time series data into the spectrum, which is shown in Fig. 2. Then we perform n-points window filtering to filter the noise within the original ECG signals and adopt notch processing to filter power frequency interference (noise frequency: 50Hz, quality factor: 30). The ECG signals are segmented by dividing the 10-second ECG signals into individual ECG beats. We first detect the R peaks of each signal by ECG detectors (Porr et al., 2022), and then slice the signal at a fixed-sized interval on both sides of the R peaks to obtain individual beats. Examples of the filtered ECG signal results after n-points window filtering, notch processing, R peak detection, and segmented ECG beats are shown in Figures. 3,4,5.

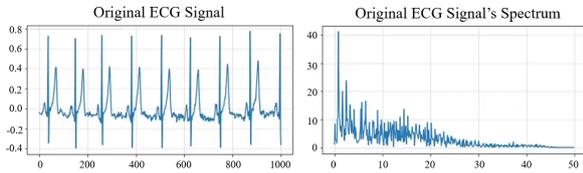

Figure 2: ECG data in the format of time series and spectrum.

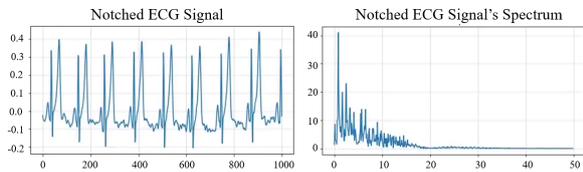

Figure 3: Filtered ECG data in the format of time series and spectrum.

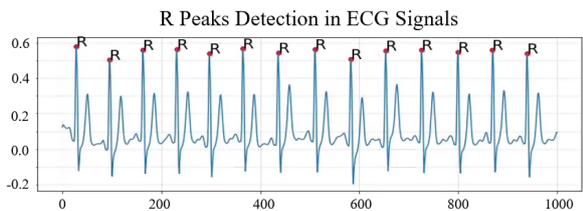

Figure 4: Detecting R peaks in the ECG signals.

Table 13: ECG statistical features in the frequency domain.

Feature Symbol	Formula
Z_1	$\frac{1}{N} \sum_{k=1}^N F(k)$
Z_2	$\frac{1}{N-1} \sum_{k=1}^N (F(k) - Z_1)^2$
Z_3	$-1 \times \sum_{k=1}^N \left(\frac{F(k)}{Z_1 N} \log_2 \frac{F(k)}{Z_1 N} \right)$
Z_4	$\frac{1}{N} \sum_{k=1}^N (F(k))^2$
Z_5	$\frac{1}{N} \sum_{k=1}^N \left(\frac{F(k) - Z_1}{\sqrt{Z_2}} \right)^3$
Z_6	$\frac{1}{N} \sum_{k=1}^N \left(\frac{F(k) - Z_1}{\sqrt{Z_2}} \right)^4$
Z_7	$\frac{\sum_{k=1}^N (f(k) - F(k))}{\sum_{k=1}^N F(k)}$
Z_8	$\sqrt{\frac{\sum_{k=1}^N [(f(k) - Z_6)^2 F(k)]}{\sum_{k=1}^N F(k)}}$
Z_9	$\frac{\sum_{k=1}^N [(f(k) - F(k))^3 F(k)]}{\sum_{k=1}^N F(k)}$
Z_{10}	$\frac{\sum_{k=1}^N [(f(k) - F(k))^4 F(k)]}{\sum_{k=1}^N F(k)}$

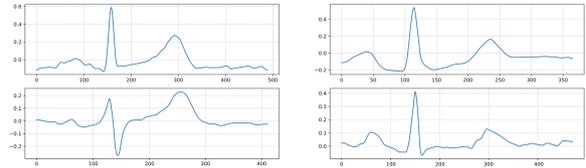

Figure 5: Extracted ECG beats divided by R peaks.

Feature Extraction Instead of directly using the time-series signals, we extract time domain and frequency domain features to better represent ECG signals. The time-domain features include: maximum, minimum, range, mean, median, mode, standard deviation, root mean square, mean square, k-order moment and skewness, kurtosis, kurtosis factor, waveform factor, pulse factor, and margin factor. The frequency-domain features include: FFT mean, FFT variance, FFT entropy, FFT energy, FFT skew, FFT kurt, FFT shape mean, FFT shape std, FFT shape skew, FFT kurt. The function of each component is shown in Table 13. An analysis of the statistics of the processed ECG data can also be found in Table 1.

D Transformer Encoders

The input for the Transformer is the ECG signal. First, we feed out the input into an embedding layer, which is a learned vector representation of each ECG feature by mapping each ECG feature to a vector with continuous values. Then we inject positional information into the embeddings by:

$$\begin{aligned} PE_{(pos,2i)} &= \sin\left(pos/10000^{2i/d_{\text{model}}}\right) \\ PE_{(pos,2i+1)} &= \cos\left(pos/10000^{2i/d_{\text{model}}}\right) \end{aligned} \quad (2)$$

The attention model contains two sub-modules, a multi-headed attention model and a fully connected network. The multi-headed attention computes the attention weights for the input and produces an output vector with encoded information on how each feature should attend to all other features in the sequence. There are residual connections around each of the two sub-layers followed by a layer normalization, where the residual connection means adding the multi-headed attention output vector to the original positional input embedding, which helps the network train by allowing gradients to flow through the networks directly.

In our model, our attention model contains N same layers, and each layer contains two sub-layers, which are a multi-head self-attention model and a fully connected feed-forward network. Residual connection and normalization are added in each sub-layer. So the output of the sub-layer can be expressed as: $\text{Output} = \text{LayerNorm}(x + (\text{SubLayer}(x)))$ For the Multi-head self-attention module, the attention can be expressed as: $\text{attention} = \text{Attention}(Q, K, V)$, where multi-head attention uses h different linear transformations to project query, key, and value, which are Q , K , and V , respectively, and finally concatenate different attention results:

$$\text{MultiHead}(Q,K,V) = \text{Concat}(\text{head}_1, \dots, \text{head}_h)W^O \quad (3)$$

$$\text{head}_i = \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \quad (4)$$

where the projections are parameter matrices:

$$\begin{aligned} W_i^Q &\in \mathbb{R}^{d_{\text{model}} \times d_k}, & W_i^K &\in \mathbb{R}^{d_{\text{model}} \times d_k} \\ W_i^V &\in \mathbb{R}^{d_{\text{model}} \times d_v}, & W_i^O &\in \mathbb{R}^{h d_v \times d_{\text{model}}} \end{aligned} \quad (5)$$

where the computation of attention adopted scaled dot-product:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (6)$$

For the output, we use a 1D convolutional layer and softmax layer to calculate the final output.

Practical Takes on Federated Learning with Pretrained Language Models

Ankur Agarwal Mehdi Rezagholizadeh Prasanna Parthasarathi

Huawei Noah’s Ark Lab, Montréal

{ankur.agarwal1,mehdi.rezagholizadeh,prasanna.parthasarathi}@huawei.com

Abstract

Real-world applications of language models entail data privacy constraints when learning from diverse data domains. Federated learning with pretrained language models for language tasks has been gaining attention lately but there are definite confounders that warrants a careful study. Specifically, understanding the limits of federated NLP applications through varying the effects of different aspects (such as data heterogeneity, the trade-off between training time and performance, the effect of different data, and client distributions and sensitivity of the shared model to learning local distributions) is necessary to evaluate whether language models indeed learn to generalize by adapting to the different domains. Towards that, we elaborate different hypotheses over the components in federated NLP architectures and study them in detail with relevant experiments over three tasks: Stanford Sentiment Treebank-2, OntoNotes-5.0 and GigaWord. The experiments with different Transformer inductive biases on the variety of tasks provide a glimpse at the understanding of federated learning at NLP tasks. Specifically, the analysis suggests that regularization due to the ensembling effect may be masquerading as domain adaptation of federated learning in NLP with pre-trained language models.

1 Introduction

The success of large pretrained language models (Devlin et al., 2019; Liu et al., 2019; Radford et al., 2019; Lewis et al., 2019) have demonstrated their applicability in consumer-based natural language processing (NLP) applications (Otter et al., 2020). While there are such massive datasets (Kiela et al., 2021; Wang et al., 2021), making models trained on these datasets to reflect the data diversity is an important challenge towards building equitable NLP systems. Hence, treating the distribution of data over the users as non-IID (McMahan and Ramage, 2017; Xu et al., 2018; Liu and Mazumder, 2021) to

better emphasize the preferences of users as personalization gets naturally extended to the consumer NLP applications.

But, recent studies highlight that pretrained language models (PLMs) (Devlin et al., 2019) tend to get their predictions skewed by the frequency effects of tokens in the data distribution (Wei et al., 2021), this is concerning from a privacy and personalization standpoint. Han and Eisenstein (2019); Ramponi and Plank (2020); Carlini et al. (2022) show that neural language models (even the large pretrained architectures) have challenges in adapting to different data distributions on generative and classification tasks alike.

Federated learning (FL) (McMahan and Ramage, 2017; Konečný et al., 2016) has been gaining popularity in machine learning as a practical way to mitigate domain adaptation with the promise of data privacy. FL as a learning paradigm focuses on learning a shared model through training data distributed over several clients. Such approaches have only recently begun to focus on NLP applications (Mammen, 2021; Lin et al., 2021). Lin et al. (2021) suggest that the success of federated algorithms can be improved through adapting over the client distribution that improves the generalization performance across the client distributions.

However, the opaqueness of the pretraining routine — primarily, quantifying what, and how much of that a language model has learnt from the pretraining corpora (Zhu et al., 2015; Devlin et al., 2019; Gao et al., 2020) cast a shadow on evaluating the effectiveness of these architectures in learning from diverse domains. Understanding the roles of different inductive biases not limited to the architecture, loss functions and data distribution becomes imperative to carefully look at claims of “domain adaptation” (Kouw and Loog, 2018). The representation of texts guided by syntax and semantic elements makes generalization to non-IID distributions in NLP more challenging if not the same when

compared to domains such as computer vision (Liu et al., 2020; Luo et al., 2021; Zhuang et al., 2021; Yang et al., 2021). Then, it becomes imperative to understand the role of different constituents in the federated learning in NLP setup to take steps in the right direction. In that regard, we investigate four major hypotheses detailing the confounding variables in federated NLP systems: (1) role of pretrained weights in FL’s domain adaptation, (2) distribution of clients, (3) Data homogeneity, and (4) robustness of personalizing to local distribution. Although the primary focus of the paper is to generate discussions along these questions, we support the discussions with relevant experiments on 3 different NLP tasks on 2 large Transformer architectures.

2 Background

Federated Learning Federated learning assumes the set up of K clients $\{C_k\}_{k=1}^K$ with different data distributions and a single server model S . Each client model, θ_{C_k} , is initialized by the server model θ_S a dedicated copy of the server model and then updated locally on the k^{th} client data distribution using an optimizer Opt_{C_k} . This distributed learning is repeated iteratively over R rounds. At each round r , the client models, $\theta_{C_k}^r$, are initialized with the aggregated weights of all the client models from the previous round ($r-1$), referred to as the central server model, θ_S^r . The rounds end with accumulation and aggregation of gradients from all the client models to update the server model with optimizer Opt_S and continued until convergence on an unseen set (D_{test}). FedOpt, a popular federated learning algorithm is shown in Algorithm 1.

Algorithm 1 FedOpt Algorithm (Asad et al., 2020)

Input: $\theta_S^0, \text{Opt}_{C_k}, \text{Opt}_S$
for $r = 1$ **to** R **do**
 for $k = 1$ **to** K **in parallel do**
 $\theta_{C_k}^r \leftarrow \theta_S^{r-1}$
 for $e = 1$ **to** E **do**
 $g_{C_k}^r \leftarrow \nabla_{\theta}(\theta_{C_k}^r | D_k)$
 $\theta_{C_k}^r \leftarrow \text{Opt}_{C_k}(\theta_{C_k}^r, g_{C_k}^r)$
 end for
 $\Delta_k^r \leftarrow \theta_{C_k}^r - \theta_S^{r-1}$
 end for
 $\Delta^r \leftarrow \frac{1}{K} \sum_{k=0}^K \Delta_k^r$
 $\theta_S^r \leftarrow \text{Opt}_S(\theta_S^{r-1}, \Delta^r)$
end for

The Performance Gap Like in (Lin et al., 2021), we compare the performance of federated server, θ_S , with θ_{central} over a common unseen set, D_{test} as in Equation 1,

$$\Delta \text{Perf} = \text{Perf}_S - \text{Perf}_{\text{central}} \quad (1)$$

where θ_{central} is trained over $\{D_k\}_{k=1}^K$ until convergence. Accuracy, F1, or Rouge score (Lin, 2004) can be used for measuring Perf.

Generalization Personalization trade-off Let the best server generalization performance is measured over D_{test} be $\mathcal{P}_{\text{server}}^*$. The generalization performance of the client model trained in r^* is measured on D_{test} be $\mathcal{P}_{\text{client}_k}^*$. The performance of the client model on D_k in round r^* measured be $\tilde{\mathcal{P}}_{\text{client}_k}$, which acts as a proxy to the personalization on D_k . Then, we measure the difference in the test loss for every client, k , between $\theta_{C_k}^*$ and θ_S^{*-1} as ΔP .

$$\Delta \mathcal{P}_k(\mathbf{x}_i) = \mathcal{P}_{\text{client}_k}^*(\mathbf{x}_i) - \mathcal{P}_{\text{server}}^{*-1}(\mathbf{x}_i) \quad (2)$$

For every $\mathbf{x}_i \in D_{\text{test}}$, the correlation between $\Delta \mathcal{P}_k(\mathbf{x}_i)$ to that of $\tilde{\mathcal{P}}_{\text{client}_k}$ measures the mutual cost of personalization to D_k on the generalization performance on D_{test} . Also, we measure the average the empirical risk of $\theta_{C_k}^*$ over D_k as $\tilde{\mathcal{P}}_{\text{client}_k}$:

$$\tilde{\mathcal{P}}_{\text{client}_k} = \frac{1}{|D_k|} \sum_{j=0}^{|D_k|} \mathcal{P}_{\text{client}_k}(\mathbf{x}_j) \quad (3)$$

We now define the trade-off metric as the slope between $\Delta \mathcal{P}_k(\mathbf{x}_i)$ and $\tilde{\mathcal{P}}_{\text{client}_k}$ over all $\mathbf{x} \sim D_{\text{test}}$ and K . $m_{\Delta P}$ measures the unit increase in generalization performance for adapting to D_k . Or $m_{\Delta P}$ estimates the cost of personalizing over the client distribution. Consequently, we make the interpretations for the metric $m_{\Delta P}$ — (a) positive slope (\nearrow) indicates that learning on local distribution aids in better generalization, (b) negative slope (\searrow) indicates that generalization inhibits the learning from local distributions, or (c) neutral (\longrightarrow) shows that the model is unaffected by learning.

3 Related Work

Multi-Domain Learning Realtime applications of most tasks have shown diverse distribution of datapoints requiring domain adaptation strategies (Daumé III, 2009; Dredze and Crammer, 2008). The effect of such domain shift in NLP has been

a topic of study for a while (Blitzer et al., 2006; Quiñonero-Candela et al., 2008; Blitzer, 2008; Ben-David et al., 2010; Cui and Bollegala, 2019). The general topic of domain adaptation in NLP shares similarity with the topics of continual learning (Sun et al., 2019), transfer learning (Devlin et al., 2019; Radford et al., 2019), multi-task learning (Collobert and Weston, 2008), and federated learning (Lin et al., 2021). Federated learning however, is different from the other paradigms since it emphasizes on the notion of preserving privacy of different local data distributions. To that, sophisticated approaches to aggregate the gradients to transfer learning from clients to the shared model (e.g. FedProx (Li et al., 2020), FedAvg (McMahan et al., 2017a), and FedOpt (Asad et al., 2020)) have showcased improvements in the generalization of the shared parameters. On the other hand, due to the many interactions of the clients with the server, communication overhead is an important aspect, and FedOpt (Asad et al., 2020) has been shown to better address it over existing federated algorithms.

Overview of Federated Learning Federated learning (McMahan and Ramage, 2017; Mammen, 2021) addresses the challenge of learning from private data spanning over multiple clients. Although the evaluation of such architectures prioritizes the generalization of the shared model, Mendieta et al. (2022) highlight that learning from the local distributions is critical towards that. The key to such efficient learning in federated architectures has been shaped by homogeneous and heterogeneous data or model (Li and Wang, 2019) distribution in clients (model architectures across clients have similar or different parameters). Further, the emphasis on privacy of client data has also been mitigated through the recent progress in knowledge distillation. However, systematic studies (Kairouz et al., 2021; Li et al., 2021) over federated architectures have identified potential biases due to unbalanced data of clients or diversity in the label distribution among others. Chen et al. (2018) propose a meta learning approach for federated learning that improves personalizing to the non-IID client distributions. Also, constraints on data privacy makes it difficult to import approaches (Kirkpatrick et al., 2017; Rolnick et al., 2019) that avoid catastrophic forgetting of distributions in continual learning tasks.

Federated Learning for language tasks Distributed training on language tasks with federated

learning has been gaining some attention. McMahan et al. (2017b) trained a differentially private language model over non-IID data distributions while Ge et al. (2020) trained a recurrent + convolutional architecture for medical named entity recognition task. Recently, Lin et al. (2021) proposed a framework that enables using modern pretrained language models on different language understanding tasks. Lin et al. (2021) discuss and hypothesizes a gap between the performance of Transformer architectures between the federated and centralized setting with data heterogeneity. Dupuy et al. (2022) analyze the effect of having clients with different amounts of data gathered from Alexa devices and suggest that non-uniform selection of devices improves the performance of the shared model.

In this work, we attempt to investigate different possible confounders for domain adaptation claims of federated systems in NLP and elaborately analyze them in the language tasks of classification, sequence tagging and sequence generation tasks that are popularly used with Transformer architectures.

4 Experiments

Models and Tasks We experiment with a focus on the *pretrain-finetune* setup that is popular with Transformer architectures on many language tasks. Of the many, we pick three tasks—Stanford Sentiment Treebank 2 (SST-2) (Socher et al., 2013), OntoNotes (v5.0) (Weischedel et al., 2013) and Gigaword (Graff et al., 2003) that fall into the broad categories of text classification, sequence tagging, text-generation respectively. The data splits are as used in (Lin et al., 2021), please refer §B for details. As for the models¹, we use BART-Base (Lewis et al., 2019) for text generation and DistilBERT (Sanh et al., 2019) for the other two tasks. In the experiments we use the models *with* (—) and *without* (----) pretrained weights²³.

Centralized Training We use batch-wise gradient descent with AdamW (Loshchilov and Hutter, 2017) as the optimizer along with a linear learning rate scheduler. We use cross-entropy for model selection across the tasks. Also, in our analysis, we

¹We use the transformer weights shared in huggingface: ‘distilbert-base-uncased’ and ‘facebook/bart-base’.

²Across the experiments the line style and the colour is used to denote the corresponding model performances.

³The without pretrained weights setting trains the models from scratch.

Dataset	Model	Metric	Pretrained	Cent.	Fed.	$\Delta(\text{Perf})$	$\Delta(\text{Rel.}\%)$
SST2	DistilBERT	Accuracy	✓	89.0 \pm 0.8	87.8 \pm 0.4	1.3	–
			✗	69.2 \pm 3.2	67.8 \pm 1.0	1.4	7.7 ▲
OntoNotes	DistilBERT	F1	✓	85.9 \pm 0.1	84.4 \pm 0.1	1.5	–
			✗	65.1 \pm 0.3	55.3 \pm 0.3	9.8	550 ▲
Gigaword	BART	Rouge1	✓	34.6 \pm 0.7	32.5 \pm 0.2	2.1	–
			✗	6.1 \pm 0.5	2.9 \pm 0.6	3.2	50 ▲

Table 1: Comparison between the $\Delta(\text{Perf})$ of federated and corresponding centralized set up when using (✓) and *not* using (✗) pretrained transformer weights. Across the 3 tasks it can be seen that the gap increases when not using pretrained weights (▲) suggesting that the pretrained weights of transformer are possibly doing the heavy lifting in domain adaptation of federated learning in language tasks.

use cross-entropy of samples in the test set to evaluate the relative performance of models compared. The complete results of the experiments are in §F.

Federated Training For the federated experiments, we partition the training dataset for the clients and train them using the FedOpt algorithm (Asad et al., 2020) to estimate the server parameter updates. Further, we use AdamW with a linear learning rate scheduler to estimate the gradients in our experiments. The round with the best server test loss is selected as the best round (For the complete results please refer to §F; for their run-time refer to §E).

Evaluation Metrics The metric of evaluation (*Perf*) is accuracy for sentence classification, F1-span for sequence tagging and ROUGE1 score for text summarization.

4.1 Motivation

Federated NLP considers two powerful learning paradigms— Federated algorithms aggregate the gradient updates over clients trained with non-identical data distributions while maintaining privacy, and PLMs trained over large corpora with a generic objective that gives a better downstream performance. Stickland and Murray (2019) and Peng et al. (2020) show that PLMs are successful in tasks that require domain adaptation. The motivation primarily relies on verifying if federated algorithms and PLMs share a synergy in the extreme domain adaptation scenario.

To that, we first study the role of pretrained weights as a confounding variable in the federated setup. The null hypothesis being the federated learning not affected much by the pretrained weights should be supported with $\Delta(\text{Perf})$ remaining similar in both cases. But, in Table 1 across different tasks we see that $\Delta(\text{Perf})$ increases when

not using pretrained weights. This suggests that the pretrained weights may be supporting the performance of federated learning in NLP applications. The corollary to this observation could be that the learning in a federated setting may not be happening from adapting to the client distributions. This raises concerns on personalization that if at all the federated NLP setup with PLM learns anything from the client distribution.

4.2 Estimating the Confounding Variables

Pretraining and Federated Learning Towards understanding the essence of the pretrained weight’s semantic prior as a confounding role in the success of FL for NLP, we continue to control for it in the remainder of the experiments. Disentangling such observations is necessary to objectively analyze the federated algorithm for language tasks.

Contribution by Client size One major challenge in the realistic setting of federated learning for data-driven tasks is the data imbalances that naturally occur among the clients (Lin et al., 2021; Dupuy et al., 2022). The distribution of number of data samples that each client has creates two distinct classes of clients— *major* and *minor* players— whose updates may affect the parameters of the shared server model differently. Generalization aside, ensuring personalization to the local distribution of data in the clients also becomes necessary in different scenarios arisen from the diverse data distributions. While extreme distributions may provide a regularization effect due to the ensemble learning (Balaji et al., 2018; Kumar et al., 2020; Stanton et al., 2021), the objective being able to better generalize through adapting to different local distributions require careful consideration of the distribution of clients. Towards understanding the limits of learning under the influence of clients

of different sizes, we evaluate the role of minor clients by ablating clients smaller than a *threshold* (τ) number of samples.

Client Personalization and Server Generalization Personalization emphasizes the shared model’s capacity to be representative of all clients’ distributions alike. But, training on the local distribution may affect the generalized representation of the shared model similar to the catastrophic forgetting in continual learning (Kirkpatrick et al., 2017) or mode collapse in generative modeling (Salimans et al., 2016). Using PLMs due to their robust semantic representations could alleviate some of these challenges. More specifically, we formulate our questions as ablation experiments: (a) How are personalization and generalization related across different tasks and client distributions (b) Does removing updates from minor players affect this relation? We study these questions in experiments with the help of $m_{\Delta P}$ metric.

Client data partitioning distribution Generalization to unseen distribution, and how well the local client distributions are personalized over the federated learning rounds is also affected by the distribution of samples over the clients. Towards understanding the effect of the sample distribution on the personalization-generalization relation we compare the learning of the server model between non-uniform distribution that is closer to real world scenario, and a more controlled uniform distribution of samples among the clients to (a) evaluate the effect of generalization by the shared model and the personalization to local distribution by varying the number of samples per client uniformly over all the clients, and (b) we perform ablations on the updates by thresholding the clients on heterogeneous data distribution set up to understand the ideal scenarios in different language tasks.

4.3 Additional Setup

Dataset Partitioning Strategies For the study, we use data selection for the clients using two different strategies. Please refer to §C for the choice of hyper-parameters for the two methods.

Random partitioning samples data over $\{C\}_{k=1}^K$ by sampling from a Dirichlet distribution over the K clients with $\alpha = 0.1$ (Lin et al., 2021). For ablation on random distribution, we use hyperparameter τ that denotes the minimum

number of samples in C_i for its parameters to be aggregated.

Uniform partitioning distributes the data uniformly over $\{C\}_{i=1}^K$, which is controlled by a hyperparameter γ . Specifically, uniform distribution is constructed by sampling *at least* γ samples from each class for each client in the classification tasks. For the text summarization dataset, we cluster the SentenceBERT embedding (Reimers and Gurevych, 2019) and use KMeans++⁴ (Arthur and Vassilvitskii, 2006) with 8 as the number of clusters, and sample uniformly over them.

Distributional Similarity We use MAUVE score (Pillutla et al., 2021) to measure the similarity between different text distributions in the experiments. The score uses GPT-2 (Radford et al., 2019) estimating the distributional similarity. Also, we use `mauve_scaling_parameter` set to 20. The score ranges between 0 and 1, where 1 indicates significant overlap.

5 Results

Following our motivation in §4.1 and questions raised for the confounders to the federated system for NLP tasks in §4.2, we structure the results to our investigation in this section.

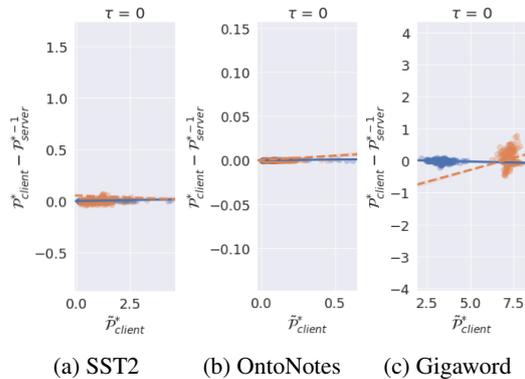

Figure 1: We observe the effect of domain shift by measuring the δ change in the loss over every sample in the test set ($\mathcal{P}_{client} - \mathcal{P}_{server}^{*-1}$) and drawing a correlation with the average loss over the train distribution in the clients ($\tilde{\mathcal{P}}_{client}$).

5.1 Effectiveness of Pretrained weights in adapting to client data distributions

An ideal model is expected to not discount the learning on the client distributions for better gener-

⁴We use the implementation in www.scikit-learn.org.

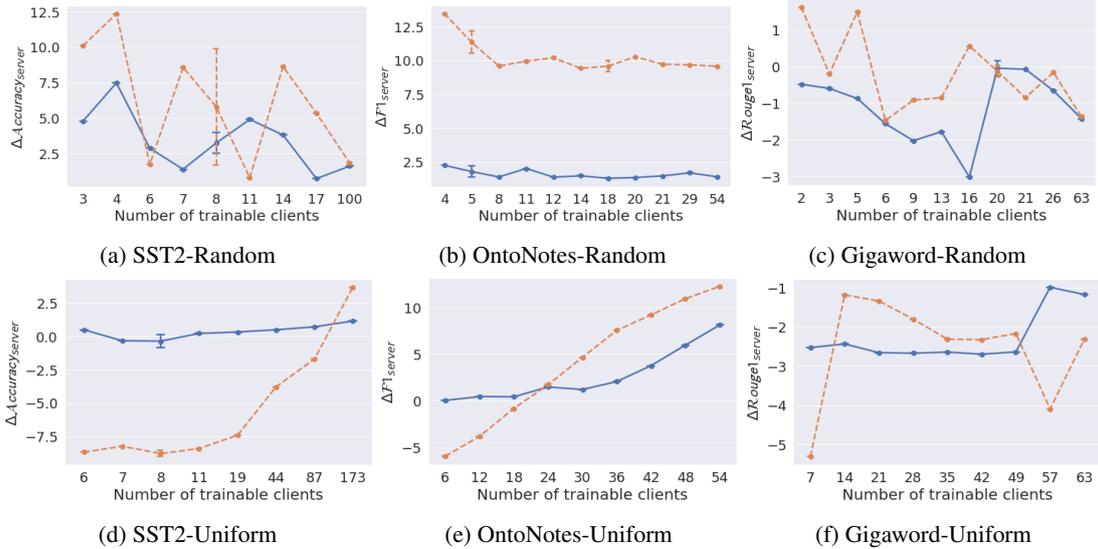

Figure 2: By varying the number of trainable clients in the random setting across the tasks, we measure the sensitivity of the shared model’s performance (Cent. – Fed.: ∇ indicates federated model performing better) to data removal as high as $\sim 55\%$ of training data (SST-2: $\sim 55\%$, OntoNotes: $\sim 33\%$ and Gigaword: $\sim 20\%$ with the smallest number of clients).

alization performance. To verify whether such discounting happens, we analyze the personalization-generalization trade-off with the $m_{\Delta P}$ metric. In Figure 1, across the datasets we observe that the correlation stayed more neutral than positive, suggesting that the pretrained model may not be learning much from the local distributions. We observe a relatively positive $m_{\Delta P}$ value when trained without the pretrained weights. This could be an anticipated behaviour, as the model relies on the information in the client distribution for generalization, unlike the pretrained weights that come with a semantic prior.

5.2 Client contributions to the metrics

We set up additional experiments to understand the contribution of clients in more detail. Particularly, we begin by studying our experiment of ablating updates from the clients that are below threshold (τ) on the *random* experiments. We hypothesize that as the threshold value is increased, the server model is restricted to learning from fewer client local distributions and the generalization performance should also decline as a result. On the contrary, we note in Figure 2 (top row) that the performance of the with pretrained model remained relatively unchanged across the datasets. However, the MAUVE scores estimated over the Ablated, Unablated and Test (Unseen) distributions of data in Table 2 suggest that the test distribution are not close to the ablated

Dataset	$U - A$	$U - T$	$A - T$
SST2	0.52 ± 0.06	0.48 ± 0.07	0.47 ± 0.07
OntoNotes	0.64 ± 0.06	0.53 ± 0.07	0.51 ± 0.06
Gigaword	0.58 ± 0.07	0.45 ± 0.07	0.45 ± 0.07

Table 2: The MAUVE score between the distribution of data in ablated (A), unablated (U) and unseen (T) splits with maximum value of τ in the random distribution setting. The values indicate the maximal distance between the distributions across the tasks.

or unablated clients’ distributions⁵. The performance of the pretrained model in the federated setup, still being little affected only suggests that pretrained models may not be learning from the local distributions that hurt the claims of personalization to these distributions.

If not adapting to the local distributions, we further investigate whether the pretrained models use the updates from client distributions as regularization. To that, we repeat the same experiments on the same datasets with the more controlled uniform distribution setting.

Do client sizes affect the gap To have a clearer picture of the client size affecting the learning contribution, we use the *uniform* distribution with γ controlling the data partitioning size uniformly over all the clients. In Figure 2 (bottom row), we observe a trend showing that the models’ performance

⁵Scores closer to 1 indicate significant overlap

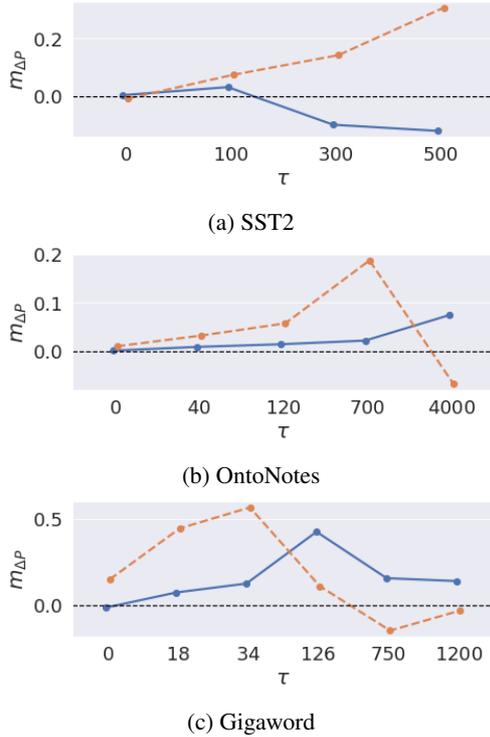

Figure 3: Impact of personalization of clients on generalization of server— $m_{\Delta P}$ values depict the impact in Random distribution strategy when ablating minor clients over different τ values.

(pretrained or not) decreases drastically as the number of clients increases and the client partitioning sizes progressively become smaller. Similar observation across the different tasks suggests that the model requires a quorum of samples to minimize the gap across (Equation 1) the different tasks in a federated setup.

Do client sizes affect the trade-off Again here, we adjust for τ in *random* setting, where the clients with less than τ number of samples are restricted from updating the server parameters. We measure $m_{\Delta P}$ values for the varying τ values in Figure 3. We observe that with updates primarily from more minor clients (lower τ value), the generalization is less affected by personalization. But, the gap being lower as shown in Figure 2 suggests that the noisy updates with fewer clients be acting as a regularizer for the server updates. Further, as the value of τ increases (Figure 3), the trade-off remains healthier until a certain value of τ and then it drops. This trend could be attributed to the fact that with a higher τ value the number of clients updating the server becomes lesser with more data points, which provides better generalization but personalization due to variance in the client distribution gets chal-

lenging.

To understand the impact of varying client distributions on the trade-off, we perform the same analysis with *uniform* distribution shown in Figure 4. The pretrained model’s generalization remains unaffected with more minor clients across SST-2 and GigaWord tasks supporting the alternate that updates from minor clients provide a regularization effect as we also see the gap to remain the same in Figure 2. On OntoNotes, while the $m_{\Delta P}$ value stays the same the gap widens as observed in Figure 2. The varying results do not provide conclusive evidence on whether the pretrained models can learn to adapt to different domains in such extreme settings. Answering this is non-trivial which requires a careful consideration of the pretraining datasets and characterization of domains based on—task, topic, syntax, style etc.

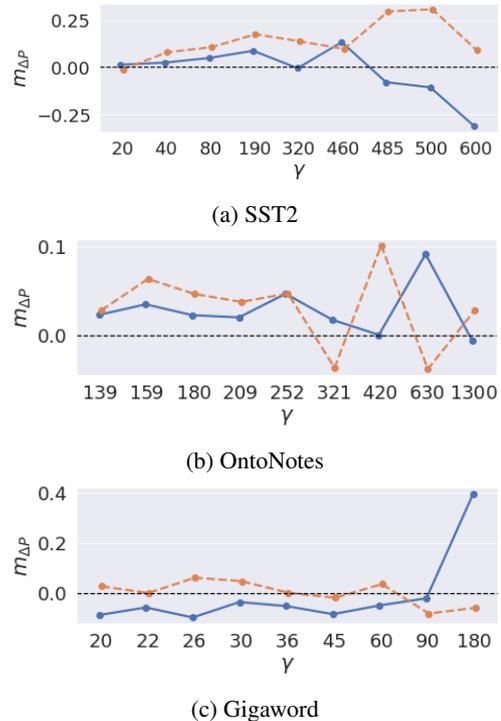

Figure 4: Impact of personalization of clients on generalization of server— $m_{\Delta P}$ values depicting the impact in Uniform distribution strategy with varying sizes of clients.

Time-Performance trade-off with varying client sizes The dropping of updates from the minor clients could also provide acceleration in the number of rounds, R , as federated learning has a communication overhead. We measure the performance of server with pretrained weights, Perf_S , over the different tasks and the number of rounds (R) taken

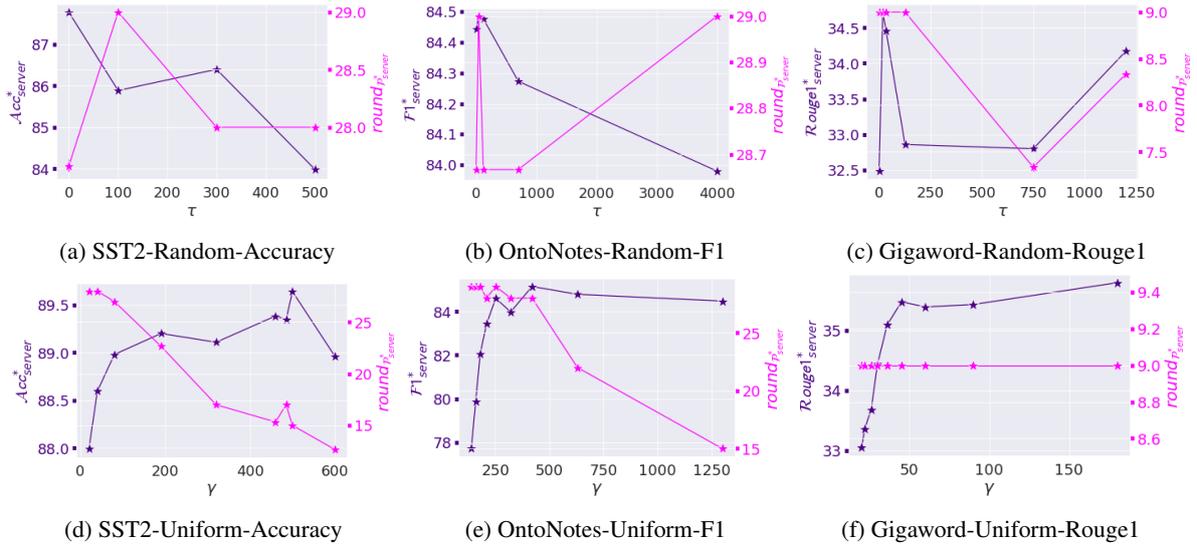

Figure 5: We compare R taken to converge when varying the number of clients in the uniform and in the random distribution settings with pretrained weights (\checkmark). We also measure the corresponding Perf_S of the server model in the task.

by the set up to converge.

In Figure 5, we compare across the tasks with *random* distribution and the *uniform* distribution of samples with pretrained weights by varying the τ and γ respectively. In the random distribution experiments, as we are discarding parameter updates from clients we observe a *not-so-steep* drop in the Perf_S of the server model in SST-2 and OntoNotes. On the other hand, in Gigaword dataset experiments the impact of dropping the clients did not affect Perf_S . With respect to R , τ value being inversely proportional to the number of clients, we did not see a drastic acceleration to the number of rounds as lesser clients also increased the difficulty of the tasks.

In *uniform* setting, by varying the number of clients without the data loss, we make two observations: (1) The Perf_S is always better than when compared with *random* setting, (2) the performance saturates after a certain γ across the tasks, and (3) the number of rounds taken by the models to converge shows drastic decrease as the number of clients decreases. We hypothesize that with only major clients the gradient updates are stable to enable faster convergence. This contradicts with the observation in (Lin et al., 2021) that shows a wider gap in the performance when training pretrained transformer models in a federated set up, which we observe only when *not* using pretrained weights. Collectively, the results hint that the federated set up with PLMs suffer from personalizing

to the client distributions, and the generalization on tasks may be a regularization of the distributed set-up.

6 Conclusion

This work explores pertinent questions that require a closer look at evaluating PLMs in the federated setting. Through empirical observations, we find that in federated learning, where the emphasis is more on personalization while ensuring privacy there could be a risk of pretrained models overlooking the client distributions. We also evaluated the effects of varying the client distributions which suggested that the gap between centralized and federated performance to be reduced when the samples are uniformly distributed over the clients. While that is ideal, the random distribution too does not suffer significant performance loss with pretrained weights. However, the critical aspect of the questions stems from the need to investigate the pretraining routine in identifying the *right* domain adaptation challenges for pretrained models. The gap being minimized while the personalization taking a toll calls for a deeper inspection to explore the limits of domain adaptation in PLMs with an appropriate evaluation framework (datasets, and metrics) that controls for the *leak* in the pretraining corpus.

Acknowledgements

We thank Guojun Zhang, and Xi Chen from the federated learning team at Huawei Noah’s Ark Lab, Montréal for the many interesting discussions. We thank the anonymous reviewers for their insightful comments to our work. We also want to reproduce our results on Mindspore⁶ in future, which is a new deep learning computing framework.

Limitations

The study, though, considers sample tasks from the different language tasks the downstream tasks generally are smaller in the size, and not much diversity with respect to the task complexity is considered. Though there is motivation for using FedOpt for training, the claims could have been further supported by exploring other possible federated algorithms. The scale of the experiments however do not play in favour of such an exhaustive study. Although the distributional similarity is measured with MAUVE, other aspects of texts n -gram, topic modelling could be explored to understand the domain shifts. Further, the study does not consider language models with different other inductive biases. The different transformer models and the effect of their respective pretraining datasets and task remain unexplored for future work. In addition to the above, the behaviour of different federated algorithms in the hypotheses we frame would also become interesting cases to scale our work.

Broader Impact

The trend of fine tuning transformer models for downstream tasks as both time and cost-effective solution for improving performance in downstream tasks has been gaining enough popularity. With federated algorithms giving access to learning from more public data while tackling the privacy concerns, it becomes worthwhile to use pretrained language models for language applications. Thus, understanding the adjustments to this federated language task learning with pretrained transformers on the claims of personalization-generalization trade-off becomes necessary. Knowledge and role of variables like client sizes and their distribution on the federated performance help identifying better decisions on setting up an appropriate domain for learning in downstream NLP tasks.

A Reproducibility Checklist

A.1 For all reported experimental results:

1. *A clear description of the mathematical setting, algorithm, and/or model:* We define the details of our experimental setup in §4.
2. *Description of computing infrastructure used:* We use multiple servers equipped with 8 NVIDIA V100 (32 GB) GPUs and 72 cores CPU (754 GB) for running our experiments.
3. *The average runtime for each model or algorithm (e.g., training, inference, etc.), or estimated energy cost and number of parameters in each model:* The details of the runtime costs per experiment and the model have been reported in Table 8. The experiment runs have been tabulated in Table 9, Table 10 & Table 11.
4. *Corresponding validation performance for each reported test result:* Not applicable.
5. *Explanation of evaluation metrics used, with links to code:* This is specified with references in paragraph titled ‘Evaluation’ in §2.

A.2 For all experiments with hyperparameter search:

1. *The exact number of training and evaluation runs:* We run all centralized and random distribution on 3 seeds while the uniform distribution experiments are run on a single seed. The random distribution leads to different client size distributions while the uniform distribution has all clients of similar size.
2. *Bounds for each hyperparameter:* The tunable hyperparameters were batch size and learning rate in both centralized and federated training. For each dataset in both cases of fine-tuning and training from scratch, we find the best learning rate in the range [0.01, 0.000001] for centralized and federated training by tuning on the exponent scale. For federated training we find the best hyperparameters in random distribution setting which we continue to use in other variants of our experiments. For the batch size, we explore in the set 8, 16, 32, 64.
3. *Hyperparameter configurations for best-performing models:* The Table 4, Table 5, Table 6 & Table 7 records the best hyperparameters in use.

4. *Number of hyperparameter search trials:* The best hyperparameters are chosen over 3 seeds.
5. *The method of choosing hyperparameter values (e.g., uniform sampling, manual tuning, etc.) and the criterion used to select among them (e.g., accuracy)* The best test loss resulting combination of hyperparameters is selected. The grid search method is used.
6. *Summary statistics of the results (e.g., mean, variance, error bars, etc.)* The tabulated results show mean and standard deviation results while the line plots are created using median as an estimator. The plots involving test or train loss account the evaluations done on a sample level. The plots using *Perf* evaluations use set of experiment level values.

A.3 For all datasets used:

1. *Relevant details such as languages, and number of examples and label distributions:* The datasets used are SST2, OntoNotes and Gigaword which are all in the English language.
2. *Details of train/validation/test splits:* This can be found tabulated in Table 3.
3. *Explanation of any data that were excluded, and all pre-processing steps:* For the task of text classification we use the complete sentences as samples instead the parsed phrases.
4. *A zip file containing data or link to a downloadable version of the data:* The references to the datasets are provided in §4.
5. *For new data collected, a complete description of the data collection process, such as instructions to annotators and methods for quality control.* Not applicable.

B Dataset Splits

Dataset	Train set	Test set	Labels
SST2	6,920	1,821	2
OntoNotes	59,924	8,262	37
Gigaword	10,000	2000	<i>N.A.</i>

Table 3: Statistics for the 3 different dataset used.

C Client Data Distribution

During the gradient accumulation, we normally use uniform weightage. For sanity check if uniform weighting is the best choice, we made comparison of the random distribution with SST2 dataset using weighted aggregation where the client gradients are weighted to their size proportions. We did not see any advantage and hence continued using the uniform weightage. The comparison in performance can be seen in Table 9.

C.1 Random Distribution

Dataset	Clients	τ
SST2	3-100	{0, 100, 300, 500}
OntoNotes	4-54	{0, 40, 120, 700, 4000}
Gigaword	7-63	{0, 18, 34, 126, 750, 1200}

Table 4: Statistics for random distribution strategy experiments. The number of clients are effected by the ablation threshold for minor clients (τ).

C.2 Uniform Distribution

Dataset	Clients	γ
SST2	5-173	{600, 500, 485, 460, 320, 190, 80, 40, 20}
OntoNotes	6-54	{1300, 630, 420, 321, 252, 209, 180, 159, 139}
Gigaword	7-63	{180, 90, 60, 45, 36, 30, 26, 22, 20}

Table 5: Statistics for uniform distribution strategy experiments. The client count increases as the number of samples per label in a client (γ) decreases.

D Hyperparameters

The experiments on random distribution for all the datasets were carried out with 3 different seeds. However, for the uniform distribution we use only a single seed for OntoNotes and Gigaword datasets. Unlike the random distribution where the sampled client sizes keeps varying dramatically, the uniform distribution has all clients with almost the same number of data samples. Thus, we relax the need for repeating experiments with multiple seeds in the uniform distribution.

Dataset	Pretraining	Epochs	Batch size	L.R.

Abstract

Propaganda aims to persuade an audience by appealing to emotions and using faulty reasoning, with the purpose of promoting a particular point of view. Similarly, metaphor modifies the semantic frame, thus eliciting a response that can be used to tune up or down the emotional volume of the message. Given the close relationship between them, we hypothesize that, when modeling them computationally, it can be beneficial to do so jointly. In particular, we perform multi-task learning with propaganda identification as the main task and metaphor detection as an auxiliary task. To the best of our knowledge, this is the first work that models metaphor and propaganda together. We experiment with two datasets for identifying propaganda techniques in news articles and in memes shared on social media. We find that leveraging metaphor improves model performance, particularly for the two most common propaganda techniques: loaded language and name-calling.

1 Introduction

Propaganda aims to influence an audience. It is a type of information that, whether true or false, tries to promote a particular agenda (Cantril, 1938) by appealing to emotions or by using faulty reasoning (Miller, 1939). Although this communication strategy comes in many forms, it is conveyed using specific persuasion techniques that exploit our psychology to sell us an idea or a point of view (Da San Martino et al., 2019b). In Figure 1, we can see an example of such techniques used in a meme shared on social media.

Another rhetorical device at the heart of many successful communication strategies is *metaphor*. Postulated as a primordial mechanism to conceptualize what we think and experience (Lakoff, 1980), metaphor works by mapping a concept in one domain (often a physical domain) to another domain (usually an abstract one) by means of a systematic

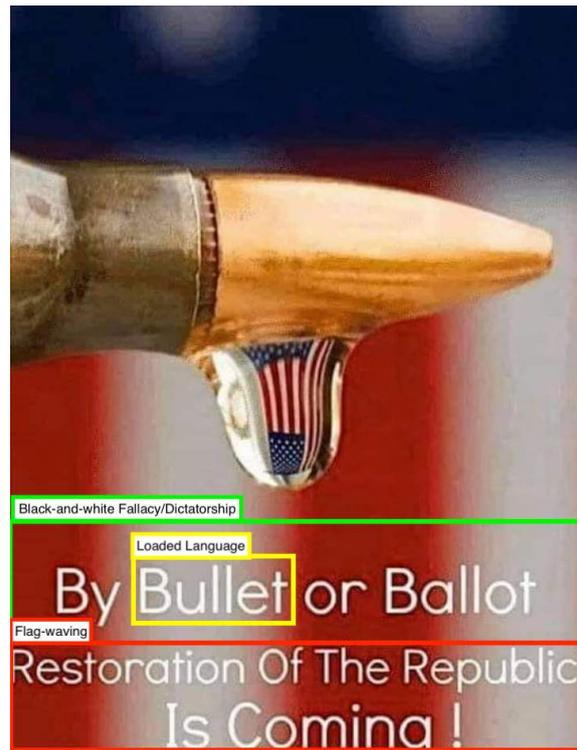

Figure 1: Meme containing propagandistic techniques (Dimitrov et al., 2021). These techniques are highlighted with bounding boxes for illustration purposes.

association. For instance, the term “*paper bullets*”¹ connects the domains of information and war, illustrating the weaponization of information.

In the same way that propaganda can exploit automatic shortcuts our brain uses to process information (e.g., stereotypes) (Tversky and Kahneman, 1974), metaphors can affect how we reason about a particular situation or issue by evoking a different semantic frame (Fillmore et al., 2006). Research shows that characterizing crime as a *beast* delivered more punishment-oriented strategies to *fight* crime (Thibodeau and Boroditsky, 2011). Con-

¹The metaphor “*paper bullets*” was used during World War II, where the Germans used tactical aircrafts to drop anti-Semitic leaflets over American troops (Margolin, 1946) as a way of psychological warfare.

versely, referring to crime as a *virus* gathered a more significant number of preventive measures to *cure* it. As a persuasive device, framing has successfully been used in politics (Howe, 1988; Ana, 1999; Lakoff, 2009) to shift the public opinion about a particular topic. Moreover, the use of metaphors by politicians in their posts on social media increases engagement with their electorate (Prabhakaran et al., 2021).

Some propagandist techniques and metaphors can exhibit a similar intention by the author. For instance, the most common technique is the use of *loaded language* to increase the emotional response of the audience (e.g., “... *disastrous* [nuclear deal]”). Likewise, metaphor can also elicit an emotionally charged reaction (Mohammad et al., 2016). The following example combines both: “the *ruinous* reforms”. Similarly, *name-calling* connects the object of the propaganda campaign with terms the target audience sees positively or negatively (Miller, 1939). This technique seeks a love or hate emotional response, and it could also alter the semantic frame (e.g., “*Crooked* Hillary” or “*Deep* State officials”).

Other salient examples where different propagandist techniques employ metaphor can be found in the Propaganda Techniques Corpus (PTC) (Da San Martino et al., 2019b), including *exaggeration* (“a *tsunami* of lies and smear”), *appeal to fear* (“[bubonic plague in Madagascar] could even *spill over* into neighboring countries and beyond”), *doubt* (“Why is the U.S. *singling out* Iran ...”) and *flag-waving* (“it is time to *take* our government *back* ...”), among others.

We explore how metaphor detection can aid propaganda technique classification under the multi-task learning paradigm. Computational modeling for propaganda detection was initially studied as a document-level classification task in news articles (Rashkin et al., 2017; Barrón-Cedeño et al., 2019; Martino et al., 2020). More recently, annotation efforts produced datasets that identify the text spans where particular forms of propaganda are used. Our work builds upon the most extensive corpus of fragment-level propaganda techniques to date (Da San Martino et al., 2019b) and on shared task 6 from SemEval-2021 (Dimitrov et al., 2021) to identify persuasive techniques in both news articles and internet memes, respectively. We analyze how a multi-task learning approach that leverages metaphor detection can improve results in propa-

ganda identification.

To our knowledge, this is the first study of the role of metaphor in computational propaganda identification. We produce the first models that combine the two phenomena and analyze their predictive capability, both quantitatively and qualitatively.

Our findings show that metaphor detection can increase performance for certain types of propaganda. We see improvements across multiple tasks covering both datasets. The gains are more pronounced for *name-calling*, with significant results for the news domain. Furthermore, our models’ predictions suggest that propagandist content uses figurative language more extensively than non-propagandist text.

2 Related work

2.1 Metaphor detection

NLP applications need to distinguish the particular intent that metaphor plays in context (Veale et al., 2016). Metaphor detection research has studied various approaches: hand-crafted features and word classes (Beigman Klebanov et al., 2016), concreteness and imageability word ratings (Broadwell et al., 2013; Turney et al., 2011), semantic classification making use of lexical databases (e.g., WordNet, VerbNet, ConceptNet) (Wilks et al., 2013; Neuman et al., 2013; Mohler et al., 2013; Tsvetkov et al., 2013), distributional semantic models (Gutierrez et al., 2016; Bulat et al., 2017; Hovy et al., 2013), and even visual (Shutova et al., 2016) or sensorial features (Tekiroglu et al., 2015). More recently, deep learning methods (Mao et al., 2019; Dankers et al., 2020; Gao et al., 2018; Rei et al., 2017; Wu et al., 2018) have been used to detect metaphors.

Current state-of-the-art textual metaphor detection is powered by large pre-trained neural network models (Su et al., 2020; Chen et al., 2020; Gong et al., 2020; Choi et al., 2021) that have been trained using datasets of billions of words. These models can leverage word representations that carry context-sensitive semantic information. As the latest shared task on metaphor detection highlights (ACL 2020) (Leong et al., 2020), more than half of the participants used BERT (Devlin et al., 2019) or its variants, widely successful pre-trained models that perform well on downstream tasks.

In addition, metaphor detection has successfully been used as an auxiliary task in multi-task learning (MTL) (Caruana, 1993) for emotion classification

(Dankers et al., 2019), political perspective, affiliation, and framing (Huguet Cabot et al., 2020); and aspect-based sentiment analysis (Mao and Li, 2021), among others. The MTL approach builds on the idea that the same model can encode valuable features for different tasks that would help each other’s performance. As metaphor is extensively used in everyday language and dramatically influences the expressiveness of the message, it can help in a significant number of semantic tasks.

2.2 Propaganda detection

Propaganda is closely related to political bias and misinformation (colloquially referred to as *fake news*) (Guess and Lyons, 2020). This area of research has gained popularity in the last decade due to concerns regarding the weaponization of social media and how it can negatively affect political discourse (Wardle and Derakhshan, 2017). Work on political bias commonly uses lexicon-based approaches to detect sentiment on political topics, while models to expose fake stories usually rely on publishing patterns and knowledge graphs (Haq et al., 2020).

However, propaganda does not necessarily have to be politically driven or rely on untrue or incorrect information. While some instances of propaganda usually do (e.g., clickbait) (Martino et al., 2020), propagandist content varies in accuracy and the acknowledgment of its sources (Jowett et al., 2012). In essence, propaganda aims to influence an audience to exercise a particular agenda (Cantril, 1938) by appealing to emotions or faulty reasoning (Miller, 1939).

Computational approaches to propaganda detection are relatively recent and were initially directed to the document classification of varying sizes, from news articles to tweets (Barrón-Cedeño et al., 2019; Rashkin et al., 2017; Volkova et al., 2017). Proposed models used BERT, LSTM (Hochreiter and Schmidhuber, 1997), Convolutional Neural Networks (CNN) (LeCun et al., 1995), and Naive Bayes models powered by Glove (Pennington et al., 2014) embeddings. These works rely to different degrees on the labeling of information sources by crowd-sourced groups or non-profit organizations (e.g., MBFC², PropOrNot³). Unfortunately, this categorization approach can introduce noise into the system. Reliable news agencies might occasion-

ally include a propagandist article to fulfill their interest. Conversely, highly propagandist media could publish a non-propagandist piece to boost their credibility.

The latest propaganda detection approaches take advantage of the rhetorical devices that propaganda uses to influence reasoning. Although the literature compiles different accounts of propagandist or persuasive techniques (Miller, 1939; Shah, 2005; Abd Kadir and Abu Hasan, 2014), they are mainly sub-types of the general principles first proposed in Cantril (1938), which share the aim of connecting an idea or propagandist object to an attitude or emotion.

The PTC corpus (Da San Martino et al., 2019b) was the first effort to classify propaganda at a more granular level. It identifies 18 persuasive techniques across 451 news articles, making it the largest of its kind. It annotates the start and end of each propagandist fragment. This corpus, and a later variant, were used in shared tasks on propaganda detection (Da San Martino et al., 2019a, 2020). The best systems used pre-trained Transformer-based models and ensembles (Yoosuf and Yang, 2019; Jurkiewicz et al., 2020; Morio et al., 2020; Chernyavskiy et al., 2020).

More recently, SemEval 2021 Task 6 (Dimitrov et al., 2021) has expanded fragment-level propaganda identification efforts outside the news corpora. It identifies propaganda techniques ingrained in the combination of textual and image data. The task’s dataset consists of 950 internet memes posted on social media with topics related to politics, vaccines, COVID-19, and gender equality. Apart from identifying 20 textual propagandist techniques, it also identifies two that are only present when in combination with the image. The most common and best-performing models used for textual tasks were the transformer-based models BERT and RoBERTa (Kaczyński and Przybyła, 2021; Gupta et al., 2021).

3 Tasks and datasets

In this work, we examine six tasks for fragment-level propagandist technique identification. Half of them use labeled data from news articles, while the others use textual information from memes shared on social media. For each domain, we perform a multi-label classification task — to identify all propagandist techniques in the dataset — and two single-label classification tasks to detect the two

²<https://mediabiasfactcheck.com>

³<http://www.propornot.com/p/the-list.html>

most common persuasive techniques: *loaded language* and *name-calling*. The single-label tasks ignore the rest of the labels in the dataset while using the same textual input as the multi-label tasks.

In addition, MTL models include metaphor detection as an auxiliary task. This task aims to detect all content words used as metaphors in a given text.

3.1 VUA Metaphor Corpus

We use the data from the ACL 2020 shared task on metaphor detection (Leong et al., 2020). Specifically, the all-POS subtask that identifies which content words (i.e., nouns, verbs, adjectives, and adverbs) are used in their metaphorical sense. The data for the task comes from the VU Amsterdam Metaphor Corpus, (Steen et al., 2010) which contains annotations for all words in 117 texts from the British National Corpus (Clear, 1993) and across four different registers: academic text, conversation, fiction, and news. The dataset covers 190K lexical units over 16,189 sentences with a train/test split of 12,109 and 4,080 sentences. The prevalence of metaphorical use for content words is 6.8% for the training set and 7.7% for the test set. We randomly sample 10% of the training split for validation.

3.2 Propaganda Techniques Corpus

The PTC corpus (Da San Martino et al., 2019b) identifies 18 propaganda techniques across 451 articles (350K tokens) from 49 news outlets. The annotations were produced by separate teams of annotators and merged through a consolidation process where all disagreements were discussed before becoming part of the final version. Each annotation identifies the technique used and its start and end within the news article. The dataset contains 20,339 sentences split into training, validation, and test sets with 14,263, 2,034, and 4,042 sentences, respectively.

The number of instances per technique and its length varies widely. The most common classes are *loaded language* with 2,547 occurrences and *name-calling* with 1,294. Those techniques have been used an average of 6.7 and 4.7 times per article, whereas all others appear a maximum of twice per article. We evaluated these two techniques separately as they provide a larger number of positive examples and can relate to metaphor as described in Section 1. Details on the number of annotations per split and their average length are shown in Table 1.

Dataset	#Annotations				Length
	Prop. technique	Total	Train	Val	Test
News					
Loaded language	2,547	1,811	304	432	23.70 \pm 25.30
Name-calling	1,294	931	154	209	26.10 \pm 19.88
All combined	7,480	5,114	927	1,439	46.99 \pm 61.45
Memes					
Loaded language	761	543	68	150	14.87 \pm 18.17
Name-calling	408	301	37	70	17.00 \pm 11.65
All combined	2,083	1,498	182	403	40.43 \pm 48.91

Table 1: Statistics on propaganda technique annotations and their average length in characters.

3.3 Propaganda detection in memes

SemEval-2021 Task 6 (Dimitrov et al., 2021) aims to identify the propagandist technique used in memes shared on social media. The images were collected from 26 public Facebook groups, which provided memes on the following topics: politics, COVID-19, pro-vaccines, anti-vaccines, and gender equality. The annotation process involved a heterogeneous group of annotators and a consolidation step. The text of the images was retrieved automatically using Google Vision API⁴ and manually corrected afterward. We focus on subtask two, which only uses the textual data of the meme to predict where in the text a particular technique is present.

The dataset contains 951 examples (16,840 tokens) divided into 688, 63, and 200 samples for train, validation, and test splits. The average number of sentences per meme is 1.68, with a maximum of 13 sentences in one image alone. Again, the most common techniques are *loaded language* with 761 annotations (36.5%) and *name-calling* 408 occurrences (19.6%) from 2,083 propagandist fragments.

We provide a summary of the textual persuasion techniques in the Appendix Section A.1 and examples in the Appendix Table 12.

4 Methods

4.1 Models

We employ the pre-trained ROBERTA-BASE model (Liu et al., 2019). ROBERTA shares its architecture with its counterpart BERT (Devlin et al., 2019), but it improves performance across many tasks due to its highly optimized training and the use of ten times more data.

⁴<http://cloud.google.com/vision>

ROBERTA tokenizes inputs using byte-pair encodings (Sennrich et al., 2016) and computes contextualised embeddings for these input tokens. We add task-specific classifiers on top of ROBERTA, consisting of a linear layer followed by the sigmoid activation function. During inference, tokens with predicted targets over 0.5 are assigned to the class corresponding to the classifier. We fine-tune all of the model parameters in our respective tasks. Since the datasets provide labels at the word level, we aggregate predictions for words consisting of multiple tokens. If the model predicts any token to belong to a particular class, we assign the label to the whole word.

4.2 Single-task learning

Our main task is to detect the text span of each propaganda technique from news articles and memes. When solely training the model on a propaganda task, we refer to this as *single-task* learning (STL). The standard propaganda task as introduced in Section 3 is *multi label*. Since propagandist fragments can overlap, we perform multi-label classification by predicting the presence of each technique independently at each token, using separate task classifiers per technique as described in Section 4.1.

In addition to the multi-label propaganda technique identification, we generate two *single-label* tasks targeting the most frequent persuasion techniques (i.e., *loaded language* and *name-calling*). Both techniques share common aspects with metaphor discussed in Section 1, making them particularly interesting for experimentation.

4.3 Multi-task learning

In the MTL setup, we train the model jointly on two tasks: one of the propaganda identification tasks and the metaphor detection task. Similar to the STL setup, we do this both for single-label and multi-label classification. As the model learns to identify metaphors, we hypothesize that the metaphor-related features benefit the propaganda technique identification.

We extend the STL models with an additional classifier to predict metaphor as the auxiliary task. All tasks share the pre-trained model (ROBERTA) in a hard parameter sharing fashion. For fine-tuning, we reuse the best configuration from the single-task models to facilitate comparison between the two strategies. We experiment with different MTL regimes attending to the following hyper-parameters:

- Task sampling ratios (r_a, r_m): these ratios are used to select a task at each update step during training. With a probability of $p_m = r_m / (r_a + r_m)$ the main task is selected, and with $p_a = r_a / (r_a + r_m)$ the auxiliary task is selected.
- Epoch sampling coefficients (c_a, c_m): these coefficients are used to update the sampling ratios at every epoch. At epoch n , $r_{m_n} = r_{m_{n-1}} \times c_m$, and $r_{a_n} = r_{a_{n-1}} \times c_a$.
- Loss scaling factors (s_a, s_m): these hyper-parameters are used to scale the losses for the main task (s_m) and the auxiliary task (s_a).

Although the MTL models have access to more data, as they are trained on two datasets, we limit their computational budget to match the one available for STL models. Every epoch, the model is trained in iterations, where the number of iterations is the same as for the STL model. Each iteration randomly selects a task for training according to its sampling probability p . We shuffle all examples in the training set at the start and after exhaustion of the training split. We fill each batch with samples from the selected task at random without replacement.

5 Experiments and results

5.1 Experimental Setup

In the implementation, we use the PyTorch framework and the pre-trained ROBERTA-BASE⁵ model from the *transformers* library (Wolf et al., 2020). We trained all models using a maximum sequence length of 512 tokens, a weight decay of 0.01, and the AdamW optimizer (Loshchilov and Hutter, 2017) with a 10% warm-up period and a cosine-based learning rate decay function. All hyperparameter search trials and the selected configurations for each task are listed in Appendix Table 11. We use the binary cross-entropy loss with modified class weights to account for class imbalances. Hyperparameter search trials are performed over five different random seeds that dictate the order of data presentation and the initialisation of the task-specific classifiers. For the final configuration, performance is computed over ten different random seeds.

To ensure that the MTL models do capture meaningful features for metaphor identification – in spite

⁵<https://huggingface.co/roberta-base>

of it being the auxiliary task – we discard hyperparameter combinations with a median F1-score below 0.6 for metaphor identification, asserting the models exceed the baseline level set out by baselines one and two of [Leong et al. \(2020\)](#).

We evaluate the performance of propaganda detection based on the micro-averaged F1 score using precision (P) and recall (R) metrics defined in [Da San Martino et al. \(2019b\)](#). These metrics give partial credit to imperfect matches to account for overlap between techniques and the significant variation in length between propagandistic fragments. We provide details of these calculations in the Appendix A.2. We use statistical bootstrapping ([Efron, 1979](#)) to test the significance of our results and detail the procedure in Appendix A.3. We detail the system and configurations used for this work in Appendix A.4 for reproducibility.

5.2 Results

5.2.1 Single-label propaganda technique detection

Table 2 shows the performance for single-label propaganda detection tasks. The MTL approach improves results for all single-label tasks. Adding metaphor increases performance in news articles by 1.02 points for *name-calling*, from 28.72 to 29.74. This growth is statistically significant under the paired bootstrap test between learning strategies. The improvement is milder for *loaded language*, with a gain of 0.22 points, although results were more stable, almost halving the standard deviation for the metric.

We observe similar results in the memes dataset. Detection of *name-calling* improves the F1 metric by 1.24 points to 57.77 when training with metaphor as an auxiliary task. This increase is also more stable, lowering the standard deviation from 2.44 to 1.26. *Loaded language* improvements are smaller, adding 0.34 points to a total of 65.5 with lower variability.

5.2.2 Multi-label propaganda technique detection

Table 3 shows the results for the multi-label propaganda identification task in the news dataset. We compare our models to previous work ([Da San Martino et al., 2019b](#)) and achieve better results using a similar pre-trained model with the same number of parameters. The multi-task models obtained the best overall performance with an F1 of 24.32 and

Model	Loaded Language			Name Calling		
	P	R	F1	P	R	F1
News						
STL	32.67	48.04	38.72 ± 1.00	24.48	35.25	28.72 ± 1.14
MTL	<u>33.60</u>	46.88	<u>38.94</u> ± 0.51	<u>26.30</u>	35.35	<u>29.74</u> ± 1.64
Memes						
STL	68.88	62.21	65.16 ± 2.16	52.39	61.70	56.53 ± 2.44
MTL	66.29	<u>64.90</u>	65.50 ± 1.62	<u>59.03</u>	57.13	<u>57.77</u> ± 1.26

Table 2: Propaganda detection performance for single-label models. Statistically significant differences between STL and MTL are underlined ($p < 0.05$).

Model	P	R	F1
Da San Martino et al. (2019b)	24.42	21.05	22.58
Multi-label STL	20.37	<u>30.42</u>	23.78 ± 2.03
Multi-label MTL	<u>21.98</u>	27.46	24.32 ± 0.48

Table 3: Propaganda technique identification results in news articles. The highest performance per model type is shown in bold. Underlined values denote statistical significance ($p < 0.05$) via paired bootstrap test between single-task and multi-task models.

a standard deviation of 0.48. The single-task models averaged 23.78 F1 score with a much higher variation ($\sigma = 2.03$).

Results for multi-label propaganda detection in memes are shown in Table 4. State-of-the-art performance for the task reaches an F1 score of 47.6, ([Gupta et al., 2021](#)) but it uses a model with 340M parameters. This model is three times larger than the ones we used (110M parameters). Comparing performance across same-size models, we see that our STL model performs best with an average F1 score of 46.22 and a standard deviation of 1.82. In contrast, the multi-task model achieves 44.81 ± 1.31 . Both models outperform the value of 43.9 ± 0.9 reported in [Gupta et al. \(2021\)](#).

In the Appendix, Tables 8 and 9 show the performance of multi-label models for all techniques in the news and memes datasets, respectively.

6 Analysis and discussion

Given the shared traits between the use of metaphor and specific propagandist techniques, we hypothesized that it can be beneficial to model them jointly. We split the analysis into two subsections discussing quantitative and qualitative aspects.

6.1 Quantitative analysis

The results show improvements across most propaganda detection tasks when trained in a multi-

Model	P	R	F1
Volta (RoBERTa-Large)	-	-	47.6 ± 1.5
Volta (RoBERTa-Base)	-	-	43.9 ± 0.9
Multi-label STL	<u>46.02</u>	46.51	46.22 ± 1.82
Multi-label MTL	42.62	<u>47.82</u>	44.81 ± 1.31

Table 4: Propaganda technique identification results in memes. We include the winning team for the shared task: *Volta Gupta et al. (2021)*. The highest performance per model type is shown in bold. Underlined values denote statistical significance ($p < 0.05$) via paired bootstrap test between single-task and multi-task models.

task setting with metaphor as the auxiliary task. We hypothesised metaphor detection would benefit the single-label tasks, due to the use of a different semantic frame in *name-calling* and emotionally charged vocabulary in *loaded language*. Improvements were more pronounced for *name-calling* in both datasets, which suggests that, as anticipated, metaphorical framing plays a role in this propaganda technique. The fact that the gain in F1-score is the largest for name calling in both datasets further strengthens this conclusion.

To further consolidate the relationship between propaganda and metaphor our models identify, we investigate the prevalence of metaphors’ predictions in propagandistic text fragments. We use our MTL models to predict metaphors on the propaganda corpora, and observe a higher percentage of metaphors in propagandist fragments than for non-propagandist content, and even higher for *loaded language* and *name-calling*. This is shown in the Appendix, in Figures 2 and 3. These model predictions hint at the likelihood that propagandist content, and some techniques in particular, may resort to metaphor more often than non-propagandist text does. Manual annotation of metaphors in propaganda datasets will allow asserting this with certainty, yet, we leave this for future work.

Although a slight improvement in task performance was observed for multi-label propaganda identification in the news dataset, this was not the case for the memes task. This task was the only one for which the MTL strategy was not superior. The memes dataset is 20 times smaller than the news dataset and includes two more labels. These challenges of size and sparsity could play a role in the utility of the MTL architecture, particularly when imposing on it the best hyper-parameters from the single-task models. We did this to facilitate the

comparison between models, but we risk ending up with a configuration especially harmful to the MTL approach. Further experimentation is needed to investigate this drop in performance.

6.2 Qualitative analysis

To validate the effect of metaphor for the tasks, we pooled the predictions for all ten models of the same type trained with different seeds. We use simple majority voting to harmonize predictions across the different runs. Next, we identify the difference in the predicted spans between single-task and multi-task models. We include gold labels and the predicted metaphors by multi-task models for analysis. Examples of models’ predictions for news articles and memes are shown in Table 5.

MTL models can detect figurative language, which contributes to detecting propaganda techniques that use this device. Idioms such as “*throw out the window*” (ref. LL.N.1) and “*kick the can down the road*” (ref. LL.N.2) are correctly identified, albeit partially, as *loaded language* in the context of the news article. This is also the case for the metaphorical use of the word “*dinosaurs*”, present in an example of *name-calling*, to convey the point of view that current social media platforms will *go extinct* (ref. NC.N.1).

Other instances of non-literal meaning deliver incorrect predictions. However, we believe that some of those instances could be considered correct. In the case of *name-calling*, the models detect “*poor sport*” (ref. NC.N.2), which is alluding to a defeated candidate in an electoral race. Similarly, the phrase “*you can throw us in jail, but you will never defeat us*” (ref. LL.N.3) signals defiance with a considerable degree of emotion which borderlines the *loaded language* category.

Conversely, the label *hardworking* used in “*hardworking Georgians*” (ref. NC.N.3) cannot be attributed to *name-calling* as it does not refer to the propagandist target of the article: Georgia gubernatorial candidate Stacy Abrams. This mislabeled example highlights the task’s difficulty and need for a broader context. Our models received individual sentences for training and inference, which is insufficient in this instance to identify the object of the propaganda campaign.

Looking at predictions on the memes dataset, we observe that the gains in *name-calling* for multi-task models were driven primarily by minimizing incorrect predictions. The examples NC.M.1 and

PT	Reference	Text fragments	
Name-calling	NC.News.1	... we will rise from the ashes of the social media dinosaurs to help build and create new platforms ...	
	NC.News.2	Talk about a poor sport , but Democrats are often like that in these races.	
	NC.News.3	“The election is over and hardworking Georgians are ready to move forward ,” he said.	
	NC.Memes.1	HOLD UP!!! Sleepy Joe broke my record?!?!?!?	
	NC.Memes.2	... the most corrupt, lying and despised member of Congress and the WORST Speaker of the house ...	
	NC.Memes.3	So Don King and Beetlejuice had a baby...	
	NC.Memes.4	WARNING SIGNS OF A CULT // ...	
	NC.Memes.5	ATTENTION PATRIOTS // MEET YOUR CIVIL WAR OPPONENTS	
	Loaded Language	LL.News.1	Political correctness needs to be thrown out the window when dealing with those who...
		LL.News.2	In other words, let’s just kick the can down the road and hope for a more reasonable Iranian regime ...
LL.News.3		You can throw us in jail , but you will never defeat us .	
LL.Memes.1		WHEN TRUMP IS REELECTED THERE WILL BE BLOOD!	
LL.Memes.2		WE ARE AT WAR!	
LL.Memes.3		FAKE WINNER	
LL.Memes.4		... UNDERCOVER FEDS DOCUMENTING THE FRAUD AND THEY’VE STEPPED INTO A TRAP	

Table 5: Example predictions of propaganda techniques. Gold labels in yellow, predictions in blue, and their intersection in green. The underline style identifies predictions only produced by one learning strategy. Predicted metaphors from MTL models are shown in bold.

NC.M.2 were the only ones containing prediction spans singular to the multi-task models. Both instances correctly label parts of the text that do not include predicted metaphors, although they contain metaphors in their vicinity. In contrast, the single-task models produced more mislabels on nouns or noun phrases, see examples NC.M.3, NC.M.4 and NC.M.5. With respect to loaded language, we observe metaphor predictions falling equally into correct and incorrect spans, see examples LL.M.1, LL.M.2, LL.M.3, LL.M.4.

7 Conclusion and Future Work

In this work, we explored the influence of metaphor detection on propaganda technique identification in a multi-task learning setup. Joint modelling of metaphor and propaganda was performed using two propaganda datasets from different domains: news articles and internet memes. We experimented with six different propaganda detection tasks, including multi-label propaganda technique identification and single-label tasks for the two most common propagandist techniques: *name-calling* and *loaded*

language, for each dataset. Incorporating metaphor detection yielded performance improvements in five of the six tasks considered, with the highest improvements observed for the *name-calling* technique. Moreover, the different datasets showed similar patterns in performance changes. We supplemented the task performance results with an analysis of the prevalence of metaphor in the propaganda corpora and qualitatively examined a range of examples of metaphorical language use in propagandist fragments. We are the first to investigate the interaction of these two phenomena and our promising results encourage further research in this direction.

In future work, we plan to extend our analysis to other propaganda techniques. In view of the emergence of datasets for other languages, such as the Arabic propaganda detection shared task at WANLP’2022 and the multilingual SemEval-2023 task 3 subtask 3 on propaganda detection in English, French, German, Italian, Polish, and Russian, we plan future multi/cross-lingual experiments.

Limitations

Although we established a positive influence of metaphor detection on propaganda technique identification, our work also has some limitations. (1) Considering that this work focused on the two most common propagandist techniques, future work could extend this analysis to cover others, although we should note that these analyses are limited by a data scarcity issue (in particular in the memes dataset). (2) While we considered six tasks, these tasks used one MTL architecture. Previous work has experimented with more advanced MTL methods (e.g., soft parameter sharing) and in the future, these methods could also benefit joint learning of metaphor and propaganda. (3) Finally, it should be emphasised that both types of propaganda employed and the types of figurative language used are very specific to cultures and languages. As such, the techniques applied in this study might not deliver the same effect when using data from different geographical locations, or data from languages other than English. Moreover, the prevalence of metaphor varies across different propagandist techniques, meaning that not every propaganda-related task will benefit from joint learning with metaphor.

Ethics and Broader Impact

Intended Use and Misuse Potential Our models can be of interest to the general public, fact-checkers, and journalists. However, they could also be misused by malicious actors. We, therefore, ask researchers to exercise caution.

Environmental Impact We would like to warn that the use of large language models requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming (Strubell et al., 2019). This is a bit less of an issue in our case, as we do not train such models from scratch, we just fine-tune them.

A Appendix

A.1 Persuasion techniques

The following list compiles the descriptions of propaganda techniques present in the PTC corpus (Da San Martino et al., 2019b) and the dataset used by SemEval-2021 task 6 (Dimitrov et al., 2021).

1. Appeal to authority: stating the validity of a claim because an expert or authority has issued it without providing any other evidence. The datasets include *Testimonials* as part of this technique, although they might not refer to an expert or authority.
2. Appeal to fear/prejudice: building support for an idea by provoking anxiety/panic to the alternative. In some instances, it leverages prejudices to obtain the desired response.
3. Bandwagon: invites the target audience to support an idea or action with the pretext that "*everyone is doing the same*".
4. Black-and-white Fallacy (Dictatorship): introduces two alternatives as the only possible options to weaken or strengthen one of them. In the extreme, it morphs into *dictatorship* when the choice is made for the audience, and all other options are considered impossible.
5. Causal Oversimplification: assuming a single cause for an issue when there might be many factors at play in reality. The data also includes *scapegoating* in this category - moving the blame to a person or group without considering the issue's complexities.
6. Doubt: questioning the credibility of something or someone.
7. Exaggeration/Minimisation: representing something as more extreme/dramatic than it is or, conversely, downplaying its significance.
8. Flag-waving: rally around a solid national sentiment to justify an action or idea.
9. Glittering generalities (Virtue)⁶: words or symbols that produce a positive image of the propagandist object by association with the preferences of the target audience.
10. Loaded Language: the use of emotionally charged words to influence an audience. It often exploits stereotypes and vagueness.
11. Name-calling: referring to the object of the propagandist campaign with a label that connects the target audience with an emotion, either positive (love, praise) or negative (fear, hate).
12. Obfuscation, Intentional Vagueness, Confusion: deliberately use unclear statements forcing the audience to produce their interpretation.
13. Red Herring: presenting irrelevant data to divert attention away from the discussed issue.
14. Reductio ad Hitlerum: seek disapproval of a position by suggesting that it is popular with a group the target audience hates.
15. Repetition: repeating the same message to subdue the audience into acceptance.
16. Slogans: brief and memorable motto or phrase to persuade the audience.
17. Smears⁶: effort to damage or question someone's reputation by propounding negative propaganda.
18. Straw Man: misrepresentation of someone's position to disprove it leaving the original argument unaddressed.
19. Thought-terminating cliché: using expressions to prevent critical thinking and meaningful discussions.
20. Whataboutism: replying with a counter-question or counter-accusation that suggests the rival is hypocritical concerning their position without refuting their argument.

⁶Only present for propaganda in memes, not for propaganda in the news dataset

A.2 Evaluation metrics for propaganda

To evaluate the model’s performance in identifying propagandist instances, we follow the methods used by preceding works. The authors of the PTC corpus (Da San Martino et al., 2019b) propose precision and recall metrics based on the overlaps between the target and predicted spans. These metrics are then used to calculate the F1 score for each technique and all techniques combined.

Should document d be a sequence of characters, we can represent a propaganda technique span by $t = [t_i, \dots, t_j] \subseteq d$. This ground truth will be compared against the predicted model outputs $s = [s_i, \dots, s_j]$. The labeling function $l(x)$ will return the propaganda technique associated with the fragment x . The function $\delta(l_a, l_b)$ will return 1 when l_a equals l_b and 0 otherwise. The groups T and S denote the group of propagandist fragments for gold labels and predictions respectively. Equation 1 calculates the overlapping number of character between two spans and divides it by a given length h .

$$C(s, t, h) = \frac{|(s \cap t)|}{h} \delta(l(s), l(t)) \quad (1)$$

In turn, Equation 2 reuses C to calculate the precision metric as the average proportion of correct prediction spans. Conversely, the Equation 3 defines recall as the average proportion of ground truth fragments covered by the predicted spans. Both metrics are similar, but while precision uses the number and length of the predictions, recall uses the gold label spans instead.

$$P(S, T) = \frac{1}{|S|} \sum_{s \in S, t \in T} C(s, t, |s|) \quad (2)$$

$$R(S, T) = \frac{1}{|T|} \sum_{s \in S, t \in T} C(s, t, |t|) \quad (3)$$

In contrast, precision and recall metrics for metaphor are calculated as a binary classification task at the word level. Only content words are considered for this task.

A.3 Significance testing

To check the statistical significance of our results, we use statistical bootstrapping (Efron, 1979). This powerful non-parametric method is recommended for evaluation metrics such as precision, recall, and F-score in NLP tasks (Dror et al., 2018). The main idea is to assess whether differences in performance

between two models originate from variability in the data rather than from the superiority of one model over the other.

First, we create 100 different bootstrap samples ($B_{1..100}$) from the test data (T) by sampling with replacement (i.e., an example can appear multiple times within the same sample while others might not be present at all). Our examples are either individual sentences from news articles or the textual information of a meme, depending on the dataset used for the task. Each bootstrap sample has the same size as the test set ($|T| = |B_n| \forall n \in \{1, 100\}$). The premise is that being the test set a representative sample from all possible data for the task; we can get a sense of the variability of the task’s data by comparing performance across multiple bootstrap samples.

After randomly generating the samples, we performed a paired bootstrap test as suggested in Dror et al. (2018). We calculate the *p-value* as the proportion of bootstrap samples where one type of model outperforms another. Since we use ten different seeds for each setup, comparing results between single-task and multi-task learning strategies requires calculating the mean across multiple models’ performances. We start by calculating the performance of all models of a particular type by averaging their scores on each bootstrap sample. We do this for single-task and multi-task models. Then, we count the number of times one strategy achieves higher performance than the other. Finally, we calculate the *p-value* as the proportion of samples where that strategy was superior. We use the standard confidence level of 95% ($\alpha = 0.05$).

A.4 Reproducibility

We adapted our source code ⁷ to achieve reproducible results. First, we enabled the use of deterministic algorithms in the *PyTorch* framework. Next, we manually set the seed for all packages involved in random number generation. We use natural numbers for the seeds starting at one and up to the number of runs for each set of hyperparameters tested. Finally, we pinned the versions for all dependencies.

The system we used had the following software: Python/3.8.2, GCCcore/9.3.0, CUDA/11.2, cuDNN/8.2.1.32. Additionally, we assigned the value ":4096:8" to the environment vari-

Multi-label	12:38	36:48
Name Calling	6:33	23:59
Loaded Language	15:06	22:36

Table 6: Average training runtime per task. This includes models discarded in hyper-parameter search trials.

able "CUBLAS_WORKSPACE_CONFIG" as suggested by Nvidia documentation⁸ to avoid non-deterministic behavior. Our models used a single GeForce 1080Ti GPU for training. The average training runtime per task is shown in Appendix Table 6.

A.5 Preprocessing

The PTC dataset used NLTK sentence splitter⁹ to break news articles into individual sentences. We detected duplicates driven primarily by boilerplate content regarding site functionality (e.g., invitation to participate in an online poll or request to subscribe to their newsletter). Duplicates were mainly short sentences that did not include any labels. We removed these instances from the training set.

We observed that the text in 454 examples (47% of the data) for the memes dataset was upper-cased. Since our model is case-sensitive, we true-cased all instances to minimize the number of out-of-vocabulary words by the tokenizer.

Lexical Semantics with Large Language Models: A Case Study of English *break**

Erika Petersen
Stanford University
epetsen@stanford.edu

Christopher Potts
Stanford University
cgpotts@stanford.edu

Abstract

Large neural language models (LLMs) can be powerful tools for research in lexical semantics. We illustrate this potential using the English verb *break*, which has numerous senses and appears in a wide range of syntactic frames. We show that LLMs capture known sense distinctions and can be used to identify informative new sense combinations for further analysis. More generally, we argue that LLMs are aligned with lexical semantic theories in providing high-dimensional, contextually modulated representations, but LLMs’ lack of discrete features and dependence on usage-based data offer a genuinely new perspective on traditional problems in lexical semantics.

1 Introduction

Pater (2019) builds a compelling case that linguistic and neural network research have great potential for common ground and common cause. His case has only grown stronger in recent years, with the arrival of large neural language models (LLMs) that provide semantically rich, contextual representations (McCann et al., 2017; Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019).

In this paper, we argue that LLMs are powerful devices for studying lexical semantics in ways that can deeply inform linguistic theory. We illustrate this with a detailed case study of the lexical semantics of the English verb *break*, building on a richly annotated dataset from Petersen (2020) and drawing on methods from prior work in this area (Camacho-Collados and Pilehvar, 2018; Tenney et al., 2019; Garí Soler et al., 2019; Reif et al., 2019; Wiedemann et al., 2019; Branco et al., 2020; Nair et al., 2020; Li and Joannis, 2021; Loureiro et al., 2021; Trott and Bergen, 2021; Apidianaki, 2022; McCrae et al., 2022). *Break* has long been

central to theoretical work in lexical semantics because it has a staggering range of senses that appear to be systematically related to its argument structure. Our central empirical finding is that LLM representations capture many of these known sense distinctions and can be used to identify new sense combinations for further analysis.

We use these findings as a chance to reflect on the core theoretical commitments of lexical semantics as they pertain to LLM-based investigations. Our discussion is centered around the three tenets of lexical semantics given in Table 1: lexical representations are *high dimensional*, *contextually modulated*, and include *discrete features*.

The high dimensionality property is not phrased as a direct claim in the literature as far as we know, but it reflects the practice of linguists, who identify numerous interacting features of lexical items. Section 2 offers a summary picture for *break*. Similarly, discreteness is often assumed by linguists working in the broadly generative tradition. For our purposes, the key question is whether there are *any* features that are discrete, since LLMs do not naturally support having such features.

Contextual modulation is a direct claim. We trace the origins to Dowty (1976, 1979), who argues that aspectual analyses need to include at least the entire verb phrase (see also Kratzer 1996). Borer (2005a,b, 2013) pushes this further, arguing that open-class lexical items are “tantamount to raw material, ‘stuff’ which is poured into the structural mould to be assigned grammatical properties” (2005a, p. 108). On this view, lexical items are mostly unvalued discrete feature representations that are fleshed out and modulated by the environment in which they appear; there may be a stock of identifiable lexical items, but they are highly abstract, with almost unlimited potential to become different items in different contexts.

A similar view is taken by work in the Generative Lexicon (Pustejovsky, 1991, 1995), which posits

*Data and code available at <https://github.com/epetsen/break-llms>.

	Linguistics	Static vectors	LLMs
High dimensionality: Lexical semantic entries consist of many features.	Yes	Yes	Yes
Contextual modulation: A word sense will be influenced by its immediate morphosyntactic context as well as the broader context of use.	Yes	No	Yes
Discreteness: The features in lexical semantic entries are discrete and highly structured.	Yes	No	No

Table 1: Core tenets. Our focus is in particular on the relationship between ‘Linguistics’ and ‘LLMs’ in this table.

an extensible lexicon that is “open-ended in nature and accounts for the novel, creative, uses of words in a variety of contexts by positing procedures for generating semantic expressions for words on the basis of particular contexts” (Pustejovsky, 2006). This also aligns with Clark’s (1997) rejection of the “Dogma of Sense Selection”, which says “Listeners determine an enumerable set of senses for each expression, and in understanding what a speaker means, they select the appropriate sense from that set.” For Clark, lexical items are highly malleable and constrained mainly by what the discourse participants can reliably communicate with each other (see also Clark and Clark 1979; Searle 1980). On all these views, lexical items are highly abstract objects that can be realized in very diverse ways.

The field of NLP has a complex relation to our tenets. Early work on symbolic grammars in NLP was clearly aligned with all the tenets. The Generative Lexicon is a prominent example and proved influential in linguistics and NLP. When distributional methods first became central to NLP, the dominant mode of lexical representation involved static vector representations. These representations align with the consensus in linguistics only regarding high dimensionality, as we discuss in Section 4.

LLMs have changed NLP’s relationship to lexical semantics considerably. With LLMs, we have a strong commitment to high dimensionality and contextual modulation and a denial of discreteness (Section 5). The points of agreement present a significant opportunity for linguists and NLP researchers to collaborate, as we hope our case study shows. The points of disagreement seem also to be opportunities for people to take new perspectives. We argue in particular that the facts surrounding *break* should lead linguists to reconsider their commitment to discreteness and embrace a more fluid, usage-based foundation for semantic theory.

2 English *Break*

English *break* is one of the best studied lexical items in lexical semantics, for a few reasons. First, it is a canonical instance of a change-of-state verb that undergoes the causative alternation:

- (1) The linguist broke the window
- (2) The window broke.

In fact, alternating change-of-state verbs are referred to as *break*-verbs (Acedo-Matellán and Mateu, 2014; Fillmore, 1970; Levin, 2017; Majid et al., 2008). The intransitive variant of the causative alternation (2) is analyzed in terms of the *unaccusativity hypothesis* (Perlmutter, 1978; Burzio, 1986; Levin and Rappaport Hovav, 1995), which says that the subjects in these cases are underlyingly internal arguments to the verb, bearing more theme-like semantic roles, and have been promoted to subject position to fulfill a subjecthood requirement. Research on *break* has also contributed to the study of the lexical properties of unaccusative verbs (Levin and Rappaport Hovav, 1995).

Second, *break* can take on a wide array of senses. Table 2 provides a partial list; we cannot hope to be comprehensive (there may not even be a fixed stock of senses; Section 5), but our examples convey the nature of the attested variation.

Third, the sense distinctions interact with the causative alternation. Whereas senses 1–4 all alternate, senses 5–11 are all strictly transitive. The non-alternating senses of *break* have informed the debate about which variant of the causative alternation (if any) is basic and which is derived (e.g. Levin and Rappaport Hovav, 1995; Alexiadou et al., 2006; Piñón, 2001). Though the debate is still unsettled, it has evinced that participation in the causative alternation is not a property of the verb itself, but of the verb in combination with its theme argument (Petersen, 2020; Spalek, 2012), just as

Frame	Sense	Frame	Sense
1. break the vase	shatter	14. break off the engagement	end
2. break the computer	render inoperable	15. break out	begin
3. break the news	reveal	16. break out of jail	escape
4. break the silence	interrupt	17. break out in hives	get
5. break the record	surpass	18. break into the building	intrude
6. break the code	decipher	19. break down the problem	analyze
7. break the law	violate	20. break down the proteins	decompose
8. break the habit	end	21. break in	enter
9. break the horse	tame	22. break in	interrupt
10. break a \$10 bill	make change	23. break free	escape
11. break the fall	lessen	24. break even	profit = loss
12. the weather broke	changed	25. break forth	emerge
13. the day broke	began	26. break to the right	turn

(a) Uses without particles/predicates.

(b) Uses with particles/predicates.

Table 2: Senses for *break*. A comprehensive account of senses may not be possible (Section 5.3).

with telicity and other aspectual properties (Dowty, 1976, 1979; Borer, 2005b).

Prior work has sought to capture the obligatorily transitive nature of some of these senses by appeal to a thematic role requirement: *break* in combination with its internal argument determines the range of semantic roles – agent, instrument, or natural force – that the subject of a transitive *break* frame may bear (Rappaport Hovav and Levin, 2012), and some frames require their subjects to be agentive (Levin and Rappaport Hovav, 1995; Piñón, 2001; Alexiadou et al., 2006; Schäfer, 2008). Since necessarily agentive subjects cannot be left unexpressed, these frames do not show intransitive variants. However, this cannot be the full story, as there are some obligatorily transitive *break* frames where the subject need not be an agent but which nonetheless do not alternate, like *the cushion broke her fall* vs. **the fall broke* (Petersen, 2020).

In addition, examples like *break the record* (sense 5) and *break the code* (sense 6) may be graded or uncertain in regard to their participation in the causative alternation. They are often assumed not to have intransitive uses (Levin and Rappaport Hovav, 1995; Piñón, 2001; Alexiadou et al., 2006; Schäfer, 2008; Rappaport Hovav and Levin, 2012), but there are attested cases like the following that suggest this is a point of variation.

- (3) Almost sixty years later, Frank Rowlett, a cryptologic pioneer and head of the “Purple” team, remembered that historic day when the code broke.

- (4) The Guinness World Record broke, our furniture didn’t.

There are also strictly intransitive uses, as in 12–13 of Table 2a. These are analyzed in the same way as the intransitive variant of alternating frames (2), i.e., as unaccusatives. Why these *break* frames do not allow a cause subject – e.g., **the Earth’s rotation broke the day* – is an open question.

As seen in Table 2b, *break* also combines with a wide range of predicates and particles to create new senses. Except for 14, 19, and 20, these uses are all intransitive, but they seem to differ from the particle-less uses in a key way: whereas intransitive particle-less *break* cases are all unaccusative, the particle cases vary in this regard. For example, *the war broke out* seems unaccusative, but *we broke into the building* has an agentive subject and so would not be analyzed as unaccusative.

A key question for lexical semantic theories is whether there is a single unifying semantic frame underlying this diverse array of senses – or, if not a single frame, then perhaps a few of them feeding into distinct sense clusters. This position is advanced, for example, by Kellerman (1978:65), for whom “[t]he various meanings of BREAK [...] can all be subsumed under a ‘deep’ meaning, ‘(cause) not to continue in existing state’, which links even the most disparate meanings of BREAK’ (see also Spalek 2012 for a similar position for Spanish *romper* ‘break’). Another approach would be to posit a few more primitive semantic dimensions that give rise to a combinatorial space of

	<i>Transitive</i>	<i>Unaccusative</i>	<i>Agent</i>	<i>Metaphorical</i>	<i>separate</i>	<i>violate</i>	<i>end</i>	<i>appear</i>	<i>out_escape</i>	<i>out_begin</i>
1. We broke the vase	1	0	1	0	1	0	0	0	0	0
2. The vase broke	0	1	0	0	1	0	0	0	0	0
3. We broke the law	1	0	1	1	0	1	0	0	0	0
4. The silence broke a procedural rule	1	0	0	1	0	1	0	0	0	0
5. We broke the silence	1	0	1	1	0	0	1	0	0	0
6. The day broke	0	1	0	1	0	0	0	1	0	0
7. The storm broke	0	1	0	1	0	0	0	1	0	0
8. Sweat broke on his forehead	0	1	0	1	1	0	0	1	0	0
9. We broke out (of jail)	0	0	1	0	0	0	0	0	1	0
10. Fighting broke out	0	1	0	1	0	0	0	0	0	1

Table 3: Partial feature-based analysis of *break* in different syntactic contexts.

predicted senses, which might in turn lead to predictions about argument structure realization and other structural and distributional properties.

3 Feature-based Theories

In this section, we take the somewhat unusual step of bringing together existing ideas from the linguistics literature into a feature space of the sort one is likely to encounter in NLP contexts. We do this for a few reasons. First, it reveals that, though theories in linguistics and NLP often take very different forms, there is actually a lot of common ground between them: on both sides, vector representations of data can serve as a common language. Second, the feature space reveals how deeply linguistic theories are committed to our contextual modulation tenet from Table 1: to honor the insights from the literature, we have to define the feature space in terms of (at least) full sentences.

Table 3 is our (highly partial) feature-based analysis. The Transitive feature captures whether a particular *break* frame has two nominal arguments or one. Causative alternation uses can then be reconstructed by looking at shared meaning dimensions that vary in their Transitive value, as in rows 1–2. We separately define an Unaccusative feature, since the uses in Table 2b show that these can come apart. This is evident especially in rows 9–10.

The Agent feature captures whether the subject of each example is agentive or not. We mentioned in Section 2 that the obligatory transitivity of some *break* frames has been traced, unsuccessfully in our view, to the agentivity of the subject of these

frames. The Agent feature in combination with the Transitive feature and the meaning dimensions reveals the incompleteness of this explanation: ‘violate’ examples, which are obligatorily transitive, may have subjects that are agentive (row 3) and non-agentive (row 4).

We have a column for Metaphorical, though coding this is sufficiently hard that it looks like a multidimensional category to us rather than a single feature. Due to the difficulty of classifying senses of *break* and other polysemous verbs as (non)metaphorical, previous literature that has engaged with this question (e.g. Kellerman, 1978; Piñón, 2001; McNally and Spalek, 2017, 2022) has used the heuristic of associating metaphorical senses with abstract participants, like *break the silence*, and non-metaphorical ones with concrete participants, such as *break the vase*. We follow this (admittedly simplifying) heuristic in our feature-based analysis. However, we agree with McNally and Spalek (2022, 6) that “the distinction between ‘literal’ and ‘figurative’ senses can become blurred over time, and sometimes can only be diachronically reconstructed”.

Following these features are a few meaning dimensions. The full class of meaning annotations we use in Section 5.3 has 72 classes, so this is just a sample. The sample was chosen to emphasize three aspects of the meanings of *break*. First, as already illustrated in Table 2, these meanings are highly diverse semantically. Second, it is difficult (and maybe even futile) to determine with confidence how many distinct (and non-overlapping) senses

1. break	11. up	1. breaks	11. brief_respite	1. break	11. breakin
2. breaks	12. trying	2. breaking	12. Nadal_netted_forehand	2. breaks	12. breaked
3. breaking	13. away	3. broke	13. loosen	3. breaking	13. broken
4. end	14. start	4. broken	14. smash	4. breake	14. legbreak
5. broke	15. get	5. Break	15. rip	5. re-break	15. reak
6. down	16. again	6. Breaking	16. overhit_forehand	6. break-	16. semi-break
7. take	17. 'll	7. breather	17. miscued_forehand	7. unbreak	17. minibreak
8. let	18. back	8. shatter	18. cut	8. breakes	18. breaker
9. going	19. out	9. crack	19. slip	9. break.	19. breaking-down
10. leave	20. off	10. breaker	20. Breaks	10. broke	20. tea-break

Table 4: Nearest neighbors of *break* in static embedding spaces. All the methods place morphological variants of *break* next to *break* itself and seem to sporadically find different senses and near synonyms of *break*. The lists given here are, in our judgment, the best from each of the three methods. For additional lists, see Appendix B.

break may express. For example, does *break* express the same meaning, ‘appear’, in row 6 as in row 7, as we suggest in Table 3? Or should these examples be seen as expressing distinct senses? Third, we believe there are some examples where *break* simultaneously expresses more than one meaning, as shown in row 8 of Table 3, where *break* shows both an ‘appear’ and a ‘separate’ meaning.

Break with particles/predicates can sometimes express meanings that particle-less *break* cannot convey: e.g. ‘escape’ in row 9. We assume that the particles/predicates contribute an irreducible meaning and reflect this in our feature-based analysis by preceding these meaning dimensions with the corresponding particles/predicates: ‘out_escape’. The particles/predicates do not determine a unique meaning, though, as we see with the two senses of *break out*: ‘out_escape’ and ‘out_begin’. And we could of course have extended this even further. There are additional clearly distinct senses like *His face broke out in hives* and *break out the champagne*, as well as cases like *break out in laughter* which might be subsumed under other senses (say, ‘out_begin’).

Potentially all of the columns are actually just informal stand-ins for much more complex concepts. The labels could be natural language predicates on par with *break*, in which case the column names are really just hooks into a larger lexical web, or they could be glosses for more intricate theoretical concepts that demand further decomposition before the theory can be regarded as complete.

In addition, we can seamlessly integrate this kind of analysis with more data-driven techniques. As an illustration, Appendix A reports on an experiment using the WordNet hypernym graph to identify extremely abstract latent meaning dimensions.

How many lexical items does this theory posit? The answer to this question is not clear. We could say that each attested combination of the features is a new sense, or we could select a few features and say that specific combinations of them correspond to distinct senses. Both decisions have a certain arbitrariness to them given the feature space itself, and we might infer from this that the theory does not posit distinct senses or distinct lexical items as first-class linguistic constructs. This may be a consequence of the contextual modulation tenet.

Relatedly, it is unclear to us what a *complete* analysis in these terms would look like. What would it mean to have determined all and only the correct features? Could it be that the investigation will always admit of further dimensions, or decomposition of existing dimensions?

In sum, it is easy to see how this analysis makes good on the central tenets in Table 1. The representations are high-dimensional vectors with discrete values. In addition, the representations themselves directly bring in context. The vector for *break* alone, if it exists in the theory at all, needs to be mostly unspecified values that only become values in specific syntactic or usage contexts.

4 Static Vector Modeling

The above feature-based analysis might be described as a *sparse vector representation* approach. We now contrast that with a dense vector representation approach that models individual lexical items as fixed (static) vectors. A variety of such methods have been developed. Here we look at the treatment of *break* by three prominent methods: word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and fastText (Mikolov et al., 2018). These methods have different learning objectives, but all

are closely related to Pointwise Mutual Information (PMI; Church and Hanks 1990; Turney 2001). In PMI, we assign weights to pairs of words w_i and w_j based on whether their observed joint probability of co-occurrence is larger or smaller than what we would expect given the null hypothesis that w_i and w_j have independent distributions. All three methods learn regularized, reduced dimensional representations according to roughly this same goal (Levy and Goldberg, 2014; Cotterell et al., 2017).

None of these methods use discrete features, and thus they are in conflict with our discreteness tenet from Table 1. The raw input to all of them is a matrix of co-occurrence counts, which could be viewed as a set of discrete distributional features. However, much of the power of these models derives from their ability to compress this information into a lower-dimensional space of continuous values in which the columns are unlikely to have direct interpretations as features.

The GloVe vocabulary is largely restricted to individual words from a fixed list. By contrast, the vocabulary used for our word2vec instance includes some phrase-like elements that were inferred by the authors using simple co-occurrence statistics, and our chosen fastText model includes sub-word components and so also ends up with a more expansive view of what counts as a lexical item.

All of these models have proven successful as representations of words and as components in larger systems. However, we find that these representations are disappointing for studying *break*. In Table 4, we show the top 20 nearest neighbors (according to cosine similarity) for some uses of these models. We chose what seemed to be the semantically richest instance of each model from a larger set of such results (see Appendix B). All of the models capture morphological variants very clearly. However, the other semantic associations generally only weakly indicate other specific senses (via associations with other words). We do see some positive benefits from the quasi-phrasal vocabulary used by word2vec and fastText, but overall these spaces look like only superficial pictures of the underlying semantic richness of *break*.

The cause for this semantic blandness likely traces to the basic design decision: every word-form has only a single representation. This means that a single vector must encode all the different senses that we see in Table 2 as well as others that we did not include there. The result is probably

something like a weighted average of these senses, which seems not to be in a particularly interesting part of the embedding space.

Adherents to our central tenets (Table 1) might have predicted this negative result. While static representations are high dimensional, they do not allow for contextual modulation. Each basic unit of the vocabulary is assigned exactly one representation. Contextual modulation may occur if the representations are embedded in a larger system, but it is not intrinsic to the vectors themselves.

5 LLM Investigations

We come now to our primary investigative tool: LLMs. We concentrate on models that have the core structure of the Transformer (Vaswani et al., 2017) and are trained at least in part using masked language modeling, which allows for bidirectional context. In the interest of space, we will mostly presuppose familiarity with these models. However, Appendix C provides an overview of their structure to try to bridge any gaps between the linguistics and NLP literature.

In our main text, we report results for RoBERTa-large (Liu et al., 2019), which has 24 layers. Our appendices cover BERT and DeBERTa. Our RoBERTa-large results are slightly better than all of these others, but the results are generally quite comparable, suggesting that all of these models can fruitfully be used for lexical semantics.

Before turning to our experiments, let's consider how LLMs relate to our core tenets from Table 1. First, the representations we obtain at each hidden layer are all high-dimensional and modulated by the context. Our experiments show that, for the case of *break*, this contextual modulation is rich and linguistically systematic. Thus, LLMs and traditional lexical semantic theories are aligned on these two tenets. However, the two theories part ways when it comes to the question of having discrete features. The column dimensions of LLM representations are continuous and highly abstract. Discrete linguistic features might be latently encoded in these representations, or extractable from them with some noise, but this does not detract from the fact that these representations are highly fluid and do not presuppose the existence of any particular features or dimensions. Rather, all the features are learned from data in a free-form way that is grounded entirely in distributions.

Layer	Probe	Control	Selectivity
1	0.33	0.03	0.30
6	0.81	0.03	0.79
12	0.83	0.03	0.80
18	0.80	0.03	0.76
24	0.86	0.03	0.83

(a) Meaning-class probing results.

Layer	Probe	Control	Selectivity
1	0.50	0.33	0.17
6	0.94	0.34	0.60
12	0.96	0.33	0.63
18	0.96	0.35	0.61
24	0.97	0.32	0.65

(b) Construction-type probing results.

Table 5: RoBERTa-large probing results. We report Macro F1 and Selectivity, which is the Macro F1 score for the task minus the Macro F1 for a control task (random assignment of tokens to classes). Results for other models are similar; see Appendix D.
