Under both settings, model performance will plateau when adding more data. The results are summarized in Table 5. Both unsupervised and supervised finetunings with synthetically-noised data significantly improve alignment quality, especially for noisy test sets, in line with our previously presented results in low-resource settings.

5.4 Additional Data on Statistical Models

We conduct additional experiments to find out whether training with additional data aids statistical models for endangered languages. We evaluate model performance on Griko-Italian.

We concatenate additional data to the examples comprising the test set. We first train the models with all 800 clean sentence pairs taken from [Rijhwani et al. \(2020\)](#) (which include the 300 sentences of the test set). Next, instead of using clean data, we substitute it with synthetically noised data and train the models.

The result is presented in Table 6. For every statistical model, training with additional clean text reduces AER. However, training with additional noisy text considerably hurts the models. The result shows that these statistical models rely on *clean text* to improve, which is almost always *unavailable* for endangered languages. This also implies that investing time in manually cleaning OCR data could be effective for these models; however, it is not always possible and contradicts the goal of reducing the human effort in this work.

6 Analysis and Discussion

In this section we conduct several analyses to better understand our method.

Incorporating Diagonal Bias As shown in Table 4, our diagonal bias markedly improves ev-

Test set	En-Fr	En-De
CLEAN-CLEAN	5.6	17.9
CLEAN-NOISY	40.5	43.8
NOISY-CLEAN	39.2	52.8
NOISY-NOISY	53.6	66.6

Table 7: awesome-align baseline on En-Fr and En-De. OCR-like noise dramatically degrades the performance.

ery test case for both endangered language pairs. Note that the attention score will be increased significantly by adding bias, which will still be a valid input for the final alignment matrix due to its alignment extraction mechanism (Dou and Neubig, 2021). In this work, we only apply diagonal bias under low-resource settings since it was shown in Dou and Neubig (2021) that growing heuristics such as grow-diag-final (Koehn et al., 2005; Och and Ney, 2000) do not achieve promising results for multiple high-resource language test sets.

Degradation of Alignment Table 7 presents the evaluation of four test sets for awesome-align in English-French and English-German. We observe a significant decline in performance when OCR-like noise is introduced. For example, with clean parallel text, the AER for English-French is 5.6%, but when OCR-like noise is added, the AER jumps to 53.6%, almost a tenfold increase.

Size of synthetic data We conduct quantitative analyses as shown in Figure 3 to examine awesome-align with different sizes of English-French synthetic data under both unsupervised and supervised settings. For space economy reasons, here we only discuss the results of the more challenging noisy-noisy test set. Note that dramatic degradation of alignment is observed when applying OCR-like noise to clean text (see Table 7). In general, the model produces better alignment as more data are used. However, there is also a trade-off on the clean-clean test set as its performance worsens in the supervised scenario. Keep in mind, though, that this situation is only observed in high-resource language pairs; for a low-resource language pair like our Griko-Italian, in limited ablation experiments we found that we have not reached the data saturation point yet as more data simply resulted in better performance for both clean and noisy text.

Varying degrees of CER In a real-world scenario, the CER of OCRed data is typically un-

known due to the absence of clean text. We investigate how different degrees of CER affect alignments by creating several English-French synthetic data with varying degrees of CER, testing them on awesome-align. We elaborate on the process and results in Appendix B.1. The main finding is that higher CER leads to greater AER, which is expected. However, we also find that mixing with different degrees of CER generally produces better results than a fixed CER throughout the corpus, suggesting that our augmentation approach could also work on the unknown CER real-world scenario.

Statistical Model vs Neural Model The question of which model to use in practical scenarios, though, remains tricky to answer. Due to similarities between Griko and Italian and prolonged language contact over centuries, the two languages follow very similar syntax; as a result, their alignment is largely monotone, which benefits models like Giza++ and fast-align. They outperform, in fact, the vanilla neural awesome-align model by a large margin (see Table 3). However, this will not always be the case. For example, most books with parallel data in the Archive of Indigenous Languages of Latin America (AILLA) mostly contain data between indigenous languages and one of Spanish or English. Now the two sides of the data come from different language families and a monotone alignment is not necessarily to be expected. In such cases, it could indeed be the case that a more adaptable neural model like awesome-align, aided by our data augmentation and diagonal biasing methods, could indeed be the best option.

Different side of OCR noise An important insight derived from Table 5 is that the performance of awesome-align deteriorates significantly more when both sides of the parallel data are noisy, as compared to when only one side is noisy. This is in fact encouraging for our envisioned application scenarios, since, as in the AILLA examples described above, we expect that OCRed parallel data in endangered languages will come with one side in a high-resource standardized language like English and Spanish which in turn we expect the OCR model to be able to adequately handle.¹³

¹³Rijhwani et al. (2020) and Rijhwani et al. (2021) make similar observations on all endangered language datasets they work with.

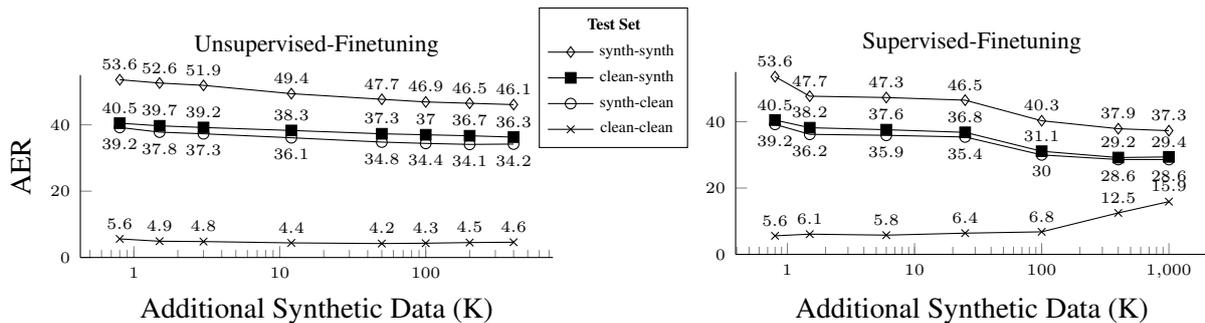

Figure 3: Ablation on English-French with varying degrees of additional synthetically noised data. Notice the log scale on the x-axis. The left-most point corresponds to no additional synthetic data (baseline). More data reduce AER for noisy test sets, especially in the supervised finetuning setting.

7 Related Work

Our work is a natural extension of previous word alignment work. A robust alignment tool for low-resource languages benefits MT systems (Xiang et al., 2010a; Levinboim and Chiang, 2015; Beloucif et al., 2016a; Nagata et al., 2020), or speech recognition (Anastasopoulos and Chiang, 2018), especially if sentence-level alignment tools like LASER (Artetxe and Schwenk, 2019; Chaudhary et al., 2019) do not cover all languages, so one may need to fall-back to word-level alignment heuristics to inform sentence-alignment models like Hunalign (Varga et al., 2007).

Research on word-level alignment started with statistical models, with the IBM Translation Models (Brown et al., 1993) serving as the foundation for many popular statistical word aligners (Och and Ney, 2000, 2003; Och, 2003; Tiedemann et al., 2016; Vogel et al., 1996; Och, 2003; Gao and Vogel, 2008; Dyer et al., 2013). In recent years, different neural network based alignment models gained in popularity including end-to-end based (Zenkel et al., 2020; Wu et al., 2022; Chen et al., 2021), MT-based (Chen et al., 2020), and pre-training based (Garg et al., 2019; Dou and Neubig, 2021). As awesome-align achieves the overall highest performance, we choose to focus on awesome-align in this work.

Some works involve improving word-level alignment for low-resource languages such as utilizing semantic information (Beloucif et al., 2016b; Pourdamghani et al., 2018), multi-task learning (Levinboim and Chiang, 2015), and combining complementary word alignments (Xiang et al., 2010b). None of the previous work, though, to our knowledge, tackles the problem of aligning data with

OCR-like noise on one or both sides. The idea of augmenting training data is not new and has been applied in many areas and applications. Marton et al. (2009) augment data with paraphrases taken from other languages to improve low-resource language alignments. While potentially orthogonal to our approach, this idea is largely inapplicable to our endangered language settings, as we often have to work with the only available datasets for these particular languages. Applying structure alignment bias on statistical and neural models is also a well-studied area (Cohn et al., 2016; Brown et al., 1993; Vogel et al., 1996; Och, 2003; Dyer et al., 2013). However, to the best of our knowledge, we are the first to apply it to low-resource languages, proving that such an approach can greatly aid the real endangered language data.

8 Conclusion

In this work, we benchmark several popular word alignment models under OCR noisy settings with high- and low-resource language pairs, conducting several studies to investigate the relationship between OCR noise and alignment quality. We propose a simple yet effective approach to create realistic OCR-like synthetic data and make the state-of-the-art neural awesome-align model more robust by leveraging structural bias. Our work paves the way for future word-level alignment-related research on underrepresented languages. As part of this paper, we also release a total of 4,101 ground truth word alignment data for Griko-Italian, which can be a useful resource to investigate word- and sentence-level alignment techniques on practical endangered language scenarios.

9 Limitations

Using AER as the main evaluation metric could be a limitation of our work as it might be misleading in some cases (Fraser and Marcu, 2007). Another limitation, of course, is that we only manage to explore the tip of the iceberg given the sheer number of endangered languages. While we are confident in the results of both low-resource language pairs, our experiments on Ainu-Japanese could potentially lead to inaccurate AER since we use the automatically generated silver alignment. In the future, we hope to eventually annotate it with either the help of native speakers or dictionaries. We also plan to explore other alternative metrics and expand our alignment benchmark on as many endangered languages as possible.

Acknowledgements

We are thankful to Shruti Rijhwani and Graham Neubig, as well as the anonymous reviewers, for their valuable comments on the early stages of this work. We would also like to thank Sina Ahmadi for his useful feedback and the GMU Office of Research Computing for the computing resources. This work was supported by NEH Award PR-276810-21 as well as through a GMU OSCAR award for undergraduate research.

A Evaluation metric

We calculate precision, recall and alignment error rate as described in [Och and Ney \(2003\)](#), where A is a set of alignments to compare, S is a set of gold alignments, and P is the union of A and possible alignments in S . We then compute AER with:

$$\text{Precision} = \frac{|A \cap P|}{|A|} \quad \text{Recall} = \frac{|A \cap S|}{|S|}$$
$$\text{AER}(S, P; A) = 1 - \frac{|A \cap S + A \cap P|}{|A + S|}$$

B Additional Analyses

B.1 Varying degrees of CER

We create eight 100k English-French synthetic datasets with different CER for each: “unified” datasets with exactly the same CER on both sides: 2, 5, 10, and one with mixed CER with equally shared portions with 2, 5 and 10 CER; and “varying” datasets with slightly different CER between the English and French side, but in the same range as the others. We then finetune the model with these synthetic training datasets and compare against the “skyline” result presented before, where the augmentation matched the level of the true CER.

The results are presented in [Table 9](#) for both the unsupervised- and the supervised-finetuning setting. Encouragingly, despite different CER in the augmentation data, there are no significant performance differences in most cases, especially for the unsupervised setting. Of course, levels of noise that match the true level tend to perform better or close to best overall. On the other hand, high levels of noise that lead to very high word error rate (WER)¹⁴ cause a large degradation in the performance of the supervised finetuning approach, but do not seem to significantly affect the unsupervised approach.

Even more encouragingly, an augmented dataset that uses a mixture of different target CER (such as having a third of the dataset having a CER around 2, a third with CER around 5, and a third around 10 – named “mixed” in [Table 9](#)) in the supervised setting further outperforms the *informed skyline* which uses additional knowledge that might not be available (the true CER of the data to be aligned). For instance, in the clean-noisy test set this model reduces AER by a further 5% (from 31.1 to 29.3)

and on the clean-clean test set it reduces AER by 19% (from 6.8 to 5.5). This means that our augmentation approach with varying levels of noise could be applied to any scenario, even if one does not know the level of noise present in the data-to-be-aligned.

¹⁴For example, a CER of around 10 translates to a WER of more than 70, meaning that (approximately) only 3 out of 10 words are correct.

	IBM 1		IBM 2		Giza++		fast-align		awesome	
	Clean OCR		Clean OCR		Clean OCR		Clean OCR		Clean OCR	
# of pairs	3844	3839	3833	3855	3810	3813	3801	3794	2978	2969
Precision	58.2	52.5	64.9	58.6	88.7	82.2	83.4	77.3	65.3	64
Recall	54.5	49.2	60.7	54.8	82.4	76.4	77.3	71.5	47.4	44.2

Table 8: Comparing the number of alignment pairs produced by models on Griko-Italian. awesome-align produces almost 25% less alignment pairs, resulting in markedly lower precision/recall and higher AER.

CER (WER) on Synthetic Data	Clean-Clean		Clean-Noisy		Noisy-Clean		Noisy-Noisy		
	UNSUP-FT	SUP-FT	UNSUP-FT	SUP-FT	UNSUP-FT	SUP-FT	UNSUP-FT	SUP-FT	
Skyline: Using exactly the CER of the test set									
7.4-4.8 (59.7-51.7)	4.3	6.8	37	31.1	34.4	30	46.9	40.3	
Unified: Exactly the same CER on both sides									
2-2 (32.2-29.1)	4.1	5.1	37.5	33.3	35.1	30.1	48.4	41.8	
5-5 (55.1-52.4)	4.3	7.4	37.2	30.4	34.6	29.8	47.4	40.0	
10-10 (72.2-71)	4.5	32.8	36.8	36.2	34.5	47.7	46.8	47.3	
mixed (55-54.1)	5.4	5.5	37.3	39.6	35.3	39.8	47.7	54.2	
Varying CER between the two parallel sides									
1.6-2.1 (27.8-29.6)	4.0	6.2	37.6	31.6	35	30.6	48.4	41.9	
4.1-5.1 (49.6-52.5)	4.3	7.7	37	29.8	34.7	30.1	47.2	40.2	
8.1-9.6 (66.9-69.5)	4.5	31.3	37.1	36.2	34.3	46.3	46.7	46.9	
mixed (47.9-50)	4.2	5.6	37	29.3	34.6	29.7	47.2	40.4	

Table 9: AER comparison for varying CER in 100K English-French augmented data used for either unsupervised or supervised finetuning. We highlight the best result under each setting and test set. Overall, most models' performance is close to the baseline, but varying amounts of noise (mixed) lead to generally the best results. Too high amounts of noise (e.g. CER around 10 with WER approaching 70) hurts the supervised approach.

Enhancing Dialogue Generation with Conversational Concept Flows

Abstract

Human conversations contain natural and reasonable topic shifts, reflected as the concept flows across utterances. Previous researches prove that explicitly modeling concept flows with a large commonsense knowledge graph effectively improves response quality. However, we argue that there exists a gap between the knowledge graph and the conversation. The knowledge graph has limited commonsense knowledge and ignores the characteristics of natural conversations. Thus, many concepts and relations in conversations are not included. To bridge this gap, we propose to enhance dialogue generation with conversational concept flows. Specifically, we extract abundant concepts and relations from natural conversations and build a new conversation-aware knowledge graph. In addition, we design a novel relation-aware graph encoder to capture the concept flows guided by the knowledge graph. Experimental results on the large-scale Reddit conversation dataset indicate that our method performs better than strong baselines, and further analysis verifies the effectiveness of each component.

1 Introduction

With the remarkable development of conversation artificial intelligence (Shang et al., 2015; Adiwardana et al., 2020; Thoppilan et al., 2022), response generation has been improved in many ways, e.g., human-like persona (Zhang et al., 2018a), empathetic expression (Rashkin et al., 2019) and knowledge injection (Dinan et al., 2019), etc. However, there still exists a series of challenges (Gao et al., 2019; Xu et al., 2020a; Huang et al., 2020). One of the most noticeable is that humans are good at naturally switching topics during conversations, while machine-generated responses are relatively dull and tend to keep the topic still (Fang et al.,

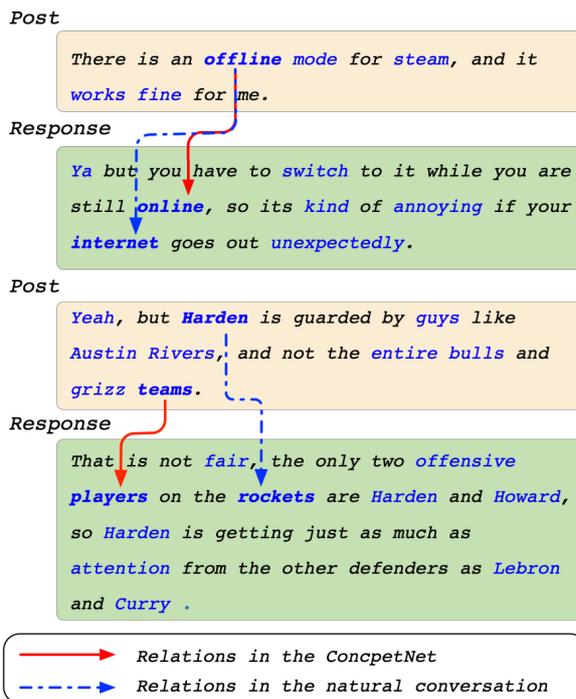

Figure 1: Two cases in the Reddit dataset. We use ConceptNet as the external knowledge graph to show concept flows in conversations. Concepts are marked in blue. Relations in the graph and those in the natural conversation are marked with red solid lines and blue dashed lines, respectively.

2018) or throw unexpected topics (Wang et al., 2018; Tang et al., 2019).

To overcome this challenge, previous works treat the topic shifts as concept flows (Zhang et al., 2020a; Zhou et al., 2018b, 2021a), which means traversing in the concept¹ space along relations in an external commonsense knowledge graph. Experimental results have shown that explicitly modelling concept flows effectively improves the relevance and engagingness of responses. However, we argue that there is a gap between the external knowledge graph and natural conversations. The most

* Equal contribution.

† Corresponding author (yang.yujiu@sz.tsinghua.edu.cn).

¹Concept is the node in knowledge graph.

frequently used ConceptNet² (Speer et al., 2017) is limited to mostly (90%) taxonomic (e.g., *IsA*) or lexical (e.g., *Synonym*) knowledge, while contains relatively small portion of commonsense knowledge (Hwang et al., 2021). In addition, concepts and relations in natural conversations are more colloquial and timely. Thus, many concepts and relations are not included in the knowledge graph, which has also been verified in our experiments. As in Figure 1, the concept flows from “offline” to “internet” and from “Harden” to “rockets” are frequently observed in human conversations, while they are both not included in the most frequently used ConceptNet.

To bridge the above gap and capture more concept flows, we propose to Enhance Dialogue Generation with Conversational Concept Flows (ECCF). Specifically, we construct an enhanced knowledge graph that consists of concepts and relations in both commonsense knowledge graph and natural conversations. First, we extract new concepts as new nodes and the high-frequency relations between concepts as new edges from a large-scale dialogue corpora. Then, we add these new nodes and new edges to the commonsense knowledge graph to construct a Conversation-Aware Knowledge Graph (CAKG). To effectively guide concept flows in conversations with CAKG, we further propose a novel Relation-Aware Graph Encoder (RAGE), which reasonably considers concepts and their relations in the graph encoding process for response generation.

We conduct a series of experiments on the large-scale Reddit conversation dataset (Zhou et al., 2018b; Baumgartner et al., 2020). Both automatic evaluation and human evaluation demonstrate that our method ECCF improves the relevance and diversity of responses, and outperforms strong baselines. Further analysis verifies the effectiveness of both CAKG and RAGE. Our research sheds light on explicitly modeling topic shifts with natural conversations.

2 Method

2.1 Overview

Given a dialogue context X , we aim to guide the topic shifts with the concepts and relations in a

²ATOMIC (Sap et al., 2019) is also frequently used, while they focus more on human emotion and reaction in the generation of empathetic responses (Sabour et al., 2021; Tu et al., 2022), which we leave for future work.

knowledge graph. Our method ECCF is shown in Figure 2, and can be summarized as follows:

1. Considering the abundant topic shifts in natural conversations, we enhance a commonsense knowledge graph G with conversational concept flows extracted from large-scale conversation data. Then we get a conversation-aware knowledge graph G_c (CAKG), which is more informative.
2. For response generation, we first encode the dialogue context X with a context encoder. Then, to capture the concept flows defined in the knowledge graph G_c , we use a graph encoder for encoding the retrieved subgraph g from G_c , which is based on the concepts in the dialogue context and their neighbor nodes. Last, we adopt a decoder with copy mechanism to generate a response and it can directly copy concepts from the subgraph g .

2.2 Knowledge Graph Enhancement with Conversational Concept Flows

We construct CAKG G_c on the basis of the commonsense knowledge graph G and a large-scale dialogue corpora Reddit (Baumgartner et al., 2020), so that G_c contains more concept flows in natural conversation. Formulating $G = \{V, E\}$ where V and E represent nodes and edges respectively, we extract new nodes V' and new edges E' from the corpora, then reconstruct $G_c = \{V \cup V', E \cup E'\}$.

To obtain conversational concepts as much as possible, we have two principles when extracting new nodes: common and concrete. First, we set a frequency threshold m and words with a frequency higher than it are regarded as candidate concepts. Second, we choose nouns as new nodes from candidate concepts because nouns have richer semantic information than other types of words³.

We utilize the GIZA++ tool to extract⁴ (Och and Ney, 2003) new edges, which represent concept flows in the conversations. The GIZA++ tool is designed to align words in the machine translation field. Its main idea is that utilize the EM algorithm to iteratively train the bilingual corpus and obtain word alignment from sentence alignment. We choose the toolkit here since concept alignments from source sentences to target sentences in

³We use the NLTK toolkit in python3 for POS tagging <https://www.nltk.org/>

⁴<http://www.statmt.org/moses/giza/GIZA++.html>

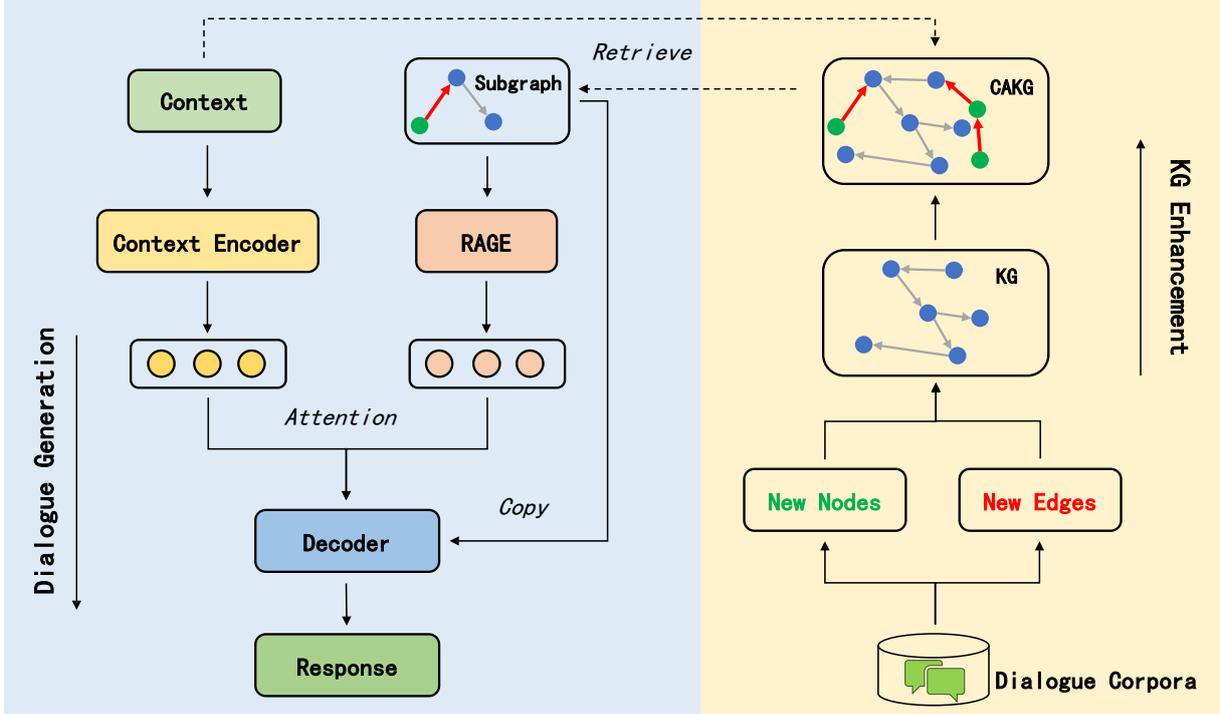

Figure 2: The pipeline of ECCF, which contains two parts. First, as in the right part, we extract new nodes and new edges from the dialogue corpora, then merge them with commonsense knowledge graph (KG) to construct conversational-aware knowledge graph (CAKG). Second, we use CAKG to guide the concept flows during the response generation process. For graph encoding, we use a relation-aware graph encoder (RAGE).

conversations are similar to bilingual word alignment. In practice, we first clean the corpora by removing all words except $V \cup V'$. Then we run the GIZA++ toolkit to get the alignment probabilities. Finally, we arrange the probabilities to select the top k alignments as new edges. More details of the alignment process can be found in their original paper (Och and Ney, 2003).

An example is presented in Figure 3. For the source concept “nurse”, we rank all the target concepts according to the alignment probabilities. The relations from “nurse” to the top k concepts are regarded as new edges, such as “nurse \rightarrow hospital”, and we attribute these edges to a new category: “DialogFlowTo”.

2.3 Response Generation with Conversation-Aware Knowledge Graph

2.3.1 Context Encoder

Given the dialogue context $X = (x_1, x_2, \dots, x_m)$, we utilize a bi-directional encoder to get the contextual representation $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_m)$.

$$\mathbf{H} = \text{Encoder}(X). \quad (1)$$

The encoder can be Transformer (Vaswani et al., 2017) or GRU (Cho et al., 2014), to be consistent

<i>source</i>	<i>target</i>	<i>alignment prob</i>	
<i>nurse</i>	<i>nurse</i>	0.0917	} <i>Top k</i> <i>add new edges</i>
	<i>hospital</i>	0.0346	
	<i>nurses</i>	0.0306	
	<i>nursing</i>	0.0254	
	<i>medical</i>	0.0231	
	\vdots	\vdots	
	<i>tests</i>	$1.096 \times 1e-7$	
	<i>expert</i>	$1.087 \times 1e-7$	

Figure 3: Extract concepts and relations from natural conversations.

with previous methods (Zhang et al., 2020a; Zhou et al., 2018b, 2021b), we utilize GRU in our experiments and choose the last word hidden states \mathbf{h}_m as the representation of dialogue context.

2.3.2 Relation-Aware Graph Encoder

Since introducing the whole graph to the generation process is unpractical and unnecessary, we retrieve a subgraph g from G_c and encode g with the relation-aware graph encoder (RAGE), which is based on the Transformer Encoder (Vaswani et al., 2017). The subgraph g derives from the concepts in the dialogue history and their one-hop and two-

hop neighbor nodes⁵. To model the interactions between the dialogue context X and subgraph g , we set a special node \mathcal{X} to connect with all nodes of g , which represents the relations between dialogue and concepts. Then, we initialize the embedding of \mathcal{X} with \mathbf{h}_m , and the embedding of g with TransE embedding (Bordes et al., 2013). To model the graph structure of subgraph g , we design a graph mask matrix M :

$$m_{ij} = \begin{cases} 0 & \text{if } i = \mathcal{X} \text{ or } j = \mathcal{X}, \\ 0 & \text{if } i \in \text{Neighbor}(j), \\ -\infty & \text{otherwise,} \end{cases} \quad (2)$$

where $m_{ij} = 0$ indicates that node i and node j are connected, while $m_{ij} = -\infty$ represents the disconnect. Further, we replace the original Multi-Head Attention (MHA) with Relation-Aware Concept Attention (RACA), which incorporates the graph structure and node relations in the attention process. The differences are as follows:

$$\begin{aligned} \text{MHA} &= \text{softmax}\left(\frac{QK^T}{\sqrt{d}}\right)V, \\ \text{RACA} &= \text{softmax}\left(\frac{QK^T}{\sqrt{d}} + M + R\right)V, \end{aligned} \quad (3)$$

where Q, K, V is the query, key, and value vectors, more details in the original paper (Vaswani et al., 2017). M represents the graph mask matrix and R denotes edge relation bias:

$$r_{ij} = q^T \times e_{ij}, \quad (4)$$

where $e_{ij} \in \mathcal{R}^d$ is edge embedding⁶, $q \in \mathcal{R}^d$ is used to transform the vector to scalar which represents relation importance in the attention process. We employ different q in different heads and layers of the graph encoder, so that we can capture abundant and diverse relation-aware concept interactions. The output of the last layer is selected as the concept representations \mathbf{G} .

2.3.3 Decoder

The decoder generates response Y based on the dialogue context and subgraph. At t -th time step, the decoder state s_t is updated as follows:

$$s_t = \text{Decoder}(s_{<t}, y_{t-1}, \mathbf{H}, \mathbf{G}) \quad (5)$$

⁵As the two-hop neighbor nodes are extensive, we select 100 two-hop nodes for each concept. For the fairness of the experiment, we use the same two-hop nodes set as in as in Zhang et al. (2020a).

⁶For the edges from a node to itself, we give them a new category: ‘‘SelfTO’’. For edges from and to \mathcal{X} , we give them two new categories: ‘‘FromText’’ and ‘‘ToText’’.

To be consistent with previous works, we utilize GRU in this paper. We employ attention mechanism to capture useful information from \mathbf{H} and \mathbf{G} , more details in (Bahdanau et al., 2015).

In addition, we also apply the copy mechanism to directly copy concepts from subgraph g . The process can be formulated as follows:

$$\begin{aligned} \sigma_t &= \text{Sigmoid}(v_s^\top s_t), \\ p_t^v &= \text{Softmax}(\mathbf{W} \cdot s_t), \\ p_t^c &= \text{Softmax}(\mathbf{G} \cdot s_t), \\ p_t &= (1 - \sigma_t) \cdot p_t^v + \sigma_t \cdot p_t^c, \end{aligned} \quad (6)$$

where p_t^v and p_t^c are the probability of generation and copy, respectively.

2.3.4 Objective Function

Our objective function has two parts, the first is the negative log likelihood of response generation:

$$\mathcal{L}_1 = - \sum_{t=1}^n \log p(x_t | x_{<t}, X, H, G). \quad (7)$$

We also supervise the copy gate as in Zhou et al. (2018a); Chen et al. (2022), so that the decoder can accurately copy concepts from the subgraph:

$$\mathcal{L}_2 = \sum_{t=1}^n q_t \cdot \log \sigma_t + (1 - q_t) \cdot \log(1 - \sigma_t), \quad (8)$$

where $q_t \in \{0, 1\}$ indicates whether x_t is a concept word from the subgraph. The final objective function is $\mathcal{L} = \mathcal{L}_1 + \mathcal{L}_2$.

3 Experiment

3.1 Dataset

Follow Zhou et al. (2018b); Zhang et al. (2020a), we conduct experiments based on Reddit conversation dataset processed by (Zhou et al., 2018b). It contains 3,384,160 training pairs and 10,000 testing pairs. We use the commonsense knowledge graph ConceptNet (Speer et al., 2017) processed by Zhou et al. (2018b), which includes 21,471 nodes, 120,850 edges, and 44 types of edge relation.

3.2 Baselines

The baselines can be divided into three groups:

- **Standard seq2seq model**(Sutskever et al., 2014). The model is based on the classical encoder-decoder framework. The encoder and decoder are GRU as our model.

Model	Bleu-3	Bleu-4	Nist-3	Nist-4	Rouge-1	Rouge-2	Rouge-L	Meteor	PPL	Ent-4
Seq2seq	0.0226	0.0098	1.1056	1.1069	0.1441	0.0189	0.1146	0.0611	48.79	7.6650
MemNet	0.0246	0.0112	1.1960	1.1977	0.1523	0.0215	0.1213	0.0632	47.38	8.4180
CopyNet	0.0226	0.0106	1.0770	1.0788	0.1472	0.0211	0.1153	0.0610	43.28	8.4220
CCM	0.0192	0.0084	0.9082	0.9095	0.1538	0.0211	0.1245	0.0630	42.91	7.8470
ConceptFlow	0.0495	0.0239	1.8838	1.8896	0.2241	0.0457	0.2032	0.0956	29.44	10.2390
GPT-2(lang)	0.0162	0.0162	1.0840	1.0844	0.1321	0.0117	0.1046	0.0637	29.08*	11.6500
GPT-2(conv)	0.0262	0.0124	1.1745	1.1763	0.1514	0.0222	0.1212	0.0629	24.55*	8.5460
DialoGPT	0.0189	0.0095	0.9986	0.9993	0.0985	0.0117	0.0971	0.0546	18.65*	9.8163
ECCF	0.0644	0.0331	2.2573	2.2661	0.2592	0.0601	0.2340	0.1091	25.98	10.8173

Table 1: Automatic Evaluations. We highlight the best scores on each metric. The PPL scores of pre-trained models are not comparable because of different tokenization. The results indicate that our ECCF gets the highest scores on most metrics.

- **Knowledge enhanced models:** MemNet(Ghazvininejad et al., 2018), CopyNet(Zhu et al., 2017), CCM(Zhou et al., 2018b) and ConceptFlow(Zhang et al., 2020a). These models explore knowledge information during the generation process.
- **Pretrained models:** GPT-2 lang(Zhang et al., 2020a), GPT-2 conv(Zhang et al., 2020a), DialoGPT(Zhang et al., 2020b). These models have a large number of parameters and have been pretrained on large corpus. GPT-2 lang and GPT-2 conv are built based on GPT-2(Radford et al., 2019).

For seq2seq, MemNet, CopyNet, CCM, GPT-2 lang and GPT-2 conv, we directly use results in ConceptFlow paper (Zhang et al., 2020a). For ConceptFlow, we run their public codes⁷. For DialoGPT, we finetune it on the dataset⁸.

3.3 Evaluation Metrics

We use the following metrics for evaluation:

- **PPL (Serban et al., 2016):** Perplexity measures the fluency of the responses.
- **Bleu (Chen and Cherry, 2014), Nist (Dodgington, 2002), Rouge(Lin, 2004) :** These metrics measure the overlap between the generated response and the ground truth.
- **Meteor (Lavie and Agarwal, 2007):** Meteor measures the relevance between generated responses and ground truth.
- **Entropy (Zhang et al., 2018b):** Entropy measures the diversity of generated responses.

⁷<https://github.com/thunlp/ConceptFlow>.

⁸<https://huggingface.co/microsoft/DialoGPT-medium>

We implement the above metrics based on the code of Galley et al. (2018)⁹.

3.4 Implementation Details

For constructing CAKG, we utilize the training dataset for extracting conversational concept flows, which includes 3,384,160 utterance pairs. The frequency threshold m is set as follows: we first arrange the frequencies of V (original concepts in ConceptNet) in the dialogue corpora as $f_1, f_2, \dots, f_{|V|}$, then, $f_{0.2 \times |V|}$ is set as m . Noun words with frequency higher than m is selected as new concepts. Further, we choose the top 20% concept relations for each concept as new edges.

For response generation, we use 2-layer GRU as context encoder and decoder, 3 layers of Transformer encoder with relation-aware concept attention as graph encoder. We choose Adam as the optimizer, the batch size, learning rate, max gradients norm, and dropout are set to 30, 1e-4, 5, 0.2, respectively. We use TransE embedding (Bordes et al., 2013) and Glove embedding (Pennington et al., 2014) to initialize the embedding of concepts and words, respectively. We train our method on 8 V100 GPUs, and it takes about 1.5 hours for one-epoch training.

4 Evaluation

4.1 Automation Evaluation

The experimental results are shown in Table 1. Except for pre-trained models, our method achieves the lowest PPL score, indicating that the responses generated by our model are more fluent. Furthermore, Bleu, Nist, Rouge, and Meteor measure the

⁹<https://github.com/DSTC-MSR-NLP/DSTC7-End-to-End-Conversation-Modeling>

Graph	Nodes	Edges	Response Nodes	0-hop Nodes		1-hop Nodes		2-hop Nodes	
				amount	golden	amount	golden	amount	golden
G	21471	120850	5.691	5.8129	0.5998	90.5138	1.2064	99.7706	0.8823
G_c	21754	218478	6.192	6.3223	0.6352	100.6227	1.4114	99.7706	0.8823

Table 2: Statistics of graphs coverage on the conversation dataset. The amount and golden are the numbers of total concepts and concepts appearing in responses, respectively. Obviously, G_c has higher coverage than G .

	Fluency		
	Average	Best @1	kappa
ConceptFlow	2.2875	0.24	0.563
ECCF	2.4325	0.30	0.603
Golden	2.6975	0.69	0.665
	Appropriateness		
	Average	Best @1	kappa
ConceptFlow	1.6200	0.12	0.480
ECCF	1.6850	0.16	0.563
Golden	2.3275	0.81	0.603

Table 3: Evaluation results by human annotators. We also present Fleiss’ Kappa in the table. Kappa values range from 0.4 to 0.6, indicating fair agreement.

relevance between generated responses and ground truth responses in different ways. Our method outperforms all baselines by large margins on these metrics, demonstrating that the responses generated by our method are more relevant to the contexts and topic-consistent with humans. For diversity, our method gets the second-highest score, only lower than GPT-2. This proves that our proposed method can generate diverse responses. It is worth noticing that, although pre-trained models are slightly better at fluency and diversity, they perform much worse in relevance (Bleu, Nist, Rouge, Meteor) compared with our method and ConceptFlow. This indicates the superiority of explicitly modeling conversational topic shifts based on a knowledge graph.

4.2 Human Evaluation

To evaluate model performances more comprehensively, we follow Zhang et al. (2020a) and hire four human annotators to judge the quality of generated responses. Specifically, we randomly sample 100 cases for ConceptFlow, ours, and ground truth responses¹⁰. Annotators are required to score responses from 1 to 3 on two aspects: fluency and appropriateness. Fluency evaluates whether a response is fluent or contains grammar errors, while

¹⁰Zhang et al. (2020a) have proved that ConceptFlow outperforms a series of baselines including GPT-2 based methods. Therefore, we only use ConceptFlow for comparison here in the case of limited human resources.

appropriateness measures whether a response is relevant and reasonable to its dialogue context.

As in Table 3, ECCF is better than the strong baseline ConceptFlow in terms of both fluency and appropriateness, the best @1 ratios of ECCF are also higher than ConceptFlow, demonstrating the superiority of our method. However, there is a large gap between ours and humans, indicating that there is still plenty of room for improvement.

5 Analysis

5.1 Conversation-Aware Knowledge Graph

Table 2 presents the statistics of ConceptNet G and our CAKG G_c . Thanks to the conversational concept flows extracted from large-scale dialogue corpora, G_c has more concepts and relations. Thus, more concepts in the responses are covered, especially for 0-hop and 1-hop concepts. This further proves the limitation of the external commonsense knowledge graph. We conduct an ablation study by replacing CAKG with ConceptNet (Ours w/o CAKG). As in Table 4, the performance drops in both relevance and diversity, which proves the effectiveness of conversational concept flows.

To further explore the relation between commonsense knowledge graph and conversational concept flows, we remove some edges in ConceptNet when constructing CAKG. As shown in Table 4, our method performs worse on relevance, fluency, and diversity, much worse when more edges are removed. Therefore, we can infer that concepts and relations in commonsense knowledge graph are also of great necessity for guiding topic flows in natural conversation. Further, both commonsense and conversation knowledge are beneficial to response generation, a reasonable way is to combine them as in our method.

5.2 Conversational Concept Flows

We conduct a human evaluation to verify the quality of the extracted conversational concept flows. Specifically, we randomly sample 100 extracted edges, and hire four human annotators to judge

Model	Bleu-3	Bleu-4	Nist-3	Nist-4	Rouge-L	Meteor	PPL	Ent-4
ECCF	0.0644	0.0331	2.2573	2.2661	0.2340	0.1091	25.98	10.8173
w/o CAKG	0.0615	0.0319	2.1448	2.1541	0.2307	0.1055	26.40	10.7081
w/o 20% edges in CN	0.0634	0.0328	2.2102	2.2194	0.2322	0.1070	27.17	10.7391
w/o 50% edges in CN	0.0502	0.0249	1.8466	1.8528	0.2044	0.0938	30.77	10.2637
w/o RAGE	0.0529	0.0267	1.9270	1.9340	0.2115	0.0976	27.81	10.4316
w/o graph mask	0.0573	0.0290	2.0694	2.0771	0.2201	0.1025	26.81	10.6822
w/o relation aware	0.0589	0.0295	2.1394	2.1472	0.2246	0.1050	26.46	10.6871
w/o dialogue node	0.0595	0.0305	2.1316	2.1402	0.2237	0.1044	27.00	10.7731

Table 4: Analysis studies for conversation-aware knowledge graph (CAKG) and relation-aware graph encoder (RAGE), CN represents ConceptNet.

whether the target concept is relevant to the source concept. The results show that 68 edges are voted as relevant, of which 47 edges that all four annotators reach an agreement. According to our manually checking, these edges mainly have three categories, as shown in Figure 4. The first type corresponds to pairs that have realistic relations, such as “nurse” and “hospital”. The second type corresponds to pairs in the same kind, such as both “ps4” and “pc” are electronic devices. The third type corresponds to pairs with POS relations, such as “perception” is the noun form of “perceptive”. These three categories are meaningful, which proves that our method can obtain beneficial knowledge from natural conversations.

5.3 Relation-Aware Graph Encoder

We further investigate the effectiveness of the proposed relation-aware graph encoder (RAGE), and conduct several ablation studies as follows:

- **w/o RAGE.** To explore the superiority of our graph encoder, we replace it with a GNN-based architecture named GRAFT-Net (Sun et al., 2018), which is used by the strong baseline ConceptFlow (Zhang et al., 2020a).
- **w/o graph mask.** We remove the graph mask to explore the effectiveness of graph structure.
- **w/o relation aware.** We remove the relation bias in relation-aware concept attention, which aims to explore the effects of relation for graph encoding.
- **w/o dialogue node.** We remove the node \mathcal{X} to study the necessity of the interactions between dialogue context and knowledge graph.

The results are shown in Table 4, and there are several findings. First, the performance drops largely

when replacing our RAGE with traditional GNN used by previous work (Zhang et al., 2020a), which proves the effectiveness of transformer architecture and relation-aware concept attention. Second, the ablation study of each component further verifies the rationality of our design. Third, removing the graph mask results in worse performance compared with removing relation aware and removing dialogue node, which shows the importance of graph structure for graph encoding.

related things	the same kind of things	form change
nurse → hospital	ps4 → pc	perceptive → perception
digest → eat	jews → arabs	pipng → pipe
rubble → buildings	bling → shiny	anarchist → anarchy

Figure 4: Several examples of high-quality concepts and relations we extracted from the conversation corpora. We classify them into three categories.

5.4 Case Study

To further investigate the performance, we present three cases in Table 5. In case 1, though the responses generated by DialogPT and ConceptFlow are proper, they are not as informative as ours. We can see that our response contains concept “episode” from G_c , which is consistent with the post and achieves a reasonable and natural topic shift. In case 2, it seems that DialogPT and ConceptFlow don’t understand the context and give wrong responses, while our method gives high-quality response that contains concepts “source”, “server” and “bug”, which are relevant to the context. In case 3, for the post about football and super bowl, DialogPT gives a short and dull response while ConceptFlow gives an unreasonable sentence. In contrast, our response is more consistent with the post. These cases show that our method generates more suitable responses, which is consistent with the automatic evaluation and human evaluation.

#1 post	i drove home last night , saw my dad for the first time in 6th months , and slept all day today . woke up and poured myself a rum and coke then started watching archer . today was a good day .
DialoGPT	i'm glad you had a good day.
ConcpetFlow	i 'm going to the same day . have a good night , man .
ECCF	i 'm going to watch the first episode of archer and see if i can get a chance to sleep .
#2 post	what do you mean ? from the alpha or from the beta ? his uav was nerfed like crazy in the beta , not being able to ping or find a monster if they 're sneaking at all .
DialoGPT	i mean from the alpha. i'm not sure if it was nerfed in the beta, but i'm pretty sure it was.
ConcpetFlow	you can see the alpha of the alpha , but it 's a bug .
ECCF	you can see the source on the server . i think he was just a bug .
#3 post	nowhere . fuck the patriots . fuck the seahawks . fuck football and fuck all these super bowl questions today .
DialoGPT	i'm with you man.
ConcpetFlow	you 're right . it 's a great way to get a new one . you can also see the seahawks and the seahawks .
ECCF	how about you ask me to watch the game ? you want to watch the world cup and see how much of a rivalry it takes to get to the point ?

Table 5: Three cases on the testset. We present responses generated by three different models. To study the impact of the knowledge graph, we mark concepts in the original ConceptNet in blue and concepts introduced by the enhanced graph in magenta.

6 Related Work

Dialogue Generation. Recently, dialogue generation (Adiwardana et al., 2020; Thoppilan et al., 2022) has achieved great progress in many aspects. Pre-trained dialogue models (Zhang et al., 2020c; Roller et al., 2021) improve the response quality largely, even reaches human performance in single-turn dialogue generation. Persona-based dialogue system (Zhang et al., 2018a) possesses a human persona and is able to converse in a more captivating way. Rashkin et al. (2019) propose empathetic response generation, which aims to recognize partner feelings and reply accordingly. To bridge the gap between human utterances and dialogue system utterances, Chen et al. (2022) propose to enhance empathetic response generation with human-like intents. In this paper, we focus on the topic shifts during conversations and propose to enhance dialogue generation with conversational concept flows.

Knowledge-Aware Dialogue Generation. One of the most crucial challenges in dialogue generation is the lack of knowledge. Plentiful works have been proposed to inject reasonable knowledge into responses. One kind of these works utilizes unstructured knowledge, e.g., Wikipedia articles (Dinan et al., 2019), goal-related documents (Feng et al., 2021) etc. Another kind of work focuses on structured knowledge. Zhou et al. (2018a) exploit concept relations in commonsense knowledge graph to imitate concept shifts in human conversation. Zhang et al. (2020a) develop this idea and propose

to explicitly model the concept flows in conversation. As we notice the gap between commonsense knowledge graph and natural conversations, we further propose to enhance dialogue generation with conversational concept flows.

There are also researches that extract information from natural conversations. Some of them extract relationships among persons on a domain-specific dataset (Yu et al., 2020; Xue et al., 2021; Long et al., 2021), while they focus on relation extraction not response generation. Others construct conversational graph from natural conversations to improve response generation (Xu et al., 2020b; Zou et al., 2021). However, their graphs only contain knowledge in conversations, while ignores the rich knowledge in commonsense knowledge graph. As shown in our analysis experiments, both types of knowledge are beneficial to response generation.

7 Conclusion and Future Work

In this paper, we argue the limitation of using external commonsense knowledge graph for response generation. To better capture topic shifts in natural conversation, we propose to enhance dialogue generation with conversational concept flows and construct conversation-aware knowledge graph. We further design a novel relation-aware graph encoder to capture the concept relations in knowledge graph. Extensive experiments on the large-scale Reddit dataset show the superiority of our method, and further analysis demonstrates the rationality of each

component. In future work, we expect to capture more structural information from natural conversations to improve dialogue generation.

Limitations

In this paper, we propose to enhance dialogue generation with conversational concept flows. Experimental results have shown that our method performs better than strong baselines. However, there are several major limitations. First, we use GIZA++ toolkit to extract concept relations, which is efficient but less expressive, as we cannot confirm the relations between concepts while they are quite different. For example, the relation between “nurse” and “hospital” is different to the relation between “thirsty” and “drink”. These relations have certain semantics and can be beneficial for response generation. Second, the experimental results in this paper are only based on one dataset Reddit. Although Reddit is large and contains 3,384,160 examples, more datasets can further verify the generalization ability of our methods. Third, we only combine conversational concept flows with ConceptNet (Speer et al., 2017), while other knowledge graphs (e.g., ATOMIC (Sap et al., 2019)) should be considered in future work to further explore the relations between conversational concept flows and commonsense knowledge.

Abstract

Mental health problems are a challenge to our modern society, and their prevalence is predicted to increase worldwide. Recently, a surge of research has demonstrated the potential of automated detection of mental health conditions (MHC) through social media posts, with the ultimate goal of enabling early intervention and monitoring population-level health outcomes in real time. Progress in this area of research is highly dependent on the availability of high-quality datasets and benchmark corpora. However, the publicly available datasets for understanding and modeling MHC are largely confined to the English language. In this paper, we introduce SMHD-GER (Self-Reported Mental Health Diagnoses for German), a large-scale, carefully constructed dataset for MHC detection built on high-precision patterns proposed for English. We provide benchmark models for this dataset to facilitate further research and conduct extensive experiments. These models leverage engineered (psycho-)linguistic features as well as BERT-German. We also examine nuanced patterns of linguistic markers characteristics of specific MHC.

1 Introduction

Mental health is a major challenge in healthcare and in our modern societies at large (Rehm and Shield, 2019; Santomauro et al., 2021). The World Health Organization estimates that 970 million people worldwide suffer from mental health conditions¹², with the rate of undiagnosed mental disorders estimated to be as high as 45% (La Vonne et al., 2012).

¹<https://www.who.int/news-room/fact-sheets/detail/mental-disorders>

²Mental disorders' can also be referred to as 'mental health conditions'. The latter is sometimes used as a broader term encompassing mental disorders, psycho-social disabilities, and mental conditions, include different types of depression, bipolar disorder, schizophrenia, anxiety disorders, chronic stress etc.. In this work, the two terms are used interchangeably.

The enormous societal impact of mental health conditions (MHC) requires prevention and intervention strategies that focus primarily on screening and early detection. The last decade has seen a surge in digital mental health research, an interdisciplinary line of research that brings together insights from computational linguistics, cognitive psychology and computational social sciences to understand the relationship between patterns of language use and mental health conditions (D'Alfonso, 2020; Schindler and Domahidi, 2022). Natural language processing, in particular, is increasingly recognized as having transformative potential to support healthcare professionals in the diagnosis and treatment of mental disorders and enable people to lead healthy lives (see Guntuku et al. 2017; Thieme et al. 2020; Chancellor and De Choudhury 2020; Zhang et al. 2022 for recent overviews of this research).

Progress in this area of research is highly dependent on the availability of high-quality datasets and benchmark corpora. Social media has emerged as an increasingly vital resource for obtaining such data, as it is now a central place for individuals to participate in discussions, share information, and seek advice. Based on data drawn from platforms such as Twitter and Reddit, recent work has developed scalable methods for constructing mental health datasets based on self-reported diagnoses or grouping individuals based on activity patterns (Coppersmith et al., 2015; Yates et al., 2017; Cohan et al., 2018; Kumar et al., 2015). However, recent reviews on the state of data used for mental health status on social media show that the vast majority of the publicly available datasets for understanding and modeling MHC are on the English language: For example, of the 102 datasets reviewed in Harrigian et al. (2021) 83% were on English with the remaining 17% distributing over five other languages: Chinese (9.8%), Japanese (3.9), Korean (1.9), Spanish and Portuguese (each < 1%). Zhang

et al. (2022) report that 81% of all the datasets are in English, followed by datasets in Chinese (10%), and Arabic (1.5%). While an overwhelming focus on English data is a theme throughout the NLP community, it is a specific concern in this domain where culture often influences the presentation of mental health disorders (De Choudhury et al., 2017; Loveys et al., 2018). Thus, there is an urgent need for publicly available, high-quality mental health datasets and benchmark models to support early detection of MHC in languages other than English.

The main contributions of this work are three-fold: (1) We introduce SMHD-GER (Self-reported Mental Health Diagnosis for German), a new large dataset of social media posts for mental health detection in the German language, and make it publicly available; (2) We provide benchmark models for the detection of four mental health conditions based on a comprehensive set of text-based features that pertain to multiple levels of language use, the German BERT-based model, and hybrid models that combine the two; and (3) We uncover nuanced patterns of linguistic markers characteristic of specific mental health conditions.

The remainder of this paper is organized as follows: In Section 2 we briefly review available social media datasets and NLP classification methods for MHC detection. Section 3 details the construction of the SMHD-GER dataset along with an ethics and privacy statement. Section 4 presents the results of a analysis of linguistic markers of specific MHC. In Section 5, we describe the modeling approach for our benchmark models, and in Section 6, we present and discuss the results. Finally, we conclude with directions for future work in Section 6.

2 Related work

In this section, we provide a concise overview of some of the most widely used self-disclosure social media datasets along with the classification methods used in the detection of mental health conditions. The self-disclosure approach to obtaining labeled data from social media was introduced in Coppersmith et al. (2014) and further refined in consecutive work (Yates et al., 2017; Cohan et al., 2018). In this approach, public self-reports of mental health diagnoses are identified through the use of carefully designed ‘diagnosis patterns’ combined with ‘diagnosis keywords’ mapped to particular mental health conditions: A user is included for

a specific MHC if one of the condition keywords occurs within a certain distance of the diagnosis pattern. Coppersmith et al. (2014) originally applied this approach to Twitter data and identified approximately 1,200 users with four MHC (bipolar, depression, PTSD, SAD) by matching diagnosis patterns in their tweets (e.g., “I was diagnosed with depression”). This dataset was employed in the shared task at the 2nd Computational Linguistics and Clinical Psychology Workshop (CLPsych 2015) that focused on identifying depression and PTSD users on Twitter (Coppersmith et al., 2015). Submissions to the task used traditional (shallow) classification models trained on unigram vectors, character language models, closed-vocabulary approaches (e.g. LIWC, Pennebaker et al., 2001) and supervised topic models. The leading systems reached average precision rates over 85% for both MHC. However, the dataset had a balanced distribution between the classes, rather than one that accurately reflect the user population. This hampered the reliable estimation of actual false alarm rates, as the number of false alarms in the general population is estimated to be 7-15 times higher than in the CLPsych 2015 test sample (Coppersmith et al., 2015).

The text content of a Tweet can contain up to 280 characters or Unicode glyphs. Thus, this format presents a barrier to capturing mental health related language signals. Recent work on compiling datasets for mental health is increasingly turning to Reddit for long-form content that can provide additional linguistic insights³: Yates et al. (2017) applied the self-disclosure approach to create the Reddit Self-reported Depression Diagnosis (RSDD) dataset, which contains 9,210 users with depression and 107,274 control users. Apart from increasing the dataset size by an order of magnitude – 969 posts per user with mean post length of 148 words, the RSDD dataset displays a realistic number of control users matched with each diagnosed user.

The main limitation of the RSDD dataset is its focus on a single mental health condition, depression. In what is to our our knowledge the most comprehensive, carefully constructed mental health dataset based on the self-disclosure approach, Cohan et al. (2018) expand on RSDD by including for eight additional MHC: The Self-reported Mental Health Diagnoses (SMHD) dataset, whose design

³Reddit (<https://www.reddit.com/>) is a social news aggregation, content rating, and discussion website without any length constraints.

underlies the current work, comprises 20,406 diagnosed users and 335,952 matched controls. Diagnosed users were identified using a refined version of the high precision diagnosis patterns used in RSDD, which incorporated synonyms in matching patterns from two synonym mapping ontologies (MedSyn, Yates and Goharian, 2013, Behavioral, Yom-Tov et al., 2013). Control users were selected based on a similar Reddit posting activity, i.e. each diagnosed user was matched with an average of 9 control users with a similar number of posts and a similar range of subreddits they posted in. Importantly, SMHD does not contain any posts that contain any mental health terms or that have been posted in a mental health-related subreddits. The detection of MHC can thus not be based on terms associated with specific mental health conditions. Along with the dataset itself, Cohan et al. (2018) provided benchmarks for both binary (MHC vs. control) and multi-class classification settings. The classification methods included several traditional (shallow) machine learning models (logistic regression, XGBoost (Chen and Guestrin, 2016), support vector machine with linear kernel) trained on tf-idf bag-of-words features, a shallow neural net model trained on character ngrams (Supervised FastText, Joulin et al., 2016), and a Convolutional neural network trained on ngram sequences represented by the FastText embeddings. Subsequent work has improved MHC detection accuracy using Hierarchical Attention Networks (Sekulic and Strube, 2019) and attention-based model using BERT representations (Jiang et al., 2020). Recently, (Zanwar et al., 2022) leveraged transformer language models (BERT Devlin et al., 2019 and RoBERTa Liu et al., 2019) in combination with attention-based BLSTM models trained on engineered language features for MHC detection.

3 Data

3.1 Data construction

In this section we describe the construction and characteristics of the SMHD-GER dataset. SMHD-GER comprises data on seven mental health conditions that correspond to branches in the DSM-5 (APA, 2013): Five conditions are top-level DSM-5 disorders: schizophrenia spectrum disorders (schizophrenia), bipolar disorders (bipolar), depressive disorders (depression), anxiety disorders (anxiety), obsessive-compulsive disorders (OCD). The remaining two conditions are one rank lower: post-

traumatic stress disorder (ptsd) is classified under trauma- and stress-related disorders, and attention-deficit/hyperactivity disorder (ADHD) under neurodevelopmental disorders. The construction of the dataset is an adaptation of the general procedure underlying the construction of the SMHD dataset described in Cohan et al. (2018): The textual data were obtained from Reddit using the Pushshift.io API Wrapper by searching for all posts mentioning any mental health (MH) terms, such as the name of a condition. The list of MH-terms was derived from the corresponding materials used for the SMHD dataset using DeepL translator⁴ followed by manual inspection and editing. We then filtered these posts to keep only those that were in German using the 'langdetect' the Python library.⁵

Diagnosed users were identified using high precision diagnosis patterns as in Cohan et al. (2018): Reddit users received a positive label for a specific MHC if and only if at least one of their posts explicitly states that they suffer from a specific condition or are engaging in behaviors indicative of it. These were triangulated with specific expressions, such as "Ich wurde diagnostiziert mit X" ("I was diagnosed with X"), where X would be filled with a specific MH-term (e.g. "Depression"). Like the MH-terms, the diagnosis patterns were derived from the corresponding materials used for the SMHD dataset using DeepL translator followed by manual inspection and editing. We then collected all posts and comments for the users with a positive label and filtered these to keep only those that (i) were in German, (ii) had no mentions of any of the MH-terms and (iii) were not posted in a subreddit related to mental health (MH-subreddit).

Control users: To compile the data used for control we collected 1049202 posts from 24981 users from r/de⁶ subreddit, and filtered out those users who (i) had used any MH-term in any of their posts or (ii) had posted in a MH-subreddits. For all remaining users we collected all the available posts and comments in German. All Reddit posts were made between August 14, 2009, and October 2, 2022 (inclusive). This procedure yielded a dataset containing 5,611 diagnosed users and 22,426 control users. On average each user in the dataset contributed 16.23 posts with a mean post length of 69 word tokens (see Table 1).

3.2 Ethics and privacy

Although we rely solely on publicly available Reddit data, mental health remains a sensitive issue, and measures to avoid risks to individuals in social media research should always be considered (Hovy and Spruit, 2016; Šuster et al., 2017; Cohan et al., 2018). Following the data handling procedures of the original SMHD (Cohan et al., 2018), we do not publish excerpts from the data, we did not attempt to contact users, and we did not attempt to identify or link users to other social media accounts. We also replace usernames with random identifiers to prevent users’ identities from being revealed without external information. The SMHD-GER dataset is made available through a data usage agreement (DUA) that protects user privacy. Specifically, the DUA specifies that no attempt may be made to publish any part of the dataset (which could lead to user identification), contact users, identify them, or link them to other user information.

An ethical issue raised by an anonymous reviewer concerns the annotation of positive mental health conditions through self-disclosure of users, as those who choose to disclose them might differ from the population of individuals living with such conditions without disclosing them. Another ethical issue concerns the use of psychometric evaluation of large text corpora leveraging LIWC-like features alone, as this approach may lack precision: Since LIWC’s diagnostic scores are based on both computational correlation and human judgment (in determining the system’s dictionaries and word categories), the outcomes may reflect evaluative biases grounded in the context of social, historical, and cultural development (Stark, 2018).

4 Analysis of Linguistic Markers

In this section, we address the exploration of nuanced patterns of linguistic markers that are indica-

tive of specific MHC. We first obtained measurements of 117 engineered language features that can be roughly divided into five groups: (1) features related to morphological and syntactic structural complexity (N=5), (2) features related to lexical sophistication, variety, and richness (N=8), (3) word-level ngram features related to register-specific language use (N=20), (4) features covering the German version of the LIWC (Linguistic Inquiry and Word Count) dictionary (N=68), and (5) word-level dictionary features from three lexicons related to emotion, affect and sentiment (N=16). An overview of these features can be found in Table 5 in the appendix.

The first group of includes surface features related to the length of production units, such as the average length of clauses and sentences, and the type and frequency of embedded structures, such as mean length of sentence or number of dependent clauses per sentence (Lu, 2010). This group also includes an information-theoretic feature based on the Deflate algorithm (Deutsch, 1996).

The second group of features probing lexical density features, such as the ratio of the number of lexical (as opposed to grammatical) words to the total number of words in a text, lexical variation, i.e. the range of vocabulary as manifested in language use as captured by text-size (corrected) type-token ratio (Lu, 2012).

The third group comprises register-based n-gram frequency features that take into account both frequency rank and the number of word n-grams ($n \in [1, 5]$). The latter were derived from four corpora compiled as to represent language use in four language registers (academic, fiction, news, spoken; see Table 6.

The fourth feature group is based on the German version of the LIWC dictionary (Linguistic Inquiry and Word Count) (Pennebaker et al., 2001).

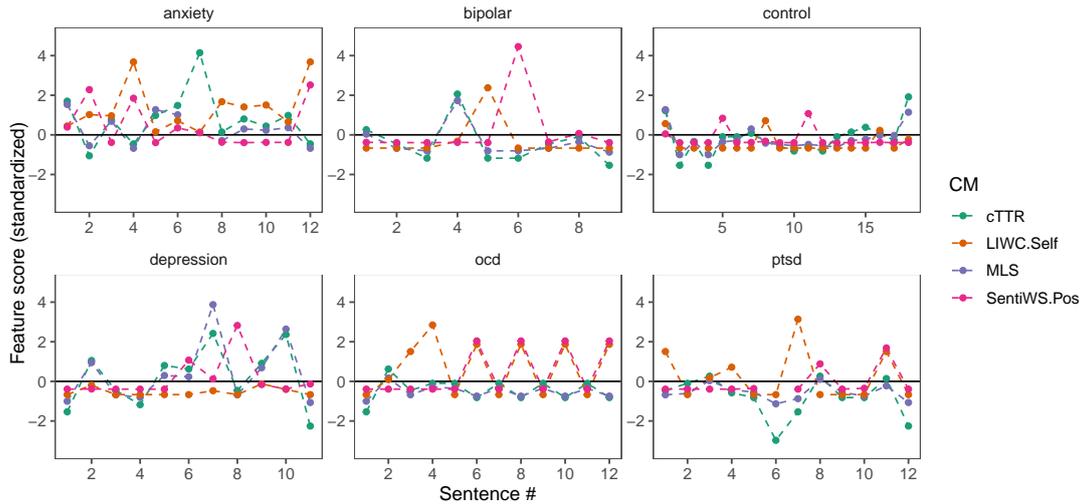

Figure 1: Within-text distributions of four textual features for six randomly selected Reddit post from as many MHC groups (cTTR = corrected Type-Token Ratio, LIWC.Self = self-focused language, MLS = mean length of sentence, SentiWS.Pos = words with positive semantic orientation). All features were z-standardized with 0 representing the corpus average.

The creators of the German version of the LIWC validated this version and demonstrated that the German LIWC categories have a high degree of equivalence to their English counterparts (Wolf et al., 2008). Building on the results of previous studies using LIWC categories for MHC detection in English (e.g. Cohan et al., 2018), we expect that subcategories of particular interest for the MHC classification task will include words with positive or negative emotions, words related to social processes (family/friends/society), pronouns that can capture inclusive (we, us) or exclusionary (you, they, them) language use, and words related to how the person feels (sad, anxious).

The fifth group includes features from three lexicons: MEemoLon (Buechel et al., 2020) is a lexicon comprising eight emotional variables with more than 100k lexical entries for eight emotional variables: Valence, Arousal, Dominance, and Joy, Anger, Sadness, Fear, and Disgust. ANGST is the German adaptation of the Affective Norms for English Words (Schmidtke et al., 2014). It comprises 1,003 German translations of the ANEW material that were rated on a total of six dimensions: the three original scales for valence, arousal, and dominance plus three additional arousal ratings on an adapted scale. SentiWS (Remus et al., 2010) is a dictionary containing 3,468 sentiment bearing German words (1,650 negative and 1,818 positive) across four word classes (adjectives, adverbs, nouns and verbs) along with their weighted senti-

ment scores.

All measurements of these features were obtained using an automated text analytics system that employs a sliding window technique to compute measurements at the level of individual sentences. These measurements capture the within-text distributions of scores for a given feature (for recent applications, see e.g. Wiechmann et al., 2022 or Kerz et al., 2022). Tokenization, sentence splitting, part-of-speech tagging, lemmatization and syntactic PCFG parsing were performed using Stanford CoreNLP (Manning et al., 2014). Examples of these within-text distributions is shown in Figure 1. Each of panels in Figure 1 shows the distributions of four of the 117 textual features for one of six randomly selected texts representing different MHC groups. We note that the distribution of feature values is generally not uniform, but shows large fluctuations over the course of the text. The six texts are characterized by different patterns of spikes of specific features: For example, the bipolar text exhibits a large spike in the SentiWS.Pos feature, which refers to words with positive semantic orientation. The OCD text is characterized by regular peaks of the LIWC.Self feature, which captures self-focused language. The anxiety text displays frequent spikes of high values (>2 standard deviations from corpus average) for three of the four features. In comparison, the control text shows less fluctuation with features scores being closer to the corpus average values. The classification mod-

els described in Section 5.1 are designed to detect and exploit these fluctuations for the detection of specific MHCs. The average scores of all features across all groups are provided in Table 8 in the appendix.

To identify profiles of language use that are characteristic of particular MHC, we compare these feature scores across users in each MHC group using factorial analyses of variance (ANOVA). We focus on those features that display significant differences across groups ($N=16$, for $\alpha = 0.05$). Figure 2 presents a cluster heatmap visualizing the patterns in the data matrix with the MHC groups and the 16 most significant language features.

The results of these analyses revealed some interesting patterns of differential language use: We find that the control group is situated at the margin of the clustering, indicating that the patterns of language use of diagnosed MHC are distinguishable from this baseline.

The language use of anxiety is distinctly different from all other MHC. It is characterized by very high feature scores on five LIWC dimensions related words referring to self-reference, death and sadness. They are further characterized by high scores on the top feature cluster, comprising words referring to anger, fear, disgust, sadness, arousal and negative emotions.

The language use of schizophrenia, is similar to anxiety in that it too displays a larger proportion of words indicating negative emotions. However, it is characterized by low scores on LIWC dimensions related words referring to self-reference. They are also characterized by low scores on the n-gram frequency features, indicating dependence on conventional phrases from specific speech registers.

A striking feature of obsessive-compulsive disorder (OCD) is its heavy reliance on such terms. A characteristic feature of (unipolar) depression is a markedly increased use of words with positive semantic orientation, in stark contrast to bipolar depression, which has significantly lower scores on this dimension. This is intriguing in light of the fact that distinguishing between bipolar disorder and recurrent unipolar depression is a major clinical challenge (de Almeida and Phillips, 2013). In general, conditions of depression and bipolar disorder, attention-deficit/hyperactivity disorder (ADHD) and post traumatic stress disorder (PTSD) display similar patterns of language use.

These findings reflect evidence in the psychiatric

MHC	# posts	mean # words	mean # chars
ADHD	1052	168.78	805.78
Bipolar	1421	150.50	853.66
Depression	974	153.89	872.87
PTSD	728	150.57	902.34
Control	12789	158.55	848.23

Table 2: Description statistics of the data used in benchmark experiments. Note: The size of the control data used in the binary MHC classification tasks were adopted to outnumber the positive cases by a factor of 9. The descriptive statistics of the control categories are based on the entire control corpus.

literature indicating that there is considerable overlap in clinical symptoms and pathophysiological processes and that depressive symptoms may also occur in the context of another psychiatric disorder (e.g., bipolar disorder) (Baldwin et al., 2002). Furthermore, psychiatric data suggest that depressive disorders (i.e., major depressive disorder and dysthymia) are highly comorbid with other common mental disorders (Rohde et al., 1991; Gold et al., 2020).

5 Experiments

5.1 Experimental Setup

In this section, we describe MHC detection experiments performed to obtain benchmark models for the SMHD-GER dataset. We conduct binary classification experiments for the top four most frequently attested MHC in the dataset, namely ADHD, bipolar, depression and PTSD. For each MHC, we use a 1:9 ratio of positive cases to controls to create a more realistic unbalanced classification setting. The size of the textual input to the models was constrained to fall between 110 words, which corresponds to the median number of words all posts, and 512 words, which represents an upper limit to the BERT models. In case no single post of a given user satisfied these constraints, we concatenated several posts from that user so that their total amount fell within the specified boundaries (Figure 5 in the appendix presents a decision tree of the selection method). Table 2 presents the descriptive statistics of the dataset used in classification experiments.

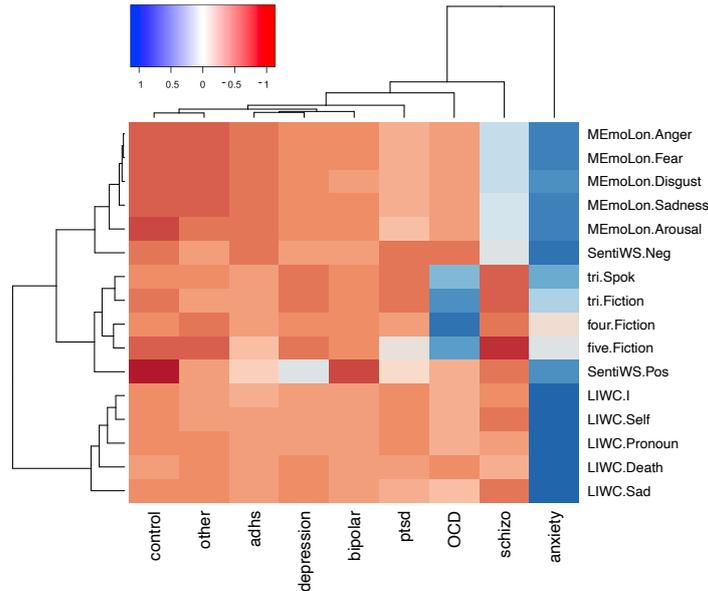

Figure 2: Heatplot of the language profiles of the nine MHC categories (on the x-axis) based on the top-16 language features (on the y-axis). Columns and rows are ordered according to the results of hierarchical clustering, with the dendrograms at the margins showing the groupings of MHC categories and features. Features with the prefix ‘MEemoLon’ refer to emotion categories from the lexicon of the same name. SentiWS.Neg refers to the category of negative words from the SentiWS dictionary. The terms ‘tri’, ‘four’ and ‘five’ refer to the size of word n-gram features from the spoken (‘Spok’) and fiction (‘Fiction’) reference corpora. Features with the prefix ‘LIWC’ refer to categories from the lexicon of the same name. Colors denote z-standardized feature scores.

5.2 Classification models

We performed experiments with three benchmark models: (1) a fine-tuned German BERT model (GBERT), (2) a bidirectional long short-term memory (BLSTM) classifier trained on measurements of linguistic features described in Section 4, and (3) hybrid model integrating GBERT predictions with the engineered language features introduced in Section 4. For (1) we used the pretrained ‘German bert-base-uncased’ (GBERT, Chan et al., 2020) model from the Huggingface Transformers library (Wolf et al., 2020) with an intermediate BLSTM layer with 256 hidden units (Al-Omari et al., 2020). For (2) - the model based solely on linguistic features, we constructed a 5-layer BLSTM with a hidden state dimension of 512. The input to that model is a sequence $CM_1^N = (CM_1, CM_2, \dots, CM_N)$, where CM_i , the output of our text analytics system for the i th sentence of a post, is a 117 dimensional vector and N is the sequence length. To predict the labels of a sequence, we concatenate the last hidden states of the last layer in forward (\vec{h}_n) and backward directions (\overleftarrow{h}_n). The result vector of concatenation $h_n = [\vec{h}_n | \overleftarrow{h}_n]$ is then transformed through a 2-layer feedforward neural network, whose activation function is Rectifier Linear Unit (Agarap,

2018). The output of this is then passed to a Fully Connected Layer FC with ReLu activation function and dropout of 0.2 and it is finally fed to a final FC layer. The output is finally passed through sigmoid function and finally a threshold is used to determine the labels. We trained these models for 100 epochs, with a batch size of 256, a sequence length of 5 and learning rate of 1e-3. The architecture of the hybrid classification model - model (3) - consists of two parts: (i) a pre-trained Transformer-based model with a BLSTM layer and FC layer on top of it and (ii) the linguistic features of the text fed into a BLSTM network and a subsequent FC layer. The FC layers of both parts take the concatenation of last hidden states of the last BLSTM layer in forward and backward direction. We concatenate the outputs of these layers before finally feeding them into a final FC layer with a sigmoid activation function. The model used to generate predictions for the test set was specified as follows: 2-layer BLSTM, 256 hidden units and a dropout of 0.2; BLSTM-PsyLing: 3-layers, hidden size of 512 and dropout 0.2. We trained this model for 12 epochs, saving the model with the best performance (F1-Score) on the development set. The optimizer used is AdamW with a learning rate of 2e-5 and a weight

Model	Metric	ADHD	Bipol.	Depr.	PTSD
Majority Class	Pre	44.85	44.85	44.84	44.82
Baseline	Rec	50.00	50.00	50.00	50.00
	F1	47.29	47.28	47.28	47.27
GBERT	Pre	50.63	50.36	49.74	50.57
	Rec	50.26	51.02	48.13	46.68
	F1	50.44	50.68	48.92	48.54

	Rec	52.45	55.31	50.18	49.86
	F1	53.22	53.97	50.26	49.92
Hybrid	Pre	51.29	51.85	51.62	53.20
	Rec	53.47	52.03	50.38	52.44
	F1	53.08	51.91	50.89	53.03

Table 3: Results of MHC prediction experiments (all values of performance metrics are macro averages)

decay of $1e-4$. Structure diagrams of the model based solely on linguistic features and the hybrid architectures are presented in Figures 4 and 3 in appendix. All models were trained using 5-fold CV of the training data as base classifiers and model stacking was performed using logistic regression as a meta-learner to adaptively combine the outputs of the base classifiers.

6 Results and Discussion

Table 3 gives an overview of the results of the MHC prediction experiments. All three baseline models displayed significant improvements in macro F1 scores over the majority baseline for all four MHC. Our PsyLing model consistently outperformed the GBERT baseline in terms of precision, recall and F1 (average improvement F1 = +2.37%; average improvement precision = 2.54%; average improvement recall = +2.93%). This result demonstrates that strong, interpretable mental health detection systems can be built if and when they make full use of the linguistic signals. The PsyLing model achieves highest performance in two of the four MHC, ADHD and bipolar disorder, with improvements over the hybrid model of +2.06% F1 for bipolar and +0.14% F1 for ADHD. However, the hybrid model improves on the performance of the PsyLing model by +3.11% F1 for PTSD and +0.63% F1 for depression.

The results of error analyses shown in Table 4 revealed that these performances were related to the divergent behaviors of the GBERT and PsyLing models for different MHCs: For Depression and PTSD the PsyLing model has a high

Model	MHC	TN	FP	FN	TP
GBERT	ADHD	1734	96	187	23
	Bipolar	2466	112	157	20
	Depression	1374	136	361	17
	PTSD	1168	96	132	14
PsyLing	ADHD	1764	66	192	18
	Bipolar	2344	127	253	31
	Depression	1333	276	231	48
	PTSD	939	268	162	41
Hybrid	ADHD	1500	330	161	49
	Bipolar	2289	260	182	24
	Depression	1633	96	138	21
	PTSD	1160	104	127	19

Table 4: Confusion matrices of the three benchmark models (TN: True Negatives, FP: False Positive, FN: False Negative, TP: True Positive)

false alarm rate, i.e. it classified users as being diagnosed, when they are in fact not (Depression: $FP_{GBERT}=136$, $FP_{PsyLing}=276$; PTSD: $FP_{GBERT}=96$, $FP_{PsyLing}=268$). On the other hand, it also correctly identified a much higher proportion of diagnosed users (Depression: $TP_{GBERT}=17$, $TP_{PsyLing}=48$; PTSD: $TP_{GBERT}=14$, $TP_{PsyLing}=41$). Our results thus indicate that the hybrid model improves on the PsyLing model for depression and PTSD by leveraging the lower false alarm rate of GBERT for these MHC. These results demonstrate that the NLP systems designed to support the diagnosis of mental disorders benefit from employing both interpretable and hybrid approaches.

7 Conclusion and Future Work

We introduced SMHD-GER, a large dataset of Reddit users with diverse mental health conditions and matched control users. The dataset was created using adaptations of the high-precision diagnostic patterns developed for the original English version (Cohan et al., 2018). Furthermore, we investigated the differences in language use between users with mental health conditions and control groups, as measured by a large set of linguistic and psychological cues. We provided strong benchmark models designed to identify diagnosed users for the four most frequently attested MHC. We found that BLSTM networks trained on within-text distributions of interpretable linguistic features consistently outperformed a Transformer-based model based on GBERT. A hybrid model combining the two approaches proved to be the most effective

method for two of the four conditions. We make our dataset available to the community in the hope that it will encourage further research into these problems and improve the reproducibility of suggested approaches.

8 Limitations

In this work, we have framed mental health detection as a binary classification task that aims to distinguish between individuals with a particular mental disorder and control users. In future work, we intend to frame it as a multi-class classification task to determine the extent to which individual mental disorders can be distinguished from one another.

Abstract

Advances in natural language processing, such as transfer learning from pre-trained language models, have impacted how models are trained for programming language tasks too. Previous research primarily explored code pre-training and expanded it through multi-modality and multi-tasking, yet the data for downstream tasks remain modest in size. Focusing on data utilization for downstream tasks, we propose and adapt augmentation methods that yield consistent improvements in code translation and summarization by up to 6.9% and 7.5% respectively. Further analysis suggests that our methods work orthogonally and show benefits in output code style and numeric consistency. We also discuss test data imperfections.

1 Introduction

Recent years have seen the rapid development of pre-trained models (PLMs) to enable knowledge transfer from generic texts to specific downstream tasks (Devlin et al., 2019; Liu et al., 2019). PLMs have been applied to the programming language domain as well, following the same paradigm of (continuing) training PLMs on code and text data, and then fine-tuning them for specific tasks (Kanade et al., 2020; Feng et al., 2020). PLMs are often adapted to programming languages by including code-specific modalities as part of the input like serialized syntax trees and data flows (Guo et al., 2021, 2022; Tipirneni et al., 2022). Such works have outperformed rule-based tools in various tasks, e.g. the CodeXGLUE benchmark (Lu et al., 2021).

Despite the abundance of raw code available for pre-training, code data that meet downstream needs stay modest in size. This is due to the fact that, unlike texts, code datasets cannot be easily curated by people without programming knowledge. For

example, code translation data in CodeXGLUE is sized at 10K, which is orders of magnitude smaller than their natural language counterparts that often include millions of instances (Kocmi et al., 2022).

We are therefore motivated to enrich data in the fine-tuning phase of code PLMs, using automatic data augmentation (DA) methods like back-translation, monolingual, multilingual, and numeric augmentation. We extensively experiment on code translation, where a programming language is converted to another, and summarization, where a textual description is produced from a code block. Even with limited resources, we can lift performance by 6.9% for translation and 7.5% for summarization compared to baselines. Through manual inspection and extra evaluation measures, we demonstrate that our methods lead to desirable enhancements special to code, namely better output code style and number correctness.

2 Methodology

2.1 Data synthesis

Back-translation (BT, Sennrich et al., 2016) is a data augmentation technique originated from machine translation, where an auxiliary model is used to construct pseudo-parallel data from monolingual resources. It can be straightforwardly applied to code translation. Formally, to train a model $f()$ that converts a programming language PL_x into PL_y , we first train an inverse model $g(PL_y) \rightarrow PL_x$ with the same parallel data. Having the inverse model $g()$, extra monolingual data in PL_y is translated into PL'_x to form pseudo-parallel pairs PL'_x - PL_y that can be used to train $f()$.

For code summarization, back-translation is not applicable as “monolingual” natural language (NL) summaries unaligned to code hardly exist. Hence we propose to use the summaries originally associated with a single programming language as a pivot for other programming languages. After

*Work done during an internship at Huawei Noah’s Ark Lab. Our code will be available at <https://github.com/huawei-noah/noah-research/tree/master/NLP/DA4CodeGeneration>

inverting code-to-text data which has source side code available in multiple programming languages ($PL_1 \rightarrow NL, \dots, PL_n \rightarrow NL$), we train a multilingual text-to-code generator, which outputs a designated programming language given a natural language summary and a target language tag ($NL + tag_{\{1, \dots, n\}} \rightarrow \{PL_1, \dots, PL_n\}$). This generator can iteratively produce code in different PL s by inputting summaries regardless of the original $PL \rightarrow NL$ alignment. These synthesized data, despite having a lower quality, can augment the training data for summarization.

2.2 Utilization of multilinguality

Currey et al. (2017) suggested that including monolingual data in the target language as an additional autoencoding (AE) objective benefits translation models trained on limited data. We migrate this objective to code translation by mixing $PL_x \rightarrow PL_y$ and $PL_y \rightarrow PL_y$ data. This effectively builds a multilingual encoder that enables knowledge transfer, given the high similarity between programming languages, namely the overlap of numerals, syntax tokens, reserved keywords, etc. This process constrains the decoder side to a single programming language PL_y to not add complexity.

In code summarization, as the target NL is fundamentally divergent from the input PL, the autoencoding objective might not be useful. In contrast, we train a “multilingual” code summarization model $\{PL_1, \dots, PL_n\} \rightarrow NL$ where the system takes an arbitrary programming language to produce a natural language summary. Such a many-to-one model allows encoder knowledge sharing too and exposes the decoder to more NL summaries.

2.3 Numeric awareness

Referenced variables and their values are unique components of programming languages; to enhance understanding of these values, previous works on pre-training suggested attending to appropriate modalities, e.g. data flow (Guo et al., 2021). Such sophisticated handling of values might not be necessary for code translation, as copying them over to the target suffices. However, given a small training size, any translation model will still only be exposed to sparse numerical input. To increase model robustness, we augment the data by creating new instances where, in all code tokens containing a number, each digit is randomly replaced with another digit, consistently on both the source and target sides. We do not distinguish

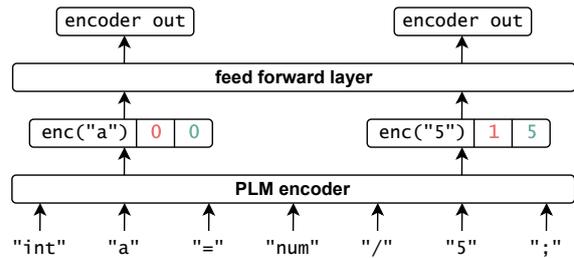

Figure 1: Numeric encoding with a PLM encoder, exemplifying how “a” and “5” are encoded differently.

between purely numerical tokens and tokens including a number. For instance, a variable “num1” could become “num4” in the augmented code pair. The method guarantees that the number-swapped synthetic code is grammatical and compilable.

Apart from numerical augmentation, we propose to include input numbers directly in the encoder output as mathematical values, complementary to their string embedding representations. As illustrated in Figure 1, we append two dimensions to the original encoder output. Particularly, one dimension (red, left) is a binary value (0/1) indicating whether the respective input is a number, while the other dimension (green, right) inherits the input’s value, or 0 if the input is not numeric. The expanded embedding can be reduced to its original size via a feed-forward layer; such a change requires no modification to the pre-trained encoder.

3 Experiments

3.1 Tasks, datasets and evaluation

We benchmark our methods on the code task suite CodeXGLUE (Lu et al., 2021). Its translation task uses code originally developed in Java and then migrated to C#, so the corresponding C#-Java snippets are considered parallel. Training, validation, and test sizes are 10K, 0.5K, and 1K. For back-translation, we translated 377K lines of monolingual Java, albeit out-of-domain, from other CodeXGLUE tasks, into C#. To ensure that the target side consists of genuine data, we only experimented with the C#→Java direction as there is no other C# code in the benchmark for BT.

The summarization task employs CodeSearchNet (Husain et al., 2019) and covers six languages: Ruby, JavaScript, Go, Python, Java, and PHP. Training sizes range from 25K to 250K, totalling 908K; validation and test sets are between 1K and 15K. We performed multilingual back-translation by re-

Table 1: Test results for C#→Java translation.

versing the dataset so no external data is introduced; this leads to a five-fold BT data of 4.5M (908K×5). All programming languages share an equal amount of original and synthetic data combined. Moreover, to compare the quality of neural back-translation against hand-written rule-based conversion, we created 80K JavaScript-summary pairs from Python-summary data using `jsbuilder`.

We report code translation results in BLEU-4 (Papineni et al., 2002), exact line matches (EM, in %), and CodeBLEU, a weighted sum of four accuracies: n-grams, weighted n-grams, syntax, and data flow (Ren et al., 2020). Code summarization performance is measured by the de facto choice of BLEU-4 on natural language texts.

3.2 Systems

For all tasks, we use the CodeXGLUE baseline, i.e. CodeBERT with a Transformer decoder, for our base and inverse models (for data synthesis). We continue training PLMs on the augmented data, then fine-tune on the original data, except for numeric augmentation where we mix the synthetic data with the training set. Monolingual and multilingual summarization experiments share the same configurations. For numeric encoding with CodeBERT, we add a feed-forward layer to make the baseline as deep as our proposed network.

To provide results with stronger baselines, we also test with GraphCodeBERT (Guo et al., 2021) for translation and UniXcoder (Guo et al., 2022) for summarization. This helps to verify the stability of data augmentation performance across distinct PLM architectures. We stick to the relevant PLMs’ hyperparameters except for batch size. Model and training details, with links to the preprocessing and evaluation scripts, can be found in Appendix A.

Table 2: Test results for code summarization in BLEU.

3.3 Results and Discussions

We first show translation results in Table 1, where back-translation surpasses baselines by a large margin for both PLMs; on top of it, autoencoding brings a small gain. Table 2 indicates that back-translation also steadily helps code summarization overall. An interesting pattern from both PLMs is that BT helps Ruby and Java less than other languages. Furthermore, learning a single multilingual model is better than learning separate monolingual models, potentially due to transfer learning between programming languages and the increase in natural language data size on the output side.

Table 3 reports the results for numeric augmentation and numeric encoding in translation. Adding number-swapped data to training surpasses the baseline, while our numeric encoding proposal under-performs the baseline. To accommodate the neural network weights which are orders of magnitude smaller than the variable values encountered in code, we investigate linear and logarithmic value scaling. As the scaling gets smaller, result numbers gradually catch up; the optimal is a logarithmic transformation, whereby the model attains the highest performance.

To directly assess our value-aware augmentation, we compute and append output token accuracies to Table 3, with a distinction between numeric and non-numeric tokens. We can observe that the numerical approaches aid number generation without compromising non-numbers, and the improvement in number correctness is generally consistent with the improvement in BLEU and EM. Additional visualization in Appendix B.2 implies that DA models can maintain numeric consistency even when the output is extremely long and complicated.

Table 4: Test results for C#→Java translation with multiple augmentation techniques.

Finally, Table 4 examines if the above methods, namely back-translation and numeric augmentation, work orthogonally. It is observed that better results are achieved when numeric augmentation is applied to the original data, but not to the back-translated data. This is probably because BT is already of inferior quality, so numerical augmentation introduces extra noise. Nevertheless, combining BT and AE with numeric augmentation over the original data leads to the best outcome.

4 Analysis

Upon inspecting the translation test outputs, we find that our data-augmented model is better exposed to the target Java language: it has learned the Java programming conventions instead of following the input code style. We present test instances focused on element retrieval methods, by listing sources, references, and outputs from the CodeBERT baseline and our BT-augmented model in Table 5. Whilst direct retrieval of an element through reference to its position is possible in Java, we observe that the baseline tends to imitate the code style in source C#, but the DA model closely follows the Java coding convention where the inbuilt method `get()` is favoured over directly accessing the attributes by indices.

We should note that in the translation test set a small proportion of code pairs seem to be divergent,

which can lead to an inaccurate estimate of translation performance. We record a few examples of these imperfections in Appendix B.1, but leave in-depth investigation and refinement for future work.

5 Related Works

Recent research at the intersection of natural language processing and programming languages concentrated on pre-training. Kanade et al. (2020) trained CuBERT to obtain embeddings for code understanding tasks. Feng et al. (2020) developed CodeBERT by training RoBERTa on bimodal text-code data with replaced token detection (Clark et al., 2020). In GraphCodeBERT, Guo et al. (2021) incorporated data flow edge prediction and data-variable alignment. Researchers expanded decoder-only models to the code domain too, e.g. CodeGPT, Codex, and Pangu-Coder (Lu et al., 2021; Chen et al., 2021; Christopoulou et al., 2022). Universal encoder-decoder code PLMs have also been presented: PyMT5, CodeT5, PLBART, UniXcoder, and StructCoder (Clement et al., 2020; Wang et al., 2021; Ahmad et al., 2021; Guo et al., 2022; Tipirneni et al., 2022). UniXcoder, which we used, adopts attention masks to control encoder-decoder behaviours in a shared encoder-decoder network.

Datasets for specific tasks concerning code are usually small, so data augmentation can help to boost performance. Roziere et al. (2020) combined

DA model    public SrndQuery getSubQuery(int qn) {return queries.get(qn);}

```

Table 5: C#-Java output translations of element retrieval methods, before and after data augmentation.

cross-lingual masked modelling and iterative back-translation to build an unsupervised code transcompiler. Ahmad et al. (2022) ran code-to-text summarization then text-to-code generation, to obtain translation data. In contrast, we train a text-to-code generation model by reversing the summarization data; our methods differ in both the procedure and the intended task. Also, Yu et al. (2022) crafted rules for source code transformation, whilst our investigation is on automatic neural methods. Finally, techniques like dead code insertion and variable renaming in malware obfuscation (You and Yim, 2010), as well as string manipulation (e.g. token noising, swapping, deletion) can be useful. Nonetheless, these methods are not task-specific, meaning they could be more appropriate for the generic code pre-training stage.

6 Conclusion

We adapt several data augmentation techniques to programming language translation and summarization. Our investigation includes data synthesis, knowledge sharing via multilinguality, and numeric-aware techniques. Enhanced performance is observed in experiments conducted on a variety of pre-trained code language models, and our analysis demonstrates that these methods can benefit output code style and numeric correctness.

7 Limitations

We identify the main limitation to lie in evaluation since we relied on automatic text metrics for both code and text generation. Ideally, code should be treated with software testing practices such as code review, compilation, unit testing, etc. Evaluation is further undermined given the test data issues

revealed in Section 4 and Appendix B.1, so more human analysis should be of interest.

We also do not cover all potential code generation tasks, e.g. code synthesis, where a code snippet is created given a textual description. In this task, the source side carries much less information than the target. We apply a back-translation-style augmentation, but it does not significantly surpass the state-of-the-art PLM. Due to space constraints, we offer some preliminary views in Appendix C.

A Model Configurations

Our training and model configurations are summarized here and in Table 6. We retain the relevant PLMs’ default configurations as much as possible, except for a grid search on the learning rate for code summarization with UniXcoder. We also changed the batch size to utilize our GPUs.

The randomly initialized Transformer decoder attached to CodeBERT and GraphCodeBERT has 6

layers, 12 heads, 768 hidden dimensions, and other hyperparameters as default in PyTorch. For the numeric encoding experiments with CodeBERT, we append 2 dimensions to CodeBERT’s 768d encoder output, then transform it back to 768d using a linear layer. To ensure a fair comparison, a 768d-to-768d layer is added to the baseline to make it as deep.

All experiments are given a fixed budget to run. We save the best checkpoint according to validation BLEU. Results in the paper are based on a single run, but the experiments were benchmarked on PLMs of different architectures to reflect stability.

B More Inspections on Translation Test

B.1 Test imperfections

We show a few translation test instances that are not perfectly parallel in Table 7. In these cases, the code in two languages will not function exactly the same when being executed.

B.2 Numeric consistency

Complementing the number accuracy figures reported in Section 3.3, we list translation outputs containing numbers in Table 9 for visualization. It conveys the idea that our DA models can ensure number consistency even in very long and complicated outputs. In the baseline outputs, for example in test #436, number incorrectness further leads to undesirable hallucinations, which can be prevented in the DA model’s output.

```

Table 7: C#-Java test instances that are not perfectly parallel, with divergence shown in bold.

C Code Synthesis with Augmentation

For code synthesis, while reversing the summarization data is a natural solution, the difficulty lies in forming the class environment (visible and usable variables and methods) because. We parse the code in a summarization instance to obtain positive tokens, as well as randomly sample tokens from other genuine code as negative signals. In other words, from $PL \rightarrow NL$ pairs, we construct code synthesis data $NL + parse(PL) + random(PL') \rightarrow PL$.

We experiment on CodeXGLUE’s code synthesis task, which samples data from CONCODE (Iyer et al., 2018) at 100K/2K/2K for training/validation/test. The source contains a text description as well as the available class variable and function names, and the target is the corresponding Java code. We reverse the Java summary data to create 181K synthetic data; to get available variable and method names, the code is parsed by javalang into tokens. Following CodeXGLUE, we use CodeGPT-adapted as a base model; we further experiment with StructCoder (Tipirneni et al., 2022) which is a more up-to-date code PLM.

The outputs are evaluated by BLEU, EM, and CodeBLEU, similar to translation. Note that the test references are not publicly available, and test predictions need to be sent to the CodeXGLUE authors for evaluation, so we report results on both the validation and test set for reproducibility.

We notice that for CodeGPT, our augmentation

work yields a small gain on validation and test sets. However, it does not improve upon the latest PLM for a few possible reasons: 1) StructCoder is remarkably stronger than CodeGPT, thus the room for improvement is small; 2) the summarization data we used to augment the synthesis task could be different in terms of topic, length, style, etc, resulting in a domain drift.

Stabilized In-Context Learning with Pre-trained Language Models for Few Shot Dialogue State Tracking

Derek Chen, Kun Qian, Zhou Yu

Dialogue NLP Lab

Columbia University

{dc3761, kq2157, zy2461}@columbia.edu

Abstract

Prompt-based methods with large pre-trained language models (PLMs) have shown impressive unaided performance across many NLP tasks. These models improve even further with the addition of a few labeled in-context exemplars to guide output generation. However, for more complex tasks such as dialogue state tracking (DST), designing prompts that reliably convey the desired intent is nontrivial, leading to unstable results. Furthermore, building in-context exemplars for dialogue tasks is difficult because conversational contexts are long while model input lengths are relatively short.

To overcome these issues we first adapt a meta-learning scheme to the dialogue domain which stabilizes the ability of the model to perform well under various prompts. We additionally design a novel training method to improve upon vanilla retrieval mechanisms to find ideal in-context examples. Finally, we introduce a saliency model to limit dialogue text length, allowing us to include more exemplars per query. In effect, we are able to achieve highly competitive results for few-shot DST on MultiWOZ.

1 Introduction

Tremendous gains have been made on dialogue state tracking (DST) using large pre-trained language models (PLMs) (Hosseini-Asl et al., 2020; Peng et al., 2021), Fine-tuning such systems though require significant amounts of data, which in turn require substantial effort to collect. Recently, prompting has emerged as a technique for achieving strong performance in a less resource intensive manner (Schick and Schütze, 2021; Liu et al., 2021). Even better performance is possible with in-context exemplars providing a pattern for the model to follow (Brown et al., 2020). Ideally, we should be able to apply these concepts to complex tasks like DST, but results so far have been limited (Madotto et al., 2021).

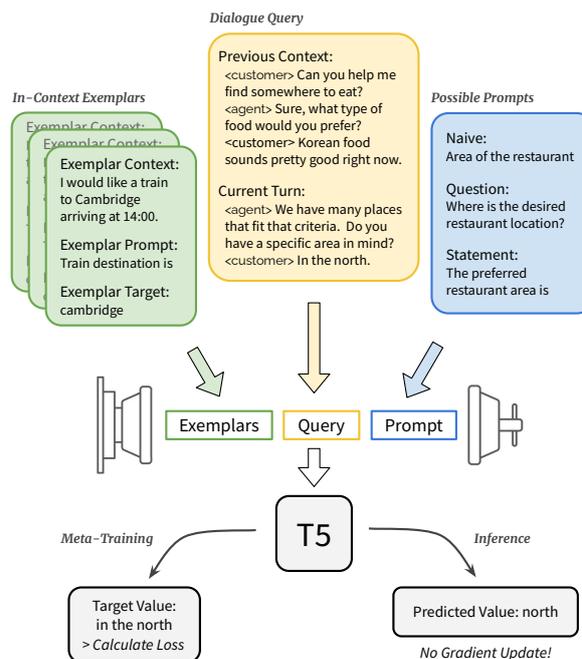

Figure 1: Our system squeezes multiple in-context exemplars, dialogue query with conversational context, and a full prompt into the finite input length of a large PLM to successfully perform few-shot dialogue state tracking, without any need for task-specific training.

One reason for the lack of progress comes from the difficulty of hand-crafting prompts (patterns) and targets (verbalizers), which are highly sensitive to exact phrasing (Lester et al., 2021a). While manually designed prompts have been found to be brittle and unstable (Gu et al., 2021), automatically designed prompts (Gao et al., 2021a) cannot be easily applied to DST since many slots are non-enumerable (Rastogi et al., 2020). A second major hurdle is around dialogue sequence lengths, which are often much longer than those for other tasks (Quan and Xiong, 2020; Kottur et al., 2021) preventing the inclusion of many exemplars for guidance. Full conversations consist of long histories going back many turns, such that the context itself (sans prompt) is already capable of filling

a model’s entire input length. Since state tracking requires carrying over previous dialogue states, naively truncating prior context effectively equates to random guessing (Heck et al., 2020; Kim et al., 2020). A third issue is selecting the exemplars themselves. Prior work recommends choosing a representative example from each class (Gao et al., 2021a), but this is not possible in many cases since most domain-slot-value label combinations simply do not appear in the dataset. Moving to the few-shot scenario further exacerbates this sparsity.

Separately, recall that our main goal is to do well in *few-shot* DST because we purposefully operate in a practical, low-resource data setting. Correspondingly, we aim to achieve good results with a similar low-resource model setting where training should be possible on a single publicly-available commodity server. This precludes the usage of gigantic models such as GPT-3, which are prohibitively expensive to train and bear high economic and environmental costs for inference alone (Strubell et al., 2019; Bender et al., 2021).

We directly tackle each of the three aforementioned issues to achieve state-of-the-art performance on MultiWOZ when restricted to models under 100 billion parameters. To minimize prompt issues, we introduce a meta in-context learning (ICL) framework to stabilize training and reduce variance in prompt performance. To deal with long dialogues, we are inspired by summarization work to condense dialogue histories and filter out non-salient sentences. Our third contribution is designing a novel loss function to train a retrieval model that selects ideal exemplars for priming our downstream model. Our analysis and ablations show that all components help improve our state tracking performance. Finally, we show that unlike other models which only work on specialized LMs, our proposed methods work on any sort of LM, and can be improved with additional training.

2 Related Works

2.1 Few-Shot Dialog State Tracking

Nearly all recent works on dialogue state tracking leverage large pre-trained LMs to achieve good performance (Heck et al., 2020; Kim et al., 2020; Peng et al., 2021). These methods require fine-tuning on large amounts of annotated data, whereas we hope to do well with minimal data.

Few-shot learning can be achieved in many ways, with transfer learning probably being the most pop-

ular, where knowledge is transferred from one domain to another (Wu et al., 2019; Campagna et al., 2020). Data augmentation also supports few-shot learning by generating additional training examples from the few-shot data (Yin et al., 2020; Summerville et al., 2020; Mi et al., 2021). Clustering techniques like prototypical networks have also shown prior success (Snell et al., 2017).

2.2 Meta In-context Learning with Prompting

This work leans on the few-shot techniques of meta-learning (Finn et al., 2017) and prompting with large PLMs (Madotto et al., 2021). Meta-learning allows you to get away with only a few examples at test time by pre-training a model to learn how to learn (Nichol et al., 2018). More recent methods which circumvent the need to calculate second-order gradients (Nichol and Schulman, 2018) have been successfully applied to the task of DST (Dingliwal et al., 2021), but still require fine-tuning on the query set.

Using prompts as natural language instructions have been found to work well on a wide variety of NLP tasks, including dialogue state tracking (Yang et al., 2022). Prompts can be brittle though, so prompt engineering has become its own complex task with numerous ideas on finding discrete prompts (Gao et al., 2021a) or tuning soft prompts, such as through adapters (Xu et al., 2022), prefix tuning (Li and Liang, 2021), or prompt tuning (Lester et al., 2021b). Others have even altered the prompt structure into code in order to fit the capabilities of the network (Lee et al., 2021). Inspired by the success of meta in-context learning on classification tasks (Min et al., 2021; Chen et al., 2022), our work aims to side-step the prompt design issue altogether. Concretely, our method applies meta-learning to teach a model to recognize arbitrary instructions, thereby eliminating the need to rely on domain expertise to craft an optimal prompt.

2.3 Exemplar Retrieval

Lastly, our work is related to retrieval with dense vectors to find good exemplars for in-context learning (Liu et al., 2022). Using dense vectors for similarity search have been applied to dialogue in the past, but mainly in the context of open-domain chat (Adolphs et al., 2021; Komeili et al., 2022) or knowledge-base retrieval (Eric et al., 2017). Lee et al. (2021) is concurrent work which leverages embeddings to search for exemplars in dialogue.

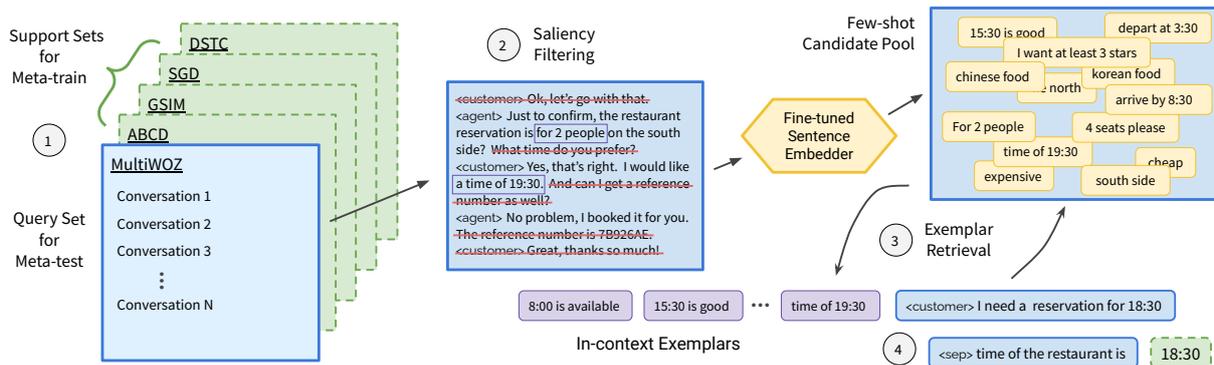

Figure 2: Our method SM2 includes (1) meta-learning with various support sets, (2) saliency filtering to remove irrelevant utterances and (3) improved exemplar retrieval from a few-shot candidate pool. Exemplars are full utterances with dialogue context, which we display as short phrases for illustrative purposes only. They are concatenated and fed into the model for prediction in Step 4. Items in green boxes, including the target value, are only available during meta-training. Purple items are raw text, while yellow ones represent their embedding vectors.

3 Our Method

This section describes our proposal of a Stabilized dialogue state tracker, which leverages Meta in-context learning, dialogue Summarization and a novel Multi-part training loss for fine-tuning a retrieval model, which we refer to as **SM2** for short.

3.1 Preliminaries

The goal of dialogue state tracking (DST) is to extract key information from the conversation as a means of understanding the customer’s intentions in each dialogue turn. More formally, given the dialogue history $H = \{C_1, A_1, C_2, A_2, \dots, C_t\}$ composed of a series of utterances between a customer C_i and an agent A_i , the model should predict the cumulative dialogue state up to current t -th turn. This state is represented as a set of (*domain, slot, value*) tuples, which our system produces by iterating over valid domain-slot pairs and then aggregating all non-null, predicted values for the given turn. A few-shot setup only allows access to $K\%$ of the available labeled data, with $k=[1,5,10]$ for our experiments, where samples are randomly selected from the full labeled dataset. While we compare to models *trained* on k -shot data, our system actually goes a step further since our eventual model receives *no gradient signal* from the task-specific data and instead relies solely on in-context learning to perform inference.

3.2 Stabilized Meta-learning

The intuition behind prompting is that large PLMs understand instructions when written in natural language (Brown et al., 2020). Thus, we write natural

language patterns in an attempt to elicit the dialogue state from the model. However, as previously discussed, minor tweaks in prompt text may cause extreme changes in generated output, leading to highly unstable results (Gu et al., 2021).

Recent works on Meta-ICL (Min et al., 2021; Chen et al., 2022) have shown promise in stabilizing the variance of prompts such that crafting the perfect prompt is no longer necessary, and instead, any reasonable natural language prompt will suffice. Classic meta-learning leverages abundant labeled data from support sets to adapt a model to quickly learn a limited-data target task, denoted as the query set. Finn et al. (2017) proposes MAML that simulates the inner adaptation step during meta-training by conducting a temporary one-step update before computing the loss. Afterwards, a costly second-order gradient is calculated in the outer loop to train the model for faster future adaptations. To get around the expensive loss calculation, variants such as FOMAML have since been developed (Nichol et al., 2018; Nichol and Schulman, 2018). Meta-ICL ingeniously avoids this calculation by replacing the inner adaptation step with in-context learning, which does not require computing gradients! More specifically, in-context learning refers to the use of exemplars to guide the model towards exhibiting ideal behavior. Critically, these exemplars are included as part of the standard model input and thus do not require gradient updates to provide a useful boost.

Following the idea of Meta-ICL, we consider each dataset as a single task and treat MultiWOZ as the held out target task. Specifically, all support datasets are transformed into the DST format for

meta-training, where the in-context inner loop consists of support set training examples. Although the model does not learn about the query set in meta-training, it *is* familiarizing itself with complex DST prompts during that time, allowing it to quickly adapt to the target task in meta-testing. Furthermore, since the prompt meaning is learned during meta-training, theoretically any prompt can be used to instruct the model, including prompts constructed from random tokens (See Table 2).

3.3 Dialogue Compression

Condensing the dialogue context not only fits more exemplars into the model input sequence, but also helps the model focus on more relevant text for predicting dialogue states. We introduce two general ideas under the umbrella of compressing long dialogues into shorter input sequences.

Context Summarization As the task name implies, DST requires tracking dialogue states over long periods of time, including slot-values that were carried over from the start of the conversation. Indeed, initial experiments validated a monotonic decrease in joint goal accuracy as each marginal utterance was removed. Therefore, as an alternative to simply removing prior utterances, we propose summarizing the dialogue history instead. The summary of all prior turns is represented as the predicted dialogue state up to that point, which is represented as a series of (domain, slot, value) tuples. We tried further limiting the input length by only including state tuples directly related to the current slot prediction, but surprisingly found that this formulation of the summary fared worse.

Saliency Filtering Many sentences within a conversation do not contain valuable information, such as "Thanks, that is all I need today." or "Good bye". In order to filter away these lines, the first instinct is to train a large model, but our situation only has access to a few labeled examples, so to keep things simple, we instead gather a small handful of heuristics to identify non-salient utterances. For example, lines that discuss a "reference number" or are excessively terse are targeted for removal. We verify the performance of our heuristics on the limited few-shot examples, where we heavily weight the model's recall of salient utterances over its precision. We take a very conservative approach since accidentally dropping a single relevant sentence can cause a severe penalty in joint goal accuracy.

3.4 Multi-part Retrieval Training

Exemplars are the only guiding signal when dealing with in-context learning, so selecting quality cases is of utmost importance. To do so, we fine-tune the sentence embedder used during retrieval by taking advantage of the limited, few-shot data available.

Exemplar Retrieval Exemplars are retrieved based on their proximity to the query example. Concretely, we first encode all available exemplars into a shared embedding space using a SBERT embedder (Reimers and Gurevych, 2019) where the raw text fed into the embedder is the exemplar's dialogue history. For each incoming query, we encode the instance in the same manner, and then compare their embeddings to rank the closest exemplars in the few-shot candidate pool (Step 3 in Figure 2). Finally, we keep pulling exemplars from the top of the stack to feed into the model until the entire context length of 512 is at capacity. Since the exemplar embeddings are pre-computed, looking for similar exemplars during inference is a very quick operation.

Embedder Fine-tuning To improve the performance of our retrieval model, we explore two categories of training techniques. Inspired by the rise of contrastive learning (Hadsell et al., 2006) as a pre-training method for NLP tasks (Gao et al., 2021b; Karpukhin et al., 2020), we first study a CONTRASTIVE loss which brings positive examples closer together while pushing negative examples further apart. In our case, exemplars sharing the same domain and slot are positive ($Y=0$) while all others are negative ($Y=1$). The loss becomes:

$$\text{Loss}(i, j) = \frac{1 - Y}{2} [\text{dist}(z_i, z_j)]^2 + \frac{Y}{2} \{ \max(0, m - \text{dist}(z_i, z_j)) \}^2$$

where z_i represents the embedding vector for utterance i while m is a margin, set to 1. We explored various distance functions (e.g. euclidean) and found that distance based on cosine similarity worked best:

$$\text{dist}(z_i \cdot z_j) = 1 - \frac{z_i \cdot z_j}{|z_i| \cdot |z_j|}$$

Since we retrieve exemplars based on cosine score, we can directly optimize for this as second technique with a MEAN-SQUARED ERROR loss. More specifically, the positive pair is assigned a target

score of 1 when the two examples share the same domain and slot and 0 otherwise, mirroring the setup of the contrastive loss. The model’s predicted cosine score is then compared against this target to calculate an averaged L2-loss. We generate κ pairs for each of N exemplars, and train our ranker with:

$$L(i, j) = \frac{1}{NK} \sum_{i=1}^N \sum_{j=1}^K \|\text{Target}(i, j) - \text{Pred}(i, j)\|^2$$

Multi-part Modification The standard method for selecting negatives has a few drawbacks since all negatives are treated the same. While this is necessary for unsupervised contrastive learning, our case deals with labeled exemplars. Even binary labels would provide a useful training signal, but we even have varying degrees of similarity. In particular, a positive example would be an exemplar that has a matching domain, slot and value. However, exemplars that contain a matching domain or slot still deserves partial consideration rather than being deemed a pure negative example. Consequently, we introduce a MULTI-CONTRASTIVE loss where the different elements of domain, slot and value are considered positive attributes, weighted with their respective lambdas. These coefficients were chosen by tuning on a held-out development set:

$$\text{Loss}(i, j) = \frac{\lambda_d + \lambda_s + \lambda_v}{4} [\text{dist}(z_i, z_j)]^2 + \frac{\lambda_n}{4} \{\max(0, m - \text{dist}(z_i, z_j))\}^2$$

where:

$$\lambda_d = 3, \quad \lambda_s = 7, \quad \lambda_v = 10 \\ \lambda_n = 1.0, \quad \text{margin} = 1.0$$

For a final loss function, we also test a novel cosine similarity loss where the target label is modified to include multiple parts, MULTI-MSE. The target is altered such that a matching domain for each pair gets $\lambda_d = 0.3$, a matching slot receives another $\lambda_s = 0.3$ boost and matching values get an additional $\lambda_v = 0.4$, where the weights are derived by tuning on the dev set. The final target score is the cumulative sum of the three components - positive pairs sharing all elements get a full score of 1, negative pairs with no matching elements receive a 0, and most pairs lie somewhere in the middle.

$$\text{Target}(i, j) = \sum_e \lambda_e [\mathbb{1}\{e_i = e_j\}], \forall e \in \{d, s, v\} \\ \text{s.t.} \quad \lambda_d + \lambda_s + \lambda_v = 1$$

Dataset	# Dialogs	# Domains	# Slots
MultiWOZ	8,438	7	24
SGD	16,142	16	214
GSIM	1,500	2	13
DSTC2	1,612	1	8
ABCD	8,034	30	231

Table 1: Statistics of involved task-oriented dialogue datasets. Note that the numbers reported are for the training portions for all datasets.

3.5 Model Input

The eventual sequence we feed into the model takes all of the above ideas into account. We start with a context summary represented as the predicted dialogue state, followed by the current turn which consists of two utterances. Each utterance includes a special `<agent>` or `<customer>` token for the respective speaker. Next, a separator token is added, along with a discrete prompt describing the domain and slot. Lastly, we prepend as many exemplars as we can fit into the model maximum token length, truncating from the beginning when necessary. This results in a final model input of:

$$[N \text{ exemplars}][\text{prev_dialog_state}][\text{agent_utt}] \\ [\text{customer_utt}] < \text{sep} > [\text{prompt}][\text{value}]$$

Notably, the final `[value]` token is only present during meta-training, and belongs to the support datasets. This value is precisely what we hope to predict when testing the left out query set.

4 Experiments

This section outlines our training implementation details as well as key experiments.

4.1 Training Setup

We consider Schema Guided Dialogue (SGD) (Rastogi et al., 2020), DSTC2 (Henderson et al., 2014), Action-Based Conversations Dataset (ABCD) (Chen et al., 2021), and Google Simulated Chat (GSIM) (Shah et al., 2018) as support sets (listed in Table 1). We then use MultiWOZ 2.1 (Budzianowski et al., 2018; Eric et al., 2019) as a query set, as well as MultiWOZ 2.4 (Zang et al., 2020) which is the cleanest version of MultiWOZ at time of writing. All datasets have dialogue compression techniques applied and use the best performing embedder for exemplar retrieval.

For our training we use T5 (Raffel et al., 2020) with both the three and eleven billion parameters

Prompt Style	Prompt Example
Statement	“The destined location of the taxi is”
Question	“Where is the destination of the taxi ?”
Schema	“<domain> taxi - rent cheap cabs to avoid traffic <slot> destination - what place you want the taxi to take you”
Naive	“destination of the taxi is”
None	“taxi destination”
Random	“blue cobra”

Table 2: Examples for different prompt styles. Here we consider a domain of “taxi” and a slot of “destination”.

versions (T5-3b/T5-11b), where our best models are selected through early stopping on validation data. We set the learning rate as $3e - 4$, employ an Adafactor (Shazeer and Stern, 2018) optimizer and cosine scheduler with warmup of 10,000 steps. Our best system uses an ensemble of exemplar embedders that were trained with of $\kappa = [20, 30, 40]$ and learning rate of $3e - 5$. More details can be found in Appendix C.

4.2 Prompt Variations

Model training can be considered stable if different prompts produce similar outcomes. To test this, we collect six prompts based on common sense and prior work. As much as possible, we use prompts designed by others to avoid biasing the rankings.

Since LMs supposedly operate on prompts as continuation of natural language, the (a) *Statement* prompt takes the form ‘The restaurant cuisine is <blank>’, where we hope the model completes the sentence with the correct slot-value. (b) A *Question* prompt reverses the meaning with ‘What is the restaurant cuisine?’ (c) *Schema* comes from (Lee et al., 2021) and MWOZ 2.2 descriptions, which aims to provide the model with the maximum amount of information. It includes a special token, name, and full description for both the domain and slot. (See Table 2) (d) *Naive* takes the opposite approach by simply following the format of “<slot> of the <domain> is <blank>”. (e) Taken even further, the *None* prompt does not use any natural language at all, instead opting to only include the domain and slot name for evaluation purposes. (f) Finally, we include a *Random* prompt which drops any notion of semantics by replacing the domain with a random color and the slot with a random animal. To empathize with the difficulty of hand-engineering a prompt, note that each option (except for random) seems reasonable, and it is hard to know a priori which one works best.

	MRR@10	NDCG@10	MAP@100
Default	16.7%	9.59%	1.81%
Contrastive	17.4%	10.6%	2.28%
Multi-contrast	17.1%	9.89%	1.90%
Mean Squared	25.1%	15.5%	3.31%
Multi-MSE	26.8%	18.4%	5.24%

Table 3: Results of fine-tuning the sentence embedder with various loss functions. Multi-part cosine is best.

As a baseline, we start with in-context learning without meta-training. We feed in the prompts directly and measure their variance as the standard deviation among scores. Then, we perform meta-learning with all prompts again and measure their results, where we expect that the variance among the scores has now decreased.

4.3 Filtering Threshold

In order to verify that our saliency model successfully removes irrelevant sentences, we employ two experts to annotate 50 dialogs, which is well below the allowed 1% of few-shot data. We then run the saliency model on this tiny evaluation set with different filtering thresholds, ranging from 0.1 to 0.9, with results illustrated in Figure 3. As the threshold increases, only sentences with high relevance are left, as evidenced by high precision and low recall. A maximum F1-score is reached at 0.6, but we would rather keep all relevant sentences at the expense of amassing a handful of irrelevant sentences than to risk missing important information. As a result, we choose 0.4 as the filtering threshold, which achieves a recall of 0.998 and acceptably high precision. Qualitative examples of irrelevant sentences that were removed can be found in section 5.4.

4.4 Retrieval Methods

We adapt SBERT (Reimers and Gurevych, 2019) to our DST task with four different objective functions: standard contrastive loss, multi-part contrastive loss, binary cosine similarity loss and multi-part cosine similarity loss. We test with number of pairs per exemplar in a range from 10 to 100 in increments of ten. We found $\kappa = 30$ to work best, which we use moving forward. As a control, we also include the default SBERT model without any further fine-tuning. We evaluate the results of training on the few-shot examples with Mean Reciprocal Rank (MRR@10), Normalized Discounted Cumulative Gain (NDCG@10) and Maximum Average Precision (MAP@100) as our metrics.

Models	Parameter	MultiWOZ2.1			MultiWOZ2.4		
	Size	1%	5%	10%	1%	5%	10%
TRADE (Wu et al., 2019)	<1B	12.58	31.17	36.18	-	-	-
SGPDST (Lee et al., 2021)		32.11	43.14	46.92	-	-	-
DS2-BART (Shin et al., 2022)		28.25	37.71	40.29	30.55	42.53	41.73
DS2-T5 (Shin et al., 2022)		33.76	44.20	45.38	36.76	49.89	51.05
IC-DST GPT-Neo 2.7b (Hu et al., 2022)	<100B	16.70	26.90	31.65	17.36	29.62	34.38
IC-DST CodeGen 2.7b (Hu et al., 2022)		20.72	29.62	33.81	21.87	33.16	37.45
SM2-3b (Our Method)		38.06	39.94	39.85	37.59	49.22	50.33
- Saliency Filtering		36.11	38.26	38.63	-	-	-
- Context Summarization		37.02	37.83	37.80	-	-	-
- Embedder Fine-tuning		27.15	30.88	31.40	-	-	-
SM2-11b (Our Method)	38.36	44.64	46.02	40.03	51.14	51.97	
IC-DST Codex-davinc 175b (Hu et al., 2022)	>100B	43.13	47.08	48.67	48.35	55.43	56.88

Table 4: DST performance using 1%, 5% and 10% of the training set. Naive prompt used for our method. Bolded numbers indicate highest performance on models under 100 billion parameters. Note that models <1B params fine-tune on task data. Ablation results are also included for dialogue compression and embedder training.

As is shown in Table 3, the multi-part cosine loss showcases the strongest ability to select meaningful exemplars. This shows the benefit of providing partial credit to all elements of the dialogue state. Surprisingly though, the multi-part contrastive loss underperformed. Preliminary error analysis revealed negative examples were successfully separated from positive examples, but the different positive examples were mixed together. We adopt the embedder trained with the MULTI-MSE for all remaining experiments.

5 Results and Analysis

The goal of this work is to achieve strong results on DST without worrying about tedious prompt-engineering. Consequently, we first analyze the ability of the best performing models and then discuss performance stability across different prompts.

5.1 Main Results

Table 4 shows that methods based on in-context learning clearly surpass those based on fine-tuning with few-shot data, as evidenced by the strong performance of SM2 as well as the concurrent work of IC-DST (Hu et al., 2022). In fact, our SM2-11b model is able to achieve the best joint goal accuracy on MultiWOZ 2.1 and 2.4 for most few-shot splits, when focused on models less than 100B parameters. Furthermore, when considering just models operating with in-context learning, SM2-3b greatly outperforms the IC-DST 2.7b models in the same order of magnitude. We note that our method is agnostic to model size, so it is certainly possible to combine them with systems larger than

100B params. Doing so would likely yield strong performance without sacrificing stability.

On that note, Table 5 shows that models trained with SM2 exhibit roughly a 2x reduction in variance over models trained under other regimes. While fine-tuning on certain prompts produces some of the highest scores we observe, other prompts yield some of the lowest, highlighting how hand-crafting prompts are wrought with danger. The instability is most pronounced for the random prompt, which meta-learning is able to smooth over. Also worth noting is that meta-learning from SM2 is able to stabilize prompt performance across multiple model types, including sequence-to-sequence (row 4) or auto-regressive LMs (row 5). This is in contrast to purely in-context models, such as those which were pre-trained on code and must always obey a rigid coding structure during inference.

5.2 Ablation Study

To evaluate the different contributions, we run three ablation experiments, each of which removes one of the key components of SM2. The results presented in Table 4 show that each change makes a noticeable impact. Without saliency filtering, model performance drops by a small, but consistent amount of roughly 1-2%. Disabling context summarization means truncating dialogue history to four utterances and precluding previous dialogue state, which causes an even bigger decrease in accuracy. Using the default SBERT embedder deals the most damage of all, leading to a nearly 10% drop. This suggests that exemplar selection is most critical for in-context learning methods.

Prompt Style	None	Naive	Schema	Statement	Question	Random	STDEV
Fine-Tune	35.3	39.2	38.7	41.1	39.3	24.7	6.02
In-Context	17.5	19.9	14.6	18.9	12.4	4.80	5.58
Pre-train	31.8	35.4	28.2	27.8	34.6	17.2	6.65
SM2 T5-3b	33.9	39.9	30.0	38.2	35.6	33.1	3.58
SM2 GPT-XL	9.70	8.70	8.50	11.4	8.90	1.20	3.53

Table 5: Joint goal accuracy over different prompt styles. Models trained with 5% of training data. The backbone model of Fine-tune and In-Context is T5-3b. Instability is measured as standard deviation of the accuracy scores.

The proposed ideas are also independently applicable to other NLP tasks. For example, compressing inputs to fit more exemplars into an model input sequence can be applied to dialogue generation with large LMs or even reading compression, which requires reasoning over long supporting paragraphs. A multi-part training mechanism can be applied to tasks that contain multiple elements, such as the premise, hypothesis and labels of NLI.

5.3 Additional Discussion

We now turn our attention to the impact of different training regimes, as shown in Table 5. Fine-tuning (row 1) serves as an oracle since it represents training directly on the data in the target domain. Unsurprisingly, SM2 reaches lower average results in comparison. In contrast, SM2 significantly outperforms in-context learning (row 2) since neither perform gradient updates, while SM2 includes a meta-learning stage. Finally, to disentangle the effects of pre-training and meta-ICL, we also compare against a baseline which does not perform in-context learning (row 3). Rather than learning the prompts, this baseline instead simply performs transfer learning from the source datasets to the target dataset. Such a setup does not work as well due to the domain shift from the source distribution to the target distribution.

Digging deeper, we notice that our method displays a meaningful jump in performance when going from 1% to 5% data, but not much when going to 10%. The increased amount of data fails to provide much marginal value since the exemplars being selected did not change much despite choosing from a larger candidate pool. Instead, the finite sequence length became the bottleneck on downstream accuracy.

The performance of the in-context methods are interesting in their own right. Statement prompt does best, while Random does worst, but despite having no training, is well above chance. This surprising result confirms other research on prompt

analysis, which found that large PLMs sometimes perform *too well*, implying that the models are actually paying attention to superficial cues rather than truly understanding the text within a prompt (Webson and Pavlick, 2021; Kavumba et al., 2022).

5.4 Qualitative Analysis

The top half of Table 6 shows an utterance with “*domain=restaurant*” and “*slots=price range, food type*”. Despite having minimal n-gram overlap with the example, the first exemplar E1 receives a high score by matching the same domain and slot of the target utterance. On the other hand, the second exemplar E2 discusses an entirely different topic, producing a low score. This demonstrates the effectiveness of the sentence embedder in distinguishing the value of these exemplars. The bottom half of Table 6 shows how the saliency model successfully conserves a large amount of token space. Short sentences and those void of any dialog state information are safe for removal. When all sentences in an utterance are filtered, then we also remove the associated speaker token. Despite our conservative thresholds, the majority of useless information is successfully trimmed out to allow the model to focus on the most pertinent areas instead.

6 Conclusion

In this paper, we presented a method of performing few-shot dialogue state tracking by leveraging large pre-trained LMs with prompts. Our technique does not require any gradient-based training for the target task and instead relies on in-context learning to guide model generation. To enable success in this low-resource setting, we stabilize training across prompts with Meta-ICL, apply saliency filtering and context summarization to reduce dialogue length, and fine-tune a sentence embedder with a custom loss objective to improve exemplar retrieval. These techniques combined allow us to reach state-of-the-art results on MultiWOZ when limited to models under 100 billion parameters.

Exemplar Retrieval			
Dialog ID	Target Utterance	Exemplar	Score
SSNG0074.json	I am looking for a restaurant in the moderate price range that serves bistro type food .	E1: I would love to help. any particular food you'd like? no , I'd just like for it to be in the east and moderately priced .	0.738
		E2: Seventeen locations meet your criteria. Would you prefer a guesthouse or a hotel? A hotel is fine whichever you recommend.	-0.074
Saliency Filtering			
PMUL0287.json	<Agent>: The phone number is 01223259988. <User>: Perfect. Can you help me with a reservation for 6 people at 14:30 this coming sunday? And please make sure I have a confirmation number to use. <Agent>:our reservation is set!		
PMUL1635.json	<Agent>: What day will you be staying? <User>: Friday and Can you book it for me and get a reference number ?<Agent>:Booking was successful. Reference number is : BMUKPTG6. Can I help you with anything else today? <User>: I am looking to book a train that is leaving from Cambridge to Bishops Stortford on Friday.		

Table 6: Examples of how exemplar retrieval and saliency filtering operate. Same colored text represents matching domain and slots. The strikethrough of text means removal of the irrelevant sentence by the saliency model.

Moving forward, we plan to explore techniques that push model and data efficiency even further. Distillation and pruning can lead to much fewer model parameters, while numerous data augmentation techniques seem promising in maximizing the advantage of limited labeled data. Lastly, rather than meta-learning across different dialog domains, we also would like to explore meta-train model with different prompt styles. With the current framework, the prompt used in inference is required to be the same as the training. However, we might want to use flexible prompts in practice. Consequently, we could meta-train across different prompt styles to allow the model to quickly learn a new prompt style during inference.

7 Limitations

Our method is model-agnostic and can be combined with larger pre-trained model over 100 billion parameters for further improvement on DST task. However, due the budget limit, this is unlikely to be directly validated. Ironically, our method also has the limitation that it cannot be combined with smaller models since the emergent behavior of being to understand prompts only seems to occur with sufficiently large pre-trained models.

Separately, the proposed saliency filtering and the exemplar retrieval module are designed based on the dialog state tracking task, but not specifically for the MultiWOZ dataset. As a result, we planned to apply our framework to other task-oriented dialog datasets, e.g. SGD (Rastogi et al., 2020) to

verify that our framework is generalizable, but have not done so yet due to time constraints. We also ran our experiments with a different model type in GPT-XL, but did not have a chance to properly tune the parameters, leading to low performance.

We would have liked to run our experiments with different random seeds. Considering the stability of our framework among different prompt styles, different random seeds should not cause high variance. However, we still need to run experiments to verify this assumption.

A Loss Functions

Gao et al. (2021b) proposes a softmax-based contrastive loss:

$$L_i = -\log \frac{e^{\text{sim}(\mathbf{h}_i, \mathbf{h}_i^+)/\tau}}{\sum_{j=1}^N e^{\text{sim}(\mathbf{h}_i, \mathbf{h}_j^+)/\tau}}$$

which is popular among NLP tasks. However, this loss function requires extremely large batch sizes to work well (Chen et al., 2020). This is especially difficult for us since we specifically target a low-resource setting with small GPU memory requirements. More critically, this softmax contrastive loss views all negatives as being the same. However, in the case of dialog state tracking, where dialog state is represented as (domain, slot, value), the matching is decided at three levels. For example, two dialogue examples can (and should) be considered a negative pair when they have different values for all three elements. In another case though, they might be considered a negative pair by not having matching “value”, but still sharing the same “domain” and “slot”. The softmax contrastive loss considers these two cases as the same, which is not ideal for the DST task. Therefore, we implement the for our experiments. The classic max-margin contrastive loss (Hadsell et al., 2006) is also unable to make a clear distinction for partial credit either, but should be able to when the loss is the sum of multiple elements. Therefore, we use the max-margin loss for our experiments.

B Filtering Results

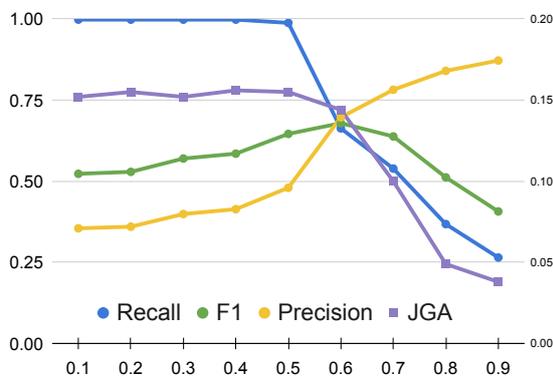

Figure 3: Graph of precision, recall and F1 when varying the acceptance threshold. Joint goal accuracy (JGA) correlates closely with recall due to the nature of DST.

C Other Implementation Details

In this section, we introduce more implementation details. For training, we search the learning rate within the interval [3e-5, 1e-4, 3e-4, 1e-3, 3e-3]. In order to deploy large pre-trained models like T5-3b and T5-11b, we first adjust the batch size. To achieve a balance between GPU memory consumption and batch performance, we alter the number of gradient accumulation steps to maintain a consistent effective batch size of 64 across runs. Furthermore, we also change everything into bitfloat 16 (BF16) and adopt AdaFactor as the optimizer to lower the number of parameters.

We additionally perform ensemble decoding for multiple times using different retrieval embedders. These sentence embedders are distinguished by being trained on different levels of kappa, where we end up choosing embedders trained with kappa of [20,30,40]. These values were selected since they were the models which had the best results as measured by MRR@10 and MAP@10. We run exemplar retrieval with these models and take the majority vote of the system.

In addition to adopting different prompts for our models, we also apply the concept of verbalizers (Schick and Schütze, 2021). More specifically, we use verbalizers to map natural sounding output to the more limited slot-values in the ontology. For example, given the prompt ‘Whether the hotel offers wifi’, we consider both ‘True’ (or ‘False’) and ‘Yes’ (or ‘No’) to be the same answer.

Abstract

Demographic factors (e.g., gender or age) shape our language. Previous work showed that incorporating demographic factors can consistently improve performance for various NLP tasks with traditional NLP models. In this work, we investigate whether these previous findings still hold with state-of-the-art pretrained Transformer-based language models (PLMs). We use three common specialization methods proven effective for incorporating external knowledge into pretrained Transformers (e.g., domain-specific or geographic knowledge). We adapt the language representations for the demographic dimensions of gender and age, using continuous language modeling and dynamic multi-task learning for adaptation, where we couple language modeling objectives with the prediction of demographic classes. Our results, when employing a multilingual PLM, show substantial gains in task performance across four languages (English, German, French, and Danish), which is consistent with the results of previous work. However, controlling for confounding factors – primarily domain and language proficiency of Transformer-based PLMs – shows that downstream performance gains from our demographic adaptation do *not* actually stem from demographic knowledge. Our results indicate that demographic specialization of PLMs, while holding promise for positive societal impact, still represents an unsolved problem for (modern) NLP.

1 Introduction

Demographic factors like social class, education, income, age, or gender, categorize people into specific groups or populations. At the same time, demographic factors both shape and are reflected in our language (e.g., Trudgill, 2000; Eckert and McConnell-Ginet, 2013). A large body of work focused on modeling demographic language vari-

ation, especially the correlations between words and demographic factors (Bamman et al., 2014; Garimella et al., 2017; Welch et al., 2020, *inter alia*). In a similar vein, Volkova et al. (2013) and Hovy (2015) demonstrated that explicitly incorporating demographic information in language representations improves performance on downstream NLP tasks, e.g., topic classification or sentiment analysis. However, these observations rely on approaches that leverage gender-specific lexica to specialize word embeddings and text encoders (e.g., recurrent networks) that have not been pretrained for (general purpose) language understanding. To date, the benefits of demographic specialization have not been tested with Transformer-based (Vaswani et al., 2017) pretrained language models (PLMs), which have been shown to excel on the vast majority of NLP tasks and even surpass human performance in some cases (Wang et al., 2018).

More recent studies focus mainly on monolingual English datasets and introduce demographic features in task-specific fine-tuning (Voigt et al., 2018; Buechel et al., 2018), which limits the benefits of demographic knowledge to tasks at hand. In this work, we investigate the (task-agnostic) demographic specialization of PLMs, aiming to impart the associations between demographic categories and linguistic phenomena into the PLMs parameters. If successful, such specialization could benefit any downstream NLP task in which demographic factors (i.e., demographically conditioned language phenomena) matter. For this, we adopt intermediate training paradigms that have been proven effective for the specialization of PLMs for other types of knowledge, e.g., in domain, language, and geographic adaptation (Glavaš et al., 2020; Hung et al., 2022a; Hofmann et al., 2022). To this effect, we perform (i) continued language modeling on text corpora produced by a demographic group and (ii)

dynamic multi-task learning (Kendall et al., 2018), wherein we combine language modeling with the prediction of demographic categories.

We evaluate the effectiveness of the demographic PLM specialization on both intrinsic (demographic category prediction) and extrinsic (sentiment classification and topic detection) evaluation tasks across four languages: English, German, French, and Danish, using a multilingual corpus of reviews (Hovy et al., 2015) annotated with demographic information. In line with earlier findings (Hovy, 2015), our initial experiments based on a multilingual PLM (mBERT; Devlin et al., 2019), render demographic specialization effective: we observe gains in most tasks and settings. Through a set of controlled experiments, where we (1) adapt with in-domain language modeling alone, without leveraging demographic information, (2) demographically specialize *monolingual* PLMs of evaluation languages, (3) carry out a meta-regression analysis over dimensions that drive the performance, and (4) analyze the topology of the representation spaces of demographically specialized PLMs, we show, however, that most of the original gains can be attributed to confounding effects of language and/or domain specialization.

Our findings indicate that specialization approaches, proven effective for other types of knowledge, fail to adequately instill demographic knowledge into PLMs, making demographic specialization of NLP models an open problem in the age of large pretrained Transformers. Our research code is publicly available at: <https://github.com/umanlp/SocioAdapt>.

2 Demographic Adaptation

Our goal is to inject demographic knowledge through intermediate PLM training in a task-agnostic manner. To achieve this goal, we train the PLM in a dynamic multi-task learning setup (Kendall et al., 2018), in which we couple masked language modeling (MLM-ing) with predicting the demographic category – gender or age group of the text author. Such multi-task learning setup is designed to force the PLM to learn associations between the language constructs and demographic groups, if these associations are salient in the training corpora.

Masked Language Modeling (MLM). Following successful work on pretraining via language modeling for domain-adaptation (Gururangan et al.,

2020; Hung et al., 2022a), we investigate the effect of running standard MLM-ing on the text corpora of a specific demographic dimension (e.g., gender-related corpora). We compute the MLM loss L_{mlm} in the common way, as negative log-likelihood of the true token probability.

Demographic Category Prediction. In the multi-task learning setup, the representation of the input text, as output by the Transformer, is additionally fed into a classification head that predicts the corresponding demographic category: *age* (below 35 and above 45¹), and *gender* (female and male). The demographic prediction loss L_{dem} is computed as the standard binary cross-entropy loss.

We experiment with two different ways of predicting the demographic category of the text: (i) from the transformed representation of the sequence start token ([CLS]) and (ii) from the contextualized representations of each masked token. We hypothesized that the former variant, in which we predict the demographic class from the [CLS] token representation, would establish links between more complex demographically condition linguistic phenomena (e.g., syntactic patterns or patterns of compositional semantics that a demographic group might exhibit), whereas the latter – predicting demographic class from representations of masked tokens – is more likely to establish simpler lexical links, i.e., capture the vocabulary differences between the demographic groups.

Multi-Task Learning. Since both losses can be computed from the same input instances, we opt for joint multi-task learning (MTL) and resort to dynamic MTL based on the *homoscedastic* uncertainty of the losses, wherein the loss variances are used to balance the contributions of the tasks (Kendall et al., 2018). The intuition is that more effective MTL occurs if we dynamically assign less importance to more uncertain tasks, as opposed to assigning uniform task weights throughout the whole training. Homoscedastic uncertainty weighting in MTL has been effective in different NLP settings (Lauscher et al., 2018; Hofmann et al., 2022). In our scenario, L_{mlm} and L_{dem} are measured on different scales in which the model would favor (i.e., be more confident for) one objective than the other. The confidence level of the model prediction for each task would change throughout

¹As suggested by Hovy (2015) the split for the age ranges result in roughly equally-sized data sets for each sub-group and is non-contiguous, avoiding fuzzy boundaries.

the training progress: this makes dynamic weighting desirable. We dynamically prioritize the tasks via homoscedastic uncertainties σ_t :

$$\tilde{L}_t = \frac{1}{2\sigma_t^2} L_t + \log \sigma_t, \quad (1)$$

where σ_t^2 is the variance of the task-specific loss over training instances for quantifying the uncertainty of the task $t \in \{mlm, dem\}$. In practice, we train the network to predict the log variance, $\eta_t := \log \sigma_t^2$, since it is more numerically stable than regressing the variance σ_t^2 , as the log avoids divisions by zero. The adjusted losses are then computed as:

$$\tilde{L}_t = \frac{1}{2}(e^{-\eta_t} L_t + \eta_t). \quad (2)$$

The final loss we minimize is the sum of the two uncertainty-adjusted losses: $\tilde{L}_{mlm} + \tilde{L}_{dem}$.

3 Experimental Setup

Here we describe evaluation tasks and provide details on the data used for demographic specialization and downstream evaluation.

Evaluation Tasks. We follow Hovy (2015) and measure the effects of demographic specialization of PLMs on three text-classification tasks, coupling intrinsic demographic *attribute classification* (AC) with two extrinsic text classification tasks: *sentiment analysis* (SA) and *topic detection* (TD). As an intrinsic evaluation task, AC directly tests if the intermediate demographic specialization results in a PLM that can be more effectively fine-tuned to predict the same demographic classes used in the intermediate specialization: PLMs (vanilla PLM and our demographically specialized counterpart) – are fine-tuned in a supervised fashion to predict the demographic class (gender or age) of the text author. SA is a ternary classification task in which the reviews with ratings of 1, 3, and 5 stars represent instances of *negative*, *neutral*, and *positive* class, respectively. TD classifies texts into 5 different topic categories. We report the F_1 -measure for each task following Hovy (2015).

Data. We carry out our core experimentation on the multilingual demographically labeled dataset of reviews (Hovy et al., 2015), created from the internationally popular user review website Trustpilot.² For comparison and consistency, we work with exactly the same data portions as Hovy (2015):

²<https://www.trustpilot.com/>

collections that cover (1) two most prominent demographic dimensions – *gender* and *age*, with two categories in each (gender: male or female; age: below 35 or above 45³) and (2) five countries (four languages): United States (US), Denmark, Germany, France, and United Kingdom (UK).

To avoid any information leakage, we ensure – for each country-demographic dimension collection (e.g., US, gender) – that there is zero overlap between the portions we select for intermediate demographic specialization and portions used for downstream fine-tuning and evaluation (for AC, SA, and TD). For TD, we aim to eliminate the confounding effect of demographically-conditioned label distributions (e.g., female authors wrote reviews for *clothing store* more frequently than male authors; vice-versa for *electronics & technology*). To this effect, we select, for each country, reviews from the five most frequent topics and sample the same number of reviews in each topic for both demographic groups (i.e., *male* and *female* for gender; *below 35* and *above 45* for age). For the intrinsic AC task (i.e., fine-tuning to predict either gender or age category), we report the results for two different review collections: the first is the set of reviews that have, besides the demographic classes, been annotated with sentiment labels (we refer to this as AC-SA) and the second are the reviews that have topic labels (i.e., product/service category; we refer to this portion as AC-TD). For these fine-tuning and evaluation datasets, we make sure that the two demographic classes (*male* and *female* for gender *under 35* and *above 45* for age) are equally represented in each dataset portion (train, development, and test). Table 1 displays the numbers of reviews for each country, demographic aspect, and dataset portion (specialization vs. fine-tuning).

For intermediate specialization of the multilingual model, we randomly sample 100K instances per demographic group from the *gender* specialization portion and 50K instances each from the texts reserved for *age* specialization concatenated across all 5 countries. For the specialization of monolingual PLMs, we randomly sample the same number of instances but from the specialization portions of a *single* country. Following the established procedure (e.g., Devlin et al., 2019; Liu et al., 2019), we dynamically mask 15% of the tokens in the demographic specialization portions for MLM.

³As suggested by Hovy (2015), the split for the age ranges results in roughly equally-sized data sets for each sub-group and is non-contiguous, avoiding fuzzy boundaries.

Country	Language	gender				age			
		Specialization		SA, AC-SA	TD, AC-TD	Specialization		SA, AC-SA	TD, AC-TD
		F	M	F / M		<35	>45	<35 / >45	
Denmark	Danish	1,596,816	2,022,349	250,485	120,805	833,657	494,905	75,300	44,815
France	French	489,778	614,495	67,305	55,570	40,448	36,182	6,570	6,120
Germany	German	210,718	284,399	28,920	30,580	66,342	47,308	5,865	8,040
UK	English	1,665,167	1,632,894	156,630	183,995	231,905	274,528	26,325	22,095
US	English	575,951	778,877	72,270	61,585	124,924	70,015	6,495	12,090

Table 1: Number of instances in different portions of the Trustpilot dataset (Hovy et al., 2015) used in our experiments. For each country (Denmark, France, Germany, UK, and US), we report the size of the specialization and fine-tuning portions, the latter for each of the two extrinsic tasks: Sentiment Analysis (SA) and Topic Detection (TD). Note that we use the same SA and TD reviews for the intrinsic AC tasks of predicting the demographic categories (denoted AC-SA and AC-TD, respectively). Numbers are shown separately for the two demographic dimensions: gender and age. For fine-tuning datasets (for SA/AC-SA, and for TD/AC-TD), we indicate the number of instances in each category (which is the same for both categories: F and M for gender, <35 and >45 for age). We split the fine-tuning datasets randomly into train, validation, and test portions in the 60/20/20 ratio.

Pre-trained language models. Given that we experiment with Trustpilot data in four different languages, in our core experiments, we resorted to multilingual BERT (mBERT)⁴ (Devlin et al., 2019) as the starting PLM. This allows us to merge the (fairly large) specialization portions of Trustpilot in different languages (see Table 1) and run a single multilingual demographic specialization procedure on the combined multilingual review corpus. We then fine-tune the demographically-specialized mBERT and evaluate downstream task performance separately for each of the five countries (using train, development, and test portions of the respective country). We report the results for two different variants of our dynamic multi-task demographic specialization (DS): (1) when the demographic category is predicted from representations of masked tokens (DS-Tok) and (2) when we predict the demographic category from the encoding of the whole sequence (i.e., review; this version is denoted with DS-Seq). We compare these demographic-specialized PLM variants against two baselines: vanilla PLM and PLM specialized on the same review corpora as our MTL variants but only via MLM-ing (i.e., without providing the demographic signal).

Training and Optimization. In demographic specialization training, we fix the maximum sequence length to 128 subword tokens. We train for 30 epochs in batches of 32 instances and search for the optimal learning rate among the following values: $\{5 \cdot 10^{-5}, 1 \cdot 10^{-5}, 1 \cdot 10^{-6}\}$. We apply early stopping based on the development set performance: we stop if the joint MTL loss does

⁴We load the bert-base-multilingual-cased weights from HuggingFace Transformers.

not improve for 3 epochs). For downstream fine-tuning and evaluation, we train for maximum 20 epochs in batches of 32. We search for the optimal learning rate between the following values: $\{5 \cdot 10^{-5}, 1 \cdot 10^{-5}, 5 \cdot 10^{-6}, 1 \cdot 10^{-6}\}$ and apply early stopping based on the validation set performance (patience: 5 epochs). We use AdamW (Loshchilov and Hutter, 2019) as the optimization algorithm.

4 Results and Discussion

We first discuss the results of multilingual demographic specialization with mBERT as the PLM (§4.1). We then provide a series of control experiments in which we isolate the effects that contribute to performance gains of demographically specialized PLMs (§4.2).

4.1 Multilingual Specialization Results

Table 2 shows the results of gender- and age-specialized mBERT variants – DS-Seq and DS-Tok – on gender and age classification (AC-SA and AC-TD) as intrinsic tasks together with sentiment analysis (SA) and topic detection (TD) as extrinsic evaluation tasks, for each of the five countries encompassed by the Trustpilot datasets (Hovy et al., 2015). The performance of DS-Seq and DS-Tok is compared against the PLM baselines that have not been exposed to demographic information: vanilla mBERT and mBERT with additional MLM-ing on the same Trustpilot data on which DS-Seq and DS-Tok were trained.

Our demographically specialized models generally outperform the vanilla mBERT across the board, both on intrinsic and extrinsic tasks, unsurprisingly with much more prominent gains on the former. The comparison against the domain-

Table 2: Results of gender-specialized (age-specialized) multilingual BERT (DS-Seq and DS-Tok) on gender (age) classification (AC-SA and AC-TD) as intrinsic task and sentiment analysis (SA) and topic detection (TD) as extrinsic evaluation tasks. Comparisons against the vanilla mBERT and mBERT additionally trained on the same review corpora but without demographic information, only with masked language modeling (MLM). For SA and TD, we separately report the performance on the test sets consisting of only one demographic class (gender: F and M, age: <35 and >45) as well as on the mixed test sets containing reviews from both demographic classes (X for both gender and age). Bold numbers indicate the best-performing model (between mBERT, MLM, DS-Seq and DS-Tok) for each country-task combination.

adaptation in which mBERT was intermediately trained only MLM-ed on Trustpilot reviews, but without demographic category prediction, however, reveals that much of the gains that DS-Seq and DS-Tok have over vanilla mBERT stem from domain adaptation: somewhat surprisingly, DS models fall behind MLM-based domain adaptation on the intrinsic tasks of gender/age classification (e.g., for age group classification on AC-SA, the DS variants fall short of MLM by 2 F_1 points), while exhibiting small but fairly consistent gains over MLM for extrinsic SA and TD tasks, both in gender and age intermediate specialization. Although the gains are not particularly convincing, the SA and TD still seem to favor intermediate demographic specialization, which is in line with findings from Hovy (2015), who also reported small but (mostly) consistent gains for these two tasks.

4.2 Control Experiments

To more precisely measure the contributions of demographic information that DS-* variants incorporate, we design further experiments that control for two key side-effects of demographic specialization: (i) language specialization and (ii) domain adaptation. We then carry out the meta-regression analysis to tease out the individual contributions of language, domain, and demographic knowledge on the performance difference between vanilla mBERT and respective intermediately specialized models (mBERT or monolingual BERT specialized on the data of the same or different domain with or without demographic signal). Finally, we compare the representations spaces of the PLMs – before and after demographic specialization – along the demographic dimension.

Controlling for Language Proficiency. Massively multilingual Transformers (MMTs) like mBERT or XLM-R (Conneau et al., 2020) suffer

from the *curse of multilinguality* (Conneau et al., 2020; Lauscher et al., 2020b; Pfeiffer et al., 2020): given a fixed capacity of the Transformer, the representations from an MMT for any individual (high-resource) language will be of lower quality than those of the monolingual PLM, as MMTs share their limited capacity over many languages. It is thus possible that demographic specialization of mBERT on Trustpilot data in our four languages leads to substantial gains over vanilla mBERT (pre-trained on 104 languages) primarily because of mBERT’s acquisition of additional language competencies for these four languages.

To test this, we additionally execute demographic specialization individually for each language (i.e., as opposed to a single multilingual specialization), starting from a monolingual PLM of that language⁵. Monolingual PLMs produce higher quality representations for their respective language than mBERT. Because of this, we hypothesize that subjecting them to demographic specialization on Trustpilot is unlikely to improve their “command” of the language substantially. Consequently, should we still see (downstream) gains from demographic specialization for monolingual PLMs, we can be more confident that they stem from the injected demographic information.

Table 3 shows the effects of demographic specialization on monolingual PLMs of the four languages. For brevity (full results in the Appendix), we average the demographic attribute classification (AC) results from two different test portions from Table 2 (having labels for different downstream tasks, AC-SA and AC-TD); for extrinsic tasks, SA and TD, we report only the score on demographically balanced test sets (denoted “X” in Table 2). The results show that, when we control for language proficiency (as monolingual PLMs are more proficient in their respective language than mBERT), the downstream gains of demographic specialization (on SA and TD) vanish. The DS-Seq and DS-Tok still retain marginal numeric (statistically insignificant) gains over MLM in gender-based specialization, but they lag behind in age-based specialization. Also, both DS-* variants and MLM display only marginal gains with respect to vanilla monolingual BERT models of the four languages: e.g., in gender-specialization and for SA, DS-Tok

⁵We use the following monolingual PLMs from Hugging-Face: bert-base-cased, bert-base-german-cased, dbmdz/bert-base-french-europeana-cased and Maltehb/danish-bert-botxo.

Country	Model	Gender			Age

Table 3: Results of gender/age-specialized **monolingual** PLMs – DS-Seq and DS-Tok – on demographic attribute classification (AC), sentiment analysis (SA) and topic detection (TD). Bold numbers indicate the best-performing model (between BERT, MLM, DS-Seq and DS-Tok) for each country-task combination.

has an average advantage of 0.7 F_1 over the non-specialized vanilla monolingual BERTs; compare this to a gain of 1.6 F_1 points that mBERT-based DS-Tok has over vanilla mBERT (Table 2). These results question the downstream usefulness of demographic specialization – suggested by findings from prior work (Hovy, 2015) and our results for multilingual PLMs (Table 2) – if one starts from the most proficient PLM for the concrete language at hand, i.e., a monolingual PLM.

Controlling for Domain Knowledge. Both simple additional MLM-ing on Trustpilot data, as well as multi-task demographic specialization training (DS-* variants), inject knowledge about the domain-specific language of reviews into the PLM. As shown by previous work (Glavaš et al., 2020; Diao et al., 2021; Hung et al., 2022a), domain adaptation generally leads to better downstream performance on in-domain data for any task. We next investigate to which extent the domain specialization is responsible for performance gains. To this end, we perform demographic specialization

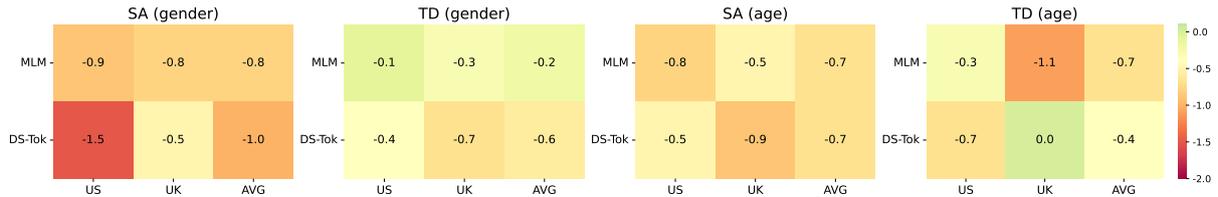

Figure 1: Evaluation results on Trustpilot for Sentiment Analysis (SA) and Topic Detection (TD) when running the intermediate specialization on out-of-domain data (RtGender (Voigt et al., 2018) for *gender* and BAC (Schler et al., 2006) for *age*). We report the delta in F_1 -score in comparison to the specialization on Trustpilot in-domain data.

Task	Selected features	all	-D	-M	-S	-C	-A
<i>gender</i>							
AC-SA	US (1.0); Denmark (0.9); MLM (0.9); DS-Tok (0.9);	0.51	-	0.56	-	0.63	0.62
AC-TD	MLM (1.0); Monoling (1.0) DS-Tok (0.9);	0.51	-	0.73	-	0.54	0.66
SA	France (1.0); DS-Tok (1.0); Denmark (0.8); MLM (0.8); In-domain (0.6)	0.92	0.94	0.95	0.94	0.97	0.98
TD	DS-Tok (0.6); MLM (0.5); In-domain (0.5)	0.33	0.36	0.35	0.34	0.35	0.40
<i>age</i>							
AC-SA	Denmark (3.0); MLM (1.5); Monoling (0.9)	1.93	-	1.98	-	2.31	2.02
AC-TD	UK (2.1); France (1.4); MLM (0.9);	0.68	-	0.69	-	1.02	0.82
SA	In-domain (1.3); DS-Tok (1.0); MLM (0.9);	0.96	1.03	0.97	0.97	0.98	1.03
TD	Denmark (1.6); <35 (0.7); DS-Seq (0.6); DS-Tok (0.6)	1.52	1.53	1.53	1.55	1.61	1.54

Table 4: Results of meta-regression analysis. We report the goodness-of-fit (RMSE) results for predicting deltas in downstream performance between specialized models and their respective vanilla PLM. Results reported for three tasks – intrinsic demographic attribute classification (AC; on datasets AC-SA and AC-TD), Sentiment Analysis (SA), and Topic Detection (TD) with both demographic factors, *gender* and *age*. We compare the results across different feature sets – for all features (**all**), and excluding individual features: domain (**-D**), mono- vs. multilingual (**-M**), fine-tuning demographic setting (e.g., F vs. M vs. X for gender; **-S**), country (**-C**), and the adaptation approach (i.e., MLM vs. DS-Tok vs. DS-Seq; **-A**). For each task, when including all features (column: **in**), we list the most important features, those with weights > 0.5 (*selected features*).

on (demographically labeled) training data from a different domain: for *gender* specialization, we use the RtGender (Voigt et al., 2018) consisting of social media posts collected from diverse sources, whereas for *age* specialization we resort to the Blog Authorship Corpus (BAC; Schler et al., 2006) containing blogposts from blogger.com.

Figure 1 displays the effects of out-of-domain specialization of mBERT on downstream SA and

TD performance (i.e., performance differences w.r.t. corresponding in-domain specialized models). Since RtGender and BAC are English-only datasets, we report the results only for US and UK (for brevity, we report the performance only on the demographically balanced test sets, i.e., setups indicated with “X” in Table 2; both DS-* variants exhibit very similar behavior, so for brevity, we only display results for DS-Tok; complete results are in the Appendix). Expectedly, the out-of-domain specialization deteriorates the downstream performance for both MLM and DS-Tok. Interestingly, MLM, which is not exposed explicitly to the demographic signal in specialization, tends to suffer less from out-of-domain specialization than the gender-informed DS-Tok. In contrast, age-informed DS-Tok seems to exhibit similar losses as MLM due to out-of-domain specialization. These results further question the hypothesis that demographic information guides downstream gains, suggested by prior work (Hovy, 2015) and our in-domain specialization results (with mBERT) from Table 2.

Meta-regression Analysis. Next, we aim to quantify, via a meta-regression analysis, the contributions of individual factors (country, in-domain vs. out-of-domain specialization, language, specialization approach, test set structure) on the task performance (AC-SA, AC-TD, SA, TD). We use the difference in performance between the specialized model and its corresponding vanilla PLM (mBERT or monolingual PLM) as the label (i.e., output, dependent) variable for the regression. We use the following input features (all one-hot encoded) as prediction variables: (i) country/language of fine-tuning/evaluation data, (ii) specialization method (MLM vs. DS-Tok vs. DS-Seq), (iii) in-domain vs. out-of-domain specialization, (iv) whether the starting/vanilla PLM is monolingual (e.g., French BERT) or multilingual (mBERT), (v) and the demographic group from which the fine-tuning/evaluation data comes from (F vs. M vs. X

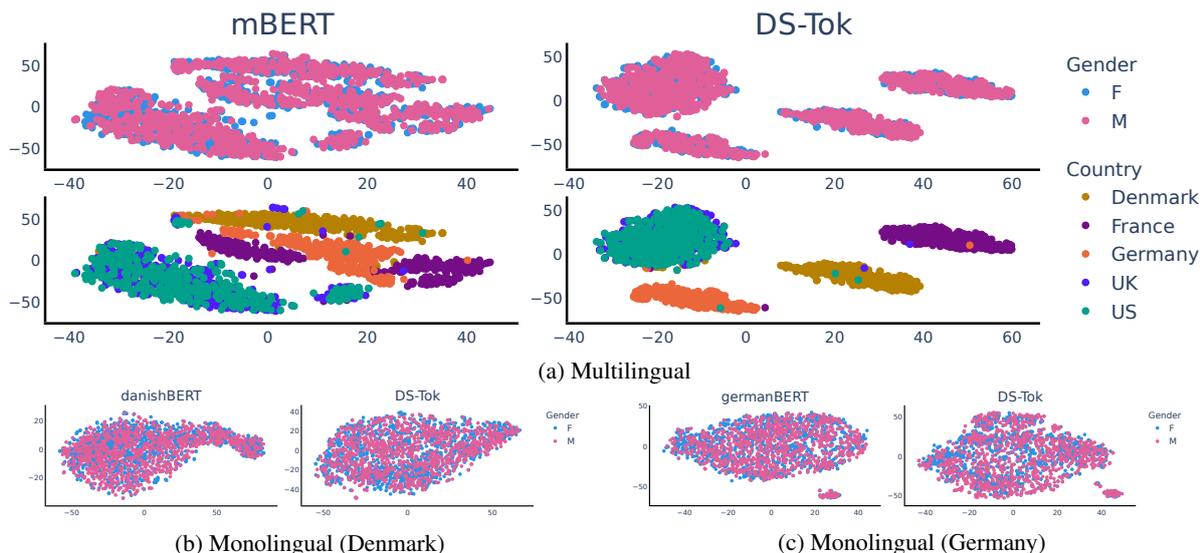

Figure 2: Results of our multilingual and monolingual qualitative analysis for *gender*. For multilingual case as plotted in (a), we show a tSNE visualization of review texts embedded with a non-specialized (mBERT) and specialized (DS-Tok) model. Colors indicate the demographic subgroup (upper figures) and countries (lower figures), respectively. For monolingual case as illustrated in (b) and (c) for Denmark and Germany, we show a tSNE visualization of texts embedded with non-specialized (danishBERT, germanBERT) and specialized (DS-Tok) monolingual PLMs. Each subfigure is plotted with 2K instances.

for gender and <35 vs. >45 vs. X for age). We then fit a linear regressor on all data points, using either the full set of features or, in ablations, excluding certain subsets; we report the goodness of fit as average root mean square error (RMSE).

We summarize the results of our meta-regression analysis in Table 4. For each task, we list the selected features (weights for **in** in parenthesis) paired with the RMSE scores. When we fit regression using all features (**all**), the country of origin of fine-tuning data (i.e., features *Denmark*, *France*, *UK*, etc.) tends to overall explain the variance of specialization effect on model performance as good as or even better than the specialization approach (demographically-informed DS-* variants and demographically-uninformed MLM). The specialization approach features (MLM, DS-Tok, and DS-Seq), however, do appear among the most important features in most settings, suggesting that knowing the specialization approach does help predict the performance of the specialized model. Note, however, that in terms of assessing whether demographic information generally improves specialization, this needs to be combined with actual task performance results from Tables 2 and 3. For example, feature DS-Tok is among the most important features for SA performance after *gender* specialization: looking at the results for DS-Tok in both Tables 2 and 3, we see that it achieves, in most cases, scores above MLM – this, in turn, suggests

that demographically-informed gender specialization does (regardless of other factors) improve the downstream SA performance. The ablation results offer a complementary view into the importance of individual features: the larger the increase in RMSE when excluding a feature (compared to using all features), the more important the feature is. The regressions in which we exclude the information on the specialization approach (**-A**) result in the highest RMSE for gender specialization on both extrinsic tasks (SA and TD). In all other setups (AC for both gender and age specialization, as well as SA and TD for age), there is another type of information, the removal of which results in a less predictable specialization effect: for instance, AC after age specialization, the **-C** setting increases the RMSE the most, representing that features indicating the demographic composition of the fine-tuning dataset – <35 , >45 or balanced (X) – jointly have the largest effect on performance.

Combining results from Tables 2 and 3 with findings from the meta-regression analysis leads to the overall conclusion that gender-based language specialization of PLMs generally leads to downstream gains, whereas age-based specialization does not.

Qualitative Analysis. Finally, we analyze the topology of the PLMs representation space before and after demographic specialization. We encode the reviews from both demographic dimensions –

(i) with the vanilla PLM (mBERT or monolingual BERT) and its DS-Tok specialized counterpart – and then compress those representations into two dimensions with t-distributed stochastic neighbor embedding (tSNE; van der Maaten and Hinton, 2008). Figure 2 depicts these representation spaces after gender-specialization (the age-specialization effects lead to similar conclusions; for brevity, we leave them for the Appendix). The tSNE plots do not show any salient gender specialization effect. In the case of mBERT, gender-specialization (corresponding DS-Tok plot) leads to the separation of representation areas according to review language and not gender of its author.⁶ In the monolingual cases (illustrated for Danish and German BERT), the space of the gender-specialized encoder visually largely resembles that of the vanilla one, indicating that the demographic specialization procedure (DS-Tok) does not impart dimensions that allow for easy separation of representation space along the specialization dimension (here: gender).

5 Related Work

Intermediate Training (Adaptation). Intermediate language modeling on texts from the same or similar distribution as the downstream data has been shown to lead to improvements on various NLP tasks (e.g., Gururangan et al., 2020). During this process, the goal is to inject additional information into the PLM and thus specialize the model for a particular domain (e.g., Aharoni and Goldberg, 2020; Hung et al., 2022a; Bombieri et al., 2023) or language (e.g., Glavaš et al., 2020) or to encode other types of knowledge such as common sense knowledge (e.g., Lauscher et al., 2020a), argumentation knowledge (e.g., Holtermann et al., 2022), or geographic knowledge (e.g., Hofmann et al., 2022).

For instance, Hung et al. (2022a) propose a computationally efficient approach by employing domain-specific adapter modules. They show that their domain adaptation approach leads to improvements in task-oriented dialog. Glavaš et al. (2020) and Hung et al. (2022b) perform language adaptation through intermediate MLM in the target languages with filtered text corpora, demonstrating substantial gains in downstream zero-shot cross-lingual transfer for abusive language detection and dialog tasks, respectively. These specialization approaches mainly rely on a single objective (e.g.,

⁶Note that the green and blue regions, indicating US and UK overlap due to shared language.

masked language modeling on “plain” text data). Instead, Hofmann et al. (2022) conduct geoadaptation by coupling MLM with a token-level geolocation prediction in a dynamic multi-task learning setup. In this work, we adopt a similar approach and perform continued language modeling on the text corpora of a specific demographic dimension.

Demographic Specialization. Language preferences vary with user demographics (Loveys et al., 2018). Accordingly, several studies have leveraged demographic information (e.g., gender, age, education) to investigate the effect of encoded sociodemographic knowledge in the representations of PLMs (Lauscher et al., 2022a) or obtain better language representations for various NLP tasks (Volkova et al., 2013; Garimella et al., 2017). Recent research studies on demographic adaptation mainly focus on (1) learning demographic-aware word embeddings and do not work with large PLMs (Hovy, 2015) or (2) leveraging demographic information with special PLM architectures specifically designed for certain downstream tasks (e.g., empathy prediction (Guda et al., 2021)). The latter, however, do not consider a task-agnostic approach to injecting demographic knowledge into language models, and also focus on a monolingual setup only. Further, what roles the different factors (i.e., domain, language, demographic aspect) in the specialization really play remains unexplored.

6 Conclusion

In this work, we thoroughly examined the effects of demographic specialization of Transformers via straightforward injection methods that have been proven effective for other types of knowledge. Initial results on intrinsic and extrinsic evaluation tasks using a multilingual PLM indicated the usefulness of our approach. However, running a series of additional experiments in which we controlled for potentially confounding factors (language and domain) and a meta-analysis indicated that the demographic aspects only have a negligible impact on the downstream performance. This observation is supported by additional qualitative analysis. Overall, our findings point to the difficulty of injecting demographic knowledge into Transformers: we hope that our in-depth analysis and findings catalyze future research on the topic of truly human-centered NLP, especially in multilingual settings.

Limitations

In this paper, we concentrated on the demographic adaptation of PLMs for a few key demographic aspects (i.e., gender and age). There are other known factors, like ethnicity and education, that we cannot explore here. However, there are likely further effects, as well as intersectional effects. We conducted our experiments using only five Western countries and four Indo-European languages (Hovy et al., 2015), ignoring other world regions and language families. However, due to the scarcity of data, we can only hypothesize that the limited effects of demographic specialization also apply to resource-lean languages (i.e., the language specialization effects are likely to outweigh the ones of the demographic specialization). Another limitation is the use of pretrained language models, which are all pre-trained on general-purpose data and are freely available. We acknowledge that results may differ for models with greater capacity that have been pretrained on data from other, more specific domains. We primarily concentrate on BERT-like models, which are only a subset of language models, and we leave language model variants for future research.

Ethics Statement

Our work deals with demographic adaptation from reviews that should be considered sensitive information. We acknowledge that the limitations in data resources and annotations (Schler et al., 2006;

Hovy et al., 2015; Voigt et al., 2018) give rise to potential risks of overgeneralizing our findings and applying our methods. These risks are due to: (1) *partial language coverage*, where languages are from Indo-European subfamilies that do not represent typologically diverse languages; (2) *limited cultural coverage* (Joshi et al., 2020), where the countries, although speaking different languages, still belong a culturally relatively homogeneous part of the world, i.e., the West; (3) *simplified gender identities* (Dev et al., 2021), where gender is modeled as a binary variable, which does not reflect the wide variety of possible identities along the gender spectrum and beyond (Lauscher et al., 2022b); (4) *unfair stereotypical biases* (Blodgett et al., 2020), namely potential harms that might arise from unfair stereotypical biases in the data (despite our efforts to balance the sample across demographic groups) or pre-encoded in the model (Lauscher et al., 2021). Further, the sensitive user profile data might bias the model towards additional demographic characteristics and lead to potentially harmful predictions and applications.

In this work, however, we are interested in advancing NLP research to understand better this fine-grained aspect of the intertwined relationship between demographic adaptation and large pretrained language models in both monolingual and multilingual scenarios. While limited data resources may hinder our ability to fully consider language coverage, cultural coverage, gender identities, and stereotypical biases, it is our obligation to be transparent about these limitations and ethical concerns and to continually work towards improving data collection and methodologies to better serve the needs and perspectives of all users. We believe these insights will lead us toward fairer and more inclusive language technologies. We hope that future research builds on top of our findings and explores other demographic factors, other groups within these factors, and also other languages and countries.

Table 7: Evaluation results on Trustpilot classification tasks (SA, TD) compared by specializing on out-domain data (RtGender (Voigt et al., 2018) for *gender* and BAC (Schler et al., 2006) for *age*) and in-domain data (Trustpilot).

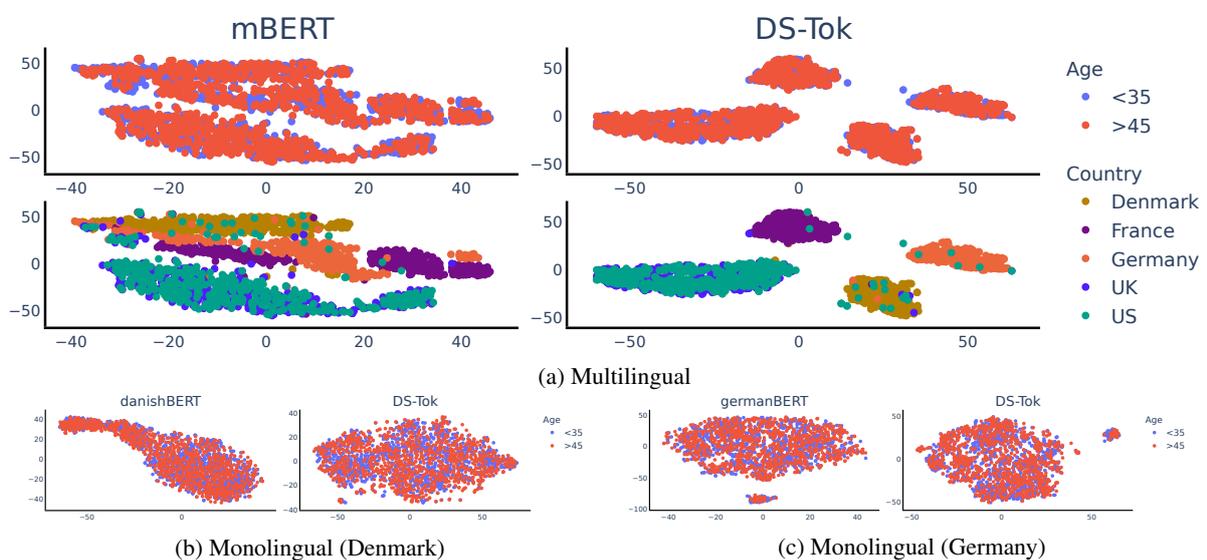

Figure 3: Results of our multilingual and monolingual qualitative analysis for *age*. For multilingual case as plotted in (a), we show a tSNE visualization of review texts embedded with a non-specialized (mBERT) and specialized (DS-Tok) model. Colors indicate the demographic subgroup (upper figures) and countries (lower figures), respectively. For monolingual case as illustrated in (b) and (c) for Denmark and Germany, we show a tSNE visualization of texts embedded with non-specialized (danishBERT, germanBERT) and specialized (DS-Tok) monolingual PLMs. Each subfigure is plotted with 2K instances.

JBLiMP: Japanese Benchmark of Linguistic Minimal Pairs

Taiga Someya and Yohei Oseki

The University of Tokyo

{taiga98-0809,oseki}@g.ecc.u-tokyo.ac.jp

Abstract

In this paper, we introduce **JBLiMP** (Japanese Benchmark of Linguistic Minimal Pairs), a novel dataset for targeted syntactic evaluations of language models in Japanese. JBLiMP consists of 331 minimal pairs, which are created based on acceptability judgments extracted from journal articles in theoretical linguistics. These minimal pairs are grouped into 11 categories, each covering a different linguistic phenomenon. JBLiMP is unique in that it combines two important features independently observed in existing datasets: (i) coverage of complex linguistic phenomena (cf. CoLA) and (ii) presentation of sentences as minimal pairs (cf. BLiMP). In addition, JBLiMP is the first dataset for targeted syntactic evaluations of language models in Japanese, thus allowing the comparison of syntactic knowledge of language models across different languages. We then evaluate the syntactic knowledge of several language models on JBLiMP: GPT-2, LSTM, and n -gram language models. The results demonstrated that all the architectures achieved comparable overall accuracies around 75%. Error analyses by linguistic phenomenon further revealed that these language models successfully captured local dependencies like nominal structures, but not long-distance dependencies such as verbal agreement and binding.

1 Introduction

The past few years have seen a remarkable success of neural language models, and some language models based on Transformer (Vaswani et al., 2017) have achieved the state-of-the-art performance in various natural language processing (NLP) tasks (Wang et al., 2018, 2019). In fact, recent neural language models are extremely successful in solving a variety of downstream tasks, but it remains to be understood how well these neural language models understand the syntax of natural languages. In order to address this question, some studies investigated the syntactic knowledge of language models

with a specially designed dataset for targeted syntactic evaluations (e.g., Linzen et al., 2016; Marvin and Linzen, 2018; Wilcox et al., 2018; Gulordava et al., 2018; Futrell et al., 2019; Chaves, 2020). However, most of these studies have focused on English and other European languages, and only few studies extended this investigation to non-European languages (Gulordava et al., 2018; Ravfogel et al., 2018). Importantly for the purpose here, even fewer studies have dealt with a wide variety of linguistic phenomena in non-English languages (Xiang et al., 2021; Trotta et al., 2021).

In this paper, we introduce **JBLiMP** (Japanese Benchmark of Linguistic Minimal Pairs), a novel dataset for targeted syntactic evaluations of language models in Japanese.¹ JBLiMP consists of 331 minimal pairs, which are created based on acceptability judgments extracted from journal articles in theoretical linguistics. These minimal pairs are grouped into 11 categories, each covering a different linguistic phenomenon. JBLiMP is unique in that it successfully combines two important features independently observed in existing datasets: (i) coverage of complex linguistic phenomena (cf. CoLA; Warstadt et al., 2019) and (ii) presentation of sentences as minimal pairs (cf. BLiMP; Warstadt et al., 2020). We evaluate the syntactic knowledge of several language models on JBLiMP: GPT-2 (Radford et al., 2019), LSTM (Hochreiter and Schmidhuber, 1997) and n -gram language models. The results demonstrated that all the architectures achieved comparable overall accuracies around 75%. Error analyses by linguistic phenomenon further revealed that these language models successfully captured local dependencies like nominal structures, but not long-distance dependencies such as verbal agreement and binding.

¹JBLiMP is available at <https://github.com/osekilab/JBLiMP>.

Table 1: Related work organized by language and linguistic phenomenon

2 Related Work

Evaluation of language models has been mainly performed by computing metrics such as perplexity. This gives us an objective standard of the performance of language models, but doesn’t provide insight into their performance on specific downstream tasks. While recent large-scale benchmarks like GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) are informative in this respect, many recent studies have sought to provide evidence that language models have learned the syntax of natural languages. In a pioneering work by Linzen et al. (2016), minimal pairs were employed to investigate whether language models are sensitive to subject-verb agreement in English. For instance, they tested whether language models assign a higher probability to *are* than *is* in (1).

- (1) a. The keys to the cabinet are on the table.
 b. *The keys to the cabinet is on the table.

Their results suggested that LSTM language models are fairly sensitive to English subject-verb agreement. However, this and related studies (e.g., Marvin and Linzen, 2018; Futrell et al., 2019) only covered a limited range of linguistic phenomena like subject-verb agreement.

In order to tackle this problem, more recent studies have introduced large-scale datasets for comprehensive syntactic evaluations (Warstadt et al., 2019, 2020). One such dataset is CoLA (Corpus of Linguistic Acceptability; Warstadt et al., 2019), which

consists of 10,000 sentences with binary acceptability labels extracted from linguistics journals and textbooks. CoLA is incorporated into GLUE benchmark (Wang et al., 2018) and has been used to evaluate the sensitivity of language models to the syntax of natural languages. While CoLA has enabled the comprehensive syntactic evaluations of language models, this dataset is not without its limitation, as noted by Warstadt et al. (2019) themselves. The limitation lies in the need to train a supervised classifier on CoLA for evaluation. In short, CoLA is designed for binary classification of acceptability judgements, but there is no clear way to map the probability of the sentence estimated by language models to binary acceptability judgements. Unfortunately, “the use of supervision prevents making strong conclusions about the sentence encoding component, since it is not possible to distinguish what the encoder knows from what is learned through supervised training on acceptability data” (Warstadt et al., 2019).

Dataset	Linguistics Journal	Minimal Pairs
CoLA (Warstadt et al., 2019)	✓	
ItaCoLA (Trotta et al., 2021)	✓	
BLiMP (Warstadt et al., 2020)		✓
CLiMP (Xiang et al., 2021)		✓
JBLiMP	✓	✓

Table 2: Comparison of JBLiMP and other existing datasets

With this limitation in mind, BLiMP (Benchmark of Linguistic Minimal Pairs; Warstadt et al.,

2020) is developed, which includes 67 datasets automatically generated from grammar templates created by linguists. These 67 datasets are grouped into 12 categories based on linguistic phenomenon, each containing 1,000 minimal pairs. Note that each pair has one acceptable sentence and one unacceptable sentence. Importantly, this dataset has overcome an aforementioned problem, because sentences are not presented as binary classification problems, but as minimal pairs: the evaluation can be readily performed by comparing the probabilities of an acceptable sentence and an unacceptable sentence. Nevertheless, BLiMP also has its limitation to overcome. Namely, since minimal pairs are automatically generated with template grammars and vocabularies, BLiMP doesn't necessarily cover complex and important linguistic phenomena (cf. Class III judgement, see [Marantz 2005](#); [Linzen and Oseki 2018](#)), compared to those datasets which are created by extracting sentences from linguistics journals.

There is also a general problem with the datasets for targeted syntactic evaluations of language models as a whole: imbalance in target languages and linguistic phenomena (cf. Table 1). In fact, most of the existing datasets have focused on English. Although some studies have extended the scope of their research to other languages ([Gulordava et al., 2018](#); [An et al., 2019](#); [Ravfogel et al., 2018](#); [Mueller et al., 2020](#)), only few studies have covered a wide range of syntactic phenomena and focused on languages other than English ([Xiang et al., 2021](#); [Trotta et al., 2021](#)).

3 JBLiMP

In order to overcome all the limitations mentioned above, we introduce JBLiMP (Japanese Benchmark of Linguistic Minimal Pairs), a novel dataset for targeted syntactic evaluations of language models in Japanese. JBLiMP is unique in that it successfully combines two important features independently observed in existing datasets (Table 2): (i) coverage of complex linguistic phenomena (cf. CoLA; [Warstadt et al., 2019](#)) and (ii) presentation of sentences as minimal pairs (cf. BLiMP; [Warstadt et al., 2020](#)). In addition, JBLiMP is the first dataset for targeted syntactic evaluations of language models in Japanese, thus alleviating the imbalance in target languages and allowing the comparison of syntactic knowledge of language models across different languages.

3.1 Data Collection

JBLiMP consists of acceptability judgments from journal articles on Japanese syntax published in JEAL (Journal of East Asian Linguistics): one of the prestigious journals in theoretical linguistics. Specifically, we examined all the articles published in JEAL between 2006 and 2015 (133 papers in total), and extracted 2,323 acceptability judgments from 28 papers on Japanese syntax (cf. Table 3). Acceptability judgments include sentences in appendices and footnotes, but not sentences presented for analyses of syntactic structures (e.g. sentences with brackets to show their syntactic structures).

3.2 Categorization by linguistic phenomenon

We categorized the extracted sentences into different groups to enable detailed analyses of results by linguistic phenomenon. The categorization mostly followed that of BLiMP ([Warstadt et al., 2020](#)) and was conducted at three levels of granularity: type, phenomenon and paradigm.

3.2.1 Type

First, the extracted sentences were categorized based on the type of acceptability judgements and how those sentences were presented in the articles. This level of categorization has 8 different types. These categories are mutually exclusive, meaning that no further typing is done for sentences in footnotes or appendices.

Acceptability: acceptability judgements that do not depend on a specific context or interpretation.

Interpretation: acceptability judgements that depend on a specific context or interpretation.

Coreference: acceptability judgements that depend on a specific interpretation of coreference.

Lexical: acceptability judgements that depend on a specific lexical item.

Footnote: acceptability judgements presented in footnotes.

Appendix: acceptability judgements presented in appendices.

Repeat: acceptability judgements repeated by the authors.

Variation: acceptability judgements that only differ in unimportant elements for theory construction. For example, (2b) below is categorized into

variation because the difference between *da* ‘is’ and *desu*, a polite form of ‘is’, is not relevant for theory construction.

- (2) a. Taro-ga atta no-wa Hanako-ni da
Taro-Nom saw that-Top Hanako-Dat is
‘It was Hanako that Taroo saw.’
- b. Taro-ga atta no-wa Hanako-ni desu
Taro-Nom saw that-Top Hanako-Dat is
‘It was Hanako that Taroo saw.’

Source	# Sentences
Takahashi (2006)	60

Total	2,323

Table 3: Number of extracted sentences by source

3.2.2 Phenomenon

Second, the extracted sentences were further categorized based on linguistic phenomena. Phenomenon basically corresponds to that in BLiMP, but some modifications were applied to make the categorization more suitable for Japanese.

Argument Structure: acceptability judgements based on the order of arguments and case marking.

- (3) a. Taroo-ga Hanako-**ni** au.
Taroo-Nom Hanako-Dat see.
‘Taroo sees Hanako.’

- b. *Taroo-ga Hanako-**o** au.
Taroo-Nom Hanako-Acc see.
‘Taroo sees Hanako.’

Binding: acceptability judgements based on the binding of noun phrases. For instance, this includes the coreference resolution of anaphors.

- (4) a. Hazimete **soitu-ni** atta
for-the-first-time him-Dat saw
hito-ga **Taroo-o** kenasita
person-Nom Taroo-Acc criticized
‘The person who saw him for the first time criticized Taroo.’
- b. *Hazimete **soitu-ni** atta
for-the-first-time him-Dat saw
hito-ga **daremo-o** kenasita
person-Nom everyone-Acc criticized
‘The person who saw him for the first time criticized everyone.’

Control/Raising: acceptability judgements based on predicates that are categorized as control or raising.

- (5) a. **Taroo-ga** korobi sokoneta.
tumbler.doll-Nom tumble failed.
‘Taroo failed to tumble.’
- b. ***Daruma-ga** korobi sokoneta.
tumbler.doll-Nom tumble failed.
‘Tumbler doll failed to tumble.’

Ellipsis: acceptability judgements based on the possibility of omitting elements in the sentences. For instance, this includes nominal and verbal ellipsis.

- (6) a. Hare-no-hi-ha yoi ga
clear-NO-day-Top good though
ame-no-hi-ha otikomu.
rain-NO-day-Top feel.depressed.
‘Clear days are OK, but I feel depressed on rainy days.’
- b. *Hare-no-hi-ha yoi ga
clear-NO-day-Top good though
ame-no-ha otikomu.
rain-NO-Top feel.depressed.
‘Clear days are OK, but I feel depressed on rainy days.’

Filler-gap: acceptability judgements based on the dependency between the moved element and the gap. For instance, this includes wh-movements and cleft sentences.

- (7) a. **Nani-o daremo** yom-ana-katta-no.
What-Acc anyone read-neg-past-Q.
'What did no one read?'
- b. ***Daremo nani-o** yom-ana-katta-no.
anyone What-Acc read-neg-past-Q.
'What did no one read?'

Island effects: acceptability judgements based on the restrictions on filler-gap dependencies such as wh-movements.

- (8) a. Taroo-ha Hanako-ga naze kare-no
Taroo-Top Hanako-Nom why he-Gen
tegami-o suteta **to** omotteiru no.
letter-Acc discarded C think Q
'Why is Taro angry because Hanako
discarded his letters?'
- b. *Taroo-ha Hanako-ga naze kare-no
Taroo-Top Hanako-Nom why he-Gen
tegami-o suteta **kara** okotteiru
letter-Acc discarded because be.angry
no.
Q
'Why is Taro angry because Hanako
discarded his letters?'

Morphology: acceptability judgements based on the morphology. BLiMP has irregular forms category for the conjugation of past tenses, but we adopted this category instead to incorporate minimal pairs on morphology in general.

- (9) a. sore-wa keesoku
that-Top measurement
kanoo-**na** ryuusi-da
possibility-Cop.Adnom particle-Cop
'That is a measurable particle'
- b. *sore-wa keesoku
that-Top measurement
kanoo-**da** ryuusi-da
possibility-Cop.Fin particle-Cop
'That is a measurable particle'

Nominal Structure: acceptability judgements based on the internal structure of noun phrases. BLiMP has determiner-noun agreement category, but we adopted this category instead, because Japanese doesn't have explicit determiner-noun agreements.

- (10) a. Watashi-ga kinoo **mita hito-wa**
I-Nom yesterday saw person-Top
suteki datta
beautiful was
'The person I saw yesterday was beautiful'
- b. *Watashi-ga kinoo **mita no**
I-Nom yesterday saw *no*
hito-wa suteki datta
person-Top beautiful was
'The person I saw yesterday was beautiful'

NPI Licensing: acceptability judgements based on the restrictions on where negative polarity items (NPIs) can appear. For instance, NPIs include *nani-mo*, a Japanese counterpart of 'any'.

- (11) a. *John-ga moshi **nani-ka**
John-Nom if something
nusun-dara, taihos-areru daroo.
steal-COND arrest-PASS be.will
'If John steals anything, he will be arrested.'
- b. *John-ga moshi **nani-mo**
John-Nom if what-MO
nusun-dara, taihos-areru daroo.
steal-COND arrest-PASS be.will
'If John steals anything, he will be arrested.'

Quantifiers: acceptability judgements based on the distribution of quantifiers such as floating quantifiers.

- (12) a. Taroo-ga tomodati-ni **huta-ri** CD-o
Taroo-Nom friend-Dat 2-CL CD-Acc
okutta.
sent.
'Taro sent two friends a package.'
- b. *Taroo-ga CD-o tomodati-ni **huta-ri**
Taroo-Nom CD-Acc friend-Dat 2-CL
okutta.
sent.
'Taro sent two friends a package.'

Verbal Agreement: acceptability judgements based on the dependency between subjects and verbs. Japanese doesn't have the same kind of subject-verb agreement as in English. Instead, this includes the linguistic phenomena such as subject honorification where the social status of subjects are reflected in the morphology of verbs.

- (13) a. **Ito-sensei-ga** Mary-o
 Ito-teacher-Nom Mary-Acc
o-home-ni-nat-ta
 Hon-praise-Lv-Past
 'Prof. Ito praised Mary.'
- b. ***Watashi-ga** Mary-o
 I-Nom Mary-Acc
o-home-ni-nat-ta
 Hon-praise-Lv-Past
 'I praised Mary.'

3.2.3 Paradigm

Finally, the extracted sentences are further categorized into 39 more fine-grained types named paradigm. Paradigm also corresponds to that in BLiMP and is basically sub-categorization of phenomenon.

3.3 Minimal pairs

For direct evaluation of language models through the probabilities assigned by these language models, we created minimal pairs using the sentences categorized above. First, we selected all the sentences that satisfy the following conditions:

- The sentences are presented as unacceptable examples (marked with '?' or '*'), for example). Exceptions are those sentences that are presented as acceptable examples, but marked with '?' or '%'.
- Type is not one of variation, repeat, footnote or appendix.
- The sentences are grouped into one of the 11 phenomena.

We deduplicated the selected unacceptable examples and removed those unacceptable examples whose (un)acceptability depends on the context. Second, since we are concerned with sentence-level acceptability judgements, we augmented incomplete sentences, replacing, for example, (14a) with (14b).

Phenomenon	# Minimal pairs
ARGUMENT STRUCTURE	140
VERBAL AGREEMENT	61
MORPHOLOGY	35
NOMINAL STRUCTURE	23
ELLIPSIS	19
QUANTIFIERS	14
BINDING	13
ISLAND EFFECTS	11
FILLER-GAP	9
NPI LICENSING	4
CONTROL/RAISING	2
Total	331

Table 4: Number of minimal pairs by phenomenon

- (14) a. *Sono futari gakusei
 that two-CL student
 'those two students'
- b. *Taroo-ha sono futari gakusei-ni atta
 Taroo-Top that two-CL student-Dat saw
 'Taroo saw those two students.'

Finally, we created minimal pairs based on the selected unacceptable sentences, on the assumption that all the unacceptable sentences for theory construction generally have their acceptable counterparts to demonstrate the contrasts in acceptability (Sprouse et al., 2013). Specifically, for each unacceptable example, we either found an appropriate acceptable example from the extracted sentences, or created a corresponding acceptable example. When creating acceptable sentences, we read the relevant papers to understand the authors' intent to present the corresponding unacceptable sentences.

3.4 Data Validation

In order to validate the quality of minimal pairs in JBLiMP, we conducted an acceptability judgement experiment with Lancers, a Japanese crowdsourcing platform.² For each minimal pair, 15 native speakers of Japanese completed a forced-choice task which reflects the evaluation procedure of language models. Specifically, annotators are asked to select the more grammatical of the two sentences, following the experimental design in Sprouse et al. (2013). To minimize the burden on annotators, we split 367 minimal pairs into 16 different groups:

²<https://www.lancers.jp>

15 groups of 23 minimal pairs and 1 group of 22 minimal pairs. Each annotator completes 22 or 23 acceptability judgements and is compensated 150 yen (\simeq \$ 1.2). The order of minimal pairs and the vertical order of acceptable and unacceptable examples within a minimal pair was randomized. Majority vote is taken to determine human-annotated acceptable sentences. For each minimal pair, if the annotation of JBLiMP and the majority vote of human annotations do not match, that minimal pair is removed from JBLiMP. In this way, 36 minimal pairs were removed, resulting in 331 minimal pairs in total (Table 4). In addition, we calculated human baseline accuracy, dividing the number of human annotations that match JBLiMP’s judgements by the total number of annotations. As a result, the human baseline accuracy was 90.90% as reported in Table 5.

4 Experiment

4.1 Models

In this paper, we evaluate language models trained by Kuribayashi et al. (2021) with JBLiMP.

GPT-2 GPT-2 (Radford et al., 2019) is one of the large-scale language models based on Transformer architectures (Vaswani et al., 2017). We evaluate two different sizes of GPT-2 models (Trans-LG, Trans-SM). Trans-LG has 24 layers, 16 attention heads, and 1024 embedding dimensions. Trans-SM has 8 layers, 6 attention heads, and 384 embedding dimensions.

LSTM LSTM (Hochreiter and Schmidhuber, 1997) is a language model based on RNN architectures (Elman, 1990), which is known to achieve a better language modeling performance than vanilla RNN language models (Sundermeyer et al., 2012). We evaluate a 2-layer LSTM language model with 1024 hidden layer dimensions and 400 embedding dimensions.

***n*-gram** We also evaluate a 5-gram language model as a baseline. This model is implemented by KenLM (Heafield et al., 2013).

Training settings (Kuribayashi et al., 2021) Training data was approximately 5M sentences extracted from news and Japanese Wikipedia. Each sentence in training data was first segmented by MeCab and then segmented into subwords by

BPE (Byte-Pair Encoding).³ All the neural language models (Trans-LG, Trans-SM and LSTM) were trained with the data of three different sizes: LG (full training data), MD (1/10 training data), SM (1/100 training data). These language models were trained with three different random seeds, and saved at four different points in the training: 100, 1,000, 10,000, 100,000 training steps.

4.2 Evaluation metrics

The probability assigned to a sentence can be mapped into acceptability judgements in multiple ways (Lau et al., 2017). In this work, we employ SLOR (Lau et al., 2017) as a mapping function, which mitigates the confounding effects of sentence lengths and lexical frequencies. SLOR score for a sentence X is defined as follows:

$$SLOR(X) = \frac{\log p_m(X) - \log p_u(X)}{|X|}$$

where $p_m(X)$ is the probability of a sentence given by a language model, and $p_u(X) = \prod_{w \in X} p_u(w)$ is the unigram probability of a sentence. Unigram probabilities are estimated via maximum likelihood estimation for each subword in the training corpus. For each minimal pair, we examine whether language models assign a higher probability/acceptability to an acceptable sentence than an unacceptable one.

5 Results and Discussion

5.1 Overall accuracy

Overall accuracy of each language model on JBLiMP is reported in Table 5. While Trans-LG achieves the best accuracy of 77.95%, all the models notably achieve the comparable accuracy and fall short of human accuracy by a wide margin, which may suggest that language models can’t necessarily recognize complex linguistic phenomena.

5.2 Accuracy by linguistic phenomenon

For each language model, we calculate accuracy by linguistic phenomenon on JBLiMP, as reported in Table 5. Analysis by linguistic phenomenon reveals that the performance of language models drastically differs depending on linguistic phenomenon. Language models achieve a relatively high accuracy on

³Vocabulary size was set to 100,000 and character coverage to 0.9995. Implementation by SentencePiece (Kudo and Richardson, 2018) was employed.

Model	Overall	Argument Structure	Verbal Agr.	Morph.	Nominal Structure	Ellipsis	Quant.	Binding	Island Effects	Filer Gap	NPI Licensing	Control Raising
Trans-LG	77.95	89.05	53.55	82.86	95.65	85.96	73.81	58.97	75.76	55.56	50.00	<u>16.67</u>
Trans-SM	76.54	89.05	44.26	82.86	97.10	89.47	71.43	46.15	84.85	55.56	75.00	<u>0.00</u>
LSTM	75.73	86.67	46.99	83.81	95.65	91.23	66.67	<u>41.03</u>	87.88	44.44	66.67	50.00
5-gram	74.02	78.57	57.38	82.86	86.96	89.47	78.57	53.85	72.73	66.67	<u>50.00</u>	0.00
Human	90.90	92.19	89.62	94.86	97.68	87.37	85.71	82.05	92.12	78.52	90.00	<u>70.00</u>
Model Ave.	76.06	85.76	50.55	83.10	93.84	89.03	72.62	50.00	80.31	55.56	60.42	<u>16.67</u>

Table 5: Accuracy of each language model and human by phenomenon. Accuracy is averaged over 3 different random seeds except 5-gram and human. All the language models are trained for 100,000 steps on full training corpus (LG). The number in bold indicates the best score within a model, while the number with underscore indicates the worst score.

phenomena like nominal structure. This phenomenon includes minimal pairs with relatively local dependencies, as exemplified in (15).

(15) Nominal structure

- a. **Watashi-ga** kinoo **mita hito-wa**
 I-Nom yesterday saw person-Top
 suteki datta
 beautiful was
 ‘The person I saw yesterday was beautiful’
- b. ***Watashi-ga** kinoo **mita no**
 I-Nom yesterday saw *no*
hito-wa suteki datta
 person-Top beautiful was
 ‘The person I saw yesterday was beautiful’

In sharp contrast, language models suffer a sharp drop in accuracy on linguistic phenomena such as verbal agreement and binding. (Here, control/raising is taken out of consideration because its data size is small compared to the other phenomena.) These phenomena generally involve relatively long dependencies: verbal agreement involves dependency between the subject and the verb of the sentence as exemplified in (16), while binding involves dependency between anaphors and their antecedents as illustrated in (17).

(16) Verbal agreement

- a. **Ito-sensei-ga** Mary-o
 Ito-teacher-Nom Mary-Acc
o-home-ni-nat-ta
 Hon-praise-Lv-Past
 ‘Prof. Ito praised Mary.’

Lower accuracy in these kinds of minimal pairs suggests that language models are less sensitive to long-distance dependencies. These results are compatible with the previous results that RNN-based language models cannot capture long-distance dependencies without explicit supervision (Linzen et al., 2016), but are not necessarily consistent with the results that Transformer-based language models can successfully capture long-distance dependencies (Goldberg, 2019).

5.3 Human confidence and model confidence

Figure 1 shows the relationship between model confidence and human confidence. Each model’s confidence on a minimal pair is defined as the difference of the SLOR scores between the acceptable and unacceptable sentence: $SLOR(X_{pos}) - SLOR(X_{neg})$ where X_{pos} is an acceptable sentence and X_{neg} is an unacceptable sentence. Human confidence on a minimal pair is defined as the number of annotators who had the same annotation as the JBLiMP. While the language models are able to make predictions with relatively high confidence for sentences with high human confidence, the confidence of the language models is low for sentences with low human confidence, i.e., for which there

are fluctuations in acceptability judgments among humans. Furthermore, many of the language models have negative confidence for the sentences with low human confidence. These results may suggest that language models have successfully captured the gradience in human acceptability judgements, whose existence was suggested in Lau et al. (2017).

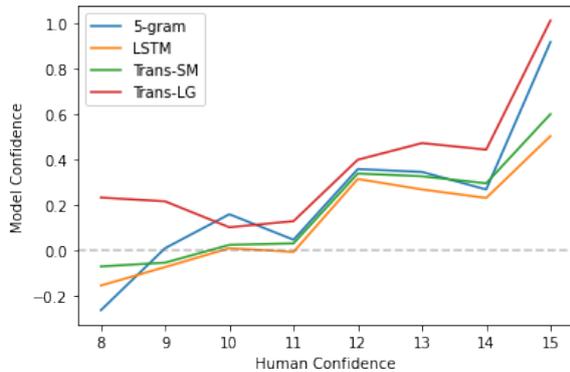

Figure 1: The relationship between model confidence and human confidence. All the neural language models are trained for 100,000 steps on full training corpus (LG).

5.4 Effects of perplexity on accuracy

We investigate the relationship between the perplexity, which is widely used as an evaluation metric of language models’ performance, and the accuracy on JBLiMP for each language model. The perplexity is calculated on the validation data in Kuribayashi et al. (2021). Figure 2 shows the language models’ accuracy on JBLiMP as a function of perplexity. In contrast to the results in Kuribayashi et al. (2021) that lower perplexity does not necessarily ensure better psychometric predictive power of language models, our results suggest that language models with lower perplexity will generally achieve better syntactic performance. Note incidentally that language models with particularly high perplexity ($> 3 \times 10^4$), represented as the points to the right of the black dashed line in Figure 2, are trained for more than 10,000 steps with relatively small data (SD or MD). These language models seem to be overfitted to the training data, and thus were taken out of consideration in this discussion.

6 Conclusion

In this paper, we introduced JBLiMP (Japanese Benchmark of Linguistic Minimal Pairs), a novel dataset for targeted syntactic evaluations of language models in Japanese. JBLiMP consists of

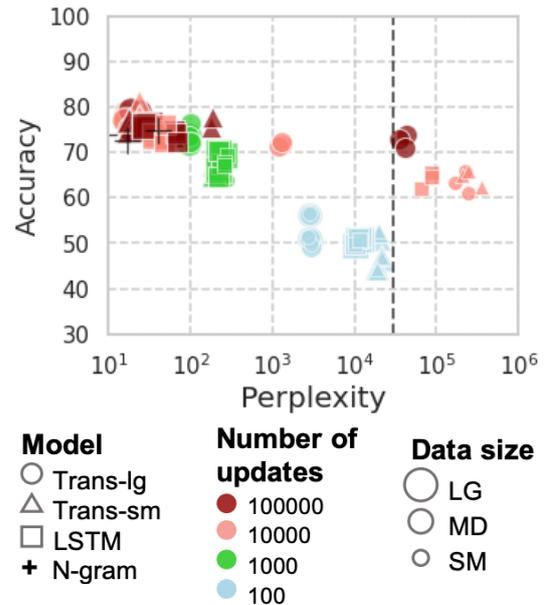

Figure 2: Models’ accuracy on JBLiMP as a function of perplexity. The perplexity is calculated on the validation data in Kuribayashi et al. (2021). The vertical dashed line in black indicates the perplexity of 3×10^4 .

331 minimal pairs, which are created based on acceptability judgments extracted from journal articles in theoretical linguistics. These minimal pairs are grouped into 11 categories, each covering a different linguistic phenomenon. JBLiMP is unique in that it successfully combines two important features independently observed in existing datasets: (i) coverage of complex linguistic phenomena (cf. CoLA) and (ii) presentation of sentences as minimal pairs (cf. BLiMP). In addition, JBLiMP is the first dataset for targeted syntactic evaluations of language models in Japanese, thus allowing the comparison of syntactic knowledge of language models across different languages. We then evaluated the syntactic knowledge of several language models: GPT-2, LSTM and n -gram language models. The results demonstrated that all the architectures achieved comparable overall accuracies around 75%. Error analyses by linguistic phenomenon further revealed that these language models successfully captured local dependencies like nominal structures, but not long-distance dependencies such as verbal agreement and binding. Finally, these detailed analyses of language models’ knowledge on complex linguistic phenomena using minimal pairs are only possible with the unique design of JBLiMP. This paper will hopefully encourage the development of the datasets with JBLiMP’s two important features in other languages.

Limitations

All the example sentences in JBLiMP were manually transcribed from linguistic journals. While this method of data collection has enabled it to cover complex linguistic phenomena, it also made it difficult to increase the size of the dataset. Additionally, the quantity of minimal pairs on a specific linguistic phenomenon is directly influenced by how often that phenomenon is discussed in linguistic journals, hence the imbalanced distribution of minimal pairs across different linguistic phenomena in JBLiMP. These problems could be overcome by collecting additional examples from linguists (if possible, the authors of the source linguistic journals in JBLiMP).

SMATCH++: Standardized and Extended Evaluation of Semantic Graphs

Juri Opitz

Heidelberg University

opitz.sci@gmail.com

Abstract

The SMATCH metric is a popular method for evaluating graph distances, as is necessary, for instance, to assess the performance of semantic graph parsing systems. However, we observe some issues in the metric that jeopardize meaningful evaluation. E.g., opaque pre-processing choices can affect results, and current graph-alignment solvers do not provide us with upper-bounds. Without upper-bounds, however, fair evaluation is not guaranteed. Furthermore, adaptations of SMATCH for extended tasks (e.g., fine-grained semantic similarity) are spread out, and lack a unifying framework.

For better inspection, we divide the metric into three modules: pre-processing, alignment, and scoring. Examining each module, we specify its goals and diagnose potential issues, for which we discuss and test mitigation strategies. For pre-processing, we show how to fully conform to annotation guidelines that allow structurally deviating but valid graphs. For safer and enhanced alignment, we show the feasibility of optimal alignment in a standard evaluation setup, and develop a lossless graph compression method that shrinks the search space and significantly increases efficiency. For improved scoring, we propose standardized and extended metric calculation of fine-grained sub-graph meaning aspects. Our code is available at <https://github.com/flipz357/smatchpp>

1 Introduction

Semantic graphs such as meaning representations (MRs) aim at capturing the meaning of a text. Typically, these graphs are rooted, directed, acyclic, and labeled. Vertices denote semantic entities, and edges represent semantic relations (e.g., *instrument*, *cause*, etc.). A prominent MR framework is *Abstract Meaning Representation (AMR)*, proposed by Banarescu et al. (2013), which anchors in a propositional knowledge base (Palmer et al., 2005).

Using a metric such as SMATCH (Cai and Knight, 2013), we can measure a distance (or similarity) between graphs, by aligning nodes, and counting matching graph triples. In fact, SMATCH measurement has various applications. It is used for selecting parsing systems that project AMR structures (Flanigan et al., 2014; May and Priyadarshi, 2017; Xu et al., 2020; Hoang et al., 2021a; Bevilacqua et al., 2021) and various other semantic graphs (van Noord et al., 2018; Zhang et al., 2018; Oepen et al., 2020; Stengel-Eskin et al., 2020; Martínez Lorenzo et al., 2022; Lin et al., 2022), for MR-based evaluation and diagnostics of text generation systems (Opitz and Frank, 2021; Manning and Schneider, 2021; Ribeiro et al., 2021; Hoyle et al., 2021), as backbone in an ensemble parsing algorithm (Hoang et al., 2021b), and for studying cross-lingual phenomena (Uhrig et al., 2021; Wein et al., 2022). Through SMATCH measured on sub-graphs, we can assess similarity of linguistic phenomena such as semantic roles, negation, or coreference (Damonte et al., 2017), a property that can be leveraged in neural text embeddings (Opitz and Frank, 2022b).

However, SMATCH measurement is non-trivial and lacks specification. For instance, SMATCH involves an NP-hard *optimization problem* of structural *graph alignment*, which distinguishes it from most metrics used in other evaluation tasks. In practice, a solution of this problem is found by employing a hill-climber. However, a hill-climber terminates at local optima, and it cannot inform us about a score upper-bound. In the end, this means that we lack information about the quality of the returned solution, potentially lowering our trust in the final evaluation. To mitigate this issue, we would like to study the possibility of optimal solution, or solution with a tight upper-bound. There are also other issues, on which we lack understanding. E.g., we do not know to what extent different pre-processing choices may affect the evaluation results, and we miss specification of SMATCH’s

popular fine grained sub-graph metrics (Damonte et al., 2017), where it is unclear how sub-graphs should be best extracted and compared.

Paper structure and contributions First, we describe and generalize the SMATCH metric (§3), and summarize recent SMATCH variants in one framework. Then we break the metric down into three modules (§4), which lets us better distribute our attention over its key components. For each module, we discuss specification of goals and mitigation of issues. In the pre-processing module (§5), we motivate graph standardization to allow safer matching of equivalent MR graphs with different structural choices. In the optimization module (§6), we test strategies for solving the alignment problem with optimality guarantees. In the scoring module (§7), we discuss standardized and extended scoring of fine-grained semantic aspects, such as causality, tense, and location.

2 Related work

Metric standardization An inspiration for us is the work of Post (2018), who propose the popular SACREBLEU framework for fairer comparison of machine translation systems with a standardized BLEU metric (Papineni et al., 2002). Specifically, SACREBLEU ships BLEU *together with* a specified tokenizer – prior to this, BLEU differences between systems could depend on different tokenization protocols. Facing the challenging problem of graph evaluation, a main contribution of our work is that we i) analyze weak spots in the current evaluation setup and ii) discuss ways of mitigating these issues, aiming at best evaluation practices.

MR metrics Cai and Lam (2019) introduce a variant of SMATCH (Cai and Knight, 2013) that penalizes dissimilar structures if they are situated in proximity of the graph root, motivated by their assumption that ‘core-semantics’ are located near the root of MR graphs. Furthermore, Opitz et al. (2020) introduce a SMATCH variant that performs a graded match of semantic concepts (e.g., *cat* vs. *kitten*), aiming at extended use-cases beyond parsing evaluation, where MRs of different sentences need to be compared. Similarly, Wein and Schneider (2022) adapt an embedding-based variant of SMATCH for cross-lingual MR comparison. We show that the different SMATCH adaptations can be viewed through the same lens with a generalized notion of triple match. Furthermore, Damonte et al.

(2017) propose fine-grained SMATCH that measure MR agreement in different aspects, such as *semantic roles*, *coreference* or *polarity*. We diagnose and mitigate issues in the aspectual assessment, and show how to extend the measured aspects.

Conceptually different MR metrics have been proposed by Anchieta et al. (2019) and Song and Gildea (2019) who aim at increased efficiency using structure extraction via breadth-first traversals, or Opitz et al. (2021) who compare MRs of different sentences with Wasserstein Weisfeiler-Leman kernels (Weisfeiler and Leman, 1968; Togninalli et al., 2019). Since significant parts of this paper are independent from SMATCH-specific scoring¹, other MR metrics can profit from our work.

3 SMATCH: Overview and generalization

We introduce SMATCH and define a generalized SMATCH, so that we can summarize recent SMATCH variants in one framework.

Preliminary I: MR graph If not mentioned otherwise, we view an MR graph a as a set of triples, where a triple has one of two types. Unary triples have the structure $\langle x, :rel, c \rangle$, where the source x is a variable and the target c is a descriptive label that shows the type or an attribute of x , depending on the edge label $:rel$.² Using variables such as x we can (co-)refer to different events and entities and capture complex events. Binary triples have the structure $\langle x, :rel, y \rangle$, where both the source x and the target y are variables.³

Preliminary II: SMATCH The idea of SMATCH is to measure structural similarity of graphs via the amount of triples that are shared by a and b . To obtain a meaningful score, we must know an alignment $map: vars(a) \leftrightarrow vars(b)$ that tells us how to map a variable in the first MR to a variable in the second MR. In this alignment, every variable from a can have at maximum one partner in b (and vice versa). Let an application of a map to a graph a be denoted as $a^{map} := \{t^{map} ; t \in a\}$, where t^{map} of a triple $t = \langle x, :rel, y \rangle$ is set to $t^{map} = \langle map(x), :rel, map(y) \rangle$ for binary triples, and $t^{map} = \langle map(x), :rel, c \rangle$

¹E.g., input standardization (§5) and sub-graph extraction for fine-grained aspectual matching (§7.3).

²E.g., $\langle x, :instance, cat \rangle$ would indicate that ‘ x is a cat’, while $\langle y, :polarity, - \rangle$ means y is negated.

³E.g., $\langle x, :location, y \rangle$, which means that x is located at y , or $\langle x, :arg0, y \rangle$ which usually indicates that y participates as the agent in the event referred to by x .

for unary triples.

Under any alignment map , we can calculate an overlap score f . In original SMATCH, f is the size of the triple overlap of a and b :

$$f(a, b, map) = |a^{map} \cap b|. \quad (1)$$

Ultimately we are interested in

$$F = \max_{map} f(a, b, map), \quad (2)$$

Finding a maximizer map^* lies at the heart of SMATCH, and we will dedicate ourselves to it later in §6. For now, we assume that we have map^* at our disposal. Therefore, we can calculate *precision* (P) and *recall* (R):

$$P = |a|^{-1}F, \quad R = |b|^{-1}F, \quad (3)$$

to obtain a final F1 evaluation score: $2PR/(P + R)$. With such a score, we can assess the similarity of MRs, and compare and select parsing systems.

Generalizing SMATCH In SMATCH, two triples are said to match if they are identical under a mapping. I.e., we match with $match(t, t') := I[t = t']$ that returns 1 if two triples t and t' are the same, and zero else (we omit the map for simplicity). Recently, SMATCH has been adapted and tailored to different use-cases. E.g., SMATCH has been extended to incorporate word embeddings (Opitz et al., 2020; Wein and Schneider, 2022) to match $\langle x, :instance, c \rangle$ triples for studying cross-lingual MRs or MRs of different sentences.⁴ On the other hand, Cai and Lam (2019) propose a root-distance bias, based on the assumption that ‘core-semantics’ lie in the proximity of an MR’s root.

We find that we can summarize such variants in one framework. We achieve this by introducing a *scaled triple matching* function:

$$match(t, t') = w_t^{t'} \cdot \begin{cases} I[t = t'], & \text{if } t_2, t'_2 \neq :inst. \\ I[t_1 = t'_1] \cdot sim(t_3, t'_3) & \text{else} \end{cases}$$

For matching concepts with embeddings, we can use an embedding similarity on the descriptive concept labels with $sim(c, c')$ and the importance

⁴Consider $\langle x, :instance, cat \rangle$ extracted from one sentence vs. $\langle y, :instance, kitten \rangle$ extracted from another sentence. A graded match is required to properly assess the similarity of the concepts.

“(d / dog :location (h / house))”

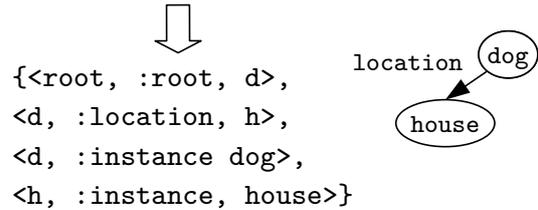

Figure 1: A serialized MR string is read into a graph.

weight $w_t^{t'} = 1 \forall t, t'$.⁵ For Root-distance biased SMATCH as proposed by Cai and Lam (2019) we set $w_t^{t'}$ such that we discount triple matches that are distant to the root.⁶

Our generalization does not change or constrain the original SMATCH. Instead, our goal was to define a more general framework of SMATCH-type metrics that unifies recently proposed SMATCH variants and show possibilities for further extension. For the following studies, we set SMATCH++ to basic SMATCH, which is recovered by setting $\forall t, t' : w_t^{t'} = 1$ and $sim(c, c') := I[c = c']$.

4 A modular view on SMATCH

To set the stage for inspection, we break SMATCH down into three modules. i) *Preprocessing*, ii) *Alignment*, and iii) *Scoring*. In particular, i) *Preprocessing* discusses any graph reading and processing in advance of the alignment. ii) *Alignment* revolves around the search mechanism used for finding an optimal mapping map^* . iii) *Scoring* involves calculating final scores and statistics that are returned to a user. For each module, we will specify its goals, assess potential weak spots and discuss mitigation.

5 Module I: Pre-processing

5.1 Module goal and current implementation

MRs are typically stored and distributed in a ‘Penman’ string format, which can serialize any rooted and directed graph into a string. The goal of this module is to project two serialized textual MRs onto two sets of triples, as outlined in Figure 1.

The target domain of this projection should be a *standardized* MR graph space, where format divergences that do not impact graph seman-

⁵That is, if the triples are not instance triples, we check whether the triples are equivalent (as in standard SMATCH), but if both triples are instance relation triples and the variables t_1, t'_1 are set to equal each other, we calculate the similarity between their descriptive concept labels.

⁶For a properly normalized final score if $\exists (t, t'), w_t^{t'} \neq 1$, we may have to change denominators in Eq. 3

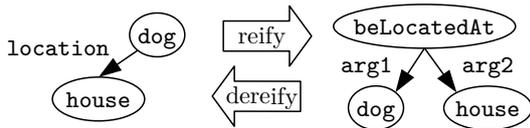

Figure 2: Outline of *location*-reification.

tics are eliminated. Original SMATCH performs pre-processing as follows: i) lower-case strings, ii) de-invert edges (e.g., $\langle x, :relation-of, y \rangle \rightarrow \langle y, :relation, x \rangle$). However, while these steps seem sensible, more steps can be undertaken to enhance evaluation.

5.2 Two structures, one meaning: reification

Some MR guidelines, including the AMR guideline, allow meaning-preserving structural graph translations (Banarescu et al., 2019; Goodman, 2019) with so called *reifications* (or *de-reification* as an inverse mechanism). A subset of relations is selected to constitute a semantic relation core set (e.g., $:arg0, :arg1, \dots, :op1, :op2, \dots$) and for all other remaining relations (e.g., $:location, :time$), we use rules to map the relation to a sub-graph, where the rule-triggering relation label is projected onto a node, and the former source and target of the relation are attached with outgoing core relations. E.g., consider Figure 2, where a reification is applied to a $\langle x, :location, y \rangle$ relation. In this case, the rule is:

- location (de)reification:

$$\begin{aligned} &\langle x, :location, y \rangle \\ &\iff \\ &\langle z, :instance, beLocatedAt \rangle \\ &\wedge \langle z, :arg1, x \rangle \\ &\wedge \langle z, :arg2, y \rangle, \end{aligned}$$

where $:arg1$ indicates the thing that is found at a location $:arg2$.

The question whether an annotator should use either means of representation, is answered in the guidelines as follows: *whenever they feel like it* (Banarescu et al., 2019). Therefore, a parser should not be penalized or rewarded for projecting reified (or non-reified) structures.

Empirical assessment of effect To understand the effect that reification can have on the final SMATCH score, it is interesting to study an edge-case: evaluating graphs that are fully reified against graphs that are fully de-reified. As a data set we take LDC2017T10, a standard AMR benchmark.

	Data setup		SMATCH	
	X	Y	Orig	rlyStd
i)	gold dereify	gold reify	73.8	100.0
ii)	gold standard	gold reify	73.9	100.0
iii)	gold standard	gold dereify	100.0	100.0
iv)	parser dereify	gold reify	60.9	82.8
v)	parser reify	gold reify	82.8	82.8
vi)	parser dereify	gold dereify	81.4	82.8
vii)	parser standard	gold standard	81.4	82.8
viii)	parser standard	gold reify	60.9	82.8
ix)	parser standard	gold dereify	81.4	82.8

Table 1: Results of meaning-preserving translations. rlyStd: score when we project X and Y into standardized reified space.

Additionally, we gather automatic parses by applying an AMR parser (Xu et al., 2020).

The results of this experiment are shown in Table 1. In the first three lines (i-iii) we compare *equivalent* translated versions of the test partition (gold vs. gold). We find that two equivalent gold standards can be judged to be very different (73.9 points, -26.1 points). A similar phenomenon can be observed when looking at the parses. The best parser score is achieved when comparing parses and references in the domain of reified graphs (82.8 points). On the other hand, if only the reference is reified, the parser score drops by 20 points (viii).

However, we also see that the results of a basic evaluation (vii) is practically the same as the result when evaluating with de-reified graphs (vi), indicating that both parser and gold annotation abstain from reification, where possible.

Discussion Having established that rule-based graph translations can enhance evaluation fairness, we pose the question: *should we prefer reification or de-reification for space standardization?*

The answer should be *reification*, since it can be seen as a form of generalization. More precisely, we note that reification of non-core relations is *always* possible. In fact, an interesting effect of reified structures is that they equip us with the means to attach further structure, or features, to semantic relations. On the other hand, however, de-reification is not always possible. It is only well-defined if there is no incoming edge into the node that corresponds to the non-core relation⁷, and if

⁷It is not clear to which node the incoming edge (that now does not have a target) should be re-attached: the $arg0$ or $arg1$ of the outgoing edges of the former node? Either choice would likely come with a change in meaning.

there are not more than two outgoing edges⁸.

However, there are also (practical) arguments against reification. Consider that de/non-reified MRs are smaller and have more edge label differentiation. This i) may facilitate more intuitive display for humans and ii) shrinks the alignment search space. Indeed, a large solution space may have ramifications for evaluation optimality and efficiency (in §6, we empirically study this issue). Therefore, when taking into account that the empirical effect size appears neglectable in the average case, these trade-offs may not always be justified, and we may instead use de-reification, where possible.

5.3 Triple removals

Duplicate triples are triples that occur more than once. We find that they are sometimes produced by some parsers. Additionally, some parsers introduce a node more than once, which results in two triples $\langle x, :instance, a \rangle$ and $\langle x, :instance, b \rangle$. Currently, SMATCH removes all such introductions of a second concept, but does not remove duplicate triples. By contrast, we propose to remove all duplicate triples, since they have no clear semantics, and stay agnostic to second introductions of a concept (in some MRs, it may be acceptable that an entity is the instance of two concepts), keeping all such triples (if they are not identical).⁹

6 Module II: Alignment

The goal of this module is solving Eq. 2, finding a map^* for optimal matching score.

SMATCH uses a hill-climber for solving Eq. 2. An issue with this is that such a heuristic terminates at local optima and cannot provide us with any *upper-bounds*. Upper-bounds, however, can inform users about the *quality* of the outputted solution and thus increase the trustworthiness of the final score (and any parser comparison that is based thereupon). Therefore, we can conclude that using a hill-climber seems **practical but may not be optimal**, especially when considering cases where fair comparison needs to be *guaranteed*. Instead, we would like to use an Integer Linear Program (ILP) to obtain the (optimal) solution. Alternatively, at least, we would like to know a tight upper-bound to inform ourselves about the trustworthiness of

⁸I.e., since reification can potentially be used to model n -ary relations, only in the case where $n = 2$ we can model the structure with a single (labelled) edge

⁹Due to rare occurrence of such phenomena in our parsed data, we find the effects of either choice to be negligible.

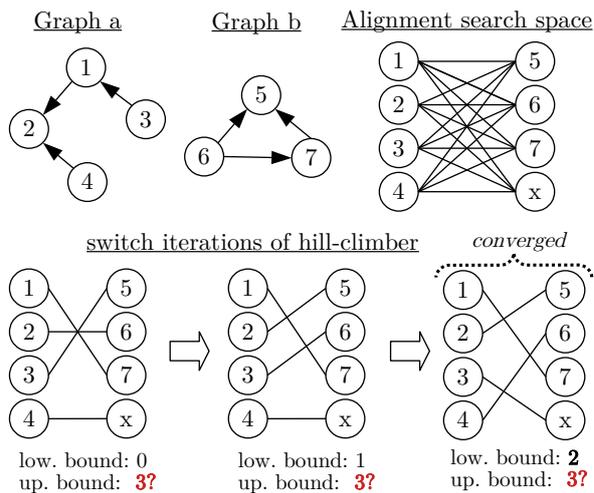

Figure 3: Sketch of search space (top) and hill-climber run (bottom). Every hill-climber step constitutes an improved lower bound, but we cannot obtain a tight upper-bound (an accessible trivial upper-bound is the amount of triples in the smaller of two graphs: 3).

the final score. But ILP is NP hard, and therefore it seems **optimal but possibly not practical**, a conception that might favor the usage of a hill-climber.

Triggered by these considerations, we review the hill-climber and the ILP and assess their effects on MR evaluation, with two desiderata in mind: evaluation quality and efficiency. Additionally, we propose a strategy for loss-less MR compression that can improve efficiency of any solver.

6.1 Practical but not optimal: hill-climber

SMATCH hill-climbing uses two operations, which we denote as *switch*, and *assign*. The *assign*-operation assigns a variable from $vars(a)$ to an unaligned variable from $vars(b)$: $(i, \emptyset) \rightarrow (i, j = map'(i))$, where map' is a candidate map. The *switch* operation does an alignment cross-over with respect to two alignment pairs, i.e.: $(i, j = map(i)) \wedge (k, l = map(k)) \rightarrow (i, l = map'(i)) \wedge (k, j = map'(k))$, where map is the current alignment and map' the candidate alignment. In each iteration, we examine all possible *switch*- and *assign* options, and greedily choose the best one.¹⁰ An example alignment procedure is shown in Figure 3.

In practice, we can resort to multiple random restarts, to find better optima. However, this hardly

¹⁰*Assign* is just a special instance of the more general *switch* so we can ablate the *assign* step. Then, *assign* becomes $(i, \emptyset = map(i)) \wedge (k, j = map(k)) \rightarrow (i, j = map'(i)) \wedge (k, \emptyset = map'(k))$, which is a *switch*.

addresses the underlying issue: we lack any information on upper-bounds, which may decrease trustworthiness of results, especially when facing larger graphs with lots of local optima.

6.2 ILP: Optimal, but less practical?

We would like to use Integer Linear Programming (ILP) for optimal solution of the graph alignment.

Problem statement Assume two graphs g, g' with node sets V, V' . Let $u(i, j)$ denote the amount of unary triple matches, given we align i from V to j from V' , counting matches of triples that involve one MR variable. On the other hand, $b(i, j, k, l)$ will denote the amount of structural binary triple matches, given we align i from V to j from V' and k from V to l from V' . Here, we count matching binary triples that involve two MR variables. Usually, these data are pre-computed. Let x indicate our current *map*, i.e., if $x_{ij} = 1$ then we align i from V to j from V' . We find our solution at

$$\begin{aligned} \max \quad & \sum_{\substack{(i,j) \in \\ V \times V}} u(i, j)x_{ij} + \sum_{\substack{(i,j,k,l) \in \\ (V \times V)^2}} b(i, j, k, l)x_{ij}x_{kl} \\ \text{st} \quad & \sum_j x_{ij} \leq 1; \quad \sum_i x_{ij} \leq 1 \\ & x_{ij} \in \{0, 1\} \quad \forall (i, j) \in V \times V' \end{aligned}$$

The constraint ensures that every node from one graph is aligned, at maximum, to one node from the other graph. By linearization, and introducing structural variables y , we obtain the equivalent ILP:

$$\begin{aligned} \max \quad & \sum_{\substack{(i,j) \in \\ V \times V'}} u(i, j)x_{ij} + \sum_{\substack{(i,j,k,l) \in \\ (V \times V')^2}} b(i, j, k, l)y_{ijkl} \\ \text{st} \quad & \sum_j x_{ij} \leq 1; \quad \sum_i x_{ij} \leq 1 \\ & y_{ijkl} \leq x_{ij}, \quad \forall (i, j, k, l) \in (V \times V')^2 \\ & y_{ijkl} \leq x_{kl}, \quad \forall (i, j, k, l) \in (V \times V')^2 \\ & x_{ij} \in \{0, 1\} \quad \forall (i, j) \in V \times V' \\ & y_{ijkl} \in \{0, 1\} \quad \forall (i, j, k, l) \in (V \times V')^2, \end{aligned}$$

where the structural variables, if active, show us countable binary triple matches. This is an NP complete problem, imposing limits on its capability to provide us with optimal solutions for larger graphs (note, however, that we can retrieve intermediate solutions and upper-bounds).

6.3 Reduced search space with lossless graph compression

We observe that in an MR a , every variable $x \in vars(a)$ is related to a concept c , e.g., $\langle x, :instance, cat \rangle$. This means that a concept c does *identify* a variable $x \in vars(a)$ iff $\forall y \in vars(a) : \langle y, :instance, c \rangle \Rightarrow y = x$. Therefore, if x denotes a *cat*, and there is no other entity in the MR that also denotes a *cat*, then x may be referred to simply by *cat*. This carries over to pairs of MRs: which are the focus of the paper – instead of considering $vars(a)$, we simply consider $vars(a) \cup vars(b)$. Therefore, we can replace all n variables from $vars(a) \cup vars(b)$ that are *identified* by concepts, with the corresponding concepts (see Appendix A.1 for a full example). This shrinks the search space by reducing the amount of variables that the optimizer has to consider. Note that such a compression is *lossless*, in the sense that the possibility of full reconstruction of the original MR is ensured. This implies that if two compressed MRs are assessed as (non-)isomorphic, then the uncompressed MRs are also (non-)isomorphic.

6.4 Solver experiments

Two questions are of main interest: 1. *RQ1, solution quality*: (How) do the final SMATCH results depend on the solver? 2. *RQ2, solution efficiency*: How does the evaluation time depend on the solver? In addition, we would like to assess how our answers to RQ1 and RQ2 might be affected by reification (resulting in a bigger search space) and MR compression (resulting in a smaller search space).

Setup We simulate a standard AMR parsing evaluation setting. We parse the LDC2017T10 testing data with six parsers: \mathcal{P}_1 (Xu et al., 2020), \mathcal{P}_2 (Cai and Lam, 2020), \mathcal{P}_3 (Lindemann et al., 2020), \mathcal{P}_4 (Zhang et al., 2019), \mathcal{P}_5 (Lyu and Titov, 2018), \mathcal{P}_6 (Cai and Lam, 2019). We evaluate the parsers using ILP or hill-climber (denoted by \triangle). As is standard, we show F1 micro corpus scores. For reference, we also run evaluation with the standard SMATCH hill-climbing script (denoted as *previous*). We observe that we successfully reproduce the scores from the standard SMATCH script with our \triangle implementation (first two lines of Table 2).¹¹

		parser scores (ranked)							time	# vars	quality

Table 2: Parser evaluation. *time* refers to the approximate total time needed to evaluate a single parser (i.e., processing 1371 graph pairs). $\triangle-N$ indicates hill-climber optimizer with N restarts. *quality*: solution quality of solver – first number is the amount of matching triples summed over all six parser evaluations (yield); second number indicates the tightest found upper-bound (which is only known by ILP).

6.4.1 RQ1: solution quality

Insight: Better alignment → safer evaluation

Importantly, we see that the ILP yields score increments for all parsers, which signals the occurrence of alignment problems, where the \triangle (despite multiple restarts) did not find the optimal solution. The effect-size is larger for reified graphs. We find differences of up to 1 point F1 score (Table 2: reify \triangle_4 vs. reify ILP). This can be explained by the growth of the alignment search space – reification makes graphs larger and introduces more MR variables. This explanation is further supported by contrasting the amount of unique final objective values against the size of the alignment space with different random initializations of the hill-climber (Appendix A.2, Figure 6). We see that i) for many graph pairs there are multiple local optima, and ii) the likelihood of finding a non-global optimum with the \triangle increases for larger/reified graphs.

We further study upper-bounds and solution quality (right column of Table 2). The ILP found the optimal solution in all cases, yielding 218072 matching triples. The \triangle_4 finds 217,700 matching triples (99.83%), which misses the mark by 350 triples. When evaluating reified graphs, the ILP returns 291370 matches and thus misses its temporary tightest upper-bound by 13 triples, indicating that in a few cases, a sub-optimal solution might have been found.¹² The \triangle_4 , however, yields only

288,597 matches (99.04%) and misses the temporary ILP upper-bound by 2,786. The growing gap underlines the degrading quality of the hill-climber when facing larger graphs.

Finally, the (slight) *differences* in increments among parsers when we evaluate them on reified graphs indicate that different parsers do make different decisions on when to reify an edge. For instance the score difference Δ for reified graphs vs. non-reified graphs (using ILP) of $\mathcal{P}_5, \mathcal{P}_6$ is 2.5 points, for \mathcal{P}_1 2 points and for \mathcal{P}_2 1.7 points. This supports our theoretical insights from §5.2 – reification can make parser comparison fairer.

6.4.2 RQ2: Solution efficiency

Insight I: ILP isn’t that impractical It seems to be commonly presumed that original SMATCH uses a hill-climber to make evaluation more practical and fast. However, our results qualify this presumption. For evaluating a full corpus (1371 graph pairs), SMATCH with ILP needs only about 48 seconds longer than original SMATCH with hill-climber (50s vs 98s). When the search space grows (due to reification) the time gap widens to a difference of 165 seconds. However, the consistent improvement of scores due to ILP (signaling sub-optimal hill-climber solutions) can make the time increase acceptable for evaluations where fairness is critical.

Insight II: MR compression increases evaluation speed

Viewing the last four rows of Table 2, we see that the MR compression i) did not lead to switched system ranks and ii) increased the evaluation speed by a large factor. Using MR compression, the ILP runs a full system evaluation in 11.7

¹¹An improvement is obtained for \mathcal{P}_5 . We find that we can mostly attribute this to a bug in the original script that prevents proper graph reading of some parses of \mathcal{P}_5 .

¹²Indeed, we find one graph by \mathcal{P}_2 , and one graph by \mathcal{P}_6 , where the ILP terminates after a 240s timeout that we set, and returns a temporary solution.

avg.	parser scores					
	\mathcal{P}_1	\mathcal{P}_2	\mathcal{P}_3	\mathcal{P}_4	\mathcal{P}_5	\mathcal{P}_6
mic.	81.5 ^{81.1} _{80.7}	80.4 ^{81.2} _{79.6}	77.1 ^{77.8} _{76.2}	76.5 ^{77.2} _{75.6}	75.2 ^{75.8} _{74.5}	73.3 ^{74.1} _{72.4}
mac.	82.6 ^{81.8} _{83.3}	81.4 ^{82.1} _{80.7}	79.0 ^{79.8} _{78.2}	78.3 ^{79.1} _{77.5}	76.2 ^{77.0} _{75.4}	75.9 ^{75.0} _{76.6}

Table 3: Evaluation with additional macro statistics and confidence intervals. Solver: ILP.

seconds for standard graphs and 27.3 seconds for the reified graphs. Given that the MR compression is lossless (c.f. §6.2), it provides us with an option for more efficient evaluation that is also safe (i.e., optimal).

7 Module III: scoring

7.1 Main scores: Precision, Recall and F1

The goal of this module is to provide the user with a final result. As discussed in §3, the main scores (Precision, Recall, and F1) follow directly from the map^* . The final score is typically micro averaged, summing matching statistics across all graph pairs before they are normalized. SMATCH++ makes two additions, macro-scoring and confidence intervals. Macro-averaging scores over graph pairs can be a useful complementary signal, specifically when comparing high-performance parsers (Opitz and Frank, 2022a). Additionally, we adopt the bootstrap assumption (Efron, 1992) for calculating confidence intervals. To make calculation feasible, bootstrapping is performed after the alignment stage. Table 3 shows results of the additional statistics. Confidence intervals range between $\pm[0.5, 1]$ points for all parsers. Macro score shows an outlier, where \mathcal{P}_6 (+2.6 points) is more positively affected than other parsers ($\pm[1.0, 1.9]$ points).¹³

7.2 Measuring aspectual semantic similarity

We observe considerable interest in applying fine-grained aspectual MR metrics (Damonte et al., 2017) for inspecting linguistic aspects captured by MRs (e.g., semantic roles, negation, etc.). Applications range from parser diagnostics (Lyu and Titov, 2018; Xu et al., 2020; Bevilacqua et al., 2021; Martínez Lorenzo et al., 2022), to NLG system diagnostics and sentence similarity (Opitz and Frank, 2021, 2022b). Formally, given an aspect of interest asp and an MR g , we apply a sub-graph-extraction

¹³We find a potential explanation in a motivation of \mathcal{P}_6 's creators to focus on semantics in proximity of an MR's top node (the proportion of such semantics increases when the graph is smaller, and smaller graphs have more influence on macro average than on micro average).

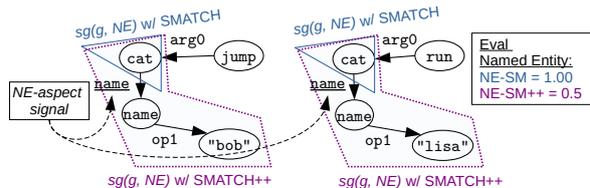

Figure 4: Named Entity (NE) sub-graph extraction with SMATCH vs. SMATCH++

function $sg(g, asp)$ to build an aspect-focused sub-graph, and compute a matching score (e.g., F1).

Review of previous implementation We study the description in Damonte et al. (2017) and the most frequently used implementation (Lyu, 2018). The treated aspects¹⁴ are divided in two broad groups: **i) alignment-based matching:** For some aspects, we extract aspect-related genuine sub-graphs, on which we calculate an optimal alignment. **ii) bag-of-label matching:** for other aspects, we detect aspect-related variables and gather associated node labels¹⁵ in a bag/list, to compute an overlap score based on simple set intersection.

E.g., *SRL*-aspect belongs to the first category **(i)**: we extract $\langle x, :arg_n, y \rangle$ relations, and their corresponding *instance* triples (here: $\langle x, :instance, c \rangle$, and $\langle y, :instance, c' \rangle$). Then we calculate SMATCH on such SRL-subgraphs. The *Negation*, *Named Entity* (NEs) and *Frames* aspect is put into the second group **(ii)**. We look for a relation/node-label that signals a particular aspect, e.g., $\langle x, :polarity, - \rangle$ (for negation) or $\langle x, :name, y \rangle$ (for NEs), we extract x , and replace x with the descriptive label c from $\langle x, :instance, c \rangle$. For *Frames*, we search for $\langle x, :instance, c \rangle$ where c is a PropBank predicate, and collect c . Finally, we can evaluate without an alignment, using set intersection.

Open questions We pose two questions:

1. Can the sub-graph extraction be improved?
2. Are there other aspects that we can measure?

7.3 Improving sub-graph extraction

Sensible range of extraction For some phenomena, the current extraction range is clearly too limited. For instance, let us consider named entities, which can be captured in more complex and nested

¹⁴See Appendix A.3 for a full overview.

¹⁵I.e., from $\langle x, :instance, label \rangle$ triples

MR structure. E.g., in AMR, one node typically indicates the type of the named entity (NE), and another multi-node structure represents its name and other attributes. Consider two AMRs a and b , from which we want to extract NE structures to measure the agreement of the graphs w.r.t. NE similarity. As shown in Figure 4, assume that one graph is about *a cat named Bob*¹⁶, while the other graph is about *a cat named Lisa*¹⁷. Obviously, the MRs have similarities in their NE structure (since there are named cats), but also differences (since the cats have different names). However, NE-focused SMATCH only extracts *cat* and *cat*, and returns maximum score.

Hence, for all finer-grained aspects that are captured by non-atomic MR structures (e.g., Named Entities), we propose to gather the full sub-graph starting at the aspect-indicating relation or node label. In the NE example, as shown in Figure 4, we would be provided a score of 0.5, better reflecting the similarity of the two NE structures.

Sub-graph compression, align and match We find a middle-ground in the advantages of the coarse matching (concreteness, efficiency) and graph alignment (safe matching) by using alignment with lossless MR compression. This is optimal and efficient, and alleviates the need to switch among fine and coarse extraction methods.

7.4 Extending fine-grained scores

Beyond negation and named entities – other semantic aspects We find that the fine-grained SMATCH metrics by Damonte et al. (2017) miss some interesting features captured by MRs. For instance, four interesting AMR aspects that are currently not captured are *cause*, *location*, *quantification*, and *tense*. SMATCH++ allows their integration in a straightforward way. An example for tense extraction is displayed in Figure 5, where our SMATCH++ sub-graph extraction extracts the complete temporal sub-graph, triggered by the edge label `:time` (if we would resort to the style of fine-grained SMATCH, we would miss larger parts of the temporal structure, only extracting the node label `end`).

Results of fine-grained parser diagnostics for *cause*, *location*, *quantification*, and *tense* are shown

¹⁶Triples: `<x, :instance, cat>`, `<y, :instance, name>`, `<x, :name, y>`, `<y, :opl, "bob">`.

¹⁷Triples: `<x, :instance, cat>`, `<y, :instance, name>`, `<x, :name, y>`, `<y, :opl, "lisa">`.

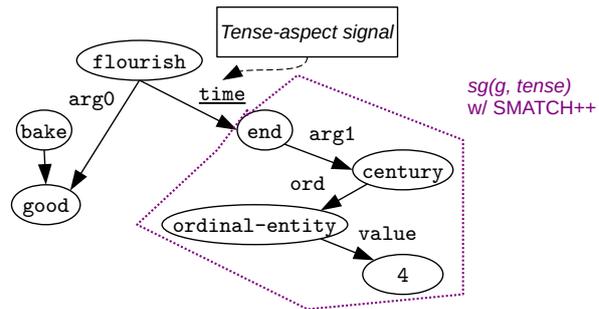

Figure 5: Temporal sub-graph extraction with SMATCH++ for an MR capturing “Baked goods flourished at the end of the fourth century”.

aspect	parser scores					
	\mathcal{P}_1	\mathcal{P}_2	\mathcal{P}_3	\mathcal{P}_4	\mathcal{P}_5	\mathcal{P}_6
cause	47.8	47.4	44.4	35.7	31.4	31.2
location	61.8	53.2↓	54.7↑	49.2↓	51.7↑	40.0
quant	69.4	67.4	58.4	56.8	56.5	55.8
tense	67.7	62.3	58.5	56.5	50.3	48.4

Table 4: Evaluation for *causal* and *temporal* structures. ↓↑ indicate switched ranks. Solver: ILP.

in Table 4.

Interestingly, we see that projecting *causality* seems hard: all parsers tend to struggle when assessing causal structures (31.2 up to 47.8 F1 points), showing much room for improvement. The temporal structures, on the other hand, can be assessed with somewhat higher accuracy (48.4 up to 67.7 points). We also see some switched ranks, indicating different parser strengths. Overall, parser score differences seem notably more pronounced than when calculating SMATCH (++) on the full graphs, showing the difficulty of capturing finer phenomena, and highlighting strengths of more recent parsers.

8 Conclusion

SMATCH++ is the first specification of a standardized, extended, and extensible SMATCH metric. We aim at i) standardized and transparent comparison of graph parsing systems, and ii) improved extensibility for custom applications.¹⁸ The applications can include finer parser diagnostics and measuring semantic sub-graph similarities such as *quantification*, *cause*, or *tense* with our fine-grained metrics.

Acknowledgments

We thank our reviewers for their helpful feedback.

¹⁸See Appendix A.4 for a summary of the default setup.

Limitations

We have to leave some questions open. First, we would have liked to shed more light on the solvers' behaviors when facing large graphs, in isolation. On one hand, our benchmark corpus indeed contains some large MRs with many variables, including reified MRs and MRs that represent multiple sentences (up to 174 variables, cf. Table 2). We have shown that ILP could cope with these harder problems, providing optimal solutions in reasonable time. When facing bigger graphs, however, we can expect that the solution quality of the hill-climber quickly degrades, while the ILP will struggle to find optimal solutions. While our graph compression strategy can help mitigate this issue by reducing the alignment search space, it would be interesting to study the quality of temporary solutions, or of solutions of LP relaxation. There are also relaxed ILP solvers (Klau, 2009) that iteratively tighten the lower and the upper-bound. They could prove useful for aligning larger MR graphs, or, at least, to find useful upper-bounds.

Second, in this paper we studied SMATCH (++) that measures *structural overlap* and assigns each triple the *same weight*. But structural differences of similar degree can have a different impact on overall meaning similarity as perceived by humans, which can have ramifications for measuring sentence similarity (Opitz et al., 2021) and meaningful evaluation of strong AMR parsers (Opitz and Frank, 2022a). Therefore, for a deeper assessment of MR similarity we may have to use conceptually different metrics, or explore SMATCH++-based strategies and (sensibly) weigh triples depending on label importance or compose an overall score by weighting measured sub-aspect similarities.

A Appendix

A.1 Lossless graph pair reduction example

Consider *the cat scratches another cat*:

$$a = \{ \langle s, :instance, scratch \rangle, \langle c, :instance, cat \rangle, \langle d, :instance, cat \rangle, \langle s, :arg0, c \rangle, \langle s, :arg1, d \rangle \}$$

and *the gray cat scratches the small plant*:

$$b = \{ \langle x, :instance, scratch \rangle, \langle y, :instance, cat \rangle, \langle z, :instance, plant \rangle, \langle w, :instance, small \rangle, \langle v, :instance, gray \rangle, \langle x, :arg0, y \rangle, \langle x, :arg1, z \rangle, \langle y, :mod, v \rangle, \langle z, :mod, z \rangle \}.$$

The lossless compression is $a' = \{ \langle c, :instance, cat \rangle, \langle d, :instance, cat \rangle, \langle scratch, :arg0, c \rangle, \langle scratch, :arg1, d \rangle \}$ and $b' = \{ \langle y, :instance, cat \rangle, \langle scratch, :arg0, y \rangle, \langle scratch, :arg1, plant \rangle, \langle y, :mod, gray \rangle, \langle plant, :mod, small \rangle \}$.

The alignment search space is reduced from a size of more than 100 candidates to 2 candidate options ($y = c$, or $y = d$).

A.2 Assessing solution quality variability in dependence of variables

We use the parses of an example parser (\mathcal{P}_5)¹⁹. For every evaluation pair, we re-start the hillclimber 20 times, and collect the scores related to the found local optima. The Y-axis in Figure 6 shows the amount of unique scores found among the 20 tries (note that there could be more unique alignments

¹⁹We ran the experiment also with parses from other systems but always ended up with essentially the same results

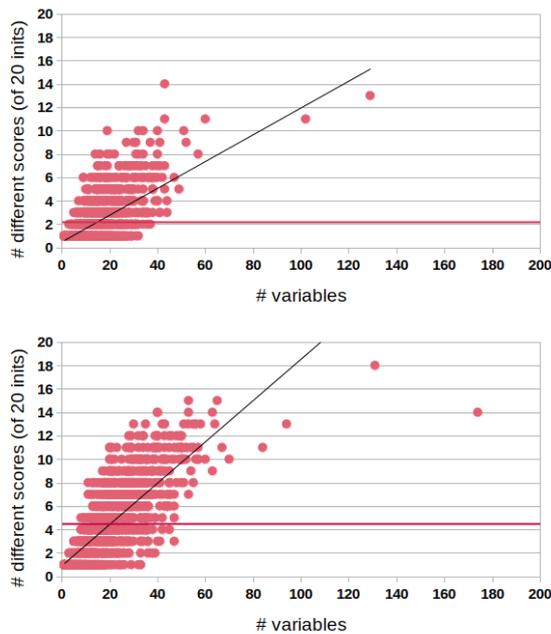

Figure 6: Assessing solution quality variability. Top: basic graphs, bottom: reified graphs. Diagonal line: linear trend. Horizontal line: arithmetic mean. See text in §A.2 for more description and §6.4.1 for discussion.

that would result in the same score – this is not captured in this Figure). The X-axis shows the amount of alignment variables. In different terms, a higher point in this Figure is equivalent to a larger pool of local optima of different quality, and thus we can conjecture a greater likelihood that the optimal solution is not returned by the hill-climber.

A.3 Aspect overview

Previously measured aspects For all aspects we retrieve F1, Precision, and Recall.

1. Measured under alignment

- (a) SRL: extract $\langle x, \text{arg}_n, y \rangle$ triples and corresponding instance triples.
- (b) Coreference/Re-entrancies: extract $\langle x, \text{rel}, y \rangle$ triples for which there is another triple $\langle z, : \text{rel}', y \rangle$ (meaning y is a re-entrant node) and also extract corresponding instance triples.

2. Measured via bag-of-structure extraction and set operations

- (a) Concepts: collect all node labels.
- (b) Frames: collect all node labels where the label is a PropBank predicate frame.
- (c) NonSenseFrames: see above, but with sense label removed

- (d) NE: Named entities, collect all node labels that have an outgoing `:name` relation.
- (e) Negation: collect all node labels that have an outgoing `:polarity` relation.
- (f) Wikification: collect all node labels that have an incoming `:wiki` relation.
- (g) IgnoreVars: replace all variables in triples with concepts, collect triples.

SRL, Named Entities, coreference (re-entrant nodes)

Additional aspects measured by us: *Cause*, *Tense*, *Location*, *Quantifier*.

We change: Add default option for extracting aspect sub-graphs, measure all aspects under alignment.

Aspects we added:

- *Cause*: Cause is modeled via `cause-01`. We extract label of `:arg1` (what is caused?) and subgraph of `:arg2`, the cause itself.
- *tense*: Tense is modeled via $\langle x, : \text{time}, y \rangle$ edge. We extract label of the thing that happens and subgraph of y , the temporal description where it happens.
- *location*: Similar to above but with `:location` edge.
- *quantifier*: Similar to above but with `:quant` edge.

A.4 Best practice

To provide a balance between efficiency, safety and meaningfulness of scores, default procedure of SMATCH++ is currently set to:

1. Pre-processing: lower-casing, duplicate-removal, de-reify where applicable.
2. Alignment: Solver: ILP. Triple-match: $w_t^t = 1 \forall t, t'; \text{sim}(c, c') := I[c = c']$
3. Scoring: Precision, Recall, F1, Bootstrap confidence intervals

An option to increase efficiency without incurring a loss in safety and meaningfulness is achieved by adding graph compression to the pre-processing. It is set as the default for fine semantic aspect scores. Also, to ensure utmost safety, we have to consider applying reification standardization (incurring a significantly longer evaluation time).

An Extended Sequence Tagging Vocabulary for Grammatical Error Correction

Abstract

We extend a current sequence-tagging approach to Grammatical Error Correction (GEC) by introducing specialised tags for spelling correction and morphological inflection using the SymSpell and LemmInflect algorithms. Our approach improves generalisation: the proposed new tagset allows a smaller number of tags to correct a larger range of errors. Our results show a performance improvement both overall and in the targeted error categories. We further show that ensembles trained with our new tagset outperform those trained with the baseline tagset on the public BEA benchmark.

1 Introduction

Current approaches to Grammatical Error Correction (GEC) fall under two broad categories: sequence-to-sequence and sequence-tagging. The former treats GEC as a machine-translation problem, "translating" from error-containing to error-free language (Yuan and Briscoe, 2016; Schmaltz et al., 2017; Junczys-Dowmunt et al., 2018; Grundkiewicz et al., 2019; Yuan et al., 2019; Rothe et al., 2021). By contrast, sequence-tagging approaches tag each input word with an edit operation such that applying the operations produces the corrected output (Yannakoudakis et al., 2017; Awasthi et al., 2019; Omelianchuk et al., 2020; Tarnavskyi et al., 2022). The basic operations include keeping a word unchanged, deleting a word, and inserting new words (Awasthi et al., 2019; Malmi et al., 2019).

One advantage of sequence-tagging over sequence-to-sequence approaches is computational efficiency: the former do not require expensive auto-regressive decoding,¹ and currently achieve competitive performance using smaller models (Tarnavskyi et al., 2022; Rothe et al., 2021).

¹Malmi et al. (2019) show that sequence-taggers can be orders of magnitude faster than comparable seq-to-seq models at inference time.

Figure 1: Our model applied to two inputs. Beneath each word is the tagger's output. Arrows denote transformations by SymSpell and LemmInflect respectively.

However, current sequence-tagging approaches require manual linguistic efforts to curate language-specific edit tags (Yuan et al., 2021). For example, Awasthi et al. (2019) introduce rule-based morphological inflection tags, like replacing the "-ing" suffix with "-ion" (e.g. completing → completion). Omelianchuk et al. (2020) introduce a wider range of operations including verb-form and noun-number changes. For verb-form inflections, they use a dictionary to map between verb forms.²

In this paper, we focus on a sequence-tagging approach. We extend the approach of Omelianchuk et al. (2020) by introducing more general transformation tags (Figure 1). Specifically, we introduce:

- A tag for correcting spelling errors.
- Inflection tags capable of a broader range of inflections than the tags introduced by Omelianchuk et al. (2020).

These modifications allow a broader range of errors to be handled by a smaller number of transformation tags, which simplifies the sequence tagging

²https://github.com/gutfeeling/word_forms/blob/master/word_forms/en-verbs.txt

problem, as well as improves the generalisation of the GEC system. Our results show that our modifications improve the system’s performance on the BEA-2019 development and test sets. Our code and model weights are publicly available.³

2 Methods

We extend the system described by Omelianchuk et al. (2020) by adding new tags to the model’s output vocabulary and modifying the inference and dataset preprocessing code to support our new tags. Our new tags perform spelling correction and morphological inflection and are described in Sections 2.3 and 2.4 below. We evaluate our tagset using the RoBERTa (Liu et al., 2019), DeBERTa (He et al., 2021b), DeBERTaV3 (He et al., 2021a), ELECTRA (Clark et al., 2020) and XLNet (Yang et al., 2019) encoders, as well as an ensemble of three encoders (see Section 2.6).

2.1 Model and Training Procedure

Our work builds on GECToR from Omelianchuk et al. (2020), which follows the sequence tagging approach to GEC. We use the same sequence tagger architecture: a pre-trained transformer encoder with two separate "tagging" and "detection" heads. We also follow the same multi-phase training procedure using the synthetic PIE Corpus (Awasthi et al., 2019), NUCLE (Dahlmeier et al., 2013), FCE (Yan-nakoudakis et al., 2011), Lang-8 (Mizumoto et al., 2011; Tajiri et al., 2012) and W&I + LOCNESS (Bryant et al., 2019) English datasets.

2.2 Baseline Tagset

GECToR’s tagset includes the basic edit tags, \$KEEP, \$DELETE, \$REPLACE_{t} and \$APPEND_{t}, which respectively leave the word unchanged, delete the word, replace the word with another word *t*, and append *t* after the input word.

The tagset also contains a set of more complex grammatical transformation or “g-transform” tags. These include case, agreement (singular/plural), verb-form and merge/split transformations. For example, there is a tag to transform a verb into its past-tense equivalent. The verb-form transformations are performed using a dictionary. Omelianchuk et al. (2020, Table 9) provide a full list of the transformations and their descriptions.

³https://github.com/StuartMesham/gector_experiment_public

2.3 Spelling Correction Tag

GECToR corrects spelling errors using its vocabulary of \$REPLACE_{t} tags. This limits its ability to generalise to unseen or rare spelling errors for two reasons. The first is that GECToR can only correct misspellings of words which appear in its output vocabulary. The second is that for each word, there are many possible misspellings that the model must learn to associate with the corrected form.

To remedy this, we introduce a new \$SPELL tag for spelling correction. When this tag is predicted during inference, we use SymSpell⁴ to produce the corrected version of the input word (see Section A.1 for details). We hypothesise that this improves generalisation because the sequence tagger need only detect spelling errors, and the corrections are performed by SymSpell. SymSpell can handle a variety of misspellings of each word and can correct words from a dictionary much larger than the output vocabulary of the sequence tagger.

2.4 Inflection Tags

We introduce inflection tags of the form \$INFLECT_{POS} where POS denotes the Penn Treebank POS tag of the desired form of the input word. When an inflection tag is predicted at inference time, the input word is inflected to the target POS specified in the tag. The inflection is achieved using the software modules spaCy⁵ and LemmInflect⁶. LemmInflect first attempts to use a dictionary for the inflection. If the input word is not in LemmInflect’s dictionary, the inflection is performed using a rule-based approach (see Section A.2 for details).

Our inflection tags offer two main advantages over GECToR’s dictionary-based verb transformations. The first is that they are not limited to verbs, but rather can be used for any inflected part of speech.⁷ The second is that words which do not appear in LemmInflect’s dictionary can still be handled using a rule-based approach (see Section A.2). We also note that GECToR’s singular/plural transformation tag only adds or removes an "-s" from the end of the input word, making it unable to handle less trivial cases such as inflecting "activity" to its plural "activities". By contrast, our system

⁴<https://github.com/wolfgarbe/SymSpell#single-word-spelling-correction>

⁵<https://spacy.io>

⁶<https://github.com/bjascob/LemmInflect>

⁷In English, the inflected parts of speech are adjectives, adverbs, nouns and verbs.

Table 1: A table showing BEA-2019 development and test set scores. The top section shows our models with varying tagsets using the DeBERTa_{5K}^(L) encoder. The middle section shows the results for our ensemble models with varying tagsets. In the table, "ensemble" denotes the encoders DeBERTa_{5K}^(L) ⊕ ELECTRA_{5K}^(L) ⊕ RoBERTa_{5K}^(L). Finally, the bottom section shows models from related work. The model labelled "(KD)" was trained using Tarnavskiy et al. (2022)'s knowledge distillation procedure. The results in the top and middle sections are averaged over 6 seeds, and the standard deviation, σ , of the test $F_{0.5}$ is shown.

applies the full dictionary and rule-based procedure to singular/plural transformations. In summary, our inflection tags handle a broader range of transformations than GECToR's transformation tags. We hypothesise that this improves generalisation.

2.5 Preprocessing

To incorporate our \$SPELL tag into the training data, we take data preprocessed with Omelianchuk et al. (2020)'s code, and for each instance of a \$REPLACE_{t} tag, we apply SymSpell to the input word. If SymSpell produces the correct output, t , we change the \$REPLACE_{t} tag to a \$SPELL tag. Otherwise, we leave the \$REPLACE_{t} tag unchanged.

For the inflection tags, we first modify Omelianchuk et al. (2020)'s preprocessing code by removing existing tags which perform inflections.⁸ Then, similar to our process for the \$SPELL tag, for each instance of a \$REPLACE_{t} tag, we attempt to inflect the input word to obtain the target word t and, if successful, change the tag to an \$INFLECT_{POS} tag. Otherwise, we leave the tag unchanged. For details about this process, we refer

⁸We remove tags g-8 to g-29 (Omelianchuk et al., 2020, Table 9).

the reader to the relevant script in our repository.⁹

2.6 Ensembling

To create ensemble models, we use the span-based voting procedure of Tarnavskiy et al. (2022). Their system takes the corrected output of each model, compares it with the input text, and extracts edit spans of the same type (insert, delete, or replace). In an ensemble of k models, spans predicted by at least $k - 1$ models are included in the output of the ensemble.

Our particular combination of encoders was chosen on the BEA-2019 development set by searching over all possible combinations of three models from the set of individual models we trained with the \$SPELL + \$INFLECT tagset.

3 Results

We report the span-based precision, recall and $F_{0.5}$ scores on the BEA-2019 development and test sets (Bryant et al., 2019) using the ERRANT scorer (Bryant et al., 2017).¹⁰ The term "basetags" indicates the tagset proposed by Omelianchuk et al.

⁹See the lemminflect_preprocess.py script in the utils directory of our repository.

¹⁰<https://github.com/chrisjbryant/errant>

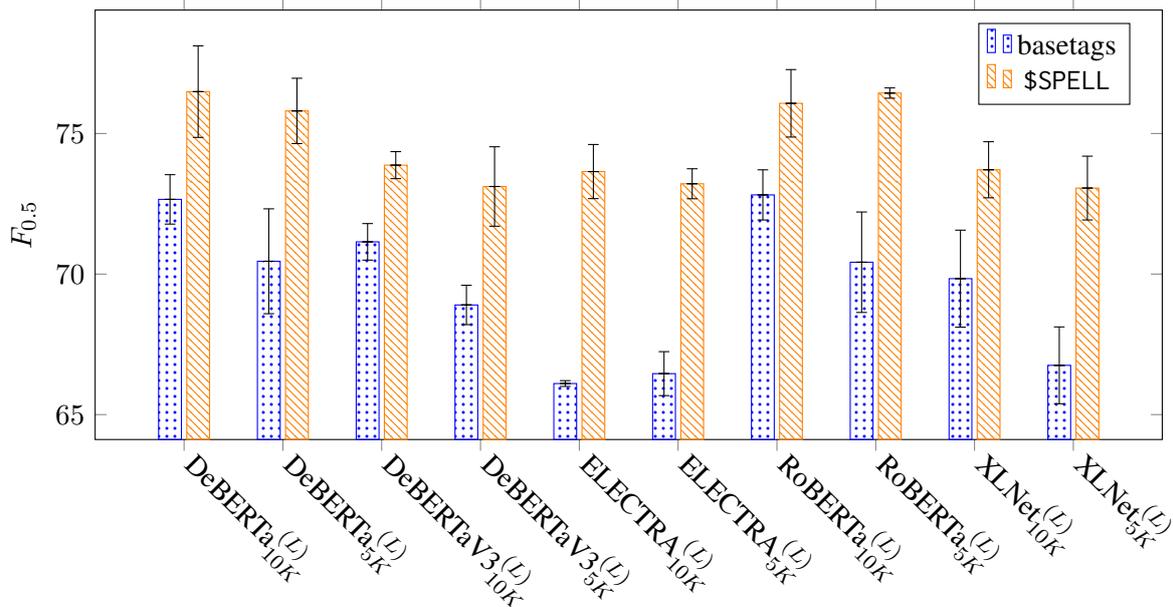

Figure 2: A bar graph showing the BEA-2019 development set $F_{0.5}$ scores for the "spelling" error category for different encoders, tagsets and vocabulary sizes. Specifically, the \$SPELL and basetags tagsets and vocabulary sizes of 5k and 10k. Each bar represents the mean score over three training runs with different seeds. The error bars show the standard deviations of the scores.

(2020), and \$SPELL and \$INFLECT denote our proposed tagsets containing the spelling and inflection tags respectively. \$SPELL + \$INFLECT denotes tagsets containing both the spelling and inflection tags. We adopt the model and tagset size notation of Tarnavskiy et al. (2022) which, for example, denotes a DeBERTa-large model using a 5k vocabulary size as DeBERTa^(L)_{5K}.

Table 1 shows the scores of our models on the BEA-2019 development and test sets. Of the three encoders chosen for our ensemble, DeBERTa^(L)_{5K} had the highest mean development set score when using \$SPELL + \$INFLECT tagset, and is thus shown in Table 1.¹¹

For the DeBERTa^(L)_{5K} encoder, on both the development and test sets, the \$SPELL and \$INFLECT tagsets provide an improvement over the basetags tagset, and the \$SPELL + \$INFLECT tagset provides a larger improvement. Similarly, for the ensemble models, on the development set, the \$SPELL and \$INFLECT tagsets show an improvement over the basetags tagset, and the \$SPELL + \$INFLECT tagset obtains the highest score. However, on the test set, the \$SPELL tagset scores the highest.

¹¹See Section A.6 for the results of the other encoders, and Section A.8 for CoNLL-2014 results.

3.1 Target Error Categories

Figures 2 and 3 show BEA-2019 development set scores in the ERRANT error categories (Bryant et al., 2017, Table 2) targeted by the \$SPELL and \$INFLECT tagsets respectively. The former targets only the "spelling" error category, and the latter targets categories related to inflection.¹² In Figure 2 we observe substantial performance improvements in the spelling category for all models. Figure 3 shows a smaller improvement in the target error categories of the \$INFLECT tagset for all models except XLNet^(L)_{10K}.

4 Discussion

In general, the \$SPELL and \$INFLECT tagsets both improve performance over the baseline tagset. The results of Section 3.1 show that the tagsets improve performance in their respective targeted error categories. This indicates that our modifications were successful.

In the results showing all error categories (Table 1), the inclusion of many non-targeted categories reduces the weighting of targeted categories, resulting in smaller apparent differences between models. For the ensemble models, the \$SPELL

¹²Specifically, the ADJ:FORM, MORPH, NOUN:INFL, NOUN:NUM, VERB:FORM, VERB:INFL, VERB:SVA and VERB:TENSE categories.

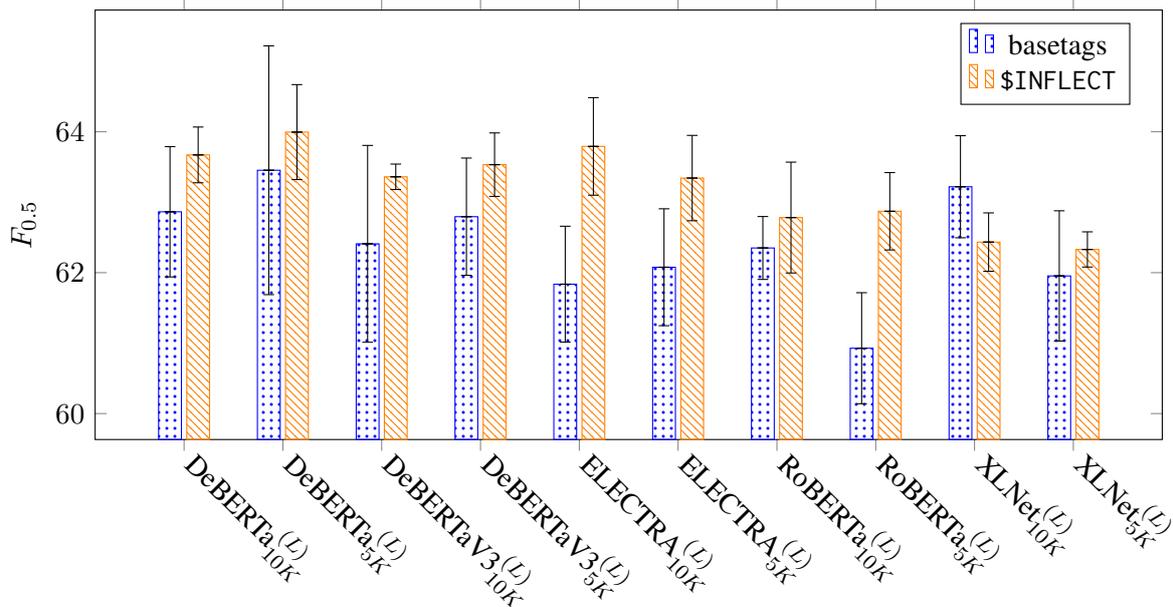

Figure 3: A bar graph showing the BEA-2019 development set $F_{0.5}$ scores for inflection-related errors for different encoders, tagsets and vocabulary sizes. Specifically, the \$INFLECT and basetags tagsets and vocabulary sizes of 5k and 10k. Each bar represents the mean score over three training runs with different seeds. The error bars show the standard deviations of the scores.

tagset obtains a higher test score than the \$SPELL + \$INFLECT tagset. This is contrary to our expectation that the combination of our modifications should provide a cumulative improvement. It is also unexpected that the ranking of the ensemble models on the development and test sets differs.

Differences in error-type frequencies in the development and test sets do not provide an explanation, since the frequency of spelling errors is lower in the test set than in the development set, and the frequencies of the error types which the \$INFLECT tagset most impacts¹³ are higher in the test set than in the development set (Bryant et al., 2019, Table 4). We therefore hypothesise that this unexpected pattern is an artefact of the variation between different random seeds.

5 Conclusions

We have motivated and described new tags for spelling correction and morphological inflection. These tags are capable of correcting a broader range of errors than previous tags, thereby improving generalisation. Our results show that the new tags improve performance both in the targeted error categories and overall for both single-encoder models and ensembles.

¹³Specifically the NOUN:NUM, VERB:FORM and VERB:SVA error types. See Section A.7 for details.

Our findings ultimately show there is great scope for improving GEC sequence-labelling model performance by introducing tags capable of correcting more general and possibly complex classes of errors.

Finally, we believe our results are of immediate value to practitioners building GEC applications since they offer improved performance without the use of seq-to-seq models which can require orders of magnitude more computation at inference time.

6 Future Work

We used SymSpell in its context-free configuration when correcting spelling errors. We chose this method because of its speed and simplicity, however, better performance could likely be obtained by switching to a context-sensitive spelling correction algorithm.

Although our experiments demonstrate a performance improvement over the results of Tarnavskyi et al. (2022), other recent work has demonstrated further performance improvements (Lai et al., 2022; Qorib et al., 2022). Our contribution is orthogonal to these, and so future work could investigate whether using our tagset for the sequence tagger used by Lai et al. (2022) or using our models in the ensemble described by Qorib et al. (2022) would yield further improvements.

Limitations

The results obtained have high variance with respect to the random seed used (see Appendix Figures 5 and 6). Due to compute limitations, we were unable to run more seeds to better observe the distributions of development and test scores.

The generalised tags we experimented with are also somewhat language specific, as, for example, the \$INFLECT tagset will not be beneficial to a language with little or no morphology.

Ethics Statement

This work is conducted in accordance with the ACM Code of Ethics.¹⁴ In this section we comment on the topics of privacy, safety and accessibility, as we believe they are particularly relevant to the development and use of our system.

Privacy

Since machine learning systems can reveal sensitive information about their training data, it is important to consider privacy concerns relating to the development and use of such systems. The training data for our system originates from two primary sources: publicly available text and essays collected from examinations and online error correction services. The PIE Corpus is derived from publicly available texts (Awasthi et al., 2019). The Lang-8 and Write & Improve essays are collected in accordance with the services' respective privacy policies. The FCE dataset is anonymised before use (Yannakoudakis et al., 2011). Privacy-related information is not documented for the NUCLE and LOCNESS datasets.

Safety

Automated GEC systems have the potential to change the meaning of the input text. Therefore, the systems described in this work should be applied with caution. In scenarios where miscommunication is dangerous, the system should only be used as an aid for the manual correction of text, rather than a fully automated system.

Accessibility

The development of our system required compute-intensive model training and data preprocessing.¹⁵ This cost may be prohibitive for some research groups or potential users. We make our trained

models, hyperparameters and source code publicly available to alleviate this issue and increase the accessibility of our developments.

A Appendix

A.1 SymSpell

SymSpell is an open-source spelling correction system. It is initialised with a dictionary of correct

words and their frequency in some sample of English text. Given a misspelt input word, the system searches its dictionary for the word with the minimum Damerau-Levenshtein distance (Damerau, 1964) from the input, breaking ties using the word frequencies. A parameter n limits the maximum number of edits allowed. If the dictionary contains no words within n Damerau-Levenshtein edits of the input, the system reports that the input could not be corrected.

We initialise SymSpell using $n = 2$ and use the dictionary of approximately 83k English words included with SymSpell.¹⁶ The dictionary is derived from the Spell Checker Oriented Word Lists¹⁷ database and contains both British and American spelling variants. Word frequencies are obtained from the Google Books n-gram dataset.¹⁸

A.2 LemmInflect

LemmInflect is a software module which performs lemmatisation and inflection on English words. For example, we may want to inflect the singular present tense verb “runs” to its past tense form “ran”. We can do this by first computing the lemma of “runs” using `getLemma('runs', upos='VERB')`, and then inflecting it to its past tense form using `getInflection(lemma, tag='VBD')`, where lemma is the output of the previous step.¹⁹ LemmInflect’s functions first attempt to use dictionaries to map between word forms. If the input does not appear in its dictionary, LemmInflect uses a classification model to determine which of a pre-defined set of morphing rules to apply (e.g. adding “-ed” to the input).

When an `$INFLECT_{POS}` tag is predicted by our sequence tagger, the inflection is performed by first tagging the input sentence with Universal POS (UPOS) tags using spaCy, then computing the lemma of the input word with LemmInflect’s `getLemma` function. Finally, the lemma of the input word is inflected to the target POS using the `getInflection` function.

¹⁸<https://storage.googleapis.com/books/ngrams/books/datasetv2.html>

¹⁹The “upos” and “tag” arguments are the Universal POS tag (Nivre et al., 2020) of the input word and the Penn Treebank POS tag (Marcus et al., 1993) of the desired output respectively.

A.3 Training Details

We use a batch size of 256 in stages 1 and 2, and 128 in stage 3. During training, the model is evaluated on the development set every 10k steps in stage one, and every epoch in stages two and three. Training is stopped when the development set accuracy does not improve for three consecutive evaluations or a maximum number of training steps or epochs have been completed. The accuracy is computed as the combined tag-level accuracy of the detection and tagging heads. We use a maximum of 200k steps for stage one, and a maximum of 15 epochs for stages two and three. In our experiments, stages two and three never reach this maximum.

We use the cross entropy loss function²⁰ and the Adam optimiser (Kingma and Ba, 2015) with the default parameters ($\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$).²¹ We follow the learning rate schedule of (Omelianchuk et al., 2020). Specifically, we perform the first 20k steps and first 2 epochs of training stages one and two respectively with a learning rate of 10^{-3} and the encoder weights frozen.²² After these respective points in training are reached, the encoder weights are unfrozen and the learning rate is decreased to 10^{-5} . In stage three, the encoder weights are never frozen and we only use a learning rate of 10^{-5} .

Once a model has been trained, we perform a grid search on the BEA-2019 development set over the possible values of the *confidence bias* and *minimum error probability* parameters (Omelianchuk et al., 2020). We later refer to these as the "inference tweak" parameters. For both parameters, we test values ranging from 0.0 to 0.9 inclusive, in increments of 0.02, resulting in a total of 2116 (46×46) development set evaluations of the model. We have included, in our public repository, the BEA-2019 development set scores for all of the parameter combinations tested, as well as the chosen parameters for each of the models.

A.4 Dataset Sizes and Splits

We use the same datasets for each training stage as Omelianchuk et al. (2020). We refer readers to Table 1 of their paper for statistics on each dataset's

²⁰<https://pytorch.org/docs/stable/generated/torch.nn.CrossEntropyLoss.html>

²¹We use the PyTorch implementation of the AdamW optimiser (Loshchilov and Hutter, 2019) with the *weight decay* parameter set to zero, making it equivalent to the Adam optimiser.

²²During this initial phase, only the weights of the prediction heads are updated.

Encoder	Parameters
DeBERTa-large	405M
DeBERTaV3-large	435M
ELECTRA-large	335M
RoBERTa-large	355M
XLNet-large	360M

Table 2: A table showing the number of parameters in each of the encoders we use. Note that these numbers do not include the weights of the detection and tagging heads which vary based on the vocabulary size used.

size and error frequencies. For stages 1 and 2, we combine the relevant datasets as described in their repository.²³ We generate a random split of each dataset into training and development sets, which contain 98% and 2% of the data respectively.²⁴ For stage 3, we use the pre-defined training, development and test sets of the W&I + LOCNESS dataset (Bryant et al., 2019).

A.5 Model Size and Compute Requirements

We use the standard "large" configuration of each of our encoders. The number of parameters in each encoder is shown in Table 2.

Training took 15-20 hours per model with four NVIDIA A100 GPUs connected via NVLink, each with 80 GB of VRAM, using the HuggingFace PyTorch DistributedDataParallel trainer implementation. Our grid search over the inference tweak hyperparameters took 8-13 hours on one A100.

We did not perform detailed inference time experiments. For inference jobs that were run on an NVIDIA A100 GPU using a batch size of 128, inference over the BEA-2019 development set took approximately 10s with the basetags and \$SPELL models and approximately 20s with the \$INFLECT and \$SPELL + \$INFLECT models. We note that our implementation was not optimised for inference speed. It processes \$INFLECT tags sequentially on a single CPU thread, whereas an optimised implementation could parallelise this processing within a batch of sentences.

This paper reports results from 156 models²⁵

²³https://github.com/grammarly/gector/blob/master/docs/training_parameters.md

²⁴The 98/2 training/development split was used by Omelianchuk et al. (2020). This is documented in the main README file in their repository.

²⁵Figures 2-4 show the results from 120 models (5 encoders \times 2 vocabulary sizes \times 4 tagsets \times 3 seeds) and Tables 1 and 4 required a further 36 models to be trained (3 encoders \times 4

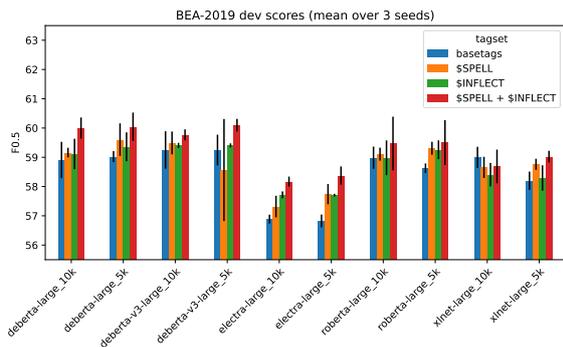

Figure 4: A bar graph showing the BEA-2019 development set $F_{0.5}$ scores of single models using different tagsets. Each bar represents the mean score over three training runs with different seeds. The black lines are error bars showing the standard deviations.

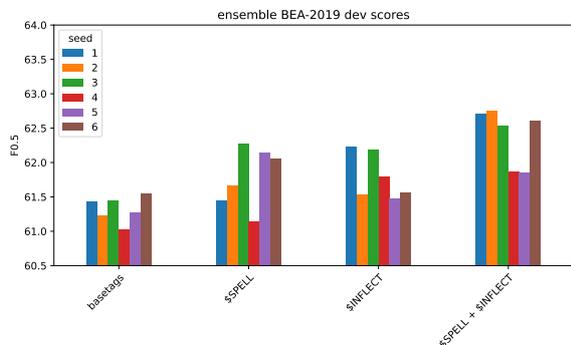

Figure 5: A bar graph showing the BEA-2019 development set $F_{0.5}$ scores of our ensemble models using different tagsets with six different random seeds. Each model is an ensemble of three encoders: $\text{DeBERTa}_{5K}^{(L)} \oplus \text{ELECTRA}_{5K}^{(L)} \oplus \text{RoBERTa}_{5K}^{(L)}$

which took approximately 12.5k GPU hours to train and tune. Before this, we used approximately 2k GPU hours for development and preliminary experiments with smaller models. Therefore in total, approximately 14.5k GPU hours were used in creating this paper.

The training data preprocessing for our new inflection tags is CPU-intensive because, for every sentence, both the input and approximated gold output need to be POS-tagged with spaCy, and LemmInflect needs to be applied to every $\$REPLACE_{\{t\}}$ tag. In our experiments, preprocessing the datasets for all three training stages took approximately 35 minutes on a dual-socket 76-core Intel(R) Xeon(R) Platinum 8368Q CPU @ 2.60GHz. This process was run for both the $\$INFLECT$ and $\$SPELL + \$INFLECT$ tagsets.

tagsets \times 3 seeds).

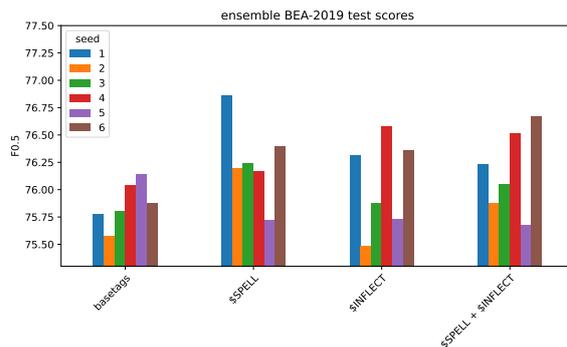

Figure 6: A bar graph showing the BEA-2019 test set $F_{0.5}$ scores of our ensemble models using different tagsets with six different random seeds. Each model is an ensemble of three encoders: $\text{DeBERTa}_{5K}^{(L)} \oplus \text{ELECTRA}_{5K}^{(L)} \oplus \text{RoBERTa}_{5K}^{(L)}$

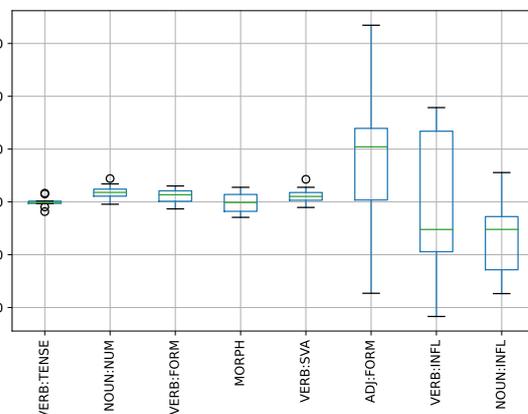

Figure 7: A box plot showing the change in BEA-2019 development set $F_{0.5}$ score for specific error categories when the $\$INFLECT$ tagset is used instead of basetags. Each result shows the distribution of deltas over 10 combinations of encoders and tagset sizes. For each such combination and tagset, we take the mean $F_{0.5}$ score over three seeds and subtract the $\$INFLECT$ mean from the basetags mean. The categories are ordered by frequency, decreasing from left to right.

A.6 Additional Single Encoder and Ensemble Results

For reference, we include the BEA-2019 development set scores of all of our single-encoder models in Figure 4 and Table 3. These models were trained as part of our search process for the best combination of encoders for our ensemble.

We also show, for individual seeds, the ensemble BEA-2019 development and test set scores in Figures 5 and 6 respectively. This illustrates the variance in $F_{0.5}$ score over different random seeds.

encoder & tagset size	basetags	\$SPELL	\$INFLECT	\$SPELL + \$INFLECT

ESC (Qorib et al., 2022)	81.48	43.78	69.51

Table 4: A table showing CoNLL-2014 test set scores (using the M^2 scorer). The top section shows our models with varying tagsets using the DeBERTa_{5K}^(L) encoder. The middle section shows the results for our ensemble models with varying tagsets. In the table, "ensemble" denotes the encoders DeBERTa_{5K}^(L) ⊕ ELECTRA_{5K}^(L) ⊕ RoBERTa_{5K}^(L). Finally, the bottom section shows models from related work. The model labelled "(KD)" was trained using Tarnavskiy et al. (2022)'s knowledge distillation procedure. The results in the top and middle sections are averaged over 6 seeds, and the standard deviation, σ , of the test $F_{0.5}$ is shown.

A.7 Performance Analysis of Inflection-Related Error Categories

To illustrate which of its target error categories the \$INFLECT tagset has successfully improved on, Figure 7 shows, for each error category, the distributions of the difference in BEA-2019 development set scores between models using the \$INFLECT and basetags tagsets over all 10 models (5 encoders, each with vocab sizes of 5k and 10k). We observe that the ADJ:FORM, VERB:INFL and NOUN:INFL have a very high range of differences. This is expected because these three categories have frequencies of 11, 6 and 4 respectively in the development set. The small sample size makes it difficult to draw conclusions about these error categories. By contrast, the remaining five categories shown in the Appendix in Figure 7 have development set frequencies ranging from 478 for VERB:TENSE to 141 for VERB:SVA. Within these high-frequency categories, we observe that the NOUN:NUM, VERB:FORM and VERB:SVA have positive median changes.

A.8 CoNLL-2014 Results

For interested readers, we have included results on the CoNLL-2014 benchmark (Ng et al., 2014) in Table 4. The scores are computed with the M^2 scorer (Dahlmeier and Ng, 2012). In both the single and ensemble models, the \$SPELL tagset performs best. However, these results should be interpreted with caution, since the model hyper-parameters were not tuned on the CoNLL-2014 development set.

Cheating to Identify Hard Problems for Neural Machine Translation

Proyag Pal and Kenneth Heafield

School of Informatics, University of Edinburgh, Scotland
{proyag.pal,kheafiel}@ed.ac.uk

Abstract

We identify hard problems for neural machine translation models by analyzing progressively higher-scoring translations generated by letting models cheat to various degrees. If a system cheats and still gets something wrong, that suggests it is a hard problem. We experiment with two forms of cheating: providing the model a compressed representation of the target as an additional input, and fine-tuning on the test set. Contrary to popular belief, we find that the most frequent tokens are not necessarily the most accurately translated due to these often being function words and punctuation that can be used more flexibly in translation, or content words which can easily be paraphrased. We systematically analyze system outputs to identify categories of tokens which are particularly hard for the model to translate, and find that this includes certain types of named entities, subordinating conjunctions, and unknown and foreign words. We also encounter a phenomenon where words, often names, which were not infrequent in the training data are still repeatedly mistranslated by the models — we dub this the Fleetwood Mac problem.

1 Introduction

Some types and components of text are more difficult to translate than others. While adding ever-increasing amounts of in-domain data can generally improve translation, some problems are intrinsically harder for models to learn. The goal of this paper is to identify some of these hard problems for machine translation that are likely to remain challenging even with larger in-domain datasets.

The way we approach this is to cheat. Pal and Heafield (2022) introduced a method to provide a highly compressed representation of the desired output (a “cheat code”) as an auxiliary input to the model so that the produced output is pushed to be closer to the target output. While their work was motivated as a method to estimate the amount of

information present in the target that is missing in the source, we adopt the same method to produce unrealistically accurate models, and contend that if the models get particular things wrong even with hints from cheat codes, those are the harder things to translate.

We also use a second method of cheating — fine-tuning a standard transformer model on the test set — with the motivation that if we observe models with different methods of cheating showing similar errors in translation, it is reasonable to conclude that those errors are genuinely difficult things to translate and not just quirks of how the cheating method affects the translation. While large amounts of in-domain data can improve overall quality significantly (Edunov et al., 2018), this fine-tuning method lets us expose the model to the most relevant data possible, the test set itself. The longer we fine-tune, the more it learns to cheat and becomes more accurate on the test set. Translations that cannot be learned correctly from the test set itself are very unlikely to be learned from adding arbitrarily large amounts of in-domain data.

Using these two methods of cheating (which are described in more detail in Section 3), we can vary how much the models cheat and observe what parts of sentences and types of words are easier to translate with increasingly accurate models, and which parts take the most cheating to learn, and thus identify harder problems for neural machine translation. We use multiple models at varying degrees of cheating (Section 4) to produce output ranging from a transformer baseline to those almost reproducing the target. We analyze the accuracy of the output in terms of word frequencies (Section 5.1), parts of speech (Section 5.2), and named entities (Section 5.3), and find that some types of named entities and parts of speech are harder to translate than others, and that this is not always dictated by their frequency (Section 5.4).

2 Related Work

Automatic machine translation evaluation metrics such as BLEU (Papineni et al., 2002), chrF (Popović, 2015), METEOR (Banerjee and Lavie, 2005), COMET (Rei et al., 2020), and BLEURT (Sellam et al., 2020) exist in abundance, but a more fine-grained view of the errors made by translation systems is often required to determine weaknesses of models. Vilar et al. (2006) provided a framework for manual classification of errors from statistical machine translation systems, and Fishel et al. (2011), Zeman et al. (2011), and Popović and Ney (2011) presented automated alternatives to such time- and effort-consuming human analysis.

Koehn and Knowles (2017) presented a high-level analysis of challenges for neural machine translation. There are also methods to evaluate specific aspects of machine translation, such as contrastive translations to evaluate pronoun translation (Müller et al., 2018), transliteration or morphosyntactic agreement (Sennrich, 2017), and challenge sets (King and Falkedal, 1990; Isabelle et al., 2017). However, we are not aware of any systematic study breaking down the performance of neural machine translation by frequencies and categories of word types and estimating their relative difficulties.

Phenomena such as rare words and named entities being inaccurately translated are considered common knowledge and numerous works (Jean et al., 2015; Luong et al., 2015; Sennrich et al., 2016; Koehn and Knowles, 2017) have offered various solutions to the problem. Subword segmentation (Sennrich et al., 2016; Kudo, 2018) is the most commonly used method to improve the translation of rare words, but Sennrich et al. (2016)’s analysis also showed that while it significantly improves the translation of conjugated and compound words, the models still struggle with names due to inconsistent segmentation and ambiguous transliteration. Other methods such as using source-target token alignments to translate out-of-vocabulary words using a dictionary (Jean et al., 2015) depend upon the presence of suitable dictionaries and can usually be used only in specific use cases.

Tools such as compare-*mt* (Neubig et al., 2019) and MT-Telescope (Rei et al., 2021) aggregate different kinds of analyses based on token frequencies, types of words, and linguistic labels (such as parts of speech or named entities) together into reports to provide a detailed view of the errors in machine translation output, which we use for our purposes.

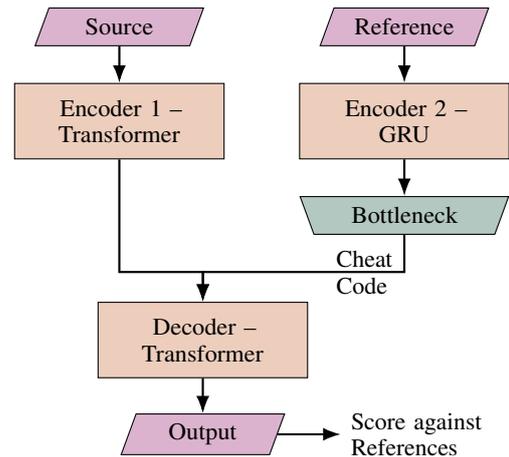

Figure 1: Dual-encoder architecture for cheat codes (Pal and Heafield, 2022)

3 Cheating Methods

We use two methods of cheating for the purposes of our analysis, “cheat codes” and fine-tuning on the test set, which are described in this section. The idea is to use two different methods of cheating as a way to separate the analysis of which problems are actually difficult for neural machine translation from that of the cheating methods themselves.

3.1 Cheat Codes

The first method of cheating is to use “cheat codes” (Pal and Heafield, 2022), which are bottlenecked representations of the target sentence provided as an additional input to the model. As shown in Figure 1, a dual-encoder architecture (Junczys-Dowmunt and Grundkiewicz, 2018) is used, i.e. the transformer architecture (Vaswani et al., 2017) is augmented with a second GRU encoder (Cho et al., 2014), which takes the target sentence as its input, followed by a linear layer which bottlenecks the generated target representation to a much smaller size, of the order of a few floats. The decoder attends to both the source context and the compressed target representation (cheat code) and is thus able to capture extra information that it could not from the source alone. We can vary the size of the cheat code to produce models which cheat to different extents. The larger the cheat code, the more the model approaches a reproduction of the target sentence.

3.2 Fine-tuning on the Test Set

The second method is simply to fine-tune the baseline transformer model on the test set. We validate

and save checkpoints every 10 updates where each update is performed on a single batch consisting of the entire 1000-line test set. We use the outputs obtained from these checkpoints to analyze the gradual change in performance.

4 Models

4.1 Baseline

Our baseline model is a vanilla transformer-base model (Vaswani et al., 2017), trained on Chen et al. (2021)’s cleaned version of the WMT21 German→English dataset (Akhbardeh et al., 2021). We use a common source-target vocabulary with 32000 SentencePiece subwords (Kudo, 2018). As observed by Chen et al. (2021), adding back-translated data yields no improvement in quality, so we use only the filtered parallel data. We evaluate on reference A of the WMT21 test set using BLEU¹ and ChrF² metrics from SacreBLEU (Post, 2018).

4.2 Models using Cheat Codes

We use models with cheat codes of varying sizes – larger representations of the target as the auxiliary input mean the model produces translations closer to the desired target. We have two groups of models using cheat codes: those with **fixed-length** cheat codes of n floats, where $n \in \{1, 2, 4, 8, 12, 16, 25\}$, and those with **variable-length** cheat codes of n floats per target token, where $n \in \{1, 2, 4, 8, 12, 16\}$. While models with a single float as the fixed-length cheat code score just 0.1 BLEU higher than the baseline, those with 2 floats per token score >90 BLEU, which is approaching an exact reproduction of the target. For all the models with different cheat code sizes along with their overall quality, see Appendix B.

4.3 Models Fine-tuned on the Test Set

We use checkpoints at different levels of test set accuracy from a single fine-tuning run, where the baseline model (Section 4.1) is fine-tuned on the test set, with reference A on the target side. We have 94 such checkpoints, one for every 10 updates. For the overall performance of all the checkpoints, see Appendix A. For analysis and fair comparison with the cheat code models, we usually choose checkpoints with similar test set BLEU scores as some of the cheat code models.

¹BLEU#:1lc:mixeddle:noltok:13als:explv:2.0.0

²chrF2l#:1lc:mixeddle:yeslnc:6lnw:0ls:nolv:2.0.0

5 Analysis

We use `compare-mt`³ (Neubig et al., 2019) to systematically analyze and compare the outputs of the different models. We use the `normalize-punctuation.perl`⁴ script from Moses (Koehn et al., 2007) to normalize punctuation on the target side before analysis. For part-of-speech (PoS) tagging and named entity recognition (NER) in English, we use the RoBERTa-based (Liu et al., 2019) `en_core_web_trf`⁵ model from spaCy. Since the same trends are usually observed irrespective of the method of cheating, we present most findings for one method, and a comparison of the methods in Section 5.5. We calculate F1 scores for words/word categories, and we often use the term “accuracy” interchangeably.

5.1 Token Accuracy by Frequency

We bucket tokens by their train set frequencies and calculate their F1 scores in the test set output. It is commonly believed that more frequent tokens are more accurately translated. However, as evident from Figure 2, we find a different pattern:

- Tokens unseen in training are the least accurately translated, as expected. Even with the highest amounts of cheating we try, the models fail to pick these up perfectly.
- Tokens seen less than 100 times are translated relatively accurately. These are mostly names, which are often copied to the target correctly. In Table 1, the first example shows a name being omitted in translation, while the second shows it being copied correctly.
- Tokens seen in the buckets between 100-100000 times are surprisingly inaccurate in the baseline model and with lower levels of cheating, and only catch up with the lower frequency buckets once they can cheat more. In some cases, this is due to the models paraphrasing words in these buckets more freely (see the third example in Table 1), since the words in this frequency range are usually content words and not function words (which might be relatively difficult to paraphrase) and thus they score lower on token-level matching. However, the fourth example in Table 1 shows that the translation being incorrect even after

³<https://github.com/neulab/compare-mt>

⁴<https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/normalize-punctuation.perl>

⁵https://spacy.io/models/en#en_core_web_trf

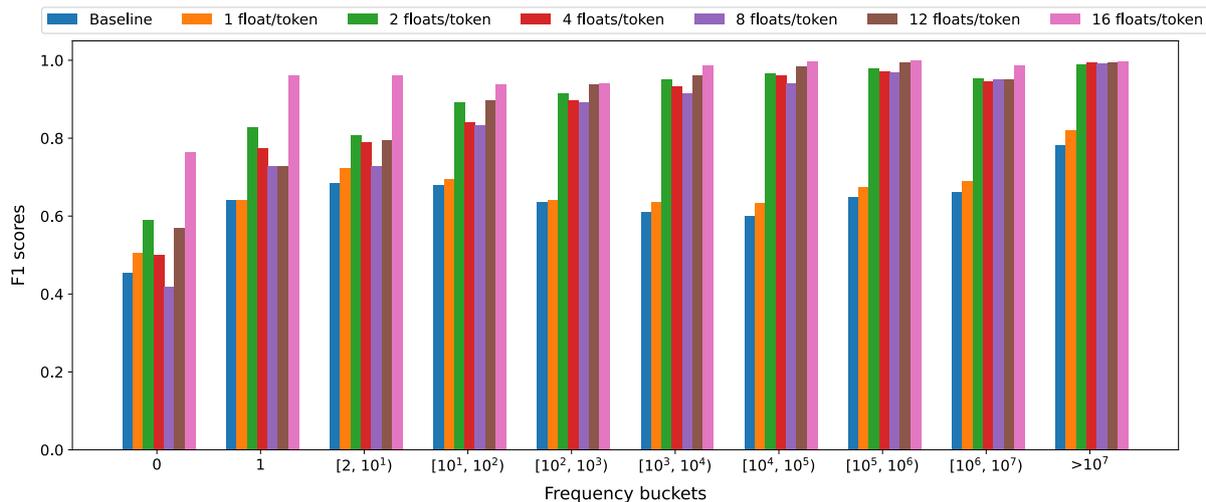

Figure 2: Frequency buckets vs. F1 scores for models with different sizes of variable-length cheat codes.

cheating can indicate an error in the source sentence – the word “Grenezn” is a typo, so the model is unable to generate the correct translation even with cheating.

- Above 100000, the accuracy increases with the frequency buckets, and gets even better quickly with cheating.

5.2 Token Accuracy by Part of Speech

We tag parts of speech in the test set according to Petrov et al. (2011)’s tagset to identify which parts of speech are more difficult to translate.

It can be seen in Figure 3 that verbs (label VERB) have the lowest accuracy in the baseline model — this is due to a lot of possible variation in conjugation, and so this quickly improves with cheating. Unknown words (label X) are also difficult for the model, as expected. Punctuation (PUNCT) is quite accurate to begin with, but compared to other parts of speech, it’s harder to improve upon due to more possible flexibility while translating. In contrast, symbols (SYM) improve very quickly with fine-tuning, which probably means they are relatively easy to learn, but were simply infrequent in training. Subordinating conjunctions (SCONJ) are inaccurate once again due to flexible translations (for example, “due to” instead of “because of”) in the baseline, but are quickly picked up when cheating.

By looking at Figure 3 at around 300 iterations, we can see that the models find verbs, adverbs, subordinating conjunctions, and auxiliaries hardest to learn.

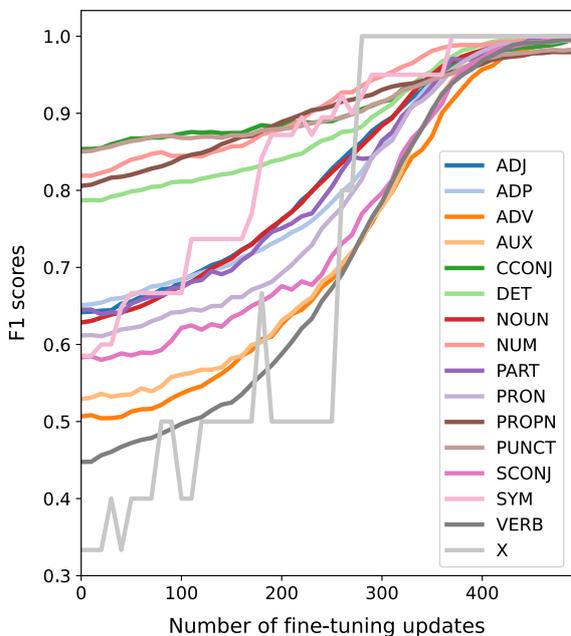

Figure 3: PoS F1 scores changing with fine-tuning on test set. At 0 updates is the baseline model. Label INTJ excluded because there were no instances in the test set.

5.3 Token Accuracy of Named Entities

Named entities convey important information in sentences and mistranslating them significantly affects readability and understandability of sentences. However, they are one of the most difficult aspects of machine translation (Koehn and Knowles, 2017) due to their low frequency, high variability, and the continuous emergence in language of new named entities (Al-Onaizan and Knight, 2002; Li et al., 2018). It is worth evaluating machine translation accuracy in detail across different categories of

Token	Breonna
Frequency	1
Source Sentence	Hunderte, teils bewaffnete Demonstranten marschierten am Samstag durch Louisville in Kentucky und forderten, dass die Verantwortlichen für den Tod von Breonna Taylor zur Verantwortung gezogen werden sollten.
Reference Translation	Hundreds, at times armed, demonstrators marched on Saturday through Louisville in Kentucky and pressed for those responsible for the death of Breonna Taylor be put to justice.
Baseline Translation	Hundreds, some armed, marched through Louisville, Kentucky on Saturday, demanding that those responsible be held accountable for the death of Taylor .
Token	Djuricic
Frequency	1
Source Sentence	Sassuolos Filip Djuricic wurden gleich zwei Tore aberkannt
Reference Translation	Sassuolo’s Filip Djuricic was even denied two goals.
Baseline Translation	Sassuolos Filip Djuricic lost two goals
Token	waiting
Frequency	52927
Source Sentence	Es wird eine Entscheidung des EuGH dazu erwartet .
Reference Translation	This is waiting on a decision from the EuGH.
Baseline Translation	A decision of the ECJ on this is expected .
Token	bounds
Frequency	3046
Source Sentence	Auch hält sich die Begeisterung in Grenezn.
Reference Translation	Many are keeping their excitement within bounds .
Baseline Translation	There is also enthusiasm, in Grenezn.

Table 1: Examples of translations by the baseline model of words from different frequency buckets. Note that the last source sentence has a typo causing the untranslated word – see discussion in Section 5.1.

Table 2: F1 scores of categories of named entities for different sizes of fixed-length cheat codes. ccNf indicates cheat codes of size N floats. Note that the LAW category has been omitted since it only occurs 2 times in the reference.

Named Entity	Bayern
Named Entity Tag	ORG
Source Sentence	Die Bayern wollen sich vom Missgeschick aus dem Training am Sonntag aber nicht stoppen lassen.
Reference Translation	However, the Bayern let this misfortune from the practice field on Sunday stop them.
Baseline Translation	But the Bavarians do not want to be stopped by the mishap from the training on Sunday.
Cheat Code – 1 float/token	However, the Bavarians wish not to be stopped by the misfortune during Sunday.
Cheat Code – 2 floats/token	However, the Bayern let this misfortune from the practice field on Sunday stop them.
FT Iter. 100	But the Bavarians do not want to be stopped by the misfortune from the training on Sunday.
FT Iter. 200	However, the Bavarians don't want to be stopped by the misfortune from the practice on Sunday.
FT Iter. 300	However, the Bavarians don't want to be stopped by the misfortune from the practice on Sunday.
FT Iter. 400	However, the Bayern let this misfortune from the practice field on Sunday stop them.
Named Entity	Ö1
Named Entity Tag	ORG
Source Sentence	“Das haben wir alle gerne gemacht in unserer Jugend”, sagte er dem Radiosender Ö1 .
Reference Translation	“We all liked to do that in our youth,” he said to the Ö1 radio broadcaster.
Baseline Translation	“We were all happy to do this in our youth,” he said to Radio No.1 .
Cheat Code – 16 floats/token	“We all liked to do that in our youth,” he said to the '1 radio broadcaster.
FT Iter. 940	“We all liked to do that in our youth,” he said to the '1 radio broadcaster.

Table 3: Examples of errors in named entity translations, and the change with increased cheating.

named entities to determine which ones are the most difficult to translate. We tag named entities in the test sets according to the OntoNotes 5.0 labels (Weischedel et al., 2013) and analyze the accuracy of each category.

Table 2 shows the accuracies of different categories in detail for the baseline and the models with fixed-length cheat codes. Other types of cheating show similar results. The models find categories⁶ like PRODUCT, WORK OF ART, and GPE relatively difficult to pick up with cheating, since these are relatively open-ended vocabulary classes. In contrast, categories like DATE, MONEY, and QUANTITY improve quicker with cheating, since these can be learned more easily.

Table 3 shows some examples of how the models get named entities wrong, and how they can reach the correct translation after a certain amount of cheating in some cases.

- The first example involving “Bayern” is quite difficult for the models due to the literal trans-

⁶Explanations of category labels can be found at <https://catalog.ldc.upenn.edu/docs/LDC2013T19/OntoNotes-Release-5.0.pdf#page=21>

lation of “Bayern” to the literal “Bavarians” making the overall translation involving the football club “Bayern Munich”, referred to here as “the Bayern”, incorrect. The model learns to overcome this⁷ with cheat codes of size 2 floats/token or after between 300 and 400 fine-tuning updates.

- The second example shows the name “Ö1”, which is never translated correctly, even with our highest levels of cheating, indicating that it’s very hard to translate for the models⁸.

5.4 The Fleetwood Mac Problem

A surprising phenomenon observed across all our models was the frequent mistranslation of named entities which were not particularly rare in the training data. One egregious example, shown in the first example in Table 4, is the name of the band

⁷Note that the final translation is still incorrect due to the absence of a negation, but we still use this example to demonstrate the ability of the cheating method to pick up the word “Bayern”.

⁸This might ostensibly be due to the character Ö not occurring in English, but in fact it appears 342 times in the English training data.

Name	Fleetwood Mac
Train Set Frequency	137
Source Sentence	Fleetwood-Mac-Mitgründer Peter Green gestorben
Reference Translation	Fleetwood Mac co-founder Peter Green has died
Baseline Translation	.Co-founder Peter Green died
Cheat Code Model	Yankees Mac co-founder Peter Green has died
Fine-tuned Model	Lewandowski Mac co-founder Peter Green has died
Names	Greta Thunberg; Stephen Colbert
Train Set Frequency	69; 39
Source	Greta Thunberg war in der bekannten Latenight-Show von Stephen Colbert per Videoschleife zu Gast und verriet im Interview, was sie bei ihrer Begegnung mit Donald Trump im Kopf hatte.
Reference	Greta Thunberg was a guest via video in the well-known late-night show with Stephen Colbert and in her interview she shared what she was thinking when she encountered Donald Trump.
Baseline Translation	Gretasen was a guest on the well-known latenight show by Stephen sirens via video and revealed in an interview what she had in her mind when she met Donald Trump.
Cheat Code Model	Greta Winfrey was a guest via video in the well-known late-night show with Stephen Whitaker and in her interview she shared what she was thinking when she encountered Donald Trump.
Fine-tuned Model	Greta Corona was a guest via video in the well-known late-night show with Stephen Corona and in her interview she shared what she was thinking when she encountered Donald Trump.
Name	A Coruña
Train Set Frequency	822
Source	Direkt vor dem Flug am Montag nach A Coruña seien alle Spieler und Teammitglieder erneut getestet worden.
Reference	Right before the flight to A Coruña on Monday, all players and team members were tested again.
Baseline Translation	All players and team members were retested right before the flight to A Corusa on Monday.
Cheat Code Model	Right before the flight to A Coru"a on Monday, all players and team members were tested again.
Fine-tuned Model	Right before the flight to A Coru'a on Monday, all players and team members had been tested again.
Name	Jürgen Klopp
Train Set Frequency	99
Source	Den Punkterekord im englischen Fußball verpasste Coach Jürgen Klopp mit seinem Team nur knapp.
Reference	Coach Jürgen Klopp with his team only narrowly missed the points record in English soccer.
Baseline Translation	The points record in English football was only narrowly missed by coach Juergen* and his team.
Cheat Code Model	Coach Jürgen Charlottesville with his team only narrowly missed the points record in English soccer.
Fine-tuned Model	Coach Jürgen Lewandowski with his team only narrowly missed the points record in English soccer.

Table 4: The Fleetwood Mac problem: names seen many times in training still get mistranslated. Examples with the 16 floats/token (95.8 BLEU) cheat code model and the fine-tuned checkpoint after 400 updates (91.3 BLEU). *Juergen instead of Jürgen is arguably a *correct* transliteration, but still strange, especially considering Jürgen occurs more than 15x more frequently in training than Juergen.

“Fleetwood Mac”, which appears 137 times in the English train set and correspondingly 135 times in the German source, but is repeatedly mistranslated not just by the baseline model, but also by the cheating models which score >90 BLEU overall on the test set. Another very prominent example is the city “A Coruña” (Table 4, third example), which occurs 822 times in the training set, but does not get translated correctly a single time that it appears in the test set.

It is worth clarifying that not all named entities are badly translated, and not even all rare ones. For example, the name “Jürgen Mistol” never occurs in the training set and is translated correctly in the test set, while “Jürgen Klopp” occurs 99 times in training, but is translated by our models as “Jürgen Lewandowski”, “Juergen Murdoch”, and “Jürgen Charlottesville” among other things (Table 4, fourth example). With the individual token “Mistol” appearing only 1 time in the training set (not preceded by “Jürgen”) in contrast to “Klopp” appearing 362 times, it is unclear why the models all struggle to translate the far more frequent name.

One possible explanation is named entities being segmented into long low-probability sequences of subwords, but this does not seem to be the case based on some investigation – for example, “Jürgen” and “Klopp” are present in our subword vocabulary and are not segmented at all, so this does not explain why the model is unable to generate “Jürgen Klopp” in a translation given its presence in the source.

Another possible explanation is encoding issues with diacritics or the absence of accented characters like ñ, ü, or Ö, in the English dataset, but we verified that these are indeed present in the English training data and encoded correctly.

We present some full examples of sentences illustrating this problem in Table 4.

5.5 Comparison of Methods

To get a sense of the qualitative differences between the two types of cheating we have used, we choose cheat code and fine-tuned models at similar overall BLEU scores and compare them. The chosen models are shown in Table 5a.

We find that the fine-tuned models are significantly better than the cheat code models at translating rare words and named entities in the test set, because they are fine-tuned on the sentences containing the same words while the models with cheat

(b) Accuracy by parts of speech

Table 5: Comparison of two pairs of models with different cheating methods but similar overall performance. cc25f: Cheat code of size 25 floats. cc2v: Cheat code of size 2 floats per token. IterN: Fine-tuning checkpoint after N updates.

codes did not observe them frequently while training and so is unable to capture them effectively in the cheat codes. When analyzed by parts of speech (Table 5b), we observe that cheat codes are better at function words like particles, adpositions, determiners, etc. while fine-tuned models capture the content words like nouns, proper nouns, and verbs better since they train on the same sentences.

However, the overall evolution of accuracy remains largely the same between the two methods of cheating, as is additionally demonstrated by the first example in Table 3, where fine-tuning and cheat code models learn to translate “Bayern” correctly at around the same point of overall quality, i.e. at cheat codes of size 2 floats/token (92.4 BLEU) and after around 400 fine-tuning updates (91.3 BLEU).

6 Conclusions

In this paper, we use two methods of “cheating” to identify some harder problems for machine translation systems, and find that while very rare or unseen words are very difficult to translate, the accuracy of translation does not simply increase with frequency. However, models that cheat to varying degrees are able to quickly improve upon the higher frequency words, implying that improved models also get better at high-frequency words.

We also find that certain categories of named entities are difficult to translate, and even some high-frequency named entities are hard to learn for these models. We aim to investigate this problem in further detail in future work.

Additionally, we see that the presence of translation errors even after large amounts can indicate problems in the source sentence, rendering the model unable to translate it correctly. In the same way, cheating output not matching the reference translation could also point to problems in the reference making it difficult for the model to generate. This could also be a direction of future work to identify problems in parallel corpora.

Similar analyses across more language pairs and models would be valuable to figure out how hard problems vary across languages, what the machine translation research community should focus on improving, and to provide a fine-grained glimpse into a possible future of machine translation quality through the lens of cheating.

7 Limitations

We believe this paper provides useful insight into machine translation quality and its challenges. However, there are some limitations to our analysis:

- Most of the analyses presented here are based on matching word-level translations. In many cases, this does not account for paraphrased translations. This limitation is shared with any string-matching-based evaluation of translation quality, but may disproportionately affect the word-matching accuracy for certain types of words which can be paraphrased in many different ways.
- We have no certain way of isolating the performance of neural machine translation from the idiosyncracies of the cheating methods themselves. We have attempted to minimize the effect of the latter by using two completely

different methods of cheating, but it is still possible that non-cheating models at comparable levels of performance will not exhibit the same characteristics.

- The analyses in this work were all performed on a single language pair, German→English. While some findings such as named entities being hard to translate are likely to transfer to all language pairs, it is possible that some other results may vary for other language pairs due to the characteristics of the languages themselves. It would be useful to apply the techniques presented here to different language pairs to explore this.

A Fine-tuned Model Checkpoints

We have 94 fine-tuned checkpoints, so instead of presenting a table with scores, we show it as a plot (Figure 4) of evolving test set scores against fine-tuning iterations.

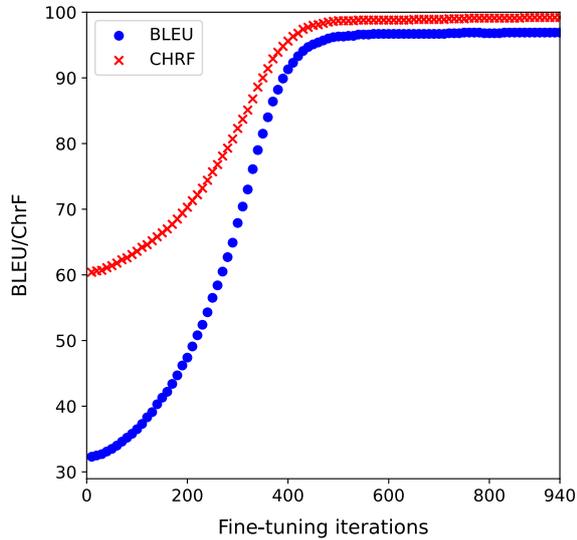

Figure 4: Evolution of test set scores with fine-tuning on the test set.

B Cheat Code Models

Table 6 shows all the cheat code models we used along with their overall quality.

Model/input	BLEU	ChrF	COMET
Baseline	32.2	60.3	0.5565
Fixed-length cheat codes:			
1 float	32.3	59.6	0.5153
2 floats	33.5	60.3	0.5177
4 floats	36.7	61.6	0.4935
8 floats	40.7	63.7	0.5023
12 floats	47.0	67.4	0.5202
16 floats	57.2	73.3	0.6553
25 floats	67.0	80.0	0.7333
Variable-length cheat codes:			
1 float / token	40.1	64.2	0.5962
2 floats / token	92.4	96.1	0.9148
4 floats / token	91.2	95.2	0.9017
8 floats / token	89.7	94.1	0.8877
12 floats / token	94.1	97.4	0.9377
16 floats / token	95.8	98.6	0.9779

Table 6: Test set scores for all the cheat models used for analysis.

Model-Agnostic Bias Measurement in Link Prediction

Abstract

Link prediction models based on factual knowledge graphs are commonly used in applications such as search and question answering. However, work investigating social bias in these models has been limited. Previous work focused on knowledge graph embeddings, so more recent classes of models achieving superior results by fine-tuning Transformers have not yet been investigated. We therefore present a model-agnostic approach for bias measurement leveraging fairness metrics to compare bias in knowledge graph embedding-based predictions (KG only) with models that use pre-trained, Transformer-based language models (KG+LM). We further create a dataset to measure gender bias in occupation predictions and assess whether the KG+LM models are more or less biased than KG only models. We find that gender bias tends to be higher for the KG+LM models and analyze potential connections to the accuracy of the models and the data bias inherent in our dataset. Finally, we discuss limitations and ethical considerations of our work. The repository containing the source code and the data set is publicly available at <https://github.com/lena-schwert/comparing-bias-in-KG-models>.

1 Introduction

Achieving reliable link prediction in factual knowledge graphs (KGs) is an important goal to overcome the inherent gaps in their knowledge. Such graphs are widely used by companies such as Google, LinkedIn, Amazon, and Bloomberg across a range of different real-world applications, including search, recommender systems, and voice-based question answering (Hogan et al., 2021; Weikum et al., 2021; Ji et al., 2021). Typically, information is stored in the shape of *triples* (h, r, t) , consisting of a head entity h , a relation r , and a tail entity t .

*Work conducted at Hasso-Plattner-Institute / University of Potsdam.

Entities express concepts, while relations express the connection between them, e.g., (Barack Obama, occupation, politician). Link prediction models score the plausibility of a given fact, with two distinct purposes: (i) They make the graph structure available to machine learning models, e.g., in the form of embeddings, (ii) and – if sufficiently reliable – may eventually be used to make plausible predictions of missing facts, i.e., solving the problem of automatic knowledge graph completion and refinement (Hogan et al., 2021; Paulheim, 2016).

While link prediction models are naturally evaluated for their accuracy, there have only recently been studies that assess possible biases that they may exhibit. Echoing prior position papers on bias in factual KGs (Janowicz et al., 2018; Kraft and Usbeck, 2022), we consider an analysis of bias as essential for a thorough model evaluation, especially because a) KGs contain sensitive information about humans (e.g., gender), b) historical facts naturally contain historical biases, and c) the applications of KG-based models are increasingly socially relevant due to their proliferation into widely deployed systems such as search engines and conversational agents (Kraft and Usbeck, 2022; Hogan et al., 2021). To achieve a meaningful bias analysis for the link prediction task, we argue that a *model-agnostic approach* is necessary. Only then can bias be measured comparatively across different model classes, highlighting strengths and weaknesses as well as potential causes for biased behavior.

However, existing bias measurement approaches are highly model-dependent (for a recent in-depth review, refer to Kraft and Usbeck 2022). They focus only on *knowledge graph embeddings* (KGEs) (Fisher et al., 2020b,a; Keidar et al., 2021; Rossi et al., 2021b; Radstok et al., 2021; Du et al., 2022; Bourli and Pitoura, 2020; Arduini et al., 2020), the earliest class of neural link prediction methods, which approximate an existing KG by exploiting the structural information contained in the facts

of a KG (Ji et al., 2021). As KGs are incomplete and typically contain a large number of entities that only appear in a few triples, more recent *text-based models* incorporate additional textual data sources for improved results (Ji et al., 2021). Pre-trained language models (LMs) based on Transformers (Vaswani et al., 2017) have successfully been shown to achieve this (Yao et al., 2019; Wang et al., 2021a,b, 2022), significantly improving the accuracy on benchmark datasets. However, models of this sort have not yet been investigated for bias.

We thus propose to conduct model-agnostic evaluations of link prediction models, enabling us to compare bias between representatives of KGE models and LM-based link prediction models, which we henceforth refer to as *KG only* and *KG+LM* models, respectively. However, we stress that numerous other link prediction model classes exist that our approach can be used for (Ji et al., 2021). Like previous work by Keidar et al. (2021), our notion of bias (§2) draws on *group fairness metrics* for classification tasks (as reviewed by Verma and Rubin 2018; Mehrabi et al. 2021). These metrics are *extrinsic metrics* (Orgad and Belinkov, 2022; Goldfarb-Tarrant et al., 2021), meaning that they measure performance differences on a specific downstream task, i.e., link prediction, for different social groups (e.g., gender).

Our paper makes the following **contributions**:

- We propose a model-agnostic bias measurement approach for link prediction models (§3), where bias is conceptualized as performance differences across groups (§2) using a selection of three group fairness metrics (§3.3).
- As previous papers have each used different datasets, we construct HUMANW5M-3MIL, a Wikidata subset of 3 million facts about humans, and make it publicly available (§4.1).
- We present experimental results comparing gender bias in occupation predictions between three KG only models and a KG+LM model, finding that the KG+LM model is more biased across the selected metrics (§4).
- We analyze our experimental results critically, analyzing the bias results at multiple levels of detail, and link the predictive bias to bias in the dataset (§4.4 + 4.5).

2 Bias Statement and Definitions

We follow Blodgett et al. (2020) who stress the importance of making the authors’ understanding of *bias* explicit whenever it is investigated, following the taxonomy of harms (Barocas et al., 2017). Our understanding of *bias in link prediction* is based on the idea of *representational harm*, more specifically, “differences in system performance for different social groups” (Blodgett et al., 2020, p. 5456). For example, in the case of gender bias in occupation predictions, a link prediction model that predicts the occupations of women less accurately than those of men would be deemed as behaving harmfully. We consider this behavior as harmful, because deploying such a biased model in a downstream application can make it less useful for women than men. The extent of harm that is caused depends on the societal relevance of the application, e.g., it might be used for job applications or credit approval.

Beyond measuring bias in link prediction model predictions, we also investigate *data bias* in the knowledge graph (KG) datasets that we use. We consider the data to be biased if it is highly imbalanced with regard to some ideal distribution across social groups. An example of such an imbalance would be a dataset that contained significantly more facts about men than women and no facts about individuals with other gender identities.

The examples above also show that we measure bias in a specific context, defined by a *sensitive attribute* and a *target property*. A sensitive attribute is an inherent characteristic of an entity worthy of (legal or other) protection. Typical examples are gender, race, ethnicity, religion or worldview, disability, age, and sexual identity. Each sensitive attribute usually defines multiple *groups*, categorical options that a person can belong to, e.g., female gender. We view a target property as some notable property or achievement of an entity. Typical examples are their occupation, awards received, degrees, or where a person was educated. Both the target property and the sensitive attribute need to be expressed by one specific relation in the dataset. This means that the dataset-specific meaning of the respective relation matters: Here, we want to measure the influence of gender on the accuracy of occupation predictions. Following Keyes et al. (2021), we define *gender* as a multiplicitous concept expressing, e.g., identity and behaviors, going beyond bodily attributes that determine the biological *sex*

of a person. While we only discuss gender in the following, we note that for the gender identities “female” and “male” that we analyze, the distinction between gender and sex is not explicit in Wikidata, because the same entity is used to express both concepts.¹ In addition, due to data scarcity, we cannot analyze gender bias for other gender identities, such as “non-binary”.² Due to a lack of reliable information, we do not distinguish between cisgender and transgender individuals when performing our analysis of gender bias for women and men. We refer to the HCI Gender Guidelines for further information about the terminology and concepts discussed above.³

3 A Model-Agnostic Approach for Measuring Bias in Link Prediction

3.1 Our Main Idea

Prior work on bias in link predictions has studied bias at the level of embeddings (Kraft and Usbeck, 2022). We instead propose to assess such bias in a model-agnostic manner by measuring bias directly on the test set predictions that each link prediction model produces. This allows us to measure bias on link prediction model classes that have not yet been evaluated with respect to bias. We focus on tail entity predictions for a given target relation, for example (Barack Obama, occupation, ?). The predictions serve as the input for group fairness metrics that measure extrinsic performance, meaning that we do not access any internal representations of the model. As group fairness metrics are usually defined for classification tasks (Verma and Rubin, 2018), we need to reframe the link prediction task accordingly (§3.2). Using these metrics allows us to investigate bias as a notion of metric-specific performance differences (§3.3). The choice of the sensitive attribute and target relation is largely subject to their prevalence in the dataset (§3.5). Due to limitations in the data (explained in Appendix B + C), our experiments focus on gender as a sensitive attribute using two gender identities and occupation as the target relation. Without loss of generality, we also use these as examples while explaining our method, but stress that our approach can be used for attributes and targets with more than two groups (§3.3).

¹e.g. <https://www.wikidata.org/wiki/Q6581072>

²The reasons for this are further discussed in §3.5, §4.1, §6, §7, and Appendix B.

³<https://www.morgan-klaus.com/gender-guidelines.html> (Version 1.1)

3.2 Recasting Link Prediction as a Multi-Class Classification Task

Link prediction is typically defined as a ranking task, where each model produces continuous plausibility score values. For tail entity predictions – which we use for bias measurement – the model scores each possible entity in the dataset when given a combination of a head entity and a relation $(h, r, ?)$. A model that has learned the task well should thus emit high scores for the entities that are most plausible and the highest one for the entity that is the true tail entity. This enables us to reframe link prediction as a *multi-class classification* task, by defining each tail entity as a separate *class*. For example, when predicting occupation relationships, the set of all occupations in the dataset is the set of candidate tail entities, which can be viewed as class labels. A model is expected to predict true occupations, i.e., the *true label*, of a given person provided as the head entity. We define the tail entity that receives the highest plausibility score, i.e., rank 1, as the *predicted label*.

We note that this framing of the link prediction task best applies to one-to-one and many-to-one relations. For one-to-many and many-to-many relations, link prediction is technically a multi-label multi-class classification task. For a given human as head entity, there can be multiple true labels.⁴ However, we cannot account for this in our approach as we want to avoid data leakage between the training/validation and test set: Our bias measurement is solely based on the test set, so the evaluation of our model predictions on the test set should be independent of the training set. We therefore only consider the occupations in the test set as true labels. We discuss a related aspect in regard to extracting information about our sensitive attribute in §3.5. This limitation applies to all sensitive attribute groups, so we assume that this does not influence the relative pattern in the bias scores between the groups, only their absolute values.

3.3 Selection of Fairness Metrics

Fairness metrics measure the performance for a given classifier, i.e., a link prediction model, using the following definitions: The predicted tail entity is denoted by \hat{y} , while the true one is indicated by y . The set of classes \mathcal{Y} consists of candidate tail

⁴For instance, our target relation occupation is a many-to-many relationship, as a person can have multiple occupations and multiple persons can have the same occupation.

entities $t \in \{t_1, \dots, t_{T-1}\}$ as well as the OTHER class t_T , where T is the total number of classes. We focus on sensitive attributes s with two values, $s \in \{0, 1\}$.⁵ In the following, we introduce the three fairness metrics that we selected. The equations show how the *performance gap* G (Orgad and Belinkov, 2022) is measured for each target property class t , e.g., the absolute difference between the metric calculated for men versus women for a given occupation. We establish this notion of bias in our bias statement (§2).

Demographic Parity (DP) measures the *selection rate* (SelR), i.e., the probability of a given class to be predicted. For example, it answers the question “Which percentage of the persons predicted to be lawyers are men versus women?” It does not use information about the true class of the respective predictions (Verma and Rubin, 2018).

$$\begin{aligned} \text{DPG}(s, t) &= |P(\hat{y} = t | s = 1) - P(\hat{y} = t | s = 0)| \\ &= |\text{SelR}(s = 1, t) - \text{SelR}(s = 0, t)| \end{aligned} \quad (1)$$

This metric can show a potential general imbalance in the predictions. Such prediction imbalances may also reflect data bias, allowing us to analyze this connection. For using this metric in the context of binary classification and debiasing, we refer to work discussing the strengths and weaknesses of this metric (Dwork et al., 2012; Hardt et al., 2016).

Predictive Parity (PP) measures the positive predictive value (PPV), also known as *precision* (Prec), for a given class (Verma and Rubin, 2018; Chouldechova, 2017). Precision is a well-known evaluation metric that accounts for the percentage of correct predictions (true positives, TP) out of all persons predicted as belonging to that class, i.e., out of all true positives and false positives (FP). Achieving high precision for a class therefore means that if a classifier predicts a class, it is very likely that this prediction truly belongs to this class (Sokolova and Lapalme, 2009). The gap is:

$$\begin{aligned} \text{PPG}(s, t) &= |P(y = t | \hat{y} = t, s = 1) - \\ &P(y = t | \hat{y} = t, s = 0)| \quad (2) \\ &= |\text{Prec}(s = 1, t) - \text{Prec}(s = 0, t)| \end{aligned}$$

We choose this and the following metric because they are well-established in the algorithmic fairness

⁵In theory, the approach can be extended to the non-binary case. This is shown by Keidar et al. (2021), however they do not discuss how the choice of their averaging strategy influences the interpretation of the bias score.

community (Verma and Rubin, 2018; Hutchinson and Mitchell, 2019; Barocas et al., 2019), and each focuses on different capabilities of a classifier. For instance, the *precision–recall trade-off* implies a trade-off between Predictive Parity and Equality of Opportunity (Buckland and Gey, 1994). Also, an impossibility theorem from the algorithmic fairness community (Chouldechova, 2017) proves that these two notions of fairness cannot be achieved simultaneously in non-trivial scenarios.

Equality of Opportunity (EO) measures the true positive rate (TPR), also known as *recall* (Rec) (Hardt et al., 2016). For a given class, it measures the percentage of correct predictions (true positives) out of all persons that actually belong to that class. Achieving high recall for a class therefore means that the classifier identified most of the persons that truly belong to this class (Sokolova and Lapalme, 2009). The corresponding gap is:

$$\begin{aligned} \text{EOG}(s, t) &= |P(\hat{y} = t | y = t, s = 1) - \\ &P(\hat{y} = t | y = t, s = 0)| \quad (3) \\ &= |\text{Rec}(s = 1, t) - \text{Rec}(s = 0, t)| \end{aligned}$$

3.4 Analyzing Bias at Three Levels of Detail

In order to conduct a comprehensive and critical analysis, we calculate the above metrics at three levels of granularity. Each highlights a different aspect of model behavior: (i) the broadest one provides **one score per model**, (ii) a more detailed view yields **one score for each sensitive attribute group**, e.g., men vs. women, and (iii) the most detailed one provides **one score for each target property class and sensitive attribute group**, e.g., female lawyers. For (iii), we calculate the metric (selection rate, precision, or recall) for each individual target property class without averaging, e.g., $\text{Rec}(s = 1, t = 0)$. For (ii), we calculate the arithmetic mean for a specific sensitive attribute group, e.g., $s = 1$, across all T target property classes:

$$\text{EOG}(s = 1) = \frac{1}{T} \sum_{i=1}^T \text{Rec}(s = 1, t_i) \quad (4)$$

Calculating the average in this way means that we use *macro-averaging* assigning all classes equal importance (Sokolova and Lapalme, 2009). For (i), we invoke Equations 1–3 and average the results, again using macro-averaging:

$$\text{EOG}(s) = \frac{1}{T} \sum_{i=1}^T \text{EOG}(s, t_i) \quad (5)$$

Table 1: Data for measuring link prediction bias on both datasets using **occupation** as the target property and **gender** as the sensitive attribute. Based on the prevalence in the test set of HUMANW5M-3MIL, we use a **minimum count threshold** of 100. This means that we consider all occupations with more than 100 occurrences as separate classes, aggregating the remaining facts in the class OTHER.

Occupation	in Test Set	with Gender	Thereof Men		Thereof Women	
other	1,534	399	336	84%	63	16%
politician	1,070	308	274	89%	34	11%
writer	262	69	58	84%	11	16%
lawyer	253	78	72	92%	6	8%
actor	158	47	34	72%	13	28%
association football player	142	32	31	97%	1	3%
poet	129	28	21	75%	7	25%
novelist	109	33	19	58%	14	42%
screenwriter	106	26	26	100%	0	0%
sum over all occupations	3,763	1,020	871	85%	149	15%

3.5 Data-Driven Choice of Target Property Classes and Sensitive Attribute

For all link prediction models, the long tail distribution typical for knowledge graph (KG) datasets (Zhang et al., 2020) presents a challenge: A small set of entities appears often, while most entities appear only a handful of times, even in large datasets. We account for this by choosing the target property classes, the sensitive attribute, and its groups based on their prevalence in the dataset. This means that each class needs to be properly represented for each sensitive attribute group, as it is also discussed in similar work in other domains (Seyyed-Kalantari et al., 2020; De-Arteaga et al., 2019). To achieve this, we reduce the number of classes significantly by **aggregating occupations below a minimum count threshold in the class OTHER**, similar to Keidar et al. (2021). The count threshold is **based on the test set of the dataset** since only this part is used for bias measurement. Using only the test set is necessary to avoid data leakage, as we directly use a model’s predictions of the target property facts as input for our measurement:

Given a trained link prediction model, we extract only the facts concerned with our selected target property from the test set tail entity predictions, i.e., the (personXY, occupation, ?) facts. For each person – corresponding to the head entity – we then search the entire dataset for their sensitive attribute information, e.g., a fact stating their gender. We argue that retrieving the sensitive attribute information from the entire dataset is reasonable and does not constitute data leakage, since we only extract ground truth facts from the dataset. To be clear, **we never predict the sensitive attribute** of a person, only their target property. This means that the *data*

basis for the bias measurement consists of persons with a **target property fact in the test set** and a **sensitive attribute fact somewhere in the dataset**.

While ensuring a sufficient data basis is necessary for a valid bias measurement, using a **minimum count threshold is also connected to the issues of data scarcity and data bias** (§2): (i) Facts about members of minority groups will naturally be less frequent than for those of the majority group. In addition, (ii) groups might be underrepresented due to biased selection processes in society that contributed to the creation of the data. In our case, the threshold leads to us only considering female and male as identities, while having to disregard other gender identities due to data scarcity and likely representation bias, as well. We argue that a bias analysis can still be performed under these circumstances, but that the **data basis and limitations should be clearly acknowledged**.

4 Experiments

4.1 Creating the HUMANW5M-3MIL Dataset

We created HUMANW5M-3MIL, a modified subset of Wikidata5M (Wang et al., 2021b) based on Wikidata (Vrandečić and Krötzsch, 2014), consisting of 3 million facts about humans, meaning that the head entity of each triple is always a human entity. For each entity in the dataset, a textual *description* consisting of the first section of the corresponding Wikipedia article in English is available as well as a short English *label* for each entity and relation (Wang et al., 2021b). We argue that a smaller dataset only consisting of human facts is useful to reduce the noise in the dataset and the time required to train and evaluate the models. This approach follows previous work (Bourli

Table 2: Prediction quality of all trained link prediction models on the test set measured using typical **accuracy metrics**. We report the metrics averaged over head and tail entity predictions and separately only for tail entity predictions. The best scores are highlighted in bold. The arrows express whether a high or a low value of the metric corresponds to high accuracy.

	Model	Prediction Type	MR ↓	MRR ↑	Hits@1 ↑	Hits@3 ↑	Hits@10 ↑
KG only	TransE	averaged	188,784	19.21	16.02	20.74	24.47
		tail	11,620	38.29	32.04	41.29	48.63
	DistMult	averaged	176,300	15.62	11.14	18.42	22.44
		tail	8,405	30.76	22.00	36.34	44.09
	RotatE	averaged	221,341	14.80	11.44	17.08	19.50
		tail	19,552	29.56	22.86	34.12	38.92
KG + LM	SimKGC _{IB}	averaged	91,588	32.96	30.19	34.08	38.02
		tail	255	64.79	60.06	67.04	73.60
	SimKGC _{IB+SN+PB}	averaged	91,737	32.91	30.31	33.93	37.60
		tail	276	64.75	60.14	66.89	73.24

and Pitoura, 2020; Keidar et al., 2021), however the respective datasets are not publicly available. We also created this dataset due to issues we find in Wikidata5M: (i) The relation P21⁶, which expresses human *sex or gender*, is not contained in the dataset, despite gender being the most frequently investigated sensitive attribute (Costa-jussà, 2019). (ii) An exploratory analysis revealed data quality issues in the entity labels such as typos or labels not matching the current English Wikidata labels. To address these issues, we merge the human facts of Wikidata5M with gender facts and English labels taken from a current Wikidata version (the truthy triples file from January 2, 2022). We ensure that each entity has a label and a description, meaning that we exclude entities that only have one or the other. For all remaining human entities, we extract the gender facts, if they exist. We limit our analysis to male and female gender, as data on non-binary gender identities and intersex people is very scarce in Wikidata (Klein et al., 2016; Zhang and Terveen, 2021)). In our case, other gender identities and intersex people are only represented by fewer than 500 occurrences combined. As the entities expressing human gender are not part of Wikidata5M and therefore lack a description, we use the first section of the Wikipedia articles for masculinity⁷ and femininity⁸. The resulting dataset contains ca. 11 million triples, which we randomly sample down to 3,101,160 triples, to reduce the dataset size. The resulting dataset, HUMANW5M-3MIL, contains 1,396,220 unique entities – 1,269,907 thereof human – and 225 relations (Table 7). Table 8 shows that HUMANW5M-3MIL is representative of the larger raw dataset,

⁶<https://www.wikidata.org/wiki/Property:P21>

⁷<https://en.wikipedia.org/wiki/Masculinity>

⁸<https://en.wikipedia.org/wiki/Femininity>

when considering the manually selected candidate relations that express sensitive attributes or target properties. For instance, the *sex or gender* relation comprises ca. 13.5% of each dataset. We use comparably large evaluation sets, as our bias score calculation is only based on the test set, specifically a [0.9, 0.05, 0.05] train/validation/test random split (compared to [99.9995, 0.00025, 0.00025] for Wikidata5M), as the evaluation split size of ca. 155,000 triples is still manageable for all models we train on our dataset. Further details about the creation process of the dataset are given in Appendix B. We make the code for creating the dataset along with the data files available.⁹

4.2 Models and Training Details

We demonstrate our model-agnostic approach by comparing two model classes: knowledge graph embeddings (KGEs) that learn only from the structure contained in the knowledge graph dataset (*KG only*) and language model (LM)-based models that further also have access to the entity descriptions and relation labels (*KG+LM*).

KG only models: TransE, DistMult and RotatE. KGEs learn a dense embedding for each entity and relation in the dataset, capturing relationships between entities in a latent space (Nguyen, 2021). We choose TransE (Bordes et al., 2013) and DistMult (Yang et al., 2015) because they are common baseline models from different model families (Rossi et al., 2021a). RotatE (Sun et al., 2019) is an expressive state-of-the-art model from the same model class as TransE. We use the self-adversarial negative sampling loss (Sun et al., 2019) for all models. After hyperparameter tuning (Appendix A), we train all models for 400 epochs, using a

⁹<https://github.com/lena-schwert/comparing-bias-in-KG-models>

Table 3: Bias in occupation predictions **averaged across all occupation classes**. The bias score correspond to performance gaps between predictions for men and women. The highest bias scores per fairness metric are highlighted in bold. DPG: Demographic Parity Gap, PPG: Predictive Parity Gap, EOG: Equality of Opportunity Gap. *: 3,763 occupation facts were available in total for HUMANW5M-3MIL.

Model Class	Model	DPG (Selection Rate)	PPG (Precision)	EOG (Recall)	# of Facts Used*
KG only	TransE	0.51	0.001	0.03	3,735
	DistMult	0.47	0.004	0.001	3,758
	RotatE	0.32	0.003	0.04	3,709
KG + LM	SimKGC _{IB}	0.57	0.04	0.08	3,726
	SimKGC _{IB+SN+PB}	0.54	0.02	0.12	3,721

Table 4: Link prediction bias results **separated for men and women** showing the absolute fairness metric scores. In some cases the absolute difference of the male and female score does not exactly match the *gap* scores in Table 3, because all results were rounded to two or three decimals. We highlight the entries with the highest difference in bold, i.e., the same entries as in Table 3. DP: Demographic Parity, PP: Predictive Parity, EO: Equality of Opportunity

Model Class	Model	DP (Selection Rate)		PP (Precision)		EO (Recall)	
		Male	Female	Male	Female	Male	Female
KG only	TransE	0.76	0.24	0.043	0.042	0.09	0.05
	DistMult	0.74	0.26	0.043	0.047	0.109	0.108
	RotatE	0.66	0.34	0.041	0.044	0.08	0.05
KG+LM	SimKGC _{IB}	0.79	0.21	0.49	0.45	0.32	0.41
	SimKGC _{IB+SN+PB}	0.77	0.23	0.51	0.49	0.31	0.43

Table 5: Deviation of predicted occupations for women from the data distribution using the KG+LM model SimKGC_{IB+SN+PB}. For each of the nine occupation classes, we calculate the difference between the selection rate and the distribution of the occupations in the test set of HUMANW5M-3MIL.

	Selection Rate	Data Distribution	Difference
averaged	0.23	0.15	+ 0.08
other	0.12	0.16	- 0.04
politician	0.15	0.11	+ 0.04
writer	0.25	0.16	+ 0.09
lawyer	0.12	0.08	+ 0.04
actor	0.33	0.28	+ 0.05
assoc. football player	0.08	0.03	+ 0.05
poet	0.40	0.25	+ 0.15
novelist	0.42	0.42	± 0.00
screenwriter	0.20	0.00	+ 0.20

batch size of 1,024, an embedding dimensionality of 512, and 32 negative samples per training triple. For TransE and DistMult a learning rate of 0.001 and for RotatE a learning rate of 0.01 is used.

KG+LM model: SimKGC LM-based models utilize pre-trained Transformers (Vaswani et al., 2017) that are fine-tuned on a knowledge graph dataset. To that end, an input sequence is created out of the entity descriptions instead of using the entity and relation IDs. We choose SimKGC (Wang et al., 2022), as it significantly outperforms earlier models with respect to accuracy and computational efficiency. It has a bi-encoder architecture using the pre-trained BERT-base (Devlin et al., 2019). One encoder learns relation-aware

head entity embeddings and the other one tail entity embeddings. The plausibility scoring of triples is then simply achieved using cosine similarity. We train the SimKGC_{IB} and the SimKGC_{IB+SN+PB} model variants to investigate whether they exhibit different bias behavior. We do not conduct hyperparameter tuning, as the parameters for Wikidata5M used in the original paper (Wang et al., 2022) deliver strong results on our validation set. SimKGC uses the InfoNCE loss with an additive margin (Le-Khac et al., 2020). We train for 1 epoch using a batch size of 1,024, a learning rate of 3×10^{-5} and a weight decay of 0.0001. We provide further details for reproducing the experiments in Appendix A.

4.3 Evaluation Protocol

We evaluate our link prediction models for accuracy using mean rank (MR), mean reciprocal rank (MRR) as well as Hits@1, Hits@3, and Hits@10 (Rossi et al., 2021a). We calculate the ranks using the *filtered setting* (Bordes et al., 2013). Since we only use tail entity predictions for measuring bias, we compute the metrics (i) averaged across head and tail entity predictions and separately (ii) only for tail entity predictions. Following §3.5, we choose gender as a sensitive attribute and occupation as the target property for measuring bias in the trained models. We describe in Appendix C how other combinations of sensitive attributes and target property are not analyzed due to data scarcity.

4.4 Model Accuracy and Data Bias Results

Referring to Table 2, we note that the Hits@1 accuracy for tail entity predictions is the most relevant metric for bias measurement, since the tail entities with rank = 1 are used as the predicted class labels, i.e., the predicted occupation. The performance on tail entity predictions is clearly higher than the one averaged across head and tail entity predictions since there are fewer unique tail than head entities, making this prediction easier. Performance on tail entity predictions varies between 11.14 (DistMult) and 60.14 (SimKGC_{IB+SN+PB}). When comparing the two model classes, the KG+LM models clearly outperform the KG only models. Among the KG only models, TransE obtains the best Hits@1 result (16.02), thus outperforming the two other more recent and complex models.

Table 1 shows the absolute counts and the relative distributions of the occupation classes over the two considered gender identities (male, female). It also shows that we choose a *minimum count threshold* of 100 facts per occupation, resulting in eight distinct occupations, aggregating the remaining ones in the class OTHER. When comparing the relative distribution of facts per gender, it is evident that the data is biased: Out of the 1,020 facts that we use for bias measurement, 85% are about men and only 15% about women, while a 50%–50% distribution would be unbiased when considering these two gender identities. The occupation with the largest gender bias in the data is *screenwriter* (100% men) and the one with the smallest bias is *novelist* (58% men, 42% women). In addition, we note again that gender identities beyond women and men are severely underrepresented in the data,

constituting only 0.005% of the gender facts, which is significantly lower than the 0.1–2% estimated by Goodman et al. (2019).

4.5 Results on Gender Bias in Occupation Predictions

For describing and analyzing the gender bias that our models exhibit in its occupation predictions, we consider the *three levels of detail* as introduced in §3.4. Tables 3, 4, and 5 refer to levels of detail (i), (ii), and (iii), respectively. These allow us to answer three different research questions.

Q1: Are KG+LM models more biased than KG only models?

As Table 3 shows, the bias scores are generally higher for the KG+LM models than for KG only models. Comparing the difference between the most biased models for each class shows that it is most pronounced for the demographic parity gap (DPG): $0.57 - 0.47 = 0.1$, followed by the equality of opportunity gap (EOG) $0.12 - 0.04 = 0.08$. These results suggest that the additional textual data the KG+LM models have access to leads to biased occupation predictions and that this has the most pronounced effect on DPG and EOG. The KG only models, in contrast, here manage to obtain fairly unbiased results, with scores close to zero. We note that the column “# of facts used” shows how many facts contributed to the score, since a fact can only be considered when the predicted tail entity is an occupation and not another type of entity.

Q2: Does the bias originate in higher-quality predictions for men or women?

To answer this question, we refer to Table 4, which shows the previously described results separately for men and women. For DP, we observe that the selection rate for predictions for men is generally higher. We connect this to the data distribution in Q3. For PP and EO we make two observations: First, most KG only models – which obtain essentially unbiased results – obtain dismal precision and recall scores (they only appear strong enough when evaluated using ranking metrics). Second, for the KG+LM models we observe opposing trends: With regard to precision, the prediction quality for men is slightly higher, while for recall, the prediction quality for women is noticeably higher. Especially the latter trend is surprising since the data for women is more limited. These observations show why this level of detail is important for a comprehensive

bias analysis: While KG only models exhibit far less bias, they predict occupations inaccurately despite an acceptable overall accuracy (Table 2). In addition, we conclude that predictions for men are not necessarily more accurate than those for the women, despite the significantly larger amount of data for men (85% of all occupation facts.).

Q3: Are there occupation classes that are predicted more often than expected based on their distribution in the data?

We may consider the demographic parity results for SimKGC_{IB+SN+PB}, our most accurate model, as an example. As explained earlier (§3.3), DP measures selection rate imbalances that we expect to mirror the data bias. Table 5 shows the per-class differences between the selection rate (predicted occupation) and the respective distribution in the data (actual occupation) when predicting the occupation of women. Whenever the difference is positive, the model predicts the given occupation for more women than expected (and vice versa). On average, the probability of women having a given occupation is overestimated by 0.08, with the occupations “poet” and “screenwriter” contributing the most to this score. Despite this, the model does predict this occupation for some women, as female screenwriters do exist in the training dataset. This might be due to the entity descriptions that this KG+LM model has access to, potentially because the person’s occupation might be similar to a screenwriter or mention related words.

5 Conclusion

We present a model-agnostic approach for measuring bias in link prediction along with the first experimental study that measures bias in language model (LM)-based link prediction models (KG+LM), comparing it with bias in knowledge graph embedding (KGE) models (KG only). Using a selection of fairness metrics and analyzing our results at three levels of detail, we find that the KG+LM models are more biased. We discuss the relationship between bias, link prediction accuracy metrics and data bias. For our experiments, we create HUMANW5M-3MIL, a subset of 3 million facts about humans contained in Wikidata (Vrandečić and Krötzsch, 2014). We have made our code and the dataset available to the public to encourage further research on these topics.

6 Limitations

In the following we discuss the limitations of our work and how they might be addressed.

Our study considers a single sensitive attribute, gender, limited to two gender identities, female and male. We also note that the approach can be extended to sensitive attributes with more than two groups, requiring additional decisions on how to average the bias scores across the sensitive attribute groups in an interpretable way. This limitation is caused by data scarcity, as we describe in §3.5, §4.1 and Appendix B + C.

Using only the test set of a dataset for bias measurement has a few methodological implications: First, the bias in the test set might not be representative of the bias contained in the other splits of the data set. In our approach we used simple random splitting, where all facts are randomly distributed over the three splits, meaning that the distribution of the relations might not be the same in all splits. This approach is called the *transductive setting*, which is currently the most prevalent method of splitting knowledge graph datasets (Wang et al., 2021b). To rule out differences between the splits to some degree, a potential solution is a stratified split, conditioned on the relations in the dataset. This would enforce, for instance, that each split has the same relative amount of gender and occupation facts. This solution is however only applicable when the researcher has control over the dataset split creation process. Second, in order to have a sufficient data basis for each target property class across sensitive attribute groups (§3.5), the dataset or the test split size needs to be quite large. However, training models on large datasets requires the availability of adequate computational resources that many researchers do not have access to.

Using fairness metrics for bias measurement means that the notion of bias is closely connected to what is considered as a “misclassification”. We note that we do not take into account the severity of misclassifications, e.g., that predicting a novelist to be a writer is less wrong than predicting them to be a diplomat. This would require a semantic analysis of the labels of both the true and the predicted tail entities. This might also be addressed by clustering entities with similar meanings together, e.g., predicting groups of occupations instead of single occupations.

7 Ethical Considerations

For our analysis of gender bias, we rely on factual statements contained in Wikidata¹⁰, a crowd-sourced, public knowledge graph. This means that we utilize gender information that was added to the platform by largely anonymous editors. These statements – and other statements describing demographics – might therefore not correspond to the self-identification of the respective persons or they might be incorrect, especially if human or automated data quality control mechanisms fail (Heindorf et al., 2019).

In addition, we acknowledge that knowledge graphs reflect a limited world view, because their creation process is subject to various biases, such as representation bias, popularity bias, and sampling bias (following the definitions by Mehrabi et al. 2021). In the field of knowledge graphs, these problems were first described by Janowicz et al. (2018) and recently reviewed by Kraft and Usbeck (2022). For example, facts about the non-Western world are underrepresented and persons with occupations in arts, sports, and science and technology are overrepresented (Radstok et al., 2021; Beytía et al., 2022).

One consequence of the biases mentioned above is our decision to only consider male and female gender in our analysis, as all other gender identities combined, such as non-binary, amount to fewer than 500 facts in the entire dataset. To analyze bias for these gender identities, a larger dataset or a different approach than ours would be necessary. We discuss these limitations and our understanding of gender in §2.

As described in our bias statement (§2), our notion of bias focuses on performance differences for different social groups. We note that this is a very specific, limited conceptualization of bias that could be extended by considering real-world distributions or normative connotations such as stereotypes. However, we believe that the contribution of our work is still useful for analyzing whether link prediction models work as intended, especially because it allows for comparing different model classes.

To conclude, we stress that the intended use of our approach is to identify concerning model behavior in a specific context defined by a sensitive attribute and a target property. We emphasize that the selected fairness metrics should not, e.g., be

used as constraints during model training without a deeper analysis of what notions of fairness are suitable in the context of how the model will be used.

Acknowledgements

We thank Lisa Gotzian and Steffen Berhorst for discussions about the bias measurement approach and for feedback on the manuscript. We further thank the three anonymous reviewers for their thoughtful comments.

A Additional Details for Reproducing the Experiments

We list the training and evaluation time as well as the hardware used for all our models in Table 6.

KG only: TransE, DistMult, RotatE. For training the KG only models on HUMANW5M-3MIL, we largely use the parameters contained in the Graphvite configuration files from the official Wikidata5M benchmark¹¹ published by Wang et al. (2021b). To adapt to our dataset, we conduct minor additional hyperparameter tuning. We explore a small grid testing 6 hyperparameter combinations for each model: batch size $\in \{512, 1024\}$, learning rate $\in \{0.1, 0.01, 0.001\}$. We train TransE and DistMult for 50 epochs (training time: ca. 3.5-7 h, evaluation time: ca. 35 min) and RotatE for 20 epochs (training time: ca. 2.5-5 h, evaluation time: ca. 65 min). We choose our final parameter configuration based on the mean reciprocal rank (MRR) on the validation set, as it has been observed to be the most stable metric among the link prediction metrics (Rossi et al., 2021a).

For all models, we use a batch size of 1,024, an embedding dimensionality of 512, and 32 negative samples per training triple. For TransE and DistMult a learning rate of 0.001, for RotatE a learning rate of 0.01 is used. We train the models for 500 epochs, evaluating after each 100 epochs. Finally, the models trained for 400 epochs are used, since the MRR performance drops slightly afterwards. We use the self-adversarial negative sampling loss (Sun et al., 2019) for all models. For TransE, we use margin $\gamma = 12$ and adversarial temperature = 0.5. For DistMult, we use margin $\gamma = 0$ and adversarial temperature = 2. Again following the Graphvite configuration files, we also apply L3 regularization with a weight of 0.002. For RotatE, we use margin $\gamma = 6$ and adversarial temperature = 0.2.

KG + LM: SimKGC. We use the pre-trained BERT-base in its “uncased” variant (Devlin et al., 2019). Since the authors trained their model on Wikidata5M, a superset of our dataset, we try using the exact same parameters as the original paper (Wang et al., 2022). We use two of their model variants to investigate whether using the self-negative (SN) and pre-batch (PB) sample types lead to different bias behavior compared to the “basic” in-batch (IB) model variant. We therefore train the SimKGC_{IB} and the SimKGC_{IB+SN+PB} model

¹¹<https://graphvite.io/docs/latest/benchmark.html>

variants, using 2 pre-batch negatives for the latter. We train for 1 epoch using a batch size of 1,024, a learning rate of 3×10^{-5} and a weight decay of 0.0001. The remaining parameters are: 400 warmup steps for the linear learning rate scheduler, gradient clipping of 10.0, dropout 0.1, temperature τ is initialized with 0.05, additive margin γ for the InfoNCE loss is 0.02, $\alpha = 0.05$ for graph-based re-ranking is used, 2-hop neighbors are considered, and a maximal token length of 50 for the entity descriptions is used. As these parameters deliver good results on the validation set, we do not conduct hyperparameter tuning.

Implementation details. All implementations are done in Python. The code and data including files to re-create the conda environment are contained in the accompanying GitHub repository¹². All models are based on the deep-learning framework PyTorch (Paszke et al., 2019).

- **KG only: Knowledge Graph Embeddings:** For training models on HUMANW5M-3MIL we use the model implementations and the training pipeline of the v1.8.1 PyKEEN library (Ali et al., 2021). This framework enables single-GPU training and the calculation of evaluation metrics.
- **KG + LM: SimKGC:** We use the implementation that was published alongside the paper of Wang et al. (2022). Their code¹³ includes the calculation of evaluation metrics. The implementations use the Huggingface Transformers library v4.15 (Wolf et al., 2020).
- **Data Bias:** We use our own Python implementation.
- **Link Prediction Bias:** For calculating the predictive parity and equality of opportunity, we use Microsoft’s fairlearn library (Bird et al., 2020), that wraps around scikit-learn’s evaluation metrics. For calculating demographic parity, we modify code from the repository published by Keidar et al. (2021).¹⁴

B Additional Details About the Creation of the Dataset

This section describes how we create the raw version of HUMANW5M-3MIL. This raw version

¹²<https://github.com/lena-schwert/comparing-bias-in-KG-models>

¹³<https://github.com/intfloat/SimKGC/>

¹⁴<https://github.com/mianzng/kgbiasdetec>

Table 6: Training runtime, evaluation runtime and hardware used for training all of our models. *: NVIDIA A100-SXM-80GB, †: AMD EPYC 7502 32-Core CPU.

Model Class	Model	Train. Time	Eval. Time	GPU(s) Used	Other Hardware
KG only	TransE	27 h	35 min	1x NVIDIA A100*	10 GB RAM, 32 CPUs [†]
	DistMult	30 h	35 min	1x NVIDIA A100*	10 GB RAM, 32 CPUs [†]
	RotatE	55 h	66 min	1x NVIDIA A100*	10 GB RAM, 32 CPUs [†]
KG+LM	SimKGC _{IB}	45 min	180 min	4x NVIDIA A100*	15 GB RAM, 50 CPUs [†]
	SimKGC _{IB+SN+PB}	45 min	180 min	4x NVIDIA A100*	15 GB RAM, 50 CPUs [†]

Table 7: Dataset statistics for the raw version of our dataset and the subsampled dataset HUMANW5M-3MIL that we use in our experiments.

	11mil. Raw Dataset	HUMANW5M-3MIL
# of entities	1,732,021	1,396,220
# of human entities	1,503,491	1,269,907
# of relations	292	225
# of train triples	-	2,791,044
# of validation triples	-	155,058
# of test triples	-	155,058
total # of triples	11,114,797	3,101,160

Table 8: Manually selected Wikidata relations of general interest for a bias analysis. This large selection can be considered as candidate relations, since they must exist in sufficient quantity to enable a robust bias analysis. We show the triple counts for each relation and the proportion of this count of the total size of each dataset. The raw dataset version contains 11,114,797 triples. Our final dataset, HUMANW5M-3MIL contains 3,101,160 triples. We ultimately only use the relations "gender" and "occupation" for our bias analysis.

contains 11,114,797 triples, 1,732,021 entities – thereof 1,503,491 human entities – and 292 relations. To reduce dataset size, we sample it down to 3,101,160 triples, creating HUMANW5M-3MIL.

Details on extracting the labels. As an alternative to using the textual descriptions for entities, i.e., the first section of the corresponding Wikipedia article, we propose using the shorter Wikidata labels. As these contain less information for the KG+LM model to process, using labels instead of descrip-

tions reduces the model runtime. We considered using the alias files provided with Wikidata5M¹⁵, but found that the entity aliases have quality issues such as typos (e.g., for the ‘human’ entity Q5, the first alias is ‘Huamn’) or aliases that do not have the same meaning as the current label (e.g., for the ‘universe’ entity Q1, the first alias is ‘Earth’s universe’). After correspondence with the first author of the

¹⁵<https://deepgraphlearning.github.io/project/wikidata5m>

paper that introduced Wikidata5M (Wang et al., 2021b), we learned that they created the alias files using the “pageterms” property of the MediaWiki API¹⁶. The faulty aliases are thus likely a result of the use of that data source and do not represent genuine entity labels. We therefore extract entity and relation labels from the January 2, 2022 truthy triples Wikidata dump¹⁷. The Wikidata dump files are updated every week and contain the most recent state of Wikidata in different data formats¹⁸. We use the truthy triples file specifically, because it only contains non-deprecated triples, which reduces the amount of metadata contained and therefore the file size.

Details on creating the subset of human facts.

We extract all facts that have a human head entity from the raw triples file provided with the original Wikidata5M files. A human head entity is identified by its “instance of human” (QXX P31 Q5) statement. This initially leads to a subset of 9,804,421 facts about humans. In order to be able to compare KG+LM models using either the shorter labels or the longer descriptions as text input, we only keep entities and relations that have both labels and descriptions. This leads to a removal of 17,528 entities and 2 relations from the dataset, due to deletions and additions that happened between the creation of Wikidata5M (based on the July 2019 Wikidata dump, Wang et al. 2021b) and the extraction of the labels (January 2022 Wikidata truthy triples dump). Removing these entities and relations means that we remove all facts that contain them, leading to 191,178 facts that are excluded in total.

Details on adding gender facts from current Wikidata.

In an exploratory analysis of Wikidata5M before creating our dataset, we counted the occurrences of facts that we considered to be of general interest for a bias analysis. With respect to the gender relation (PID: P21) we found that its count is unexpectedly low (about 4,000) compared to the number of human entities in the dataset (1.5 million). Furthermore, we found that these facts express animal sex and not human gender, because the head and tail entities are non-human (tail enti-

ties: Q44148, Q43445). When filtering for gender facts in the human facts subset, we only found 384 facts overall. Through correspondence, the first author of the paper that introduced Wikidata5M (Wang et al., 2021b) informed us that they used Wikidata’s “wbgetentities” API¹⁹ to align Wikidata and Wikipedia entries. Since the Wikidata entities for male²⁰ and female gender²¹ are linked to the same Wikipedia page describing gender²², the API might have therefore omitted facts containing these entities. We therefore use the January 2022 truthy triples dump to extract the gender facts as well. We extract 1,243,734 facts with gender *male* and 258,204 facts with gender *female*. Persons with other gender identities, such as *non-binary*, or intersex people have fewer than 500 occurrences in the entire dataset.

We therefore consider only two gender identities within the context of this study, as the data scarcity would not allow our models to properly represent the other gender identities contained in the dataset.

Adding the gender facts for women and men entails adding two new (tail) entities to the dataset (Q6581072, Q6581097). As these entities do not have descriptions in the original dataset, we use the first section of the Wikipedia articles for masculinity²³ and femininity²⁴.

C Considering Additional Sensitive Attributes and Target Properties

Beyond measuring gender bias in occupation prediction, we did consider using other target properties and sensitive attributes for the analysis of the HUMANW5M-3MIL subset. However – in contrast to using “gender” and “occupation” – we found the respective data bases to be lacking.

The relation “educated at” is the target property with the second-highest counts in HumanWikidata5M. In total, the 438,207 facts have 9,330 different tail entities, i.e., educational institutions such as universities. In the test set, the 8,684 “educated at” facts still have 1,919 different tail entities, only 3 of those with more than 100 occurrences. If the minimum count threshold were set at 100, this would result in an “other” class with 8,439 facts, leading to a very imbalanced class distribution. In

²²<https://en.wikipedia.org/wiki/Gender>

²³<https://en.wikipedia.org/wiki/Masculinity>

²⁴<https://en.wikipedia.org/wiki/Femininity>

Table 9: Data basis for measuring link prediction bias using **occupation** as the target property and **country of citizenship** as the sensitive attribute. This shows the insufficient data basis for a bias analysis: Even the three best represented countries of citizenship (sum over all occupations ≥ 50) are not sufficiently represented across the individual occupations in the test set of HUMANW5M-3MIL.

Occupation	in Test Set	with Citizenship	USA	France	UK	Other
other	1,534	437	146	33	41	217
politician	1,070	278	104	11	9	154
writer	262	68	9	13	4	42
lawyer	253	76	50	1	1	24
actor	158	44	18	5	2	19
association football player	142	34	2	1	10	21
poet	129	38	2	8	2	26
novelist	109	29	17	3	3	6
screenwriter	106	38	9	5	2	22
Sum over all occupations	3,763	1,042	357	80	74	531

addition, the three most frequent tail entities are “Harvard University” (270 facts), “Yale University” (121 facts), and “University of Michigan” (104 facts), which represent a very limited selection of all educational institutions contained in the dataset. We therefore disregard “educated at” as a target property.

Moving on to additional potential sensitive attributes, the relation “country of citizenship” is the most promising candidate with 1,143,007 facts in HumanWikidata5M. However, when creating an overview of counts per occupation class similar to Table 1, it becomes evident that the data for each sensitive attribute group, i.e., country, is very limited (Table 9). While there are in total 18,396 country of citizenship facts in the test set, this information is only available for 1,020 of the 3,763 occupation facts. The three countries with the highest counts are all Western countries, namely USA (357 facts), France (80 facts), and the UK (74 facts). Even for these countries, the majority of the occupation classes are only represented by 0 to 5 facts. The 110 other countries represented in the test set are all aggregated in the “other” class, which is again the largest class with 531 facts. This means that the sensitive attribute groups are already quite homogeneous, while the “other” group contains the majority of diverse information about “citizenship”. Compared to using two groups for “gender” as the sensitive attribute, choosing the sensitive attribute groups as above would thus result in an unrealistic and uninformative comparison. We hence decided against including “country of citizenship” as a sensitive attribute.

Similar considerations apply to the other relations of interest listed in Table 8, since these also have too few facts per target property class or a very

broad distribution over sensitive attribute groups.

Divergence-Based Domain Transferability for Zero-Shot Classification

Alexander Pugantsov and Richard McCreadie
School of Computing Science, University of Glasgow, UK

Abstract

Transferring learned patterns from pretrained neural language models has been shown to significantly improve effectiveness across a variety of language-based tasks, meanwhile further tuning on intermediate tasks has been demonstrated to provide additional performance benefits, provided the intermediate task is sufficiently related to the target task. However, how to identify related tasks is an open problem, and brute-force searching effective task combinations is prohibitively expensive. Hence, the question arises, *are we able to improve the effectiveness and efficiency of tasks with no training examples through selective fine-tuning?* In this paper, we explore statistical measures that approximate the divergence between domain representations as a means to estimate whether tuning using one task pair will exhibit performance benefits over tuning another. This estimation can then be used to reduce the number of task pairs that need to be tested by eliminating pairs that are unlikely to provide benefits. Through experimentation over 58 tasks and over 6,600 task pair combinations, we demonstrate that statistical measures can distinguish effective task pairs, and the resulting estimates can reduce end-to-end runtime by up to 40%.

1 Introduction

As the accuracy of neural models continues to increase, so does the computational cost of training and storing them. One approach of mitigating such cost is through using pretrained models to enhance performance on a downstream task, a paradigm commonly referred to as *transfer learning*. However, when and why transfer learning works is not concretely understood. Traditionally, selecting the best settings, i.e. tasks and hyperparameters, for transfer often involves an extensive trial-and-error process over many combinations and can quickly make the prospect of applying transfer learning undesirable. As such, it would be valuable to estimate whether a task pair combination

will be effective pre-training, i.e. estimate the *transferability* of a source task to a target task.

The most optimal transferability metric would be resource-efficient, such that it is capable of accurately predicting the final performance of the model whilst minimising the amount of processing required to compute it. To this end, several works (Van Asch and Daelemans, 2010; Ruder and Plank, 2017; Ramesh Kashyap et al., 2021) have focused on estimating transferability prior to fine-tuning, using statistical measures of divergence between the underlying feature spaces of model pairs. Domain divergence measures are used to produce a notion of distance between pairs of domains by comparing their representations and have seen significant usage in works which investigate the correlation between their estimations and performance change (Van Asch and Daelemans, 2010; Ramesh Kashyap et al., 2021).

Subsequent transfer learning works have also demonstrated that competitive model performance can be achieved on some target tasks even if no training samples for that task are available, an approach known as *zero-data/shot learning* (Larochelle et al., 2008). In this work, we investigate the effectiveness of domain divergence measures in estimating the performance of zero-shot classification models, wherein models further tuned on one source task are used to directly predict on the test set of a target task without any target training samples. Specifically, we leverage the information captured by these measures as features to an auxiliary learner, whose outputs are used to rank the most effective source model for transfer to a given target task. Through the analysis of 58 sentiment classification domains, we: (1) perform a correlation analysis between each independent measure and each source-target, macro-averaged F_1 -score performance output; (2) and, for each target task, we train a series of auxiliary regression models to predict their projected performance;

(3) we then convert these into rankings of source–target pairs and evaluate the capability of our learners to find the best source model for each given target domain.

2 Experiment Setup

Measures: Ramesh Kashyap et al. (2021) provide categories of divergence measures; two of which we use in our work: *Geometric* measures which calculate distances between continuous representations such as word embeddings and *Information-theoretic* measures which capture the distance between representations such as frequency-based distributions over co-occurring n-grams. We do not report higher-order measures as in the aforementioned work, but instead report *moments*-based features, which better describe the characteristics of our individual term distributions—namely the mean, variance, skewness, and kurtosis of our distributions—as features to our learner. Following prior work (Tsvetkov et al., 2016; Ruder and Plank, 2017), we further complement the above measures by making use of several metrics that capture diversity and prototypicality such as entropy-based features; in our work, these measures are used with probability distributions, and are, as such, categorised here as information-theoretic. Specifically, we use the following metrics:

- **Geometric:** Cosine distance, l_1 - (or Manhattan dist.) and l_2 -norm (or Euclidean dist.).
- **Information-theoretic:** Rényi and Jensen-Shannon divergences (Wong and You, 1985; Rényi et al., 1961), Bhattacharyya Coeff. (Bhattacharyya, 1943), Wasserstein distance (Kantorovich, 1960), Entropy and Rényi Entropy (Shannon, 1948; Rényi et al., 1961), Simpson’s Index (Simpson, 1949).
- **Moments-based:** Mean, variance, skewness, and kurtosis (σ^n where $n \in [1..4]$).

Representations: To compute the above metrics, we use two different representations from prior work by Ruder and Plank (2017), specifically 1) discrete probabilities of the most common terms across domains, using a fixed-size vocabulary V , where $|V| = 10,000$; and 2) a summation over probability-weighted term embeddings in each document, averaged to produce a single vector:

- (1) **Term Distributions (TD)** (Plank and van Noord, 2011): $t \in \mathbb{R}^{|V|}$ where t_i is the probability of the i -th word in the vocabulary V .

- (2) **BERT Embeddings (BE)** (Devlin et al., 2018): $\frac{1}{n} \sum_i v_{w_i} \sqrt{\frac{a}{p(w_i)}}$ where n is the number of words with embeddings in the document, v_{w_i} is the pretrained embedding of the i -th term, $p(w_i)$ its probability, and a is a smoothing factor used to discount frequent probabilities. Following guidelines by Ruder and Plank (2017), we use this representation with geometric-based measures only, as embedding vectors can be negative.

Generally, since we are using these representations in a zero-shot setting, we compute divergences between the source-task training set (D_S) and the target-task test set (D_T). Entropy and moments-based measures are not used to estimate divergence between domains but used only to compute within-domain characteristics, i.e. on individual term distributions.

Datasets and Domains: We make use of two ratings prediction datasets with classes in the range 1-5 and, similarly to Zhang et al. (2015), reformulate the task as a binary sentiment classification task by merging the provided labels; 1-2: negative and 3-4: positive. We focus on similar, within-task (i.e. sentiment classification) datasets to (1) remove task variation as a variable, (2) and to highlight the effectiveness of using statistical measures to compute divergence between similar domains which may have very minute differences in semantics and other linguistic phenomena. The first is the *Amazon Product Reviews* dataset, using the review title and review content fields as features and divide the dataset by the product category labels. As a supplementary contribution to our work, we create the *Multi-Domain Yelp Business Reviews* dataset by extending the original *Reviews* and *Business* datasets provided by the *Yelp Dataset Challenge*, mapping top-level¹ categories of businesses to their respective reviews. After filtering out low-sample ($\leq 30,000$) domains, we have 42 and 16 domains for the Amazon and Yelp datasets, respectively.

Implementation Details: We use BERT_{base} (Devlin et al., 2018) as our base model in the experiments. With both runtime- and storage-efficiency in mind, we make use of adapter modules (Pfeiffer et al., 2020) and train each of the domains as a source task adapter, leaving the rest of BERT’s

parameters frozen. More implementation and hyperparameter details can be found in Appendix A.

We divide our experiments into two separate settings by source-task sample size, $N_S \in [1000, 25000]$. We train 116 source-task adapters ($58 D_S \times 2 N_S$ settings), and evaluate a total of 6,612 source-target combinations for analysis. For our auxiliary learner, we use an XGBoost (Chen and Guestrin, 2016) regression model. We split our training and test sets by the target task and train 2,900 regression models (for each of the 58 target domains, 2 sample sizes settings, 5 feature sets, and over 5 random seeds).

Table 1: Spearman's ρ correlations between each measure and source-target macro-averaged F_1 -score performance. Asterisk denotes measure was statistically significant ($P \leq 0.05$).

To evaluate whether the aforementioned statistical measures are predictive of task pair transferability, we perform a correlation analysis between the

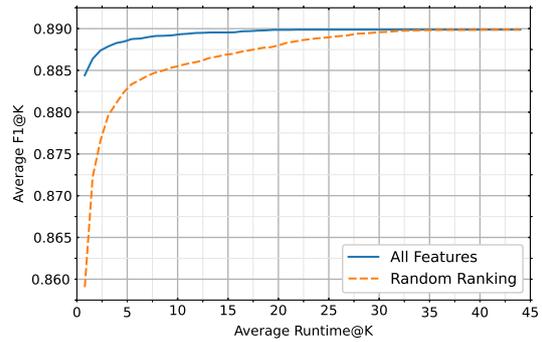

source-target pairs within each domain, where we contrast the statistical measure (which provides information about D_S , D_T , or the differences between them) and the resultant performance (measured using macro-averaged F_1) when using D_S to tune a model for application on task T . Table 1 reports Spearman's Rho (ρ) across all sample size settings for each statistical measure. Higher correlations (distance from 0) indicate increasing predictiveness of the statistical measure of transferability.

Using the interpretation of Spearman's Rho (ρ) correlation coefficients by Dancy and Reidy (2007), we make the following observations: (1) Geometric measures exhibited a moderate-to-strong correlation for Term Distributions across both sample size settings, and strong correlations at $N_S = 25000$ for BERT Embeddings; (2) Between-domain Information-theoretic measures also showed moderate-to-strong performance correlations; (3) All entropy-based measures (aside from Simpson's Index for D_T) had a weak or negligible correlation with performance; (4) Out of all of the higher-order moments of Term Distributions, only the skewness and kurtosis of D_T (σ^3 and σ^4) seemed to have a moderate relationship at $N_S = 1000$, and, generally, the moments of D_T seemed to be more correlated than that of D_S .

Overall, divergence measures with both representations seemed to be more predictive of source-target performances than with entropy or moments-based metrics. However, since it is unlikely that each measure was independently capable of predicting performance, we trained a series of regression models for each target task, combining these measures. Specifically, we train an XGBoost (Chen and Guestrin, 2016) regression model (XGBRegressor) with each of the feature sets as our inputs, over five

(a) Average F1@K vs. Runtime@K for $N_S = 1000$.

Figure 2: F1@K averaged across tasks vs. Total Runtime@K of source-task adapters. Higher is better. Runtime is reported in hours.

random seeds, for each of the 58 target domains and 2 sample size settings, producing 2,900 models for evaluation.

Figure 1 shows the *Average NDCG@K* values for each of these feature sets. We average the NDCG@K values across each of the 58 domains, and again over each of the 5 seeds. For both models, we achieve the best quality ranking using all of the features (*ALL*). Moreover, using divergence measures with both sets of representations (*DIV_{TD, BE}*) achieved a better ranking than using them in isolation (*DIV_{TD}* or *DIV_{BE}*) for both settings. It is also interesting to note that the feature set containing only the entropy and moments-based ($H + \sigma$) values achieve better performance than that of those estimated via divergence measures when the source sample size is significantly limited, coinciding with patterns found in our correlation analysis (Table 1); it may be the case that these features are more discriminative in cases where divergence measures are not as expressive.

Finally, we evaluate the practical, downstream application of our regression models by considering how they may be used to reduce the search time in finding appropriate source models for transfer. For this experiment, we assume the user has a particular training budget K to train task pairs for transfer. The more task combinations that are tried, the more likely the user is to find a better-performing model for a particular task. We use our regression models to determine the order of task pairs to be tried, using the best feature set from our prior experiments (See Fig. 1). We compare with a random ordering of source-task models, which we average over five random seeds to reduce variance. Figure 2 shows the results of our experiments. For $N_S = 1000$, the best macro-averaged F_1

performance score over all tasks is 0.8482 which, with a grid search over all task combinations, would require 4.7 hours of training. With our approach, we can achieve a 44% reduction in training time from 4.7 to 2.6 hours to achieve the same performance. For $N_S = 25000$, we can achieve the maximum score of 0.8899 through a grid search of all source-target combinations at a cost of 42.4 hours of training time. With our approach, we can achieve the same score with only 24.9 hours of training or a 41% reduction in training time.

In determining the overall runtime of our approach, we factor in the computational cost associated with generating the features required to train our regression models. Our feature generation process consists of three stages: (1) the generation of term distributions and embedding representations, (2) the computation of statistical measures in Table 1, (3) and the execution of regression experiments using the *ALL* feature set. A total of 232 term distributions and an equivalent number of embedding representations (58 target domains each with separate training and test sets, in two different sample size settings) were generated. The generation of both sets of representations takes 5.7 minutes at $N_S = 1000$ and 45.9 minutes at $N_S = 25000$. The time taken to compute all statistical measures across both representations is 3 minutes at $N_S = 1000$ and 6.6 minutes at $N_S = 25000$. Finally, the time taken to run the regression experiments was 5.4 minutes in total. Despite the added computational cost, our approach has resulted in a substantial reduction in end-to-end runtime, boasting a 40% reduction at $N_S = 1000$ and a 39% reduction at $N_S = 25000$, demonstrating the efficiency of our approach and the value-add of predicting which task pairs are transferable beforehand.

4 Conclusions and Future Work

In this paper, we have shown that domain divergence measures and other statistical quantities are predictive of zero-shot transferability between tasks, and that this can be used to markedly reduce time when developing effective zero-shot models. Indeed, by predicting which source-target task pairs were likely transferable pre-tuning, we were able to reduce the end-to-end time taken to find the best source-target task pairs (trained on 1,000 source-task samples) by 40%. On the other hand, while we have demonstrated the value of using these metrics in performance estimation, there are a number of further directions worth investigating, namely: (1) examine the transferability across a wider range of domain and task types; (2) investigate more complex, higher-order measures such as those outlined by Ramesh Kashyap et al. (2021); (3) and to experiment with few-shot and other limited data settings.

Limitations

The most pronounced limitation in our work is the small variance in performance scores. As can be seen in Figure 2, the difference between the lower and maximum performances is small. The difference between the minimum and maximum average performance is 0.0305 and 0.0320 for $N_S = 1000$ and $N_S = 25000$, respectively. Even at the individual, source-target model level, the standard deviation of performance scores at each source-task sample size setting is 0.0363 and 0.0311. As such, the benefits of zero-shot transfer are not as apparent between these domains as they would be where the domains are more textually distinct. Nevertheless, we believe it is notable that statistical measures of domain divergence and the other metrics were sufficiently capable of discerning between more effective source-task pairs, even when the domains were similar, illustrating the promise of this approach.

A Implementation Details

Data Preparation. For each task, we sample a holdout validation set for early stopping and a test set, both of size 2,500 (10% of the maximum sample size), which remains fixed across both sets of experiments. After filtering by sample size, i.e. dropping domains with less than 30,000 samples, we had a total of 58 domains for comparison. Prior to sampling, the total number of domains are 43 and 22 for Amazon and Yelp datasets, respectively. We use the same five seeds for both data and model training.

Hyperparameters. We largely follow the recommended learning rate setting of $1e-4$ (Pfeiffer et al., 2020; He et al., 2021) for adapter training. We set the max number of epochs to 50 and an early stopping patience of 5 non-decreasing epochs. We set the maximum input length to 256 and use a batch size of 32. For the adapter configuration, we make use of the PfeifferConfig (Pfeiffer et al., 2021) with default settings.

Computing Infrastructure. We run our experiments on $3 \times$ NVIDIA® TITAN™ RTX GPUs, with 130 Tensor TFLOPs of performance, 576 tensor cores, and 24 GB of GDDR6 memory. For the CPU, We use 4.5 cores of Intel® Xeon® Gold 5222 Processor (16.5MB Cache, 3.80 GHz) and 96GB of RAM, split across three docker containers.

EDU-level Extractive Summarization with Varying Summary Lengths

Abstract

Extractive models usually formulate text summarization as extracting fixed top- k salient sentences from the document as a summary. Few works exploited extracting finer-grained Elementary Discourse Unit (EDU) with little analysis and justification for the extractive unit selection. Further, the selection strategy of the fixed top- k salient sentences fits the summarization need poorly, as the number of salient sentences in different documents varies and therefore a common or best k does not exist in reality. To fill these gaps, this paper first conducts the comparison analysis of oracle summaries based on EDUs and sentences, which provides evidence from both theoretical and experimental perspectives to justify and quantify that EDUs make summaries with higher automatic evaluation scores than sentences. Then, considering this merit of EDUs, this paper further proposes an EDU-level extractive model with Varying summary Lengths (EDU-VL¹) and develops the corresponding learning algorithm. EDU-VL learns to encode and predict probabilities of EDUs in the document, generate multiple candidate summaries with varying lengths based on various k values, and encode and score candidate summaries, in an end-to-end training manner. Finally, EDU-VL is experimented on single and multi-document benchmark datasets and shows improved performances on ROUGE scores in comparison with state-of-the-art extractive models, and further human evaluation suggests that EDU-constituent summaries maintain good grammaticality and readability.

1 Introduction

Automatic text summarization aims at aggregating information in long document(s) into a shorter piece of text while keeping important information. Extractive summarization and abstractive summarization are two categories of it. This paper focuses

Document: (...) [The second audio,] [taken from dash cam video from inside a patrol car,] [captures a phone call between Slager and someone] [CNN believes] [is his wife.] (...)

Table 1: Example to demonstrate redundant information in sentence. Content within [] indicates an EDU.

only on the extractive task which formulates summarization as identifying salient textual segments in document (Lunh, 1958). Under the supervised learning framework, this task is further formulated as a label classification task, i.e., encoding textual segments and predicting labels on the encoded vectors. Recent state-of-the-art models (Liu and Lapata, 2019; Zhong et al., 2020; Liu et al., 2021; Ruan et al., 2022) on this task tend to be Transformer-based since BERT (Devlin et al., 2019) shows significantly better performance than RNN on most natural language understanding tasks.

Most existing works extract sentences from the document and some works further (Xu and Durrett, 2019) propose post-processing steps to prune the generated summary. The only exception is the few works (Liu and Chen, 2019; Huang and Kurohashi, 2021), which extract finer-grained textual segments, i.e., discourse-level text or EDU, with little justification. The intuition is that a sentence consisting of multiple clauses is inevitable to contain less important information. As demonstrated in Table 1, partially removing a clause in the sentence is conducive to generating a summary. Certainly, such an intuitive explanation does not provide enough evidence and support to justify the use of finer-grained textual segments such as EDU to substitute sentences. Considering such a gap in existing research, the first main motivation of this paper is to propose and conduct the comparison analysis be-

tween sentences and EDUs to disclose and justify whether using EDU is a theoretically advanced and application-advantaged extractive unit.

When selecting textual segments, the top- k strategy with k fixed for all documents is dominant in deciding the length of the generated summary. Some works (Zhong et al., 2020; Chen et al., 2021) manage to output summaries with different lengths, i.e., various numbers of extracted segments, via formulating the problem as deriving a subset of sentences from the combination of top- k sentences. Due to the foreseeing explosion of the combination of sentences to form subsets, these approaches are limited to generating summaries with relatively small values of k . To overcome such a weakness, the second main motivation of this paper is to propose and develop an approach allowing varying lengths for extractive summarization without explicit limitation on the maximum value of k , i.e., the maximum length.

Following the above motivations, the comparison analysis between EDUs and sentences ascertains that EDU is a better text unit for the extractive task because EDU-level summaries achieve higher automatic evaluation scores than sentence-level summaries. This conclusion is justified from two perspectives. Theoretically, a formal theorem about this conclusion could be derived from the property that EDU is essentially part of a sentence. Experimentally, results of comprehensive analysis about oracle summaries of five datasets further quantify this conclusion, i.e., how much the ROUGE scores of EDU-level oracle summary are higher than sentence-level oracle summary.

Based on the aforementioned conclusion and foundation, this paper further proposes and develops an EDU-level extractive model and algorithm, which generates summaries with varying lengths, i.e., EDU-VL. We extend Transformer-based pre-trained language model with an extra classification layer to encode EDUs in a document and predict the corresponding probabilities. Multiple k values are provided to the model to generate a set of candidate summaries under the flexible top- k strategy for the document. Multiple Transformer encoder layers encode the full document and candidate summaries individually. Finally, a similarity score with the encoded document is calculated for each candidate summary and the one with the highest score is the final output of EDU-VL.

Experiments are conducted on five benchmark

datasets from different domains and with various writing styles. The experimental results suggest that EDU-VL achieves better performance than all state-of-the-art extractive baselines on single-document summarization datasets CNN/DailyMail, XSum, Reddit, and WikiHow, in terms of three ROUGE metrics. With direct comparison to the multi-document model, EDU-VL still achieves comparable performance on the multi-document summarization dataset Multi-News. Human evaluation is further carried for the summaries generated by EDU-VL to assess the syntax structure of EDU-constituent summaries. The results provide evidence for the good grammaticality and readability of EDU-constituent summaries and therefore justify the applicability.

The contributions of this paper are threefold:

- 1) We justify and quantify that EDU-level achieves higher automatic evaluation scores than sentence-level oracle summary from both theoretical and experimental perspectives, indicating that setting EDU as the extractive text unit is exploitable and superior in applications.
- 2) We propose a varying summary lengths-enabled extractive model with EDU-level text unit. Such a model and its learning algorithm encodes EDUs in a document and outputs a summary with varying length by making k in the top- k extraction strategy varying.
- 3) Our proposed model achieves superior performance on four single-document summarization datasets on three ROUGE metrics. Human evaluations show that the generated EDU-constituent summaries maintain good grammaticality and readability.

2 Related Work

2.1 Neural Extractive Summarization

The extractive text summarization task aims at extracting salient textual segments from the original document(s) as a summary. A tendency observed among extractive neural models is that the architecture changes from RNN (Nallapati et al., 2017; Xu and Durrett, 2019) to Transformer-based models, e.g., BERT (Zhang et al., 2019; Liu and Lapata, 2019) and Longformer (Liu et al., 2021; Ruan et al., 2022). GNN also gained extensive attention in recent years and is usually stacked after

an RNN (Wang et al., 2020; Jing et al., 2021) or Transformer-based encoder (Cui et al., 2020; Kwon et al., 2021) to supplement graph-based features. Some research works integrated neural networks with reinforcement learning (Dong et al., 2018; Gu et al., 2022) or unsupervised learning frameworks (Liang et al., 2021). In general, it can be said that taking a pre-trained Transformer-based language model as the starting point to encode textual segments in a document is currently the state-of-the-art approach among neural extractive models. Therefore, the Transformer-based models, i.e., RoBERTa (Liu et al., 2019) and BART (Lewis et al., 2020), are used as the basic building blocks in this paper.

2.2 Sub-sentential Extractive Summarization

Most previous works about the extractive task focused on generating sentence-level summaries, though some of them (Xiao et al., 2020; Cho et al., 2020; Ernst et al., 2022) utilized sub-sentential features. Early works by Marcu (1999); Alonso i Alemany and Fuentes Fort (2003); Yoshida et al. (2014); Li et al. (2016) exploited extracting discourse-level textual segments as the summary but those approaches were tested on small datasets. More recent works by Liu and Chen (2019); Xu et al. (2020); Huang and Kurohashi (2021) were evaluated on relatively larger datasets. However, whether the discourse-level textual segments are a better alternative than sentences as the extractive text unit was not justified in those works. To fill this gap, we provide justification for this research question from both theoretical and experimental perspectives in this paper.

2.3 Flexible Extractive Summarization

Extractive summarization task is usually formulated as extracting the top- k number of salient textual segments from a document. The fixed k value for all documents results in the lack of variety in the length of the generated summary. Few works (Jia et al., 2020; Zhong et al., 2020; Chen et al., 2021) managed to output summaries with varying lengths. However, either it requires extra effort for hyper-parameter searching on validation dataset to find a valid threshold, or formulating the problem as selecting a subset of top- k sentences makes the variety of lengths limited to small lengths due to the explosive nature of combination. In this paper, we propose a model with varying k values but without explicit limitation on the length or the need to do hyper-parameter searching.

3 Oracle Analysis of EDUs and Sentences

Oracle analysis refers to the analysis of oracle summary whose definition is stated in Section 3.1. We conducted oracle analysis from both theoretical and experimental perspectives to justify and quantify that discourse-level summary achieves higher scores on automatic evaluation metrics than sentence-level summary.

3.1 Theoretical Formulation

Elementary Discourse Unit (EDU), the discourse-level textual segment in this paper, refers to the terminal node in the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) tree which describes the discourse structure of a piece of text. EDUs are non-overlapping and adjacent text spans in the piece of text and a single EDU is essentially a segment of a complete sentence, i.e., the sentence itself or a clause in the sentence (Zeldes et al., 2019). Namely, a sentence can always be expressed with multiple EDUs, i.e., for the s -th sentence in a document, there is $sent_s = [edu_{s_1}, \dots, edu_{s_m}]$. Consequently, a one-way property from sentence to EDU regarding expressiveness is derived.

Expressiveness Property For any given subset of sentences in a document, i.e., $[sent_i, \dots, sent_j, \dots, sent_k]$, there is always a subset of EDUs in the document, i.e., $[edu_{i_1}, \dots, edu_{i_m}, \dots, edu_{j_1}, \dots, edu_{j_m}, \dots, edu_{k_1}, \dots, edu_{k_m}]$, having identical content.

Oracle Summary The set of salient textual segments that have greedily the highest ROUGE score(s) with the reference summary is the oracle summary for a document. It signifies the upper bound of performance that an extractive summarization model could achieve on ROUGE metrics.

Denote the sentence-level oracle summary as \mathcal{OS}_{sent} and the EDU-level oracle summary as \mathcal{OS}_{edu} . Based on the aforementioned property and definition, Theorem 1 can be derived and its detailed proof is provided below.

Theorem 1. *Given a document \mathcal{D} and its reference summary \mathcal{R} , for any derived \mathcal{OS}_{sent} , there is always an \mathcal{OS}_{edu} having $ROUGE_{F_1}(\mathcal{R}, \mathcal{OS}_{edu}) \geq ROUGE_{F_1}(\mathcal{R}, \mathcal{OS}_{sent})$.*

Proof. For ROUGE-N, let f_n be a function that generates the set of n-grams for the string s and g be a function that calculates the number of overlapping elements between two sets x and y ,

i.e.,

$$\begin{aligned} f_n(s) &= n\text{-gram}(s), \\ g(x, y) &= \text{match}(x, y). \end{aligned}$$

The recall and precision formulas of the ROUGE-N metric between the reference summary \mathcal{R} and sentence-level oracle summary \mathcal{OS}_{sent} are

$$\begin{aligned} \text{R-N}_{\text{recall}, \mathcal{OS}_{sent}} &= \frac{g(f_n(\mathcal{R}), f_n(\mathcal{OS}_{sent}))}{|f_n(\mathcal{R})|}, \\ \text{R-N}_{\text{precision}, \mathcal{OS}_{sent}} &= \frac{g(f_n(\mathcal{R}), f_n(\mathcal{OS}_{sent}))}{|f_n(\mathcal{OS}_{sent})|}. \end{aligned}$$

There is always an EDU-level summary \mathcal{S}_{edu} having $\mathcal{S}_{edu} = \mathcal{OS}_{sent}$. Let \mathcal{S}_{edu}^{sub} be the subset of EDUs in \mathcal{S}_{edu} having equivalent number of overlapping n-grams as \mathcal{S}_{edu} , i.e.,

$$\mathcal{S}_{edu}^{sub} \subseteq \mathcal{S}_{edu} = \mathcal{OS}_{sent}$$

and

$$g(f_n(\mathcal{R}), f_n(\mathcal{S}_{edu}^{sub})) = g(f_n(\mathcal{R}), f_n(\mathcal{OS}_{sent})).$$

The number of words in \mathcal{S}_{edu}^{sub} is smaller than or equal to the number of words in \mathcal{OS}_{sent} , i.e.,

$$|\mathcal{S}_{edu}^{sub}| \leq |\mathcal{OS}_{sent}|,$$

and consequently, the number of n-grams is correspondingly smaller or equal, i.e.,

$$|f_n(\mathcal{S}_{edu}^{sub})| \leq |f_n(\mathcal{OS}_{sent})|.$$

Therefore, the precision score for \mathcal{S}_{edu}^{sub} is larger than or equal to \mathcal{OS}_{sent} and their recall scores are the same, i.e.,

$$\begin{aligned} \text{R-N}_{\text{precision}, \mathcal{S}_{edu}^{sub}} &= \frac{g(f_n(\mathcal{R}), f_n(\mathcal{S}_{edu}^{sub}))}{|f_n(\mathcal{S}_{edu}^{sub})|} \\ &\geq \frac{g(f_n(\mathcal{R}), f_n(\mathcal{OS}_{sent}))}{|f_n(\mathcal{OS}_{sent})|} \\ \text{R-N}_{\text{precision}, \mathcal{OS}_{sent}} &= \frac{g(f_n(\mathcal{R}), f_n(\mathcal{OS}_{sent}))}{|f_n(\mathcal{OS}_{sent})|} \end{aligned}$$

and

$$\text{R-N}_{\text{recall}, \mathcal{S}_{edu}^{sub}} = \text{R-N}_{\text{recall}, \mathcal{OS}_{sent}}$$

Therefore, the EDU-level subset of \mathcal{OS}_{sent} , i.e., \mathcal{S}_{edu}^{sub} , is found to have higher or equal F1-scores on ROUGE-N metrics than \mathcal{OS}_{sent} , i.e.,

$$\text{R-N}_{\text{F}_1, \mathcal{S}_{edu}^{sub}} \geq \text{R-N}_{\text{F}_1, \mathcal{OS}_{sent}}$$

That is to say, it is guaranteed to have an EDU-level summary having higher or equal R-N scores than \mathcal{OS}_{sent} . By taking this \mathcal{S}_{edu}^{sub} as \mathcal{OS}_{edu} , we have $\text{R-N}_{\text{F}_1, \mathcal{OS}_{edu}} \geq \text{R-N}_{\text{F}_1, \mathcal{OS}_{sent}}$.

A similar proof process can be conducted

Text Unit	R-1	R-2	R-L
CNN/DailyMail

on ROUGE-L. Therefore, for any \mathcal{OS}_{sent} , there is always an \mathcal{OS}_{edu} having $\text{ROUGE}_{\text{F}_1}(\mathcal{R}, \mathcal{OS}_{edu}) \geq \text{ROUGE}_{\text{F}_1}(\mathcal{R}, \mathcal{OS}_{sent})$. \square

3.2 Empirical Justification

Five datasets from different domains were analyzed from the experimental perspective and experimental settings are listed in Appendix A. Table 2 presents the ROUGE scores of \mathcal{OS}_{sent} and \mathcal{OS}_{edu} on training datasets. \mathcal{OS}_{edu} gains significantly higher ROUGE scores on all datasets. Larger improvements are observed on ROUGE-1 (6.3-10.04) and ROUGE-L (7.38-11.38) on the majority of datasets, and improvement on ROUGE-2 is smaller but there is still an increase.

Figure 1 shows the comparison of breakdown ROUGE scores between two text units on the CNN/DailyMail training dataset and details about other datasets could be found in Appendix B. Recall scores on all three metrics are approximately equal between the two text units, suggesting that the amount of salient information in both is equal. However, precision scores are observed with a significantly higher value on \mathcal{OS}_{edu} , suggesting the length of \mathcal{OS}_{edu} is smaller.

The experimental results quantify the potential gains that EDU-level oracle summary could achieve on five datasets and the breakdown scores indicate that EDU-level oracle summary is less redundant than sentence-level oracle summary.

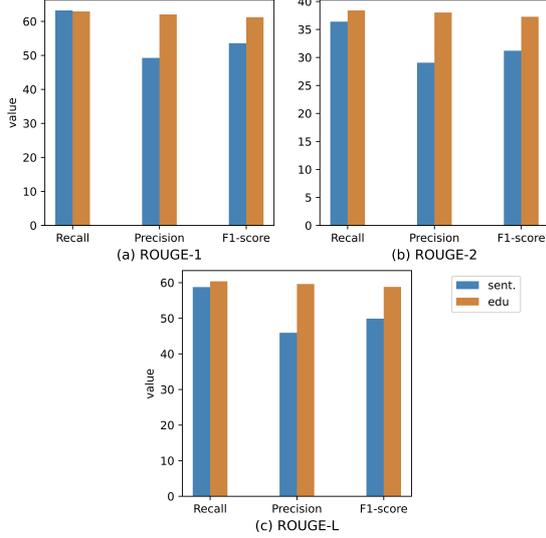

Figure 1: Breakdown ROUGE scores of sentence/EDU-level oracle summaries on CNN/DM training dataset.

4 EDU-level Extractive Model with Varying Summary Lengths

4.1 Problem Formulation

Suppose a document \mathcal{D} consists of m EDUs, i.e., $\mathcal{D} = [edu_1, \dots, edu_m]$, the i -th EDU consists of n_i words, i.e., $edu_i = [w_{i1}, \dots, w_{in_i}]$, and the reference summary wrote by human is denoted as \mathcal{R} . The set of ground truth labels for each EDU could be derived from \mathcal{R} , i.e., $L = [l_1, \dots, l_m]$, via a greedy algorithm as previous works did. Our proposed model aims to generate a summary via selecting one summary from the set of candidate summaries \mathcal{C} where $\mathcal{C} = [cand_1, \dots, cand_c]$ and $cand_j$ consists of EDUs with top- k_j probabilities that are also predicted by the proposed model.

4.2 Model

Figure 2 illustrates the architecture of our proposed model. From bottom to top, firstly, the EDU-level block generates a representation vector and probability for each EDU in a document. Secondly, the candidate summary generator aggregates EDU representation vectors to generate several candidate summaries with varying lengths by specifying different k values. Different from the previous top- k strategy where k is a fixed value, multiple k values are provided to the proposed model, allowing different numbers of EDUs being extracted to form different candidate summaries with varying lengths for the same document. Lastly, the document-level block encodes each candidate summary and selects one of the candidate summaries as the final model

output. In this way, the proposed model decides the most suitable summary length, i.e., k , for each document.

EDU-level Block Given input document $\mathcal{D} = [w_{11}, \dots, w_{mn_m}]$ where w_{ij} denotes j -th word in i -th EDU, [CLS] and [SEP] tokens are inserted into \mathcal{D} at the start and end of each EDU. We adapt the pre-trained Transformer-based language model (PLM) as the EDU encoder, e.g., RoBERTa. The hidden states of [CLS] tokens derived from the PLM are taken as EDU representations, i.e., edu^E in Equation (1). A classification layer is further applied on EDU representations to predict probabilities, i.e., \mathbf{P} in Equation (2).

$$[edu_1^E, \dots, edu_m^E] = \text{PLM}_\theta(\mathcal{D}) \quad (1)$$

$$P_i(y_i = 1) = \sigma(\mathbf{W}^c edu_i^E + \mathbf{b}^c), \quad (2)$$

where θ is the set of all trainable parameters in PLM; \mathbf{W}^c and \mathbf{b}^c are trainable parameters in classification layer, and $\sigma(\cdot)$ denotes sigmoid function.

Candidate Summary Generator Given a pre-defined extraction lengths set $\mathcal{K} = [k_1, \dots, k_c]$, the s -th candidate summary, $cand_s$, consists of EDUs whose probabilities are in top- $k_s(\mathbf{P})$, i.e., $[edu_{i_1}, \dots, edu_{i_j}, \dots, edu_{i_k}]$ where $i_j \leq m$ and $P_{i_j} \in \text{top-}k_s(\mathbf{P}), j = 1, 2, \dots, k_s$. The initial representation vector, $cand_s^C$, for $cand_s$ is the concatenation of representation vectors of EDUs in it. The initial document representation vector, \mathcal{D}^C , is aggregated from the representation vectors of all EDUs.

Document-level Block Multiple Transformer encoder layers (MTL) are stacked to encode document-level information for document \mathcal{D}^C , and all candidate summaries, e.g., $cand_s^C$, separately, and generate \mathcal{D}^D and $cand_s^D$ in Equation (3). Then cosine similarity, i.e., sim_s in Equation (4), is computed between the encoded document representation and the encoded s -th candidate summary representation. The candidate summary with the highest similarity with the document is taken as the final model-generated summary.

$$[\mathcal{D}^D, cand_s^D] = [\text{MTL}_\eta(\mathcal{D}^C), \text{MTL}_\eta(cand_s^C)] \quad (3)$$

$$sim_s = \text{cosine}(\mathcal{D}^D, cand_s^D), \quad (4)$$

where η is the set of trainable parameters in MTL.

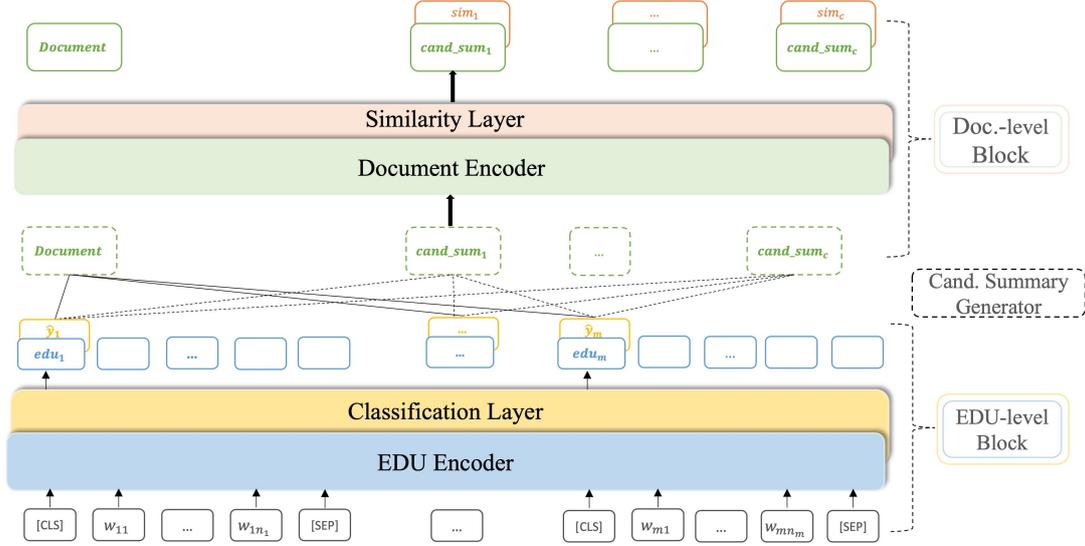

Figure 2: Model architecture. The EDU-level block encodes and predicts a probability value for each EDU in the input document; The candidate summary generator generates a set of candidate summaries based on the predicted probability values; The document-level block encodes the whole document and candidate summaries and generates similarity values between them. The final output is the candidate summary with the highest similarity score.

Training Algorithm 1 summarizes the model learning procedure. The model encodes EDUs in the document and predicts the probability for each EDU (lines 1-2), generates indices of EDUs for candidate summaries with different lengths which are derived from different k values (lines 3-4), encodes the whole document and candidate summaries and calculates similarity scores (lines 7-10), and selects the best candidate summary (line 16) in an end-to-end manner. Inspired by Zhong et al. (2020) that the candidate summary having a higher ROUGE score with the reference summary is expected to have a higher similarity score with the whole document, during training, ROUGE scores for each $(\mathcal{R}, cand_s)$ pair are calculated and used to sort the set \mathcal{C} in descending order (lines 5-6) to align with the loss function in Equation (7). Besides, to better emphasize those important EDUs, the EDU-level oracle summary, denoted as $cand_{gt}$ here, is introduced to the training process and assumed to have the highest ROUGE score (lines 12-13).

4.3 Objective Function

Binary cross entropy is calculated on the outputs of the classification layer in the EDU-level block, as in Equation (6). Contrastive learning loss is calculated on the outputs of the similarity layer in the document-level block, as in Equations (7-9). The final training loss \mathcal{L} in Equation (5) is

$$\mathcal{L}_{bce} = -\sum_{i=1}^m (l_i \log(P_i) + (1 - l_i) \log(1 - P_i)) \quad (6)$$

$$\mathcal{L}_{con} = \mathcal{L}_1 + \mathcal{L}_2, \quad (7)$$

where

$$\mathcal{L}_1 = \sum_{s=1}^c \max(0, \text{sim}_s - \text{sim}_{gt} + \gamma_1) \quad (8)$$

$$\mathcal{L}_2 = \sum_{i < j}^c \max(0, \text{sim}_j - \text{sim}_i + (j - i) * \gamma_2) \quad (9)$$

5 Experiments

5.1 Datasets

CNN/DailyMail (Hermann et al., 2015) is the most commonly used news dataset for the extractive task with human-written highlights as reference summary. The non-anonymized version was used in our experiments. **XSum** (Narayan et al., 2018) is another news dataset with the first introductory sentence in the article as the reference summary. **Reddit** (Kim et al., 2019) is a dataset crawled from the social media forum with the content in the section TL;DR as the reference summary. Experiments were conducted on the TIFU-long version. **WikiHow** (Koupaee and Wang, 2018) is a dataset crawled from the question-answering website with the first sentence in each paragraph as the reference summary. **Multi-News** (Fabbri et al., 2019) is a multi-document dataset with one summary for a cluster of documents. We follow Zhong et al.’s (2020) setting to split Reddit and Multi-News datasets and concatenate multiple documents into one single document. The detailed statistics of the five datasets in our experiments can be found in Appendix C.

5.2 Baselines

Various extractive models are selected as baselines. **HETFORMER** (Liu et al., 2021) modifies Longformer with longer input lengths to implement multi-granularity attention and selects sentences. Among models generating summaries with varying lengths, **MATCHSUM** (Zhong et al., 2020) selects among a set of candidate summaries derived from a trained sentence-level extractive model; **HAHSUM** (Jia et al., 2020) transforms a document into a heterogeneous hierarchical graph and flexibly selects sentences based on a threshold. Among models with sub-sentential segments as input, the **Proposed** model by Huang and Kurohashi (2021) is another Longformer-based model but extracts EDUs based on the constructed heterogeneous graph; **DISCOBERT** (Xu et al., 2020) and **D-SUM** (Liu and Chen, 2019) are models extracting discourse-level textual segments but they differ in whether integrating GNN into the model.

SGSUM (Chen et al., 2021) is a multi-document model by encoding all documents within one cluster individually and selecting the best sub-graph. **FAR** (Liang et al., 2021) is an unsupervised ranking model considering facet-specific information.

5.3 Experimental Setting

EDU segmentation of sentences in the document is conducted by NeuralEDUSegmentation² (Wang et al., 2018). To facilitate the training process, the calculation of ROUGE scores is avoided by pre-selecting the set of candidate summaries based on the predicted probabilities by the fine-tuned RoBERTa on the extractive task for each dataset. The pre-trained “roberta-base” or “bart-base” is adapted as the EDU encoder and enlarged to handle the first 768 BPEs of each document. The number of Transformer encoder layers is 4 by default. Following Liu and Lapata (2019), a similar greedy algorithm is applied to generate ground truth labels for EDUs (also for oracle summaries in Section 3.2) and the pseudo-code is in Appendix D. The trigram strategy is applied when forming the final EDU-constituent summary during validating and testing.

We follow Zhong et al.’s (2020) setting to set up $\gamma_1 = 0$ and $\gamma_2 = 0.01$. ρ is set as 100 based on our observation during training. Adam optimizer is used. The batch size is 5 to fit the GPU memory limit during training and 60 during validating or testing. Every 6k steps are defined as one epoch; the training process could take up to 100 epochs and early stopping is activated with patience as 10 epochs and R-2 as the metric. Experiments are conducted on a single Nvidia-v100-16GB GPU. The F1-scores of ROUGE-1/2/L³ (Lin, 2004) are taken as the automatic evaluation metrics. More details are provided in Appendix E.

5.4 Experimental Results

CNN/DailyMail Table 3 shows the results. The top section includes F1-scores of oracle summaries and the Lead-3 method. The second section presents the F1-scores reported in the original papers of all baselines. The last section lists the F1-scores of our proposed model.

Our proposed model outperforms the unsupervised baseline, FAR, by a large margin, aligning with the observation from other supervised

EDU-VL _{BART}	27.01	7.06	22.70

Table 4: F1-score results on test dataset of XSum and Reddit. The number of Transformer encoder layers in BART version of XSum is 6 and 2 for both versions of Reddit.

baselines. Compared with discourse-level baselines, i.e., D-SUM, DISCOBERT and Proposed, our proposed model achieves an improvement of at least 1.03/0.81/1.44 on R-1/2/L. When compared against other two varying lengths-enabled models, i.e., HAHSUM and MATCHSUM, our proposed model achieves better R-1 result on a small scale (0.12) and R-2/L on a larger scale (0.8/1.81). Our proposed model also beats HETFORMER which allows longer input length by a similar scale pattern. It is observed that the RoBERTa version of our proposed model performs slightly better than the BART version. The experimental results suggest that our proposed model achieves better performance than all baselines on the R-1/2/L.

XSum and Reddit The results in Table 4 show that our proposed model outperforms the baseline model, MATCHSUM, by a large margin on all three metrics (1.57/1.12/3.94 and 1.92/0.89/2.57 on R-1/2/L for XSum and Reddit, respectively). The RoBERTa version of our model only achieves

w/o VL	44.32	21.38	42.12

Table 6: Ablation analysis on test dataset of CNN/DM.

slightly better result on R-1 than the BART version.

WikiHow and Multi-News As shown in Table 5, our proposed model achieves significantly better performance on WikiHow dataset, beating both MATCHSUM and FAR by at least 2.16/1.47/3.08 on R-1/2/L. For the Multi-News dataset, our proposed model outperforms HETFORMER, MATCHSUM and FAR. It is noteworthy that SGSUM is initially designed to incorporate multiple documents, meaning that its input document is more complete than ours. Though our proposed model underperforms SGSUM on R-2, our proposed model achieves comparable result on R-1 and better result on R-L. The BART version of our proposed model outperforms the RoBERTa version on all three metrics on both datasets. To sum up, our proposed model performs better on WikiHow dataset and comparably on Multi-News dataset when compared against the corresponding state-of-the-art baselines.

5.5 Analysis

Ablation Analysis We further conduct ablation analysis by removing specific characteristics in our model and the result is presented in Table 6. Both letting the model extract sentences under the same

architecture and removing the document-block to disable the varying lengths characteristic reduce model performance on all three metrics. A larger decrease is observed in the sentence-level model.

Human Evaluation We randomly sample 50 summaries generated by our model from the CNN/DailyMail test dataset and conduct detailed qualitative analysis. For each summary, we combine EDUs from the same sentence together as one textual segment. Then referring to the dependency tree of the corresponding sentence, we evaluate the syntactical completeness of the extracted textual segment. Out of 221 extracted textual segments in all 50 summaries, 68% are syntactically complete and 32% are not. It is noteworthy that about half of those incomplete ones are subordinate clauses, whose syntax structure is close to being complete. Out of these complete ones, 44.7% are the whole sentence itself because all EDUs in that sentence are extracted; 55.3% maintain complete syntax structure after dropping some EDU(s) in that sentence (as the example shown in Table 7). Therefore, it is safe to believe that even sentences split into multiple EDUs, the model is capable to maintain the syntax structure by choosing multiple EDUs in a sentence and in some cases, filtering out some redundant information without breaking the completeness of the syntax.

Generated Summary Examples Table 7 provides an example of a summary generated by our proposed model, which illustrates that the model manages to selectively drop redundant information in sentences by operating on the EDU-level while maintaining an informative and readable summary.

6 Conclusion

In this paper, we verify and quantify the argument that the EDU-level summary achieves higher automatic evaluation scores than sentence-level summary from both theoretical and experimental perspectives. We further propose an EDU-level extractive summarization model and develop its learning algorithm, which generates summaries with different lengths for different documents. The experimental results demonstrate that our model achieves superior performance on four single-document summarization datasets and comparable performance for multi-document summarization with direct comparison with the multi-document model. In the future, we will explore integrating the EDU-

Reference Summary: Arnold Breitenbach of St. George, Utah, wanted to get ‘CIB-69’ put on a license plate. That would have commemorated both Breitenbach getting the Purple Heart in 1969 and his Combat Infantryman’s Badge. The Utah DMV denied his request, citing state regulations prohibiting the use of the number 69 because of its sexual connotations.

Table 7: Example from model-generated summary. Content within [] represents an EDU and subscript number ij indicates it is the j -th EDU in the i -th sentence in the document. Each color represents information in a sentence in reference summary. Italic denotes content selected by *our proposed model*.

level summary generated by our model into the abstractive summarization model.

Limitations

Though EDU is defined as a clause in a sentence, current EDU segmenters are still underdeveloped due to the limited training dataset and usually split a sentence into consecutive EDUs, which breaks the syntactic structure. Occasionally some extracted EDUs from a sentence fail to recover a complete syntactic structure. Therefore, a more sophisticated segmenter could further improve the segmentation, or some post-processing treatments could be developed to address such a potential issue specifically.

Abstract

In French, the placement of the adjective within a noun phrase is subject to variation: it can appear either before or after the noun. We conduct experiments to assess whether transformer-based language models are able to learn the adjective position in noun phrases in French—a position which depends on several linguistic factors. Prior findings have shown that transformer models are insensitive to permuted word order, but in this work, we show that finetuned models are successful at learning and selecting the correct position of the adjective. However, this success can be attributed to the process of finetuning rather than the linguistic knowledge acquired during pretraining, as evidenced by the low accuracy of experiments of classification that make use of pretrained embeddings. Comparing the finetuned models to the choices of native speakers (with a questionnaire), we notice that the models favor context and global syntactic roles, and are weaker with complex structures and fixed expressions.

1 Introduction

In French, the placement of the adjective is subject to a considerable amount of variation—a phenomenon that has been under close scrutiny among linguists. Generally speaking, adjective placement in anteposition or postposition is attributed to many intertwining, linguistic processes, rather than a few rigid grammatical rules. However, the order of the adjective can be crucial to the meaning of the noun phrase; in the titular example, *chère maison* means “dear house” but *maison chère* means “expensive house”.

Meanwhile, natural language processing researchers investigate whether language models built by transformer architectures are able to capture some of the inner workings of human language during their learning process. So far, research has shown that the high performance of such models does not imply the understanding of basic concepts

such as grammatical order because the transformer architecture is non-sequential by design.

We are exploring whether transformer-based language models are capable of perceiving the adjective’s position in a sentence with regard to its head noun, with a variety of experiments. Our goal is not to set a new state-of-the-art, but to explore if and how this information on word order is learned and used in tandem with the contextual word embedding information. While previous work has shown that transformer models are insensitive to word order (Pham et al., 2021; Gupta et al., 2021), finetuned models were successful in classifying adjective position (Sinha et al., 2021b). We also tested variations of finetuning training sizes and the use of attention masks to hide either the context of the sentence or the head noun and adjective.

For most adjectives, classifying their position is a relatively easy decision based on frequency; to observe the models’ underlying competencies in more complex cases, we carried out an error analysis and additional experiments and visualizations on the pretrained versions of the models. We also had the opportunity to conduct an experiment with native French speakers, to compare their choices in challenging cases of adjective placement to the models’ predictions.

Our findings show that finetuned models are capable of learning word order and efficiently classifying it; this knowledge is fainter in pretrained embeddings, but some layers demonstrate some specialization. Finetuning a model helps to learn these variations in adjective position and very successfully select the correct one. CamemBERT models were more successful than FlauBERT models over all experiments and captured more positional information in the finetuned adjective embedding. However, all transformers models show weaknesses (to different degrees) in complex cases of adjective/noun dependent phrases and fixed expressions.

2 Position of adjective in French noun phrases

While traditional grammar proposes that adjectives in French follow the noun, in a noun phrase, linguistic analysis supports that adjectives are mobile, i.e. can be placed in anteposition or postposition relative to the noun (Abeillé and Godard, 1999). However, most adjectives tend to appear in specific positions; adjectives that accept only anteposition, only postposition, and those that alternate position (Benzitoun, 2013). For example, ordinal adjectives in *-ième* (e.g. *troisième* ‘third’), are almost always anteposed to the noun, the adjectives *exotique* ‘exotic’, *idéal* ‘ideal’, *populaire* ‘popular’, *moderne* ‘modern’, *géant* ‘giant’, *naturel* ‘natural’ are always postposed, and the adjectives *énorme* ‘huge’, *immense* ‘immense’, *superbe* ‘superb’ alternate between the two possible position (Larsson, 1994; Benzitoun, 2014).

The preferred position of an adjective depends on its features and frequency; for example, Benzitoun (2014) claims that the adjective *prochain* ‘next’ in plural form does not occur in postposition (based on corpora statistics), but the singular does. Wilmet (1980, 1981) calculated that the most frequent adjectives in a corpus of literary works tend to precede the noun. However, chromatic adjectives (e.g. *rouge* ‘red’) which are of high frequency are always postposed to nouns when not a part of a multi-word expression. Adjectives derived from nouns and adjectives have a very strong tendency to be postposed (Forsgren, 2016; Goes, 1999). Wilmet (1981) and Forsgren (1978) support that the length of the adjective affects its position; short adjectives (e.g. *bon* ‘good’, *beau* ‘pretty’) tend to antepose, while longer adjectives and derivatives can only be postposed.

Semantic factors may also affect the position of an adjective with respect to its head word. For example, adjectives with multiple meanings may have different meanings in different positions; e.g. *propre* when anteposed refers to possession ‘own’, but when postposed means ‘clean’ (Thuilier, 2013). Benzitoun (2014) also presents the concept of adjective-noun pairs, where the meaning of the noun influences the position of the adjective. These pairs differ from fixed expressions because it is possible to create a pair with a different order (and different meaning), while fixed expressions are lexicalized and do not allow the existence of a variation with a different meaning. For example, the

lexicalized phrase *arts premiers* (where *premier* is postposed) has a very specific meaning (‘arts of the non-Western world’) compared to *premiers arts* ‘first arts’ where it used in its literal sense and is not a lexicalized phrase.

The presence of more dependents in the noun phrase also affects the position of the adjective. The presence of an adverbial modifier to the adjective may force the adjective phrase to postposition or increase the occurrence of the adjective in postposition, or at least allow more flexible positioning of the adjective phrase relative to the noun (Forsgren, 1978; Thuilier, 2013). A definitive case of postposition happens when an adjective has a multi-word modifier, e.g. a prepositional phrase (Thuilier, 2013). Postposition is also favored when there are multiple adjectives defining the noun. Thuilier (2013) also suggests that elements in the syntactic phrase are ordered by increasing length (known as *increasing* or *relative mass*). However, it may not apply to high-frequency adjectives such as *magnifique* ‘magnificent’ (Larsson, 1994).

3 Word order and transformer models

There has been extensive work on analyzing the syntactic and semantic capabilities of transformer models and their pretrained word embeddings, with positive and negative findings on the abilities of these models to capture linguistically salient word relations. In this review, we focus on word position and word order findings.

The addition of absolute word order (i.e. the sequential order of words) to the training process of contextual word embedding models has proven quite beneficial. Transformer models with bidirectional training, which captures adjacent word order, showed improvement compared to the original self-attention neural networks (Yang et al., 2019). Transformer models trained with masked language modeling, such as BERT and RoBERTa, are able to learn absolute word positions, but they also learn structural word positions (i.e. phrase position in hierarchical tree structures) and make use of them (Wang et al., 2019; Wang and Chen, 2020). Multiple experiments combine absolute and structural word positions to create better-informed and better-performing word embeddings (Wang et al., 2020; He et al., 2021; Chang et al., 2021; Wang et al., 2021).

However, experiments on already pretrained language models and shuffled word order tell a dif-

ferent story. [Pham et al. \(2021\)](#) conducted experiments on BERT-based models (BERT, RoBERTa, ALBERT) with GLUE classification tasks, and showed that tasks such as sentiment analysis were not affected by shuffled word order, except for the grammatical correctness task. [O’Connor and Andreas \(2021\)](#) conducted experiments on the effect that context variation has on transformer models’ usable information, and discovered that word shuffling has a negative effect, whether the shuffling was implemented on short or long distances among words. [Gupta et al. \(2021\)](#) conducted similar experiments with GLUE tasks and observed that model performance was lower on shuffled word orders (in methods that render a sequence ungrammatical and incomprehensible to humans) but close enough to support that models rely more on embedding information rather than sequential context. [Sinha et al. \(2021b\)](#) confirm that pretrained language models are insensitive to word order in tasks of Natural Language Inference and show that, on some occasions, classification is successful only with certain (random) word order variations of an input sequence. They also conducted experiments on finetuned models and noted finetuning’s positive influence on learning word order. Finetuning improved performance on tasks of inference and grammaticality as well (even with models pretrained with scrambled word order) ([Sinha et al., 2021a](#)). For French, [Li et al. \(2021\)](#) conducted experiments, on the transformer models’ capacity to capture long-range object-verb agreement and word order (in one of their experiments). They observed that models performed worse with scrambled inputs, and increasingly worse, for increasingly complex relations.

4 Experiment 1: Finetuning and classification of adjective position

4.1 Methodology

Given the findings from previous work, highlighting the syntactic and semantic capacities of transformer models as well as also their weakness in learning word order, we want to test whether transformer models are able to classify the position of the adjective in a sentence.

In order to provide the two possible positions that the adjective may have in a noun phrase, we provide a pair of sentences as input: the first sentence of the input has the adjective always anteposed to the noun, and the second sentence al-

ways postposed. We label the two-sentence sequences with ‘0’ if the first sentence is correct (i.e. the correct order is anteposition) and ‘1’ if the second sentence is correct (i.e. postposition)—see example in [Table 1](#). The sentences are separated by the specific end-of-sequence token of each model. With this task, we aim to observe if word order is insignificant to the models or if they are able to capture the preferred word order between two sentences with identical tokens and different word order. We finetuned the transformer models for 4 epochs based on the guidelines by [Devlin et al. \(2019\)](#) and [McCormick and Ryan \(2019\)](#) (see [Section 4.2](#) for datasets and details).

We also run the same experiment with a one-sentence input, with the original sentence without any permutations. The models were finetuned for 4 epochs as well, with the original sentence and its label of ante-/postposition. This method is less informative, as the model is not aware of the different possible positions of the adjective, and will only predict correctness.

In order to further study the contribution of different tokens in the input sequence, we also finetuned the models with blocked attention to certain tokens; we used the attention mask, which is an array that instructs the model’s self-attention mechanism to attend to specific tokens of the input sequence, by assigning 1s to the “visible” tokens and 0s to the “invisible” ones. In addition to the *default* setting of attending to all tokens, we tested a *pair* setting, in which all tokens are masked except for the adjective and its head noun, and a *context* setting, in which the adjective and noun are masked and all the other tokens are visible. Our goal is to observe whether the adjective-noun pair is significant enough to encapsulate their preferred positions or not, and whether the context contains (enough) information on preferred adjective-noun positions even without explicit information on the pair. We present a visualization of what an input sentence looks like in these settings in [Table 2](#).

4.2 Datasets

We extracted sentences with correct adjective-noun pairs from two parsed corpora: the frWaC corpus ([Baroni et al., 2009](#)) and the French corpora of Universal Dependencies 2.9 (UD; [Zeman et al., 2021](#)), in different combinations¹.

¹The list of corpora can be found at <https://universaldependencies.org/fr/>

On construit les éléments de plus haut niveau .	
↓	
SENTENCE	LABEL
On construit les éléments de plus haut niveau.	0
</s>On construit les éléments de plus niveau haut.	

Table 1: An example input of two sentences for the original sentence *On construit les éléments de plus haut niveau* ‘We build the higher level elements’. We only shift the position of the adjective-noun pair in the noun phrase, without affecting any other elements of the phrase (e.g. the dependent adjective *plus*).

MASK	TOKENS
Default	on construit les éléments de plus haut niveau
Pair	on construit les éléments de plus haut niveau
Context	on construit les éléments de plus

Table 2: Use of attention masks for the sentence: *On construit les éléments de plus haut niveau*. In this sentence, the adjective-noun pair is *haut niveau* (the adjective is before the noun). The label for all three inputs is [0]. For the double-sentence input, the same process will be followed for the second sentence of the input *On construit les éléments de plus niveau haut*.

We used all UD sentences and selected 120K relevant sentences from frWaC, with a 2/3 ratio of anteposition/postposition, which is roughly the ratio documented in the literature and the one that occurs in our corpora²—this ratio is also beneficial since anteposed adjectives are fewer but more frequent. However, we excluded the adjectives and words which were incorrectly parsed as adjectives, such as numerals, pronouns such as *autre*, *certain*, *chacun*, *quelque* which may have other linguistic functions than an adjective. In addition, we also excluded the adjectives and the nouns which were tokenized into subwords by the transformer model tokenizers, in order to create the attention mask described in Section 4.1.

The sentences of the two datasets were combined and used in various ways. In one setting, we trained the model only with frWaC, and used the UD sentences as an additional test set. In another one, we added a subset of the UD sentences to the train set and tested on the rest of UD; we also finetuned the model just with the (significantly) smaller UD dataset. When applicable, we tested both with frWaC and UD sentences. The size of the datasets is presented in Table 3.

²Measured on 1M frWaC sentences and the entire UD corpora.

Dataset	Train	Val.	frWaC test set	UD test set (entire)	UD test set (part)
frWaC	76,164	7,672	7,740	19,437	5,151
frWaC + UD	91,615	7,672	7,740	-	5,151
UD	13,905	1,546	7,740	-	5,151

Table 3: Dataset sizes for the finetuned models.

4.3 Transformer models

We used two monolingual French transformer-based models, available from the HuggingFace Python library (Wolf et al., 2020), CamemBERT (Martin et al., 2020) and FlauBERT (Le et al., 2020). CamemBERT is the pioneering monolingual French model and is built based on the RoBERTa architecture and trained on monolingual data. Experiments showed its advantage on traditional NLP tasks over multilingual transformer models. The authors also highlight the base version’s high performance with a fraction of the size of the large version. FlauBERT is a monolingual French BERT-based model trained with multiple, heterogeneous corpora and a more extensive tokenization procedure. It has been shown to (slightly) outperform CamemBERT on French benchmark tasks.

4.4 Baselines

The simplest baseline we can establish is based on frequency in our corpus: we assign each adjective a label of ante-/postposition based on its most frequent position in the training set. We also performed classification with more classical NLP methods, namely a logistic regression model on bag-of-words, implemented with `scikit-learn` (Pedregosa et al., 2011), and a CNN-based classifier, more sensitive to word order, implemented with PyTorch (Paszke et al., 2019).

4.5 Results

The results for the two-sentence input experiment can be found in Table 4 (and for the one-input in Table 7 in Appendix A). We can already observe that frequency yields a quite high accuracy, the bigger the training set is and the smaller the test set is. The CNN classifier is very successful when the training set is large enough. Therefore, it comes as no surprise that the finetuned transformer models made very few mistakes, with the overall accuracy being close to 100%. The results were consistently high, even when testing with a different dataset (frWaC and UD). However, with a much

Model	frWaC train			frWaC+UD train		UD train

Table 5: Classification results of the finetuned models with attention masks. Values in *italics* indicate that the model completely failed to classify.

smaller training set, results were slightly lower (as expected; finetuning guidelines recommend a training set of at least 100K inputs). In comparison, the accuracy of the one-sentence finetuning experiment is 11-12% lower, which is even lower than the frequency-based baseline and the CNN classifier.

The results of the experiments with attention masks are presented in Table 5 (and Table 8 in Appendix A for the one-input finetuning). In these experiments, the models’ attention mechanism had access to only certain tokens. When attention was only allowed to the adjective and noun pair, the Flaubert models were unable to classify, while the Camembert models showed equally outstanding performance with the frWaC sentences (but lower performance with the UD test sets). Meanwhile, masking the adjective and noun pair and only allowing attention to the rest of the sequence was surprisingly successful for the finetuned models with the larger training sets (except for camembert-large), reaching similar accuracies to those of the no-mask finetuned models. For the one-input finetuning experiment, we notice that, for the masked context scenario, performance rose drastically only for CamemBERT models and only in the frWaC domain, while the Flaubert models were again unsuccessful. For the masked adjective-pair scenario and for the UD domain, the performance is significantly lower.

4.6 Qualitative analysis

In most cases, the models make very few mistakes, which are not consistent among models. Moreover, the models are very confident in their choices, assigning high probabilities to all predictions (see Figure 1 in Appendix).

Focusing on the frWaC training set with the UD dataset as the test set, we notice that most of the sentences that were mislabeled are ones where the adjective could possibly be in a different position, with a different meaning than the original one (i.e. the utterance remains grammatical when the adjective-noun order is reversed). For example, the sentence *Une école a ouvert dans une ancienne église en 1950* ‘A school opened in a former church’ remains correct with *ancienne* postposed to the noun, but the meaning of the adjective becomes ‘old’. The context provided by the sentence is not sufficient to decipher the actual meaning, and native French speakers agree that both sentences are grammatical. On the other hand, mistakes in the classification of sentences such as *Les créations sensuelles, modernes et orientales se font remarquer* ‘The sensual, modern and oriental creations stand out’ uncover the models’ shallow perception of syntactic relations –these mistakes were, however, very rare. Finally, we notice a few badly-parsed and badly-formed sentences in the dataset, which were not enough to warrant a redesign, but were confusing to the models.

5 Experiment 2: Pre-existing knowledge in pretrained embeddings

The previous experiment shows that the finetuned transformer models are quite successful in classifying the adjective’s position when asked to distinguish between two possible positions. The following part of this research aims to observe whether this capability is given by the finetuning, or whether the pretrained models had already learned enough information on the adjective’s preferred position, with regard to its context.

5.1 Classification with adjective embeddings

The layers of a transformer model specialize in creating different dynamic word embeddings, which capture and interact with a word’s context in a different way than the previous layer. Therefore, the adjective embedding might contain the syntactic, contextual, and semantic information that determine its position with regard to the noun. We extracted the word embeddings for the adjective of each sentence, per layer, and we trained a simple logistic regression model –built in the same way as in Section 4.4. We used the frWaC training set and tested on the frWaC test set and on the entire UD dataset.

The results of the classification for the two test sets can be seen in Figure 2 in Appendix C. The classification results for the frWaC test set are quite low –close to being non-classifiable– except for the `flaubert_base_uncased` model, which unexpectedly reached 97% accuracy on the last layer. Results for the UD test set were more unpredictable, with a few layers of *camembert-base* reaching a very high accuracy, but the final layer having the lowest accuracy. On the other hand, the `flaubert` models had a progressively better performance, but they are not as good as their finetuned counterparts nor as the baselines.

5.2 Adjective [MASK] probabilities with Masked Language Models

Pretrained models can predict the tokens that can fill a masked position in a sequence. We use this method to retrieve the probability that the models have assigned to the adjective in the sentence, specifically in the position it was found in. We make use of the sentences of the frWaC test set. (These probabilities are presented in Figure 3 in Appendix D.) We observe that overall the models assigned higher probabilities to anteposed adjectives

being in anteposition, than to postposed adjectives in postposition; apart from the stricter linguistic constraints for anteposed adjectives, this could also be due to the fact that transformer models favor token frequency, and most of the most frequent adjectives in French are anteposed, while postposition harbors far more adjectives. Additionally, we observe that CamemBERT models give higher probabilities in the predictions of both anteposed and postposed adjectives.

When we shifted the [MASK] position from its original place to the opposite one, and asked the models to assign the adjective’s probability in the “wrong” position, the probability of the adjectives was close to zero for at least 85% of the cases, even for anteposed adjectives which are more versatile.

6 Experiment 3: Human vs Transformers judgments of adjective order

6.1 Methodology and Dataset

We had the opportunity to carry out an additional experiment on adjective word order, in which we studied how native French speakers and the finetuned transformer models dealt with challenging cases of adjective position, caused by structural or semantic idiosyncrasies. As observed in the previous experiments, the models demonstrated weaknesses in cases of adjacent adjectives that did not belong to the noun phrase, and their choices did not always align with the original sentence in cases of semantic ambiguity relating to the adjective position. These cases cannot always be coined as errors, since native speakers may also make similar choices whether intentionally (e.g. different comprehension of context) or unintentionally (e.g. haste, lack of attention).

The structure of the experiment is the same as in Experiment 1, where speakers and the finetuned models were presented with a sentence containing a noun-adjective pairing, and its variation having the target adjective in the opposite position. Regardless of the original order, each sentence pair of the two positions was presented in the order of anteposition-postposition. We created 89 prompt sentences, written by a native French speaker or extracted and modified from frWaC, and evaluated by French speakers. The full dataset can be found in Appendix F. The sentences are split into four categories based on the type of relations that the adjective has with the noun, or the context of the sentence:

1. *Presence of adjective/noun dependent*: The only categorical constraint that governs the position of the adjective in French is the presence of a dependent to the adjective, which forces the position of the adjective to postposition. However, if the dependent is to the noun, the position of the adjective is not restricted. We included sentences with the same adjectives and dependents either to the adjective or the noun.

2. *Fixed expressions*: Adjectives in fixed expressions will always have a fixed position in this specific context and meaning. Apart from sentences with fixed expressions we selected, we added sentences with the adjectives found in those expressions, but not in restrictive structures.

3. *Structural persistence*: Speakers are sensitive and tend to reuse repeating syntactic constructions (*syntactic priming*, (Branigan et al., 1995)). The presence of a noun phrase with an adjective in a certain position may influence the processing of the next noun phrase, especially if it contains the same adjective. We want to test the extent of this effect on native speakers and our models.

4. *Blocked and mobile adjectives*: In this category, we are including adjectives which are (almost) always found in postposition, and adjectives with free position depending on the meaning (*propre, ancien*). This category serves both as a control group, but could also provide unexpected results.

6.2 Questionnaire diffusion

While the finetuned models received all sentences as a test set, we divided the prompt sentences in 3 questionnaires, ensuring that there is equal distribution of the four categories in each. The participants were asked to select the sentence that sounded “most natural” to them, out of the two position variations. In order to eliminate outliers or non-native speakers of French, at the start of each questionnaire we asked for input of first language, and to confirm that they were native speakers of French (and also to acclimatize the participants with the experiment) there was a mini-tutorial with two sentence pairs which could not be mistaken by French speakers. The questionnaire was built with LimeSurvey³ and distributed to French university students and French locals. Out of the 71 participants who completed the questionnaire and were

Model	Micro avg.	Macro avg.
camembert-base	0.3326	0.1629
camembert-large	0.5801	0.4673
flaubert_small_cased	0.6014	0.3711
flaubert_base_cased	0.433	0.3446
flaubert_base_uncased	0.5192	0.3298
flaubert_large_cased	0.3688	0.3554

Table 6: Correlation between the average choice of the speakers and each model’s output. Micro-averaged is aggregating all sentences regardless of category while macro-average is category-sensitive.

not considered outliers, each version of the questionnaire had 22-25 participants, i.e. each sentence pair was evaluated by at least 22 speakers.

6.3 Quantitative and Qualitative Results

We calculated the average selection over all speakers and used this as the baseline to make judgments for our models. In Table 6 we are presenting the Pearson correlation between the speakers’ and the models’ choices, in order to see which of the models was closer to the behavior of the speakers. The model that achieved the highest micro- and macro-averaged correlation was `camembert-large`, although `flaubert_small_cased` model was slightly better at micro-averaged correlation – an interesting finding, since this model is created for debugging purposes and its results are unreliable. The `camembert-base` and `flaubert_large_cased` models showed the lowest correlations, and all models except for `camembert-large` did not show a strong positive correlation (>0.4) in the macro-averaged correlation.

We also examined the speakers’ decisions and the models’ predictions per category and performed error analysis. For the *presence of adjective/noun dependent* category, the speakers preferred longer adjectives in postposition, even when the dependent phrase was attached to the noun: for example, the speakers unanimously chose the postposed variation of the sentence *Ils vivent une différente relation sans amour*. “They lived a different relationship without love.” and so did most of the models. However, for shorter adjectives, the speakers chose anteposition when there was a noun dependent and postposition when there was an adjective dependent. The models however did not present a uniform behavior, with some models mostly preferring postposition (`camembert-large`) or anteposition (`flaubert-large-cased`), while the more successful ones made mistakes on the shorter adjectives.

In the *fixed expressions* category, the speakers naturally did not make any mistakes on the fixed expressions, and were able to differentiate between the fixed and the free position of the same adjective in different contexts. However, the models made several mistakes on very common fixed expressions, e.g. *la grasse matinée* “the morning of sleeping in”, but were not mistaken on expressions with a short adjective, e.g. *bénéfice net* “net benefit” (i.e. the short adjective was not anteposed, while its variations in non-fixed phrases are commonly anteposed). In the category of *structural persistence*, the speakers were able to make their choices for the adjective position despite being primed by a previous noun phrase with the opposite adjective position, e.g. they preferred the variation *Il lui a offert des volumineuses plantes à fleurs volumineuses*. “He offered them voluminous plants with voluminous flowers.” for the noun phrase *fleurs volumineuses*. However, all the models predicted anteposition, and this could have been affected by the adjectives being in the same wordform. Finally, in the *blocked/mobile* adjectives category, the speakers did not make any inexplicable choices, and always preferred postposition for the postposed adjectives (e.g. *chromatic*) and both positions for the mobile adjectives (despite the length). The only model which made mistakes on the postposed adjectives was `flaubert-large-cased`, while the other models made very few mistakes on mobile adjectives—decisions which are to some extent acceptable, since the meaning may be different but still grammatical.

7 Discussion

Previous work on exploring transformer models has supported that their success in NLP tasks is heavily based on their vast training data and efficient learning of frequencies. Our experiments, compared to a frequency-based uninformed baseline, show that there are more complex operations in play. Transformers were more efficient than sequential-order-learning neural networks, and were in fact able to differentiate between two sentences with identical tokens and slightly different word order. Finetuning is more efficient with a larger training corpus and different domains, but can still be successful with a smaller dataset if necessary.

When the models’ attention mechanism only has access to the context, and not to the adjective-noun pair itself, they were still quite capable of classi-

fying adjective position even without attending to it. This observation is consistent with the linguistic description that supports that adjective position is also determined by context and not solely by the noun phrase. However, the fact that CamemBERT models were extremely successful in identifying position without the use of context, while Flaubert models failed completely, is caused by the models’ different architectures and choices in the way the tokens are handled. In our more detailed experiments, we saw that CamemBERT models assign an overall higher probability to adjectives, regardless of their position, and that, at least for the UD dataset, the adjective embeddings were, in some layers, very informed on the preferred word position. This knowledge is correlated to the learned contextual word embeddings, rather than the word itself, as we observed a lack of semantic similarity in the visualization.

Regarding the models’ mistakes in the testing phase, they were either caused by low-frequency adjectives, bad parsing, or ambiguous meaning which may be grammatical and acceptable in both adjective positions. However, comparing the models to human performance showed their true strengths and weaknesses; when they are successful, the models tend to follow a more rigid syntactic structure and favor postposition, as it is the most frequent adjective position over all adjectives. They showed severe problems in recognizing some fixed expressions, and were more easily swayed than humans by being primed with the same adjective. In cases where both positions were possible, they usually preferred the more “traditional” postposition. These findings may demonstrate that the models base their decisions on adjectives more on frequency rather than the syntactic and semantic information of a particular adjective, and are impervious to factors that affect speakers’ decisions such as length, difficulty of processing with regard to cognitive load, and substantial or subtle semantic differences.

8 Conclusion

In this work, we aimed to study the capabilities of transformer-based language models in understanding word order, specifically the order of adjectives in a noun phrase in French. Our findings, for pretrained models, confirmed previous ones which claimed that these models are agnostic to word position. However, the process of finetun-

ing and classification with two variations of the sentence (one correct and one with permuted adjective order) was very successful, which proves that the models are capable of learning and becoming sensitive to word order. Concerning the use of attention masks, the CamemBERT models were very capable of classifying word order by only attending to the adjective and noun, while for the Flaubert models it was impossible. The differences between the two architectures were also reflected in our study of the pretrained word embeddings and the adjective probabilities, where we noticed that CamemBERT’s adjective embeddings were better informed. The adjective embeddings themselves, for all models, seem to contain more contextual than word-specific information, which makes different iterations of an adjective differ from each other. In our experiment comparing native speakers to the models’ preferences, we observed that the models showed weakness in structures with dependents, fixed expressions, and priming, and reverted to the grammatically-established postposition more than humans. Therefore, the models’ understanding of the position relies both on context and on shallow syntactic roles, but is lacking semantic nuances. We also observed that the information on position is specialized in some layers –and easily learned via finetuning.

Limitations

This work has been conducted in the French language, due to the available language resources and transformer models in this high-resource, in addition to the authors’ adept knowledge of the language and its linguistic properties. We decided to focus on the specific phenomenon of adjective placement because it offers the possibility to study the models’ sensitivity to word order on pairs with one grammatical and one ungrammatical sentence, but also with pairs where both sentences were grammatical. The finetuning of the transformers models, especially of the large versions, was made possible with the use of a server with GPU clusters, provided by our institution.

Table 8: Classification results of finetuning models with only one sentence as input and with attention masks. Values in *italics* indicate that the model failed completely to classify.

B Probabilities of predicted labels during classification

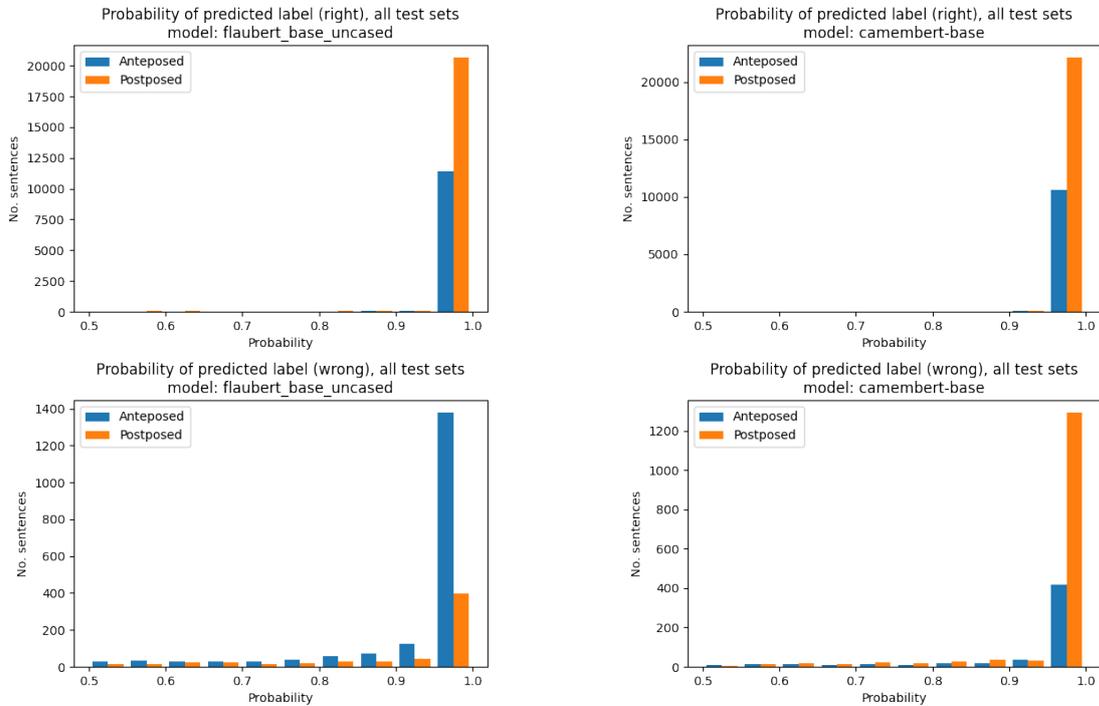

Figure 1: The probability of predicted labels, for wrong and correct predictions, from the frWaC train set and both test sets.

C Classification based on the adjective’s pretrained embedding, with logistic regression

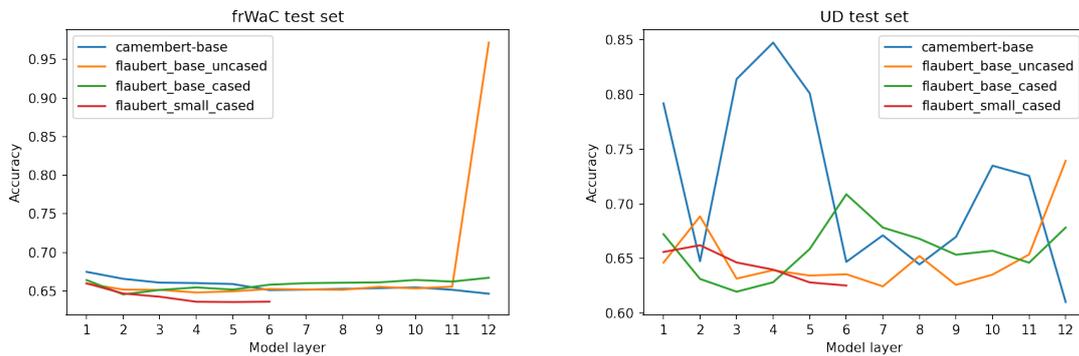

Figure 2: Logistic regression accuracy trained with layer-specific adjective embeddings, with our two large test sets.

D Adjective [MASK] probabilities with Masked Language Models

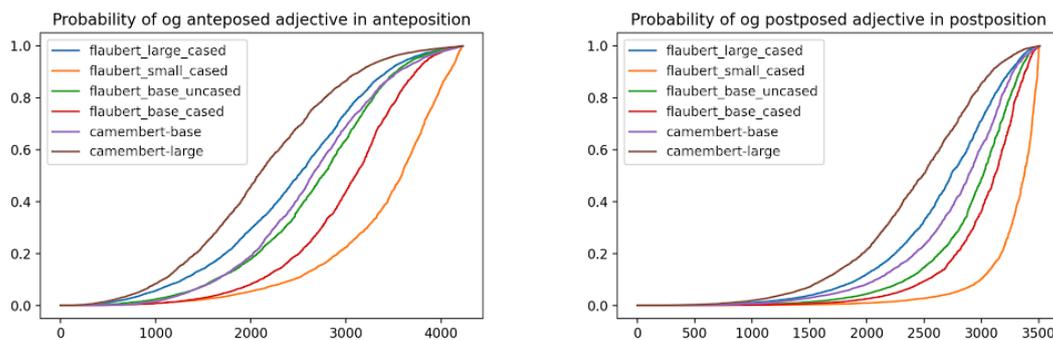

Figure 3: The assigned probability of each adjective instance, when placed in its original position which has been masked (anteponition/postponition), for each model.

E Visualizing adjective pretrained embeddings per layer

We extract layer-specific embeddings of some transformer models, and use them to visualize static embeddings by reducing their dimensions and plotting them on a 2-dimensional space, in order to observe their closest neighbors and possible clusters or patterns emerge. We selected a few frequent adjectives from the literature, either with a preferred position or without: *grand*, *petit* for always-anteponed, *naturel* for always-postposed, *ancien* for ambivalent. All the embeddings of each adjective (from the different sentences it appeared in) were used and plotted per layer.

We reduced the embeddings’ dimensional with t-distributed Stochastic Neighbor Embedding (t-SNE) from `scikit-learn` and plotted with `matplotlib`. Some of the plots are presented in Figure 4. Our intuition was that the anteponed and postposed adjectives would form clusters. However, we could not observe discernible clusters in any of the data –the closest being for some early layers, for some adjectives, and for complex word forms rather than the base ones.

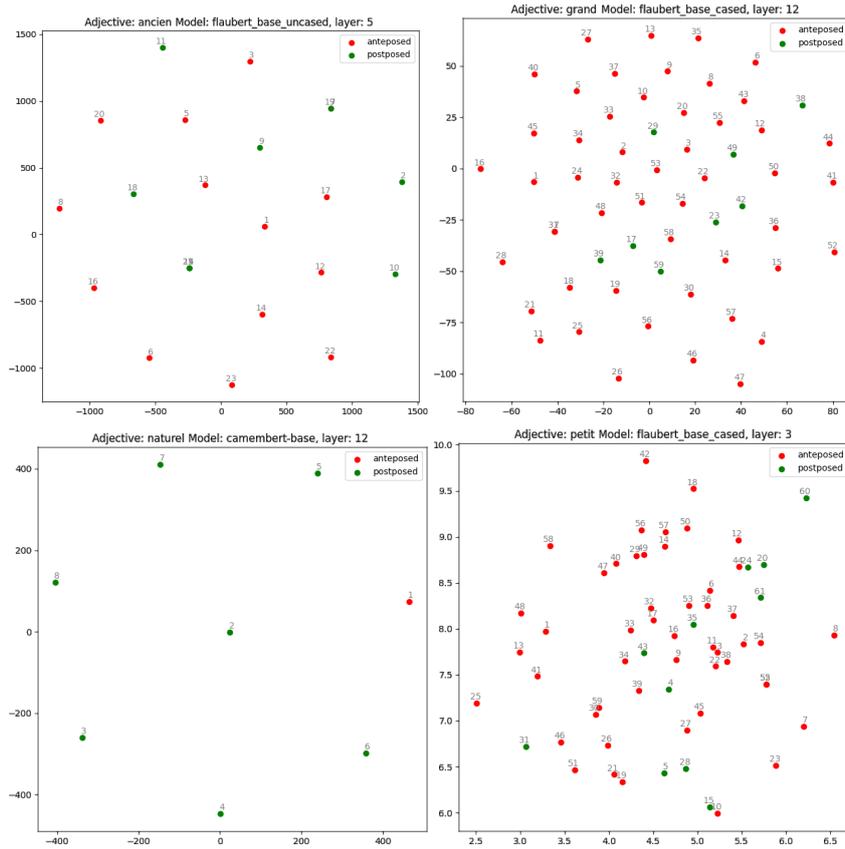

Figure 4: Embedding projections for base-form adjectives *ancien* ‘old’, *grand* ‘large’, *naturel* ‘natural’, *petit* ‘small’ –from various layers and models. The numbers correspond to the sentence id.

F Dataset for questionnaire (with English translations)

We have annotated in italics the sentences for which the French speakers preferred anteposition.

On the Role of Reviewer Expertise in Temporal Review Helpfulness Prediction

Mir Tafseer Nayeem

Abstract

Helpful reviews have been essential for the success of e-commerce services, as they help customers make quick purchase decisions and benefit the merchants in their sales. While many reviews are informative, others provide little value and may contain spam, excessive appraisal, or unexpected biases. With the large volume of reviews and their uneven quality, the problem of detecting helpful reviews has drawn much attention lately. Existing methods for identifying helpful reviews primarily focus on review text and ignore the two key factors of (1) **who** post the reviews and (2) **when** the reviews are posted. Moreover, the helpfulness votes suffer from scarcity for less popular products and recently submitted (a.k.a., cold-start) reviews. To address these challenges, we introduce a dataset and develop a model that integrates the reviewer's expertise, derived from the past review history of the reviewers, and the temporal dynamics of the reviews to automatically assess review helpfulness. We conduct experiments on our dataset to demonstrate the effectiveness of incorporating these factors and report improved results compared to several well-established baselines.

1 Introduction

Many customers rely on online reviews from non-professionals, on daily basis, to decide what products to buy (e.g., *Amazon*), what hotels to stay at (e.g., *TripAdvisor*), what restaurants to eat (e.g., *Yelp*) and even what books to read (e.g., *Goodreads*). A recent survey of Bizrate Insights reward members found that approximately 98% of online shoppers research a vendor via online reviews before making a purchase decision (Kats, 2018). Since the reviews are expected to describe the actual experiences and opinions of users, they can provide a reliable source of reference, improving other customers' confidence, comfort, and the overall shopping experience (Foo et al., 2017; Gamzu

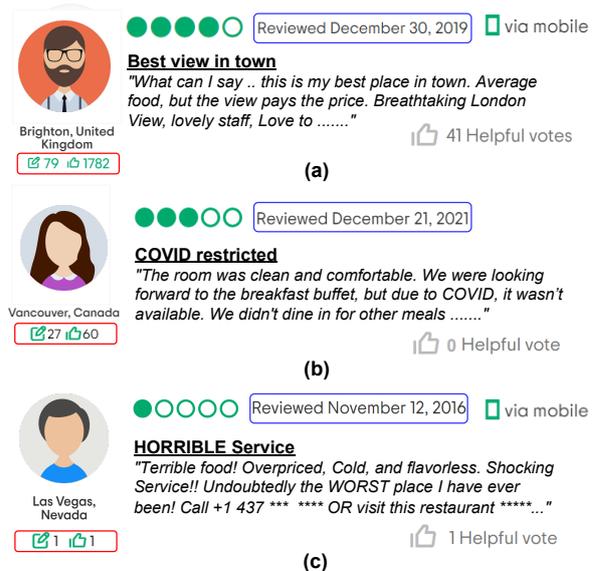

Figure 1: A snapshot of three reviews with the reviewers' history information: Review *a* has accumulated more helpful votes but is posted almost two years before Review *b*; on the other hand, Review *b* (a.k.a., cold-start review) contains time-sensitive information, describing the current conditions and Review *c* is likely a spam review. Photos of the reviewers are replaced with avatars for privacy reasons.

et al., 2021). However, despite their tremendous benefits, online reviews are often of mixed qualities. While many reviews are informative, others provide little value and may contain excessive appraisal or spam (see Figure 1-c). There are multiple factors that affect the quality of a review, including the reviewers' life experience, educational background, and the motive for writing the review (Du et al., 2021), and these factors are not usually explicit in the review text. All these pose challenges for customers who are less experienced in a subject area and need the reviews the most, simply because there is less incentive for more experienced users to use the reviews. Moreover, customers usually have limited patience for reading reviews – most customers read less than 10 reviews before mak-

ing a purchase decision about an item (Murphy, 2016). The large volume of reviews and their unpredictable quality and the limited customer patience demand better review utilization strategies to manage the information overload.

One standard method to identify more informative reviews is to ask for feedback from customers or site visitors who read them. By asking, “*Was this review helpful to you?*,” or “*Did you find this review helpful?*” at the end of each review, online platforms can crowdsource helpfulness votes from other customers. As a result, user reviews that gain the most helpful votes are shown first to the potential buyers to make the decision easier. However, the voting data suffers from scarcity (Siersdorfer et al., 2010) since only a tiny proportion of customers are willing to cast helpfulness votes. The scarcity is even more severe in reviews of less popular products and more recently submitted reviews (a.k.a., cold-start reviews) (Liu et al., 2008), despite the fact that more recent reviews may in fact contain more relevant and time-sensitive information (e.g., “*New COVID Restrictions*” or “*Dirty Pool Area*”) as shown in Figure 1-b but no helpfulness vote.

In this paper, we study the confluence of the reviewing history of reviewers and the review text for helpfulness identification. First, we observe that people who post more reviews and earn more helpful votes are more likely to be better reviewers. Second, trustworthy reviewers (e.g., Figure 1-a) are less likely to be posting fake or biased reviews, and their reviews are more likely to earn more helpful votes; otherwise, they will be ruining their reputation. Third, those who have been to more hotels or restaurants across different cities have a better basis for comparison and writing critical reviews. To the best of our knowledge, existing works only focus on review content and neglect the reviewers and their reviewing history. Integrating the review text with the reviewing history of the reviewers is the problem studied in this paper.

Our main contributions are summarized as follows:

- We introduce a new dataset with both review text and reviewer’s history, to highlight the importance of integrating the two sources for review helpfulness.
- We propose a model incorporating the reviewer’s expertise and temporal information of reviews in helpfulness prediction.

- We present a detailed case-study to interpret the model behavior and highlight potential directions to be addressed in the future.

2 Related work

More traditional approaches on review helpfulness prediction focus solely on the text of reviews, and some consider both text and images to guide the prediction. In general, the task can be addressed using a predictive model based on hand-crafted features such as structural (Susan and David, 2010; Xiong and Litman, 2014), lexical (Kim et al., 2006; Xiong and Litman, 2011), syntactic (Kim et al., 2006), emotional (Martin and Pu, 2014), semantic (Yang et al., 2015), and arguments (Liu et al., 2017) from the review text. These features may be fed into a conventional classifier such as SVM, Random Forest, or gradient boosting to identify helpful reviews. These methods heavily rely on manual feature engineering, which is labor-intensive and time-consuming.

Inspired by the remarkable progress of deep neural networks, more recent studies make use of deep neural models, which can learn both intrinsic and extrinsic features given labeled data. Chen et al. (2018) uses a text-based CNN model to automatically capture the character-level, word-level, and topic-level features for helpfulness prediction. Fan et al. (2018) uses an end-to-end multi-task neural architecture with the help of an auxiliary task, such as rating regression, to boost the performance of the review helpfulness identification. Liu et al. (2021) and Han et al. (2022) use both text and images to guide the review helpfulness prediction. Since the image field is usually optional in reviews, a large volume of reviews contain only text, for which these multimodal models would produce inconsistent results.

3 Review Helpfulness Prediction

3.1 Dataset

To the best of our knowledge, there is no human-annotated dataset that is publicly available for the task of review helpfulness prediction with the reviewers’ attributes and review date. Therefore, we build our dataset by scraping reviews from TripAdvisor¹. Out of 225,664 reviews retrieved, close to one third have no helpful votes. We filter such reviews, and this reduces the number of reviews to 161,541. Table 1 presents the summary of

¹<https://www.tripadvisor.com>

	Train	Valid	Test
Total #Samples	145,381	8,080	8,080
Avg. #Sentences	7.82	7.80	7.81
Avg. #Words	152.37	152.25	148.90

Table 1: Our dataset statistics.

our dataset with train, validation, and test splits². Following (Liu et al., 2021), we leverage a logarithmic scale ($\lfloor \log_2 n_{\text{votes}} \rfloor$) to categorize the reviews based on the number of votes received. Specifically, we map the number of votes into five intervals (i.e., [1,2), [2, 4), [4, 8), [8, 16), [16, ∞)), each corresponding to a helpfulness score $Y \in \{1, 2, 3, 4, 5\}$, where the higher the score, the more helpful the review.

3.2 Proposed Model

Review Helpfulness Prediction (RHP) can be modeled as a supervised machine learning task where the input contains information about the reviews (\mathcal{R}) and the reviewers (\mathcal{U}). Let $\mathcal{R}_i = ([s_1, \dots, s_N], t_i)$ denote a review posted at time t_i with sentences s_1, \dots, s_N , and $\mathcal{U}_i = (n_i, m_i)$ denote a reviewer who posts n_i reviews and earns a total of m_i helpful votes. We formulate the review helpfulness prediction as a multi-class classification where we seek to find a model f that minimizes the loss function \mathcal{L} , i.e.

$$\min_{\theta} \mathcal{L}(f(\theta, \mathcal{R}, \mathcal{U}), Y), \quad (1)$$

where Y is the ground-truth, θ is the model parameter and the output of the model is a helpfulness class $\hat{Y} \in \{1, 2, 3, 4, 5\}$. The learning task is to find the best parameter that minimizes the above equation.

We encode the review sentences using BERT (Devlin et al., 2019; Xu et al., 2019). We concatenate the review sentences together while inserting a [CLS] token at the start and a [SEP] token at the end. If $\mathbf{h}^{[\text{CLS}]}$ denotes the embedding vector of the special [CLS] token and $\mathbf{h}^{(i)}$ denotes the embedding vector of the i -th token, we extract the last hidden state of $\mathbf{h}_i^{[\text{CLS}]}$ to represent the review sentences and apply a linear transformation to get a final contextualized representation $x_h \in \mathbb{R}^K$, where Θ is a non-linear activation function.

$$[\mathbf{h}^{[\text{CLS}]}, \mathbf{h}^{(1)}, \mathbf{h}^{(2)}, \dots] = \mathbf{BERT}([\text{CLS}] s_1, \dots, s_N [\text{SEP}]), \quad (2)$$

²We present our dataset construction details in Section A of the Appendix.

$$x_h = \Theta(\mathbf{MLP}(\mathbf{h}_i^{[\text{CLS}]])). \quad (3)$$

Generally, users who post more reviews and earn more helpful votes are likely to be better reviewers. Such users may have been to more hotels and restaurants across the globe and have a better basis for comparison. We define the term *reviewer expertise* as the mean number of helpful votes received per review, written as $e_s = m/n$ for a reviewer who posts m reviews and earns n overall helpfulness votes. We use a linear layer to get a weighted representation of the expertise score (h_s).

$$h_s = \mathbf{MLP}(e_s) \quad (4)$$

Previous approaches for this task fail to consider the temporal nature of the reviews. Older reviews are more likely to accumulate more helpfulness votes than newer reviews but are not necessarily the most relevant describing the current conditions (e.g., *new COVID restrictions*). One-time problems such as broken bathrooms and dirty pool area are likely to be addressed and to be less relevant. Let t_d be the relative age of a review in days, for example, as of the day the reviews are scraped. We use a linear layer to get a weighted representation of the relative review age.

$$h_t = \mathbf{MLP}(t_d). \quad (5)$$

It should be noted that both the review age and the reviewer expertise are normalized to a fixed range $[a, b]$ before being used in the linear layers in Equations 4 and 5. If \mathcal{X} denotes a set of scores (e.g., reviewers expertise score), a score $x_i \in \mathcal{X}$ is normalized into z_i as follows:

$$z_i = (b - a) \frac{x_i - \min(\mathcal{X})}{\max(\mathcal{X}) - \min(\mathcal{X})} + a \quad (6)$$

In our case, both review age and reviewer expertise are scaled into the interval $[0, 1]$.

We concatenate the textual representation (x_h), expertise representation (h_s), and temporal representation (h_t) to get a final embedding

$$o_{\text{final}} = h_s \oplus x_h \oplus h_t, \quad (7)$$

where \oplus is a concatenation operator. The final helpfulness prediction layer feeds o_{final} into a linear layer and use softmax activation to get the final predicted helpfulness class \hat{Y} .

$$\hat{Y} = \mathbf{softmax}(W_r \cdot o_{\text{final}} + b_r), \quad (8)$$

Baseline Models	Acc. (↑)	MAE (↓)	MSE (↓)
ARH	58.73	0.476	0.619
UGR + BGR	62.76	0.464	0.674
TextCNN	62.82	0.444	0.608
MTNL	62.77	0.458	0.653
BERTHelp	63.03	0.432	0.591
Our Ablations	Acc. (↑)	MAE (↓)	MSE (↓)
RHP (ours)	65.18[†]	0.393[†]	0.491[†]
- <i>w/o Expertise</i>	63.87	0.421 [†]	0.550 [†]
- <i>w/o Temporal</i>	63.40	0.437 [†]	0.592
- <i>w/o Expertise + Temporal</i>	62.92	0.446	0.617

Table 2: Performance compared to our baseline models and the result of our ablation study (↑ indicates higher values for a better performance and ↓ indicates lower values for a better performance). † reported results are statistically significant in paired t-test by taking BERTHelp (Xu et al., 2020) as a reference with the confidence of 95% (p -value < 0.05).

$$\mathcal{L} = \mathcal{L}_{CE}(\hat{Y}, Y) \quad (9)$$

where $W_r \in \mathbb{R}^{K \times K}$ and $b_r \in \mathbb{R}^K$ denote the projection parameter and a bias term respectively. We use the cross-entropy loss function \mathcal{L}_{CE} with respect to the ground truths helpfulness class (Y).

3.3 Experiments

We evaluated the performance of the proposed model³ compared to well-established baselines. We compare our system with ARH (Kim et al., 2006), UGR + BGR (Xiong and Litman, 2011), TextCNN (Chen et al., 2018), MTNL (Fan et al., 2018), and BERTHelp (Xu et al., 2020). We didn’t perform any explicit preprocessing of the review text. We discuss the baseline systems, preprocessing, and hyperparameters used for our experiments in Appendix (Section B & Section C).

3.3.1 Results

As part of a detailed evaluation of our algorithm, we report our model’s performance compared with the baselines in terms of Accuracy (**Acc.**), Mean Average Error (**MAE**), and Mean Squared Error (**MSE**). As shown in Table 2, our final model outperforms the baselines in terms of all the metrics. Our ground-truth values consist of 5 classes which correspond to five helpfulness scores $\{1, 2, 3, 4, 5\}$, where the higher the score, the more helpful the review. To gain more insights into the performance of our prediction model, we also evaluate our algorithm in terms of **MAE** and **MSE**, which assess the fine-grained differences between the ground-truth

and the predicted helpfulness scores. Our **RHP** model consistently outperforms the baselines with a good margin, which means when misclassified, our model predictions are very close to the actual helpfulness scores. We conduct detailed ablation studies to demonstrate the effects of different components of our **RHP** model by removing expertise (denoted as *w/o Expertise*) and removing temporal information (denoted as *w/o Temporal*). The ablation test results on our dataset are summarized in Table 2. We can observe that the temporal feature has the largest impact on the performance of our model, and the impact of expertise is also significant. This suggests that the reviewer’s expertise and temporal information of the reviews play a key role in review helpfulness prediction. Therefore, it is no surprise that combining all components achieves the best performance on our proposed dataset.

3.3.2 Analysis

We also present a detailed analysis to provide more supportive evidence of our arguments. To this end, we randomly selected m examples for each class of reviews considering helpfulness votes. Then, we extract Top K (where $K = 5$) n -grams from each class of reviews to identify the most relevant keywords or topics in reviews to assess what aspects are most talked about the items (e.g., hotels or restaurants).

Preprocessing Our preprocessing step includes tokenization, lemmatization, removal of stopwords, Part-Of-Speech (POS) tagging, and filtering punctuation marks. We use the NLTK⁴ to preprocess each sentence and obtain a more accurate representation of the information. Moreover, we also add ‘hotel’ and ‘restaurant’ in the stopwords list as they frequently occur in every review and are not meaningful in our context.

Extracting Candidate n -grams We remove the sentiment words and emojis using VADER⁵ (Hutto and Gilbert, 2014), a “gold-standard” sentiment lexicon especially attuned to microblog-like contexts. As the sentiment expressed in reviews are highly subjective, we are interested in extracting only the aspects or topics (e.g., *room*, *location*, *customer service* etc.) for which the opinions are

³Code, dataset, and model checkpoints: <https://github.com/tafseer-nayeem/RHP>

⁴<https://www.nltk.org/>

⁵<https://github.com/cjhutto/vaderSentiment>

Helpfulness Class	Unigram	Bigram
Class #1 Helpful Votes [1, 2)	'room'	'front desk'
	'staff'	'coffee maker'
	'location'	'breakfast buffet'
	'time'	'sofa bed'
	'service'	'swim pool'
Class #2 Helpful Votes [2, 4)	'room'	'front desk'
	'staff'	'shampoo conditioner'
	'service'	'customer service'
	'location'	'resort fee'
	'time'	'pool area'
Class #3 Helpful Votes [4, 8)	'room'	'front desk'
	'staff'	'resort fee'
	'time'	'customer service'
	'service'	'coffee maker'
	'view'	'city view'
Class #4 Helpful Votes [8, 16)	'room'	'front desk'
	'staff'	'resort fee'
	'service'	'customer service'
	'time'	'minute walk'
	'pool'	'life jacket'
Class #5 Helpful Votes [16, ∞)	'room'	'front desk'
	'time'	'resort fee'
	'service'	'bed bug'
	'staff'	'beach chair'
	'pool'	'cable car'

Table 3: Top 5 unigrams and bigrams extracted from five different classes of reviews divided according to helpfulness votes. For each column, green color indicates the overlap with all 5 classes, whereas blue for 4, orange for 3, and red for 2 overlaps.

expressed. Therefore, we keep only the nouns⁶ (with POS tags 'NN' and 'NNS') for extracting the aspects or topics.

Ranking Candidate n -grams We extract the unigrams and bigram collocations for each of the review classes. Then, we rank the unigrams by counting the frequency of occurrences and bigrams using likelihood ratios (Manning and Schütze, 1999) to obtain Top K . We present the Top 5 unigrams and bigrams in Table 3 grouped according to helpfulness classes and ordered by descending ranking scores.

Table 3 shows a high overlap of n -grams among different classes of reviews, which further strengthens our argument that helpfulness does not entirely depend on the review text but rather the confluence of the review text, reviewing history of reviewers (*who post the reviews*), review age (*when the reviews are posted*). Generally, older reviews (i.e., review age) were present longer than the newer reviews in the platform and had more time to accumulate helpful votes.

⁶As adjectives and adverbs may contain sentiment towards aspects.

[Free WiFi, Free parking, Location, Room, Staffs, Front Desk, Food, swimming pools, foods, Bar, Air conditioning, Non-smoking rooms, Fitness center, ATM on site, Shuttle service, Room service, Spa,]

[CLS] We could not have been happier with our choice for our family's 3 night stay in Las Vegas recently. The location was perfect. We stayed in a 2 bedroom villa, which was so spacious and had a great view of the Vegas lights and airportThe bathroom to the main bedroom had a fabulous big bath. The beds very comfortable. Dinner in the restaurant in the lobby one night, the food and service were both great. We particularly liked the restaurant and bar next to the pool on level 5, very relaxing for lunch [SEP]

Figure 2: Top 10 ranked tokens of the RHP model shown in green colors with the color intensity indicating the importance of the tokens in the overall prediction.

3.4 Case Study

To gain more insights into the review helpfulness prediction task, we present a detailed case-study to interpret the model behavior and highlight the most important features of this task. Models are interpretable when humans can readily comprehend the reasoning behind model predictions and decisions made (Kim et al., 2016). To this end, we randomly selected a sample with Helpfulness Class = 3 from our test set and used Captum⁷ to interpret the words/tokens that contributed the most to the prediction. As can be seen in Figure 2, the top-ranked words are highly representative of the aspects/facilities listed on the restaurant page. We can conclude from this observation that users tend to look for specific aspects in reviews to find them helpful. We also notice that the use of personal pronouns (e.g., I, we, they, etc.), describing personal experiences, contributes to the helpfulness prediction. People often find reviews useful if it comes from others' experiences and personal pronouns are a good indicator of it.

4 Conclusion and Future Work

In this paper, we develop a model incorporating the reviewer's expertise and temporal information in reviews to predict the helpfulness, especially for unreliable and cold-start reviews. Furthermore, we present a detailed analysis to interpret the model behavior and provide reasoning behind model predictions. For future work, we will look into the problem of personalized review helpfulness prediction to model the demographics and cultural differences of the reviewers.

⁷Captum (<https://captum.ai/>) is an open-source, extensible library for model interpretability that uses the integrated gradients method (Sundararajan et al., 2017).

Limitations

Despite the effectiveness of incorporating the reviewer's history and temporal information of the reviews in helpfulness prediction, our current studies still have several limitations, which can pave the path for future research.

For simplicity, like existing works, we assume that all the users rate reviews unanimously. However, the diversity of demographics, age, and cultural background also affect how users give, receive, and understand the sentiments expressed in reviews. Users may focus on different review aspects based on their preferences (i.e., "5 stars, party every night" vs "5 stars, always quiet and peaceful"). It would be interesting to see how to incorporate personal preferences for the helpfulness prediction task.

Another limitation of our work is that we only worked with reviews written in English. As a result, we filter out the reviews written in other languages and notice code-switched reviews when the reviewers alternate between two or more languages in a single review. We aim to extend this work to support more languages.

Ethics Statement

In our data scraping process, we took into account ethical considerations. We obtained data at an appropriate pace, avoiding any potential DDoS attacks. Additionally, we eliminated any Personal Identifying Information, such as names, telephone numbers, and email addresses, from the data set.

Acknowledgements

We thank all the anonymous reviewers for their valuable feedback and constructive suggestions for improving this work. A Dataset Construction

Publicly available datasets which are mostly used for this task are Amazon⁸ (He and McAuley, 2016; McAuley et al., 2015) and Yelp⁹. In Yelp dataset, the user votes are distributed among three categories such as “Useful”, “Funny” or “Cool”, where “Useful” voting feature was introduced much later than the other two categories. Therefore, many good reviews already in the dataset may not have been marked useful. On the other hand, the Amazon dataset does not contain the reviewers’ reviewing history and helpfulness votes to evaluate our hypothesis studied in this paper. Moreover, for Amazon, the samples come from various categories such as Books, Electronics, Clothing, Beauty, Shoes and Jewelry, Grocery, Pet Supplies, etc – the total helpfulness votes for the reviewers are coming from different categories and it’s not explicit in the fields from Amazon website. Therefore, it’s hard to devise expertise because of domain diversity.

We build our dataset by scraping reviews from TripAdvisor¹⁰, a travel site that offers online hotel and restaurant reservations and a platform for sharing the travel experiences of users. We take reviews from January 1st, 2015 until January 1st, 2020, and extract only those written in English. For each review, we extract the review text, the total helpfulness votes and the posting time, and for each reviewer, we extract the number of reviews contributed and the cumulative helpfulness votes. The attributes we extracted are summarized as follows:

⁸http://jmcauley.ucsd.edu/data/amazon/index_2014.html

⁹<https://www.yelp.com/dataset>

¹⁰<https://www.tripadvisor.com>

• Reviews

- Review Text

- Review Posting Time

• Reviewers

- Total Number of Reviews Contributed
- Cumulative Helpful Votes

B Baseline Systems

We compare our system performance with the following baselines.

- **ARH** (Kim et al., 2006) & **UGR + BGR** (Xiong and Litman, 2011) use machine learning-based methods with hand-crafted features such as *structural*, *lexical*, *syntactic*, *emotional*, *semantic*, and *meta-data* from the review text to address this task. These features are fed into conventional classifiers such as SVM, Random Forest, and gradient boosting to identify helpful reviews.
- **TextCNN** (Chen et al., 2018) employs a text-based CNN model (Kim, 2014) to automatically capture the character-level, word-level, and topic-level features for helpfulness prediction.
- **MTNL** (Fan et al., 2018) utilizes end-to-end multi-task neural learning (MTNL) architecture for classifying helpful reviews. They take the help of an auxiliary task, such as rating regression, to boost the performance of the original task, which is review helpfulness identification.
- **BERTHelp** (Xu et al., 2020) develop their helpfulness prediction model using pre-trained BERT (Devlin et al., 2019). They design a regression model using BERT-based features extracted from review texts, star rating, and product type information from Amazon product review dataset (He and McAuley, 2016).

C Preprocessing & Hyperparameters

Preprocessing We didn’t perform any explicit preprocessing of the review text. Instead, we use BertTokenizer to avoid the out-of-vocabulary (OOV) problem, which uses WordPiece (Wu et al.,

2016) for tokenizing the sentences into words or subwords. In addition, we add special tokens to the start (e.g., [CLS]) and end of each review text (e.g., [SEP]) and truncate all sentences to a single constant length (e.g., 512).

Hyperparameters We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of $3 \times e^{-5}$ and a batch size of 32. We use BERT_{BASE} (Wolf et al., 2020) pre-trained model with a fixed vocabulary. We run the training for 5 epochs and check the improvement of validation (*dev set*) loss to save the latest best model during training.

Towards a Unified Model for Generating Answers and Explanations in Visual Question Answering

Chenxi Whitehouse, Tillman Weyde, Pranava Madhyastha

City, University of London

{chenxi.whitehouse, t.e.veyde, pranava.madhyastha}@city.ac.uk

Abstract

The field of visual question answering (VQA) has recently seen a surge in research focused on providing explanations for predicted answers. However, current systems mostly rely on separate models to predict answers and generate explanations, leading to less grounded and frequently inconsistent results. To address this, we propose a multitask learning approach towards a **Unified Model for Answer and Explanation generation (UMAE)**. Our approach involves the addition of artificial prompt tokens to training data and fine-tuning a multimodal encoder-decoder model on a variety of VQA-related tasks. In our experiments, UMAE models surpass the prior state-of-the-art answer accuracy on A-OKVQA by 10~15%, show competitive results on OK-VQA, achieve new state-of-the-art explanation scores on A-OKVQA and VCR, and demonstrate promising out-of-domain performance on VQA-X.¹

1 Introduction

Contemporary models for visual question answering (VQA) and commonsense reasoning are typically trained discriminatively to select the best answers from Multiple-Choice questions or to classify single-word answers to a predetermined vocabulary (e.g. Anderson et al., 2018). Such settings often lead to limitations such as encouraging models to find superficial correlations (Ye and Kovashka, 2021) or penalising model performance even when the answers are plausible (e.g. synonyms and multi-word expressions, and morphological variations are not considered correct). Most current explanation generation models are trained independently of the QA model and the explanations are usually generated after the QA model has provided an answer. As a result, these explanation models lack access to the process that generated the answer and thus

the grounding of the explanation is limited to the answer text.

We posit that a unified model that simultaneously performs answer prediction and explanation generation is a more effective and consistent approach for VQA. Generative models, such as GPT-3 (Brown et al., 2020), T5 (Raffel et al., 2020), or OFA (Wang et al., 2022a), have been shown to be successful at rapidly adapting to downstream tasks and generating high-quality open-ended text, and hence are suitable candidates for this unified approach.

We propose a multitask learning approach for multimodal transformer-based encoder-decoder models, towards a **United Model for Answer and Explanation generation (UMAE)**. In addition to the current trend of separate answer prediction and explanation generation based on the answers, our approach adds the capability of jointly generating answers and explanations together. Inspired by the success of artificial prompt tokens in Neural Machine Translation (NMT) (Johnson et al., 2017), we extend and demonstrate the efficacy of the artificial prompt-based method for VQA in a multitask setup. We augment training instances with artificial prompt tokens, enabling the model to distinguish different tasks while learning shared semantic features. Experiments on a combination of three knowledge-intensive VQA datasets, OK-VQA (Marino et al., 2019), A-OKVQA (Schwenk et al., 2022), and VCR (Zellers et al., 2019), show that the UMAE models achieve a new state-of-the-art (SOTA) answer accuracy on A-OKVQA, new SOTA explanation score on VCR, and competitive out-of-domain performance on VQA-X (Park et al., 2018). UMAE supports the generation of the answer to a question, the explanation for a given question and answer, and both together jointly, making the model efficient and flexible. An illustration of the training setup is shown in Figure 1.

In summary, our main contributions are as follows: (1) the UMAE framework where answers and

¹Code is available at: <https://github.com/chenxwh/UMAE>.

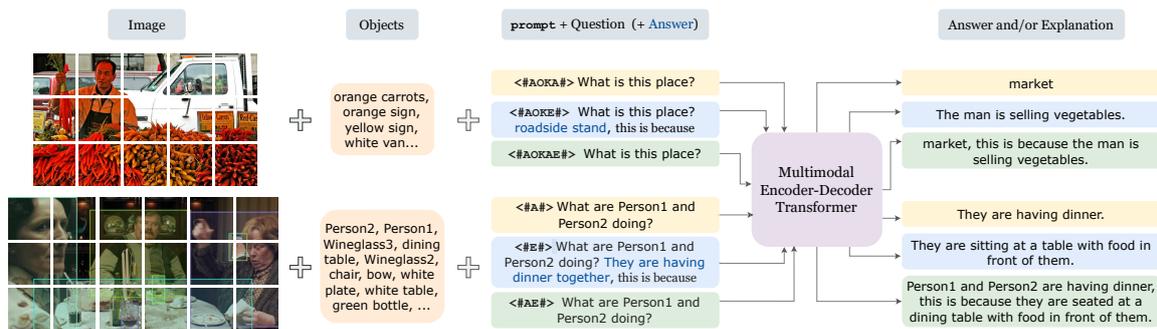

Figure 1: Illustration of UMAE: we train a multimodal encoder-decoder model on the mix of VQA tasks for jointly optimising answer and explanation, where we distinguish the training instances and target output with artificial prompt tokens (e.g. `<#AOKA#>`). The top and bottom examples are from A-OKVQA and VCR, respectively.

explanations can be generated by a single unified model (§3.1); (2) a simple and efficient training approach that uses multitask learning with artificial prompts and demonstrates its ability to generalise across domains (§4); (3) a method to map generated answers to Multiple-Choice options via evaluating the perplexity of the generation (§3.2); (4) new SOTA results by UMAE, particularly for explanation generation and promising out-of-domain performance (§5).

2 Related Work

Multimodal Transformer-based Models achieve SOTA performance on various vision-language tasks (Chen et al., 2020; Li et al., 2020; Cho et al., 2021; Wang et al., 2022c; Zhang et al., 2021). They showcase the possibility of capturing richer multimodal semantic coherence than discriminatively trained models and are further capable of generating self-explanations. Pretrained on multitask settings with natural language instructions, e.g. “*what does the region describe?*”, models like OFA (Wang et al., 2022a) are claimed to have the capability to transfer to unseen tasks and domains via similar instructions. However, contrary to these claims, we observe that pretrained OFA is incapable of generating valid explanations through simple natural language instructions (§5).

Artificial Prompt Tokens have previously been explored for NMT by Johnson et al. (2017); Mitzalis et al. (2021). They propose a single model with the traditional NMT model architecture (usually for one language pair) and jointly train on different language pairs with added artificial prompts, e.g. 2_{es} to distinguish the target language. This approach has been found to foster implicit cross-lingual bridging and exhibit zero-shot translation

capability. In this paper, we exploit a similar approach with artificial prompts for answer and explanation generation in VQA with a united model. This enables the model to learn shared features among tasks and datasets in various domains.

Explanation Generation for VQA has gained growing interest in research. However, most recent approaches use separate models to predict answers and generate explanations (Dua et al., 2021). Wu and Mooney (2019) generate explanations with an object detector and a GRU unit for text embedding, then train on a subset of VQA-X in which the explanations contain the objects most attended to by the model. Kayser et al. (2021) develop an e-UG model combining UNITER (Chen et al., 2020) for processing multimodal input and GPT-2 (Radford et al., 2019) for generation. In contrast, in this paper, we propose using a single united model for more grounded answer and explanation generation.

3 Methodology

3.1 Multitask Learning with Artificial Prompt

We formulate three generation settings: $Q \rightarrow A$: answer prediction; $QA \rightarrow E$: explanation generation conditioned on the answer; and $Q \rightarrow AE$: *joint* answer and explanation generation for a given question. We hypothesise that by training the model to generate both the answer and its explanation *simultaneously*, the result answer and explanation will be more grounded and consistent.

We use a pretrained multimodal encoder-decoder transformer as our base model (here we build on the openly released version of OFA as a strong baseline), and finetune the model on a mix of VQA datasets from different domains.

Different from OFA, for each image in the VQA datasets, we first extract objects and attributes us-

MODEL	OK-VQA		A-OKVQA				VCR		BERTSCORE VAL
	<i>direct answer</i>	<i>multiple choice</i>			<i>direct answer</i>	<i>multiple choice</i>

Table 2: Explanation Scores. OFA* is the pretrained OFA, showing the transferability of OFA for generating explanations with natural language instructions. Results with e-UG are from Kayser et al. (2021). We show the best results of A-OKVQA and VCR in bold. The last row in blue shade shows *out-of-domain* performance.

ing a bottom-up top-down attention-based model, which is crucial for open-domain VQA tasks (Anderson et al., 2018). We then add artificial prompt tokens at the beginning of the textual input to signal the generation task (answer, explanation, or both) and the dataset². For $Q \rightarrow \text{AE}$, we concatenate answers and explanations with a separator in between. Finally, we mix all training instances, each consisting of an image (processed in patches), objects and attributes, and textual input with artificial prompts.

3.2 Perplexity as Multiple Choice Metric

To map the generated output to Multiple-Choice options, in previous work the predictions are loosely matched with options or gold answers using embedding-based methods, such as GloVe embedding similarity (Schwenk et al., 2022). In contrast to these approaches, we propose to evaluate each option as a *text generation* task, by feeding the model the information that was used to generate the answer as a prompt, and calculating the likelihood of each option being generated. Formally, given an option $Y = (y_1, y_2, \dots, y_t)$ with t tokens,

²Artificial prompt tokens are added as special tokens to the tokenizer to avoid bias in the pretrained embeddings. However, we note that these tokens may be biased w.r.t their association with specific tasks after training, which is an intended effect.

we calculate the probability of each token y_i being generated by feeding the image, objects, and question, as well as the first $i - 1$ tokens from Y to the model p_θ . The perplexity is then calculated with: $\text{PPL}(Y) = \exp \left\{ -\frac{1}{t} \sum_i^t \log p_\theta(y_i | y_{<i}) \right\}$, which reflects the probability of option Y being generated by the model. Finally, the option with the lowest perplexity is chosen as the answer.

We also compare the performance of our approach, using perplexity as the metric, with GloVe embedding similarity for A-OKVQA (see Table 1).

4 Experimental Setup

We primarily evaluated our proposed UMAE approach using pretrained OFA³ as the base model on three knowledge-intensive VQA datasets: OK-VQA, A-OKVQA and VCR⁴. We split the original train set into train and validation set (95%-5%) for all three datasets. Since the test set is not publicly available for A-OKVQA and VCR, we use the original validation set for experimental analyses. We prepare training instances⁵ as introduced

³<https://github.com/OFA-Sys/OFA>

⁴See Appendix A for datasets details.

⁵Specifically, we add $\langle \#OKA\# \rangle$ for OK-VQA (only answers are available), $\langle \#A\# \rangle$, $\langle \#E\# \rangle$, $\langle \#AE\# \rangle$ for VCR, and $\langle \#AOKA\# \rangle$, $\langle \#AOKE\# \rangle$, $\langle \#AOKAE\# \rangle$ for A-OKVQA.

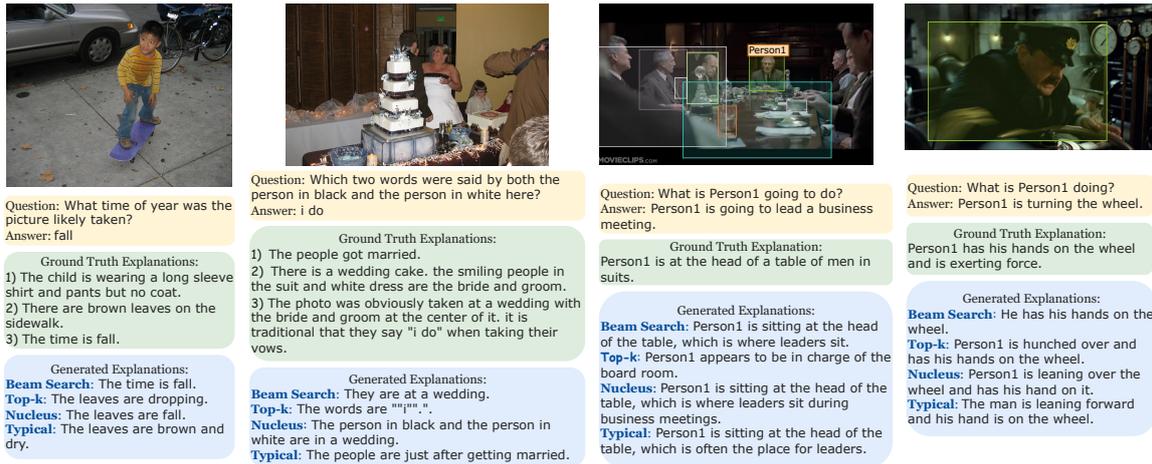

Figure 2: Examples of generated explanations from $UMA_{E_{ALL}}$ model with different decoding strategies. The two examples on the left are from A-OKVQA and the two on the right are from VCR.

in §3.1. Additionally, for VCR, we draw coloured highlights around the referenced entity on the images, following Zellers et al. (2021) (Appendix A). To account for the imbalance in size among the datasets, we up-sample instances in OK-VQA and A-OKVQA, and shuffle all instances to train the $UMA_{E_{ALL}}$ model.

For ablation studies, we finetune OFA for separate answer prediction ($OFA_{Q \rightarrow A}$) and explanation generation conditioned on answers ($OFA_{QA \rightarrow E}$). To better understand the impact of mixing datasets from different domains, we also train $UMA_{E_{A-OKVQA}}$ and $UMA_{E_{VCR}}$, focusing on all three answer and explanation generation tasks but only using data from a single dataset: either with A-OKVQA or with VCR. Details of training parameters are included in Appendix B.

We use beam search for generating answers and additionally experiment with different decoding methods including top-k sampling, Nucleus sampling (Holtzman et al., 2020), and Typical sampling (Meister et al., 2022), for generating explanations. We evaluate answer accuracy as well as explanation quality with automatic NLG metrics and e-ViL scores (Kayser et al., 2021). e-ViL scores consist of S_T (task/answer accuracy), S_E (explanation score), and overall S_O (product of S_T and S_E), where S_E is the harmonic mean of NGRAMScore (the harmonic mean of n-gram scores ROUGE-L (Lin and Och, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), and SPICE (Anderson et al., 2016)) and additionally the BERTScore (Zhang et al., 2020), a learned similarity metric over contextual representations of sentences.

5 Results and Discussion

5.1 Answer Accuracy

Table 1 presents our observations for answer accuracy on $Q \rightarrow A$ task over the three datasets. We also evaluate VCR answers using BERTScore as the answers for VCR are usually sentences. We observe that $UMA_{E_{ALL}}$ outperforms $OFA_{Q \rightarrow A}$ on all datasets, improves the prior SOTA on A-OKVQA by 10~15%, and achieves competitive results on OK-VQA. For models that are finetuned on A-OKVQA, we also see a salient improvement (+9%) with the proposed mapping of options by perplexity in Multiple-Choice, instead of GloVe embeddings similarity⁶. We conducted several ablation studies on the dependency of the modality for the answer accuracy in A-OKVQA, where we find the visual encoder is crucial for performance. Details are included in Appendix C.

5.2 Explanation Evaluation

Table 2 shows e-ViL scores (§4) for explanations using automatic NLG metrics⁷. Following the same setup as in Kayser et al. (2021), an explanation is evaluated only if the answer predicted by the system is correct⁸. We observe that pretrained OFA with natural language prompts, e.g. “*what is the explanation for the answer?*” or “*this is*

⁶Preliminary experiments with NLG metrics (BERTScore and BLEU) for selecting the options given generation were sub-optimal.

⁷Nucleus sampling shows best results and is reported. Detailed scores with different decoding methods are shown in Appendix D.

⁸A limitation of evaluating all explanations is that explanations of wrong answers may get high scores with n-gram metrics, even though they are justifying wrong answers and should be penalised.

MODEL	S_E	BLEU4	R-L	MET.	CIDEr	SPICE	BERTSc.
OFA _{Q->A} +OFA _{QA->E}	42.4	20.0	44.2	19.3	66.7	19.1	85.1
UMA _E -OKVQA	45.8	23.6	47.9	21.7	78.0	20.5	86.9
UMA _E _{ALL}	46.8	24.9	49.5	22.3	84.1	20.8	87.3

Table 3: Explanation scores on the same subset of A-OKVQA.

because” performs poorly, as most generated explanations are words (“*yes/no*”) or short-phrases⁹. We compare UMAE models (on all and individual datasets) with prior best results from e-UG (see §2), and standard separated trained baselines (OFA_{Q->A}+OFA_{QA->E}). UMAE_{ALL} achieves better results across all datasets, showing the advantage of mixing tasks and datasets in different domains. For out-of-domain evaluation on VQA-X, UMAE_{ALL} also shows mostly competitive results. Examples of explanation generation are shown in Figure 2 and Appendix E.

Since e-ViL only evaluates an explanation if a model generates the correct answer, the subset of explanations evaluated varies by model. To fairly compare explanations on the same subset, we propose only using the subset of samples where all models provide correct answers for explanation prediction. Table 3 shows the results on A-OKVQA with such a subset of 770 candidates, where UMAE_{ALL} shows an even higher explanation score. This highlights that UMAE_{ALL} generates explanations that overlap significantly better with gold explanations.

In summary, our experiments demonstrate that the UMAE model leads to improved answer and explanation generation and allows for the flexibility to generate different types of outputs, including answers, explanations, or both. We observe that UMAE exhibits promising results in jointly generating both the answer and explanation. We further provide a comparative evaluation in Appendix F as a first step towards comparison as there is currently no standard evaluation setup for the joint answer and explanation evaluation.

5.3 Error Analysis

To better understand the generated answers and errors, we randomly sample 50 errors in OK-VQA and A-OKVQA. Our analysis reveals the following main error types, where the first three are related to

⁹BERTScore is not representative of the validity of outputs from OFA*. We refer the reader to an exposition of the problems associated with NLG metrics in Caglayan et al. (2020).

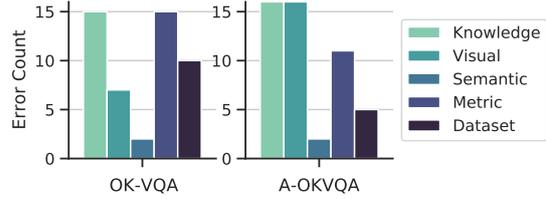

Figure 3: Error type distribution in 100 random samples from A-OKVQA and OK-VQA.

model performance: (1) *Knowledge*: the implicit knowledge learned by the model is insufficient for answering some of the knowledge-intensive questions, such as questions asking *when* a certain sport was invented; (2) *Visual*: the model fails to identify the visual attributes correctly, such as questions about *recognising object shape or material*; (3) *Semantic disassociation*: the model misinterprets questions or fails to match the intended semantic meaning. For example, it may answer what *an object is* instead of a more complex question such as *what is commonly packed in it* (e.g. answering "suitcase" instead of "clothes"); (4) *Metric*: the evaluation metric may penalise some of the plausible answers, especially when searching for exact match answers (mostly due to the difference of singular/plural or phrases with/without space in between); and (5) *Dataset*: errors due to issues in the datasets themselves. We discuss prominent issues in dataset quality briefly in Appendix G and further present the distribution of error types in Figure 3.

6 Conclusions

In this work, we propose UMAE, a unified model that generates answers and explanations in VQA using a multitask learning approach for multimodal encoder-decoder models, where artificial prompt tokens are added to distinguish different tasks while learning shared semantics. Evaluation of our approach on various VQA tasks shows that UMAE outperforms prior best models and separately trained baselines in both answer and explanation scores, where we also demonstrate the benefit of using perplexity as the metric for mapping generated answers to Multiple-Choice options. Additionally, UMAE offers flexibility in output and can generate explanations for datasets without explanations for training, e.g. OK-VQA, while also improving answer quality. Through case studies and error analysis, we identify potential areas for future improvement, including dataset quality.

Limitations

We discuss the limitations of our work in the following two aspects. Firstly, the experiments with our proposed framework and finetuning approach are primarily on the OFA model. We believe our approach applies to any multimodal generative model, however, it would also provide insights to experiment with more models. Secondly, regarding the evaluation of our proposed joint framework, to better evaluate the generated explanation quality, especially to evaluate the difference between explanations generated jointly with answers and generated conditioned on the answers, human judgement would be an important criterion compared to automatic NLG metrics.

Acknowledgements

We acknowledge the support of Apoorv Khandelwal from AI2 for providing us with results for the evaluation of our model predictions over a hidden test set. This was valuable for our earlier draft of the paper. We would like to thank the anonymous reviewers who provided valuable feedback on the previous draft of our paper.

A Datasets

The datasets used in the paper are as follows:

OK-VQA (Marino et al., 2019) is a knowledge-based VQA dataset that requires outside knowledge beyond the images to answer the questions. It has train and test splits of size 9,009 and 5,046. Each question is provided answers by five annotators. To use the VQA (Antol et al., 2015) metric, each annotated answer is then repeated twice to form a gold answer set with 10 answers. Since no explanation is provided, we only train $Q \rightarrow A$ task on OK-VQA.

A-OKVQA (Schwenk et al., 2022) is currently the largest knowledge-based VQA dataset split into 17.1K, 1.1K, and 6.7K for train, validation, and test, respectively. The questions cover four knowledge types: visual, commonsense, knowledge bases, and physical. For each question, it provides both multiple-choice answers and 10 free-form answers (annotated by 10 different people), as well as three explanations. Images in both OK-VQA and A-OKVQA are from MSCOCO (Lin et al., 2014), and answers in both datasets are in single words or short phrases.

VCR (Zellers et al., 2019) is a large multiple-choice dataset for Visual Commonsense Reasoning. The train, validation, and test splits have 191.6k, 21.3k, and 26.5k instances, respectively. Each question has four answer options in sentences, and the correct answer is further provided with four explanation options. Images in VCR are from movie clips (Rohrbach et al., 2017). Bounding boxes of entities are provided associated with mentions such as `Person1` in questions, answers and explanations. We follow Zellers et al. (2021) and draw coloured highlights around the referenced entity on the images, where entity names and the coloured highlights are consistent in the entire dataset, expecting the model to learn the association between the coloured bounding box and the entity.

VQA-X (Park et al., 2018) contains a subset from the VQA_{v2} (Goyal et al., 2017) dataset and further provides three explanations for each question. The image-question pairs are split into train, validation, and test with 29.5k, 1.5k, and 2k instances, respec-

QUESTION	OBJECTS	IMAGES	ACCURACY
✓	✓	original	50.39
✓	✗	✗	39.16
✓	✗	random	33.48
✓	✓	✗	33.28

Table 4: Ablation on the modality dependency for answer accuracy of A-OKVQA.

tively. We only use the original test set to evaluate the zero-shot performance of the trained models.

B Hyper-Parameters and Training

We begin with the pretrained weights from the original OFA-large¹⁰, which is trained on vision-only tasks including Image Classification, language-only tasks including Sentence Classification, Text Summarisation, as well as various vision-language tasks including Image Captioning, Visual Question Answering and Visual Entailment. Adam is used as the optimizer and cross-entropy is the loss function. We set the learning rate to 10^{-5} , the warm-up ratio to 0.4, and the patch image size to 480. We shuffle all the training examples and use batch size 16. Due to the large size of VCR, we train for 30 epochs on models involving VCR (OFA_{Q->A} for VCR, UMAE_{VCR} and UMAE_{ALL}), and up to 100 epochs for other models. We report the empirical performance with checkpoints that perform best on the validation set (the 5% split from the original train set). For A-OKVQA, we additionally report the answer accuracy on the original test set.

C Ablations on Modality Dependency

We conduct several ablation studies to investigate the dependency of object features and images on the performance of our model UMAE_{ALL} for answer accuracy of A-OKVQA, where we removed images, replaced them with random images, and removed extracted attributes and features. Results in Table 4 show that the visual encoder is crucial for performance and that visual objects alone are not sufficient for answer prediction. Using a random image would introduce noise and therefore performs worse than not including the image at all. We did not test removing the question because we believe the model needs the questions to be able to provide answers.

Table 6: Explanation scores with automatic NLG for generated explanations from $Q \rightarrow AE$ with $UMAE_{ALL}$ model. The last two rows (with blue shadow) indicate out-of-domain performance.

D More Explanation Scores

For decoding, we evaluate the performance of beam search with the size of 5, top-k sampling with k from $\{50, 100, 200, \dots, 1000\}$, and Nucleus and Typical (Meister et al., 2022) sampling, both with p from $\{0.1, 0.2, \dots, 0.9\}$. We show the details of the NLG scores using different decoding strategies for explanations generated from $QA \rightarrow E$ in Table 5, and $Q \rightarrow AE$ in Table 6.

E Examples of Generated Explanations

Examples of the explanations generated with beam search and Nucleus sampling for A-OKVQA are shown in Figure 4, and VCR in Figure 5.

F Joint Generation Performance

We present the results of the proposed $Q \rightarrow AE$ task where answers and explanations are jointly generated. We parse the generated sequence to the answer and the explanation and use the same sets of metrics as the separate generation for evaluation. Results for answers in Table 7 and explanations in Table 8. For answers, since the perplexity metric does not directly compare the generation,

TASK	A-OKVQA	VCR	VQA-X
	MC (GOLVE)	BERTSCORE	DA
Q->A	65.67	81.91	77.65
Q->AE	65.67	82.30	69.60

Table 7: Evaluation of answers generated given questions ($Q \rightarrow A$) and jointly generated with explanations ($Q \rightarrow AE$). MC stands for Multiple Choice, DA for Direct Answer. The last column with a blue shadow indicates out-of-domain performance.

DATASET	S_E		NGRAMSCORE		BERTSCORE	
	QA->E	Q->AE	QA->E	Q->AE	QA->E	Q->AE
A-OKVQA	50.82	47.01	35.69	32.15	88.21	87.39
VCR	40.27	37.02	26.70	24.02	81.91	80.68
VQA-X	40.67	39.67	26.69	25.85	85.40	85.21

Table 8: Scores of explanations generated given answers ($QA \rightarrow E$) and jointly generated with answers ($Q \rightarrow AE$). The last row with a blue shadow indicates out-of-domain performance.

we show the Multiple-Choice accuracy using the Glove metric for A-OKVQA and BERTScore for VCR answer sentences.

	OK-VQA	A-OKVQA	
	DA	MC (GLOVE)	DA
BEST	80.94	80.74	66.20
AVERAGE	54.98	71.53	57.29
WORST	16.37	59.35	41.46

Table 9: Human performance on OK-VQA and A-OKVQA measured from the ground truth answers.

G Datasets Quality and Issues

As mentioned in [subsection 5.3](#), during error analysis we found that many errors are due to the issue in the dataset itself. Concretely, we observe the following issues in the existing datasets: (1) wrong answers (2) subjective or unanswerable questions (3) typos or unclear expressions (4) not requiring images or knowledge to answer the question as designed.

Furthermore, since the answer and explanation for a question in VCR are obtained from the same person who authored the question, this may result in severe subjectivity in the answers or explanations. For example, we find that many questions in VCR require knowledge of the *movie plot* from which the image is extracted, rather than *common-sense reasoning* to answer the questions. While human annotators have an implicit understanding of the movies, the dataset itself does not contain relevant contextual information.

We show some of the issues in the datasets below. [Figure 6](#) shows examples from VCR that require an understanding of the movie plot to generate answers. [Figure 7](#) shows examples from OK-VQA where questions and answers are subjective or ambiguous. [Figure 8](#) shows examples from A-OKVQA and VQA-X that either contain wrong answers, questions that do not need visual input or typos which severely impact the model generation (“house” should be “horse”).

To understand the inter-annotator agreement for the datasets, we further measure the best, average and worst human performance on OK-VQA and A-OKVQA by selecting the most common answer, a random answer, and the least common answer, respectively, from the 10 ground truth answers for each question. We calculate the performance using the VQA metric for direct answers, and the GloVe metric for Multiple Choice for simplicity. Note that we also remove the answer selected from the ground truth answers when measuring human performance. From the results in [Table 9](#) we can

see that the average performance on both datasets is relatively poor, which indicates the noise in the datasets. The quality of the datasets needs to be more carefully inspected so that the model performance evaluated on these datasets can be more meaningful.

Question: Why is the woman wearing goggles?
 Answer: protection

Ground Truth Explanations:
 0) The woman is wearing goggles for protections.
 1) The snow goggles this woman wears protects her eyes from the sun and other bits of debris she might encounter skiing downhill.
 1) There is a lot of sun glare and snow flying up when skiing.

Explanation Generation:
 Beam: The woman needs protection.
 Nucleus: The woman is skiing and needs protection.

Answer + Explanation Generation:
 Beam: protection, this is because The woman wants to protect her eyes.
 Nucleus: protection, this is because The woman is wearing goggles to protect her eyes from the sun.

Question: What time of day is it likely right now?
 Answer: morning

Ground Truth Explanations:
 0) It is sunny out. there are fruit on the table, so it likely is time for breakfast.
 1) The time is morning.
 2) You can see the light shining in through the window and door.

Explanation Generation:
 Beam: The people are using umbrellas because it's raining.
 Nucleus: The people are using umbrellas to keep from getting wet.

Answer + Explanation Generation:
 Beam: morning, this is because The sun is shining through the window.
 Nucleus: morning, this is because There is light coming through the window.

Question: What has caused the elephants to turn brown?
 Answer: dirt

Ground Truth Explanations:
 0) These elephants have been rolling around in the mud.
 1) The elephants are covering themselves in the naturally occurring brown substance that is near the water.
 2) The elephants are dirty.

Explanation Generation:
 Beam: The elephants are in mud.
 Nucleus: The elephants are standing in dirt.

Answer + Explanation Generation:
 Beam: mud, this is because The elephants are muddy.
 Nucleus: mud, this is because The elephants are in the mud.

Question: What are the umbrellas placed in the sand to block?
 Answer: sun

Ground Truth Explanations:
 0) They are on a beach on a sunny day, and the umbrellas give cool and shade from the sun.
 1) The umbrellas block sun.
 2) Umbrellas provide shade.

Explanation Generation:
 Beam: The umbrellas block the sun.
 Nucleus: The umbrellas are blocking the sun.

Answer + Explanation Generation:
 Beam: sun, this is because The umbrellas block the sun.
 Nucleus: sun, this is because The umbrellas are placed in the sand to block the sun.

Question: Why are the people lining up?
 Answer: boarding

Ground Truth Explanations:
 0) The people are near a plane as if they want to get on.
 1) The people are boarding.
 2) The people are lined up facing the plane. people line up facing transportation vehicles when they are preparing to board.

Explanation Generation:
 Beam: The people are lined up to board a plane.
 Nucleus: The people are lined up to board a plane.

Answer + Explanation Generation:
 Beam: board plane, this is because The people are lined up to board the plane.
 Nucleus: board plane, this is because The people are boarding a plane.

Question: What is the white appliance the people are looking in being used to store?
 Answer: food

Ground Truth Explanations:
 0) The appliance is a fridge.
 1) Perishable food is kept in this little refrigerator, which is too small for many people, but just right for one or two.
 2) There are multiple edible items in the fridge already.

Explanation Generation:
 Beam: The appliance is a refrigerator.
 Nucleus: The appliance is a fridge.

Answer + Explanation Generation:
 Beam: food, this is because The appliance is a fridge.
 Nucleus: food, this is because The appliance is a fridge.

Question: Why are the people using umbrellas?
 Answer: it's raining

Ground Truth Explanations:
 0) There is rain and the people are being sheltered by umbrellas.
 1) The people want rain protection.
 2) They are protecting themselves from getting wet from the rain.

Explanation Generation:
 Beam: The people are using umbrellas because it's raining.
 Nucleus: The people are using umbrellas to keep from getting wet.

Answer + Explanation Generation:
 Beam: rain, this is because The people are using umbrellas because it is raining.
 Nucleus: it's raining, this is because The people are using umbrellas to stay dry.

Question: The layout of buildings most resembles which period?
 Answer: historical european

Ground Truth Explanations:
 0) The cars are on the left side of the road, so it is either the united kingdom or Ireland.
 1) The high pitched roofs and the stone architecture is from then
 2) The layout is from the olden days.

Explanation Generation:
 Beam: The buildings are old.
 Nucleus: The buildings are from the late nineteenth century.

Answer + Explanation Generation:
 Beam: medieval, this is because The buildings look like medieval buildings.
 Nucleus: medieval, is because The buildings look like medieval buildings.

Figure 4: Examples of generated answers and explanations for A-OKVQA.

Question: What event are Person2 and Person8 walking away from?
 Answer: A wedding reception.

Ground Truth Explanation:
 Everyone is really dressed up, and the lights give the area a fairy tale ambiance which is typical of a wedding.

Explanation Generation:
 Beam: Person2 is wearing a pink dress and Person8 is wearing a suit.
 Nucleus: Person2 is wearing a pink dress and Person8 is holding hands with her.

Answer + Explanation Generation:
 Beam: Person2 and Person8 are walking away from a wedding, this is because Person2 and Person8 are holding hands and wearing formal clothing.
 Nucleus: They are walking away from a wedding, this is because There are balloons and strings of lights above them.

Question: Is Dog2 a living creature?
 Answer: No, Dog2 is a stuffed animal.

Ground Truth Explanation:
 Dog2 is immobile, and wouldn't be still with so much prey around. Dog2 is also obviously a toy, based on the coloration.

Explanation Generation:
 Beam: Teddybear1 and Teddybear2, and Teddybear5 are stuffed animals, Dog2 is a stuffed animal.
 Nucleus: Dog2 is a stuffed animal, and stuffed animals are not alive.

Answer + Explanation Generation:
 Beam: No, Dog2 is not a living creature, this is because Dog2 is a stuffed animal.
 Nucleus: No, Dog2 is not a living creature, this is because Dog2 is a stuffed animal, stuffed animals are not alive.

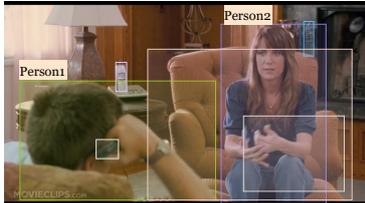

Question: How does Person2 feel about this performance?
 Answer: Person2 is slightly impressed by what she sees.

Ground Truth Explanation:
 Person2 has a slight smirk on her face.

Explanation Generation:
 Beam: Person2 has her arms crossed and a slight frown on her face.
 Nucleus: Person2 has her arms crossed and a slight frown on her face, which suggest she is not impressed.

Answer + Explanation Generation:
 Beam: Person2 does not like what she is hearing, this is because Person2 has her arms crossed and a frown on her face.
 Nucleus: Person2 is not impressed by it, this is because Person2 is looking down and frowning, and her arms are crossed, which is a sign of disapproval.

Question: What is Person2 doing?
 Answer: Telling Person1 something important.

Ground Truth Explanation:
 Person2 is focused on Person1 and waving their hands to emphasize what they're saying.

Explanation Generation:
 Beam: Person2 is sitting across from Person1 who is on the phone.
 Nucleus: Person2 is sitting in a chair and is looking at Person1 who is on the phone.

Answer + Explanation Generation:
 Beam: Person2 is listening to Person1 talk on the phone, this is because Person2 is sitting in a chair facing Person1 who is on the phone.
 Nucleus: Person2 is telling Person1 a story, this is because Person2 is sitting in a chair and Person1 is on the phone.

Question: Why does Person1 have a pointy hood on his cloak?
 Answer: Person1 is a wizard.

Ground Truth Explanation:
 Pointy hoods are usually used to depict a wizard character.

Explanation Generation:
 Beam: Wizards often wear pointy hoods.
 Nucleus: Wizards often wear pointy hoods and robes.

Answer + Explanation Generation:
 Beam: Person1 is trying to hide his identity, this is because Person1 is standing in front of Person2 and Person3, and Person4 who are all looking at him.
 Nucleus: Person1 is a wizard, this is because Wizards often wear pointy hoods and robes.

Question: Does Person1 drink alcohol?
 Answer: Yes Person1 drinks alcohol.

Ground Truth Explanation:
 Person1 has a full beer in front of him.

Explanation Generation:
 Beam: Person1 has a cup of beer in front of him.
 Nucleus: Person1 is drinking from Cup2.

Answer + Explanation Generation:
 Beam: Yes, Person1 drinks alcohol, this is because Person1 has a cup of beer in front of him.
 Nucleus: Yes, he does drink, this is because He has Cup2 in front of him and it is full of beer.

Figure 5: Examples of generated answers and explanations generation for VCR.

Question: Why is Person 3 wearing a life jacket?

Answer Options:
 0) The boat has a leak, and Person3 is scared of drowning.
 1) The boat is sinking and the life jacket will help them float.
 2) Person3 is piloting the ship.
 3) Person9 is wearing a life vest in case the ship sinks.

Generation: Person3 is on a boat.

Question: Why did Person1 drop Person3?

Answer: Person1 dropped Person 3 by accident.

Explanation Options:
 0) Person1 can upon Person3 in the woods, and kissed her; she awoke, and he dropped her off the bier.
 1) Person2 is Person3's mother. Person3 is an infant and can't walk on his own.
 2) Person3 is stuck in the toilet as Person1 is pulling her out.
 3) Person3 is bent over and appears unsteady. Person1 looks concerned for her.

Generation: Person1 is kneeling over the body of Person3.

Figure 6: Questions that require knowledge of the movie plots to generate the answers from VCR.

Question: Is this legal or illegal?

Ground Truth Answers:
 legal (6), illegal (4)

Generation: legal

Question: In which country are the transportation regulations loose enough to allow vehicles like these?

Ground Truth Answers:
 india (8), china (2)

Generation: england

Question: How long does it take to cook?

Ground Truth Answers:
 45 minutes (4), 20 minutes (2), 25 minutes (2), minute (2)

Generation: 1 hour

Question: What nationality is this food?

Ground Truth Answers:
 american (4), mediteranian (2), greek (2), asian (2)

Generation: italian

Figure 7: Examples of subjective questions from OK-VQA.

Question: What country headquarters this plane company?

Answer: usa

Ground Truth Explanations:
 0) The headquarters are the us.
 1) The company name is virgin atlantic that was founded and has headquarters in london england.
 2) The airplane has virgin atlantic livery. this company is based in england.

Question: How long does the average giraffe live?

Answer: 20-30 years

Ground Truth Explanations:
 0) Giraffes can live a long time.
 1) 20-30 years is the lifespan.
 2) I looked up this answer on the internet since there is no way to tell the answer from the picture.

Question: What is the brown house doing?

Answer: walking

Ground Truth Explanations:
 0) it has two legs up and two down and it is moving.
 1) only two feet are touching the ground.
 2) he is moving slowly on a mountain range.

Figure 8: Issues in the datasets that severely impact the model generation: wrong answers (left, from A-OKVQA), questions do not need visual input to answer (middle, from A-OKVQA), and typo (right, from VQA-X).

Machine Translation between Spoken Languages and Signed Languages Represented in SignWriting

Abstract

This paper presents work on novel machine translation (MT) systems between spoken and signed languages, where signed languages are represented in SignWriting, a sign language writing system. Our work¹ seeks to address the lack of out-of-the-box support for signed languages in current MT systems and is based on the SignBank dataset, which contains pairs of spoken language text and SignWriting content. We introduce novel methods to parse, factorize, decode, and evaluate SignWriting, leveraging ideas from neural factored MT. In a bilingual setup—translating from American Sign Language to (American) English—our method achieves over 30 BLEU, while in two multilingual setups—translating in both directions between spoken languages and signed languages—we achieve over 20 BLEU. We find that common MT techniques used to improve spoken language translation similarly affect the performance of sign language translation. These findings validate our use of an intermediate text representation for signed languages to include them in NLP research.

1 Introduction

Most current machine translation (MT) systems only support spoken language input and output (text or speech), which excludes around 200 different signed languages used by up to 70 million deaf people² worldwide from modern language technology. Since signed languages are also natural languages, Yin et al. (2021) calls for including sign language processing (SLP) in natural language processing (NLP) research.

From a technical point of view, SLP brings novel challenges to NLP due to the visual-gestural modality of sign language and special linguistic features

¹Code and documentation available at <https://github.com/J22Melody/signwriting-translation>

²According to the World Federation of the Deaf: <https://wfdeaf.org/our-work/>

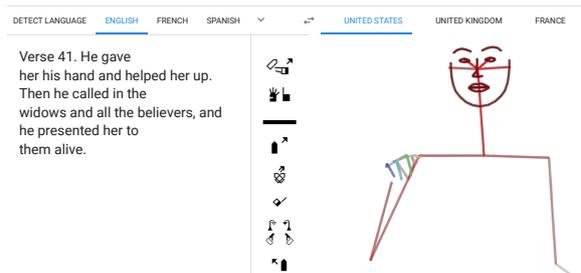

Figure 1: Demo application based on our models, translating from spoken languages to signed languages represented in SignWriting, then to human poses.

(e.g., the use of space, simultaneity, referencing), which requires both computer vision (CV) and NLP technologies. Crucially, the lack of a standardized or widely used written form for signed languages has hindered their inclusion in NLP research.

However, sign language writing systems do exist and are sporadically used (e.g., SignWriting (Sutton, 1990) and HamNoSys (Prillwitz and Zienert, 1990)). Therefore, we adopt the proposal of Yin et al. (2021) to formulate the sign language translation (SLT) task using a sign language writing system as an intermediate step (illustrated by Figure 1): given spoken language text, we propose to translate to sign language in a written form, then transform this intermediate result into a final video or pose output³—and vice versa. According to this multi-step view of SLT, in this work we study translation between signed languages in written form and spoken languages. We use *SignWriting* as the intermediate writing system.

SignWriting has many advantages, like being universal (multilingual), comparatively easy to understand, extensively documented, and computer-supported. In addition, despite looking pictographic, it is a well-defined writing system. Every

³Note that the second step, animation of SignWriting into human poses or video, is not included in this research. In the demo application, spoken language text is translated directly into sign language poses, resulting in low-quality output.

sign can be written as a sequence of symbols (box markers, graphemes, and punctuation marks) and their location on a 2-dimensional plane.

To our knowledge, this work is the first to create automatic SLT systems that use SignWriting. Our main contributions are as follows: (a) we propose methods to parse (§3.3), factorize (§3.4), decode (§4.3), and evaluate (§4.3) SignWriting sequences; (b) we report experiments on multilingual machine translation systems between SignWriting and spoken language text (§4); (c) we demonstrate that common techniques for low-resource MT are beneficial for SignWriting translation systems (§5).

2 Background

2.1 Sign language processing (SLP)

SLP (Bragg et al., 2019; Yin et al., 2021; Moryossef and Goldberg, 2021) is an emerging subfield of both NLP and CV, which focuses on automatic processing and analysis of sign language content. Prominent tasks include pose estimation from sign language videos (Cao et al., 2017, 2021; Güler et al., 2018), gloss transcription (Mesch and Wallin, 2012; Johnston and Beuzeville, 2016; Konrad et al., 2018), sign language detection (Borg and Camilleri, 2019; Moryossef et al., 2020), sign language identification (Gebre et al., 2013; Monteiro et al., 2016), and sign language segmentation (Bull et al., 2020; Farag and Brock, 2019; Santemiz et al., 2009).

Besides, tasks including sign language recognition (Adaloglou et al., 2021), translation, and production involve transforming one sign language representation to another or from/to spoken language text, as shown in Figure 2⁴. We find that existing works cover gloss-to-text (Camgöz et al., 2018; Yin and Read, 2020) (where “text” denotes spoken language text), text-to-gloss (Zhao et al., 2000; Othman and Jemni, 2012), video-to-text (Camgöz et al., 2020b,a), pose-to-text (Ko et al., 2019), and text-to-pose (Saunders et al., 2020a,b,c; Zelinka and Kanis, 2020; Xiao et al., 2020).

2.2 Motivation

Our work is the first to explore translation between spoken language text and sign language content represented in SignWriting⁵. We focus on a sign language writing system for the following reasons:

⁴In the paper, we distinguish between a phonetic “writing system” (e.g., SignWriting) and “glosses” (lexical notation, marking the semantics of each sign with a distinct category).

⁵Related work based on HamNoSys: Morrissey (2011); Sanaullah et al. (2021); Walsh et al. (2022)

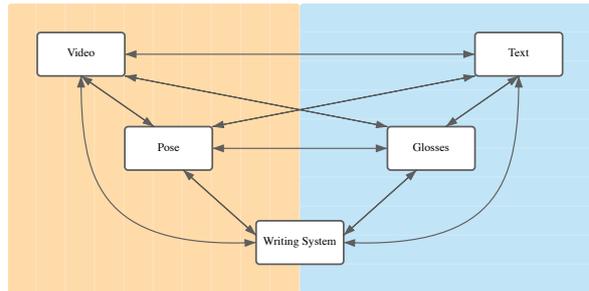

Figure 2: SLP tasks. Every edge on the left side represents a task in CV (language-agnostic). Every edge on the right side represents a task in NLP (language-specific). Every edge crossing both sides represents a task requiring a combination of CV and NLP. Figure taken from Moryossef and Goldberg (2021).

(a) currently an end-to-end (video-to-text/text-to-video) approach is not feasible. State-of-the-art systems either have a BLEU score lower than 1 (Müller et al., 2022a) or work only on a very narrow linguistic domain, e.g., Camgöz et al. (2020b,a) work on the RWTH-PHOENIX-Weather T data set which covers only 1,231 unique signs from weather reports (less than what we use in Table 2); (b) a writing system is lower-dimensional than videos (not all parts of a video are relevant in a linguistic sense), while adequate to encode information of signs; (c) written sign language is a closer fit to current MT pipelines than videos or poses; (d) a phonetic writing system is a more universal solution than glossing since glosses are semantic and therefore language-specific, and are an inadequate representation of meaning (Müller et al., 2022b).

2.3 SignWriting, FSW, and SWU

SignWriting (Sutton, 1990) is a featural and visually iconic sign language writing system (introduced extensively in Appendix A). Previous work explored recognition (Stiehl et al., 2015) and animation (Bouزيد and Jemni, 2013) of SignWriting.

SignWriting has two computerized specifications, Formal SignWriting in ASCII (FSW) and SignWriting in Unicode (SWU). SignWriting is two-dimensional, but FSW and SWU are written linearly, similar to spoken languages. Figure 3 gives an example of the relationship between SignWriting, FSW, and SWU⁶. We use FSW in our research instead of SWU to explore the potential of factorizing SignWriting symbols and utilizing numerical values of their position (§3.3, §3.4).

⁶Online demonstration: <https://slevinski.github.io/SuttonSignWriting/characters/index.html>.

language pair	#samples	#puddles
en-us (American English & American Sign Language)	43,698	7
pt-br (Brazilian Portuguese & Brazilian Sign Language)	42,454	3
de-de (Standard German & German Sign Language)	24,704	3
fr-ca (Canadian French & Quebec Sign Language)	11,189	3

Table 1: Relatively high-resource language pair statistics.

puddle name	language pair	#samples	#signs	mean sequence len
Literature US	en-us	700	9,922	24
ASL Bible Books NLT	en-us	11,667	51,485	24
ASL Bible Books Shores Deaf Church	en-us	4,321	44,612	31
Literatura Brasil	pt-br	1,884	19,221	13

Table 2: Primary sentence-pair puddles. Mean sequence length is measured by the mean number of words in the spoken language sentences.

• symbols: S1f010, S18720, etc.;	Source	Target
• positional numbers x and y: 515, 483, etc.;	symbol	S1f010
• punctuation marks (special symbols without box markers): S38800, etc.	X	515
	Y	483
	relative X	0 → “Hi”
	relative Y	1
	symbol core	S1f0
	column	1
	row	0

We further factorize each symbol into several parts regarding its orientation (see Figure 7 in Appendix A for an explicit motivation of this step). For example, the symbol S1f010 is split into:

- symbol core: S1f0;
- column number (from 0 to 5): 1;
- row number (from 0 to hex F): 0.

For positional numbers, which have a large range (from 250 to 750) and are encoded discretely, we hypothesise that models might have difficulty understanding their relative order. Therefore, we further calculate two additional factors that denote a symbol’s relative position (based on the absolute numbers) within a sign: relative x and relative y, both ranging from 0 to #symbols - 1.

We provide a full example of the result of FSW parsing in Listing 1 in Appendix C.

3.4 Factored machine translation

We use a factored machine translation system (Koehn and Hoang, 2007; Garcia-Martinez et al., 2016) to encode or decode parsed FSW sequences. We argue that this architecture is suitable because

Figure 4: Representation of translating a FSW symbol together with its factors to English.

concatenating all parsed FSW tokens results in sequences much longer than the maximum length of many Transformer models (e.g., 512).

From another perspective, the essential information units are the symbols. Nevertheless, the positional numbers are necessary to determine how symbols are assembled. The same symbols can be arranged differently in space to convey different meanings.

In our setup, we treat the symbols (including punctuation marks and box markers) as the primary source/target tokens and the rest as source/target factors that are strictly aligned with each source/target token (illustrated by Figure 4).

Depending on the translation direction, factored FSW representations need to be encoded or decoded. For encoding (when FSW is the source), we embed each factor separately and then concatenate

them to the aligned symbol’s embedding. For decoding (when FSW is the target), we use only a subset of factors (absolute x and y) because others are irrelevant for prediction, and additional weighted cross-entropy losses are calculated.

4 Experiments and results

This section introduces three lines of experiments on both bilingual and multilingual SignWriting translation. We use Transformer models (Vaswani et al., 2017) that support source and target factors. See Appendix B for more details on our training configuration.

4.1 Initial exploration with a bilingual model

For a first exploration, we train a bilingual model that translates from American Sign Language (ASL) to English (en-us). The purpose of this experiment is (a) to demonstrate that automatic SignWriting translation is feasible and (b) to explore different strategies for data processing and hyperparameters.

We use roughly 40k parallel training samples comprising roughly 15k sentence pairs and 25k dictionary pairs. The quality of spoken language translation is measured by BLEU (Papineni et al., 2002) and chrF2 (Popović, 2015). Table 3 shows the evaluation results on the test set.

4.2 Multilingual sign-to-spoken translation

Here we extend our initial bilingual model to a multilingual setting, translating from multiple signed languages to multiple spoken languages. We define two data conditions:

- **high-resource:** using roughly 100k parallel training samples (roughly 17k sentence pairs and roughly 83k dictionary pairs covering four language pairs),
- **adding low-resource:** in addition to the high-resource data, use all additional language pairs in SignBank that have at least 1k parallel samples (most of which are dictionaries). The total number of training examples grows to roughly 170k, covering 21 language pairs (Table 7).

The exact factorization strategy and model hyperparameters are informed by our bilingual experiments reported in Table 3.

Evaluating dictionary entries For these multilingual models, many of the training samples are dictionary entries, and so are some test samples. To evaluate the translation quality for dictionary entries, we use top-n accuracy, which tests whether one of the top-n translation candidates from beam search matches the entry from the reference.

Table 4 shows the evaluation results on the test set.

4.3 Multilingual spoken-to-sign translation

Finally, we train multilingual models that translate in the reverse direction, from spoken languages to signed languages. The data and model configuration are the same as for the multilingual sign-to-spoken model under high-resource data condition.

FSW decoding strategies SignWriting utterances are parsed into a factored FSW representation (§3.3, §3.4) and are used for encoding successfully, yet it is not obvious how to best decode to FSW. We try the following strategies: (a) predicting everything (including positional numbers) as target tokens all in one long target sequence, inspired by Chen et al. (2022); (b) predicting symbols only (as a comparative experiment); (c) predicting symbols with positional numbers as target factors.

During decoding in the test phase, we apply beam search only for the main target token prediction. Target factors do not participate in beam search, i.e., each target factor prediction is the argmax of the corresponding output layer distribution. We shift target factors to the right by 1 to condition their prediction on the previously generated target symbol.

Evaluation of FSW output Due to variations of SignWriting symbols based on different orientations that do not change meaning (Figure 7), evaluating FSW output only at the token (symbol) level is not sufficient. Therefore, we evaluate the output symbols (e.g., line 4 in Listing 1) not only with BLEU, but also chrF2++, which captures both word-level and character-level statistics. Additionally, we evaluate the output positional numbers by mean absolute error (MAE) to measure the distance between predicted positional numbers and the ones from the FSW reference (e.g., lines 5 and 6 in Listing 1). Let x be the predicted sequence of positional numbers and y be the gold sequence:

$$MAE(x, y) = \frac{1}{|x|} \sum_{i=1}^{|x|} |x_i - y_i|$$

	model	BLEU	chrF2
E1	baseline (lowercase training and test data)	22.5	-
E2	E1 + dictionary data	25.2	-
E3	E2 + BPE	27.0	46.2
E4	E3 + x,y as factors	27.5	46.5
E5	E4 + symbol core as source + row, col as factors	23.1	41.2
E6	E4 + relative x, y as factors	28.1	47.5
E7	E6 + aggressive dropout + tied softmax	31.4	52.0
E8	E7 + symbol core, row, column as factors	32.0	52.7
E9	E8 + remove lowercasing	30.8	51.2
E10	E9 + smaller BPE vocab 2000 to 1000	29.5	50.8

Table 3: Translation quality of ASL→en-us bilingual models. Note that E1 to E8 are trained and evaluated with all spoken language data lowercased, while from E9 to all later experiments we remove the lowercasing, so we expect a little performance drop for the later experiments. We introduce chrF2 as an evaluation metric starting from E3.

language	metrics	4 language pairs (100k)	21 language pairs (170k)
en-us (40k)	BLEU	29.5	25.0
	chrF2	49.8	47.0
	top-1	0.37	0.33
	top-5	0.52	0.45
en-sg (1k)	top-1	-	0.20
	top-5	-	0.27
pt-br (40k)	BLEU	23.8	6.4
	chrF2	44.3	17.5
	top-1	0.12	0.09
	top-5	0.17	0.15
mt-mt (4k)	BLEU	-	10.1
	chrF2	-	29.8
	top-1	-	0.05
	top-5	-	0.05
de-de (20k)	top-1	0.22	0.15
	top-5	0.31	0.27
de-ch (4k)	top-1	-	0.04
	top-5	-	0.06
fr-ca (10k)	top-1	0.04	0.07
	top-5	0.08	0.10
fr-fr (1k)	top-1	-	0.16
	top-5	-	0.24
fr-ch (8k)	top-1	-	0.07
	top-5	-	0.09

Table 4: Translation quality of multilingual sign-to-spoken models (partial results on the most frequent languages). Languages without sentence pairs are only evaluated by top-n accuracy. Empty cells mean that a language pair is not supported by the model. In the parentheses are the rough numbers of samples.

	model	BLEU	chrF2++	MAE x	MAE y
E1	2symbol+numbers	6.6	23.1	-	-
E2	2symbol	25.6	44.2	-	-
E3	2symbol+factors (w=1)	19.9	39.1	46.5	52.6
E4	2symbol+factors (w=0.5)	21.9	40.8	46.8	52.7
E5	2symbol+factors (w=0.2)	22.9	42.0	47.4	53.0
E6	2symbol+factors (w=0.1)	22.0	41.7	46.4	52.2
E7	2symbol+factors (w=0.01)	21.0	40.9	48.4	58.3

Table 5: Translation quality of multilingual spoken-to-sign models. Evaluated in BLEU (on symbol, higher is better), chrF2++ (on symbol, higher is better), and MAE (on positional numbers, lower is better). w denotes the weight between each factor’s loss and the main target loss.

language	BLEU (on symbols)	chrF2++ (on symbols)
en-us (40k)	35.7	58.4
pt-br (40k)	1.9	14.9
de-de (20k)	17.3	43.2
fr-ca (10k)	5.3	19.1

Table 6: Translation quality of multilingual spoken-to-sign model ($w=0.1$) per language. In the parentheses are the rough numbers of samples per language.

where if the predicted and gold sequences do not have the same length, they are padded with zeros.

Table 5 shows the results of evaluation on the test set. Table 6 shows the results of multilingual evaluation on *E6* ($w=0.1$) of Table 5.

5 Discussion

5.1 Effect of adding dictionaries, BPE, and low-resource optimizations

As shown in Table 3, enlarging the sentence-level training data (15k sentence pairs) with 25k dictionary pairs improves the translation quality by 2.7 BLEU (*E1* vs. *E2*). Likewise, applying BPE segmentation to the spoken language side also improves translations by 1.8 BLEU (*E2* vs. *E3*).

We evaluate several low-resource “tricks” (Sennrich and Zhang, 2019) including aggressive dropout and weight tying⁹. These low-resource optimizations borrowed from spoken language MT prove to be effective for sign language translation as well, as they result in an improvement of 3.3 BLEU and 4.5 chrF2 (*E6* vs. *E7* in Table 3).

⁹The tying is only between the target embedding and the softmax output matrix since the source and target languages are of a very different nature and therefore cannot be tied.

5.2 Utilizing positional numbers

In earlier sections we introduce novel methods to parse and factorize FSW (§3.3, §3.4). However, from a model training perspective it is unclear how to best utilize additional factors such as positional numbers. In *E4*, *E5*, *E6*, and *E8* of Table 3, we explore different ways of including factors.

We find that the best strategy is explicitly adding all additional information (x , y , relative x , relative y , symbol core, column number, row number) as source factors while keeping symbols as the primary source tokens. This strategy achieves the state-of-the-art performance of 32.0 BLEU and 52.7 chrF2 in *E8*.

5.3 Generating positional numbers

We explore different ways of generating positional numbers in Table 5. As a first attempt, we treat them as normal target tokens in *E1*, which results in poor performance and overly long target sequences, and long beam search decoding time.

In all subsequent experiments, we treat positional numbers as target factors and generally achieve over 20 BLEU (evaluating on symbols). In *E2*, we translate only the symbols as a baseline. Then we also try translating with target factors and varying the weights between factors and the pri-

mary target, i.e., symbols. Finally, we observe that $E6$ ($w=0.1$) leads to the best trade-off between generating symbols and positional numbers.

5.4 Multilingual performance

We discuss multilingual performance mainly based on Table 4. Generally speaking, the more resources a language has in the multilingual model, the better its performance (Zhou et al., 2021). The two target languages most frequent in the training data—American English (en-us, 40k) and Brazilian Portuguese (pt-br, 40k)—have the highest translation quality.

Multilingual transfer effects We observe examples of both positive and negative multilingual transfer. Evidence shows that a relatively high-resource language can help a related low-resource language. For instance, the performance of Singaporean English (en-sg, 1k) is likely improved by American English (en-us, 40k), which is almost as good as Standard German (de-de, 20k).

The comparable bilingual en-us model ($E9$ in Table 3) outperforms en-us in our multilingual sign-to-spoken model in Table 4 by 1.3 BLEU and 1.4 chrF2. However, when extending the training data from 4 to 21 language pairs, we observe severe degradations: en-us drops by 4.5 BLEU and 2.8 chrF2; Brazilian Portuguese (pt-br) drops by 17.4 BLEU and 26.8 chrF2.

Such findings are in line with previous work on highly multilingual translation systems. For example, Aharoni et al. (2019) finds that average per-language performance drops when the number of languages increases. We conclude that SignWriting translation suffers from a similar *curse of multilinguality*.

5.5 Side-by-side SignWriting example

Finally, to gain intuition for how well the translation model signs, we give a side-by-side example of SignWriting graphics. We compare the reference and model prediction of an ASL utterance corresponding to an American English utterance from the Bible corpus, shown in Figure 5.

We ask an ASL user proficient in SignWriting for a translation of the predicted SignWriting back to English to assess the quality of the prediction.

Similar patterns appear in both: in the beginning, the model signs “Verse 41” in the same way as in the reference; the graphics in the top parts of all the columns are consistent; and we see correct sym-

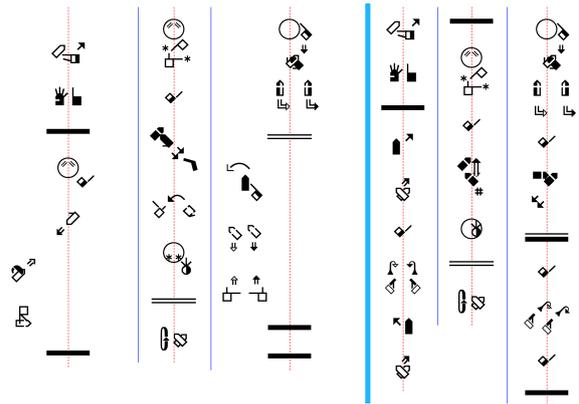

Figure 5: Side-by-side SignWriting example. ASL translation of the English sentence “Verse 41. He gave her his hand and helped her up. Then he called in the widows and all the believers, and he presented her to them alive.” Separated by the vertical bold (light blue) line, the left is the gold sentence, and the predicted sentence is on the right. The predicted sentence translated back to English is “Verse 41. His hand he gives her hand. Then he helped up, all believers he warned: he put there.”

bols sometimes predicted with slightly different positions.

More translation examples can be seen in Appendix D.

6 Conclusion

This work explores building bilingual and multilingual translation systems between spoken and signed languages. Instead of representing sign language as videos (or as continuous features derived from videos) common in previous research, we propose to represent sign language in SignWriting, a sign language writing system. We argue that using a written form is more amenable to well-established NLP techniques.

However, encoding or decoding SignWriting in an MT system requires specialized tools. Therefore, we propose novel methods to parse, factorize, decode, and evaluate SignWriting sequences. Our factorization technique divides SignWriting sequences into meaningful units such as sign symbols and positional numbers. The factors are then encoded or decoded by a factored Transformer model.

As a result, we achieve over 30 BLEU in the bilingual setting and over 20 BLEU for some high-resource language pairs in both directions in the multilingual setting.

Using SignWriting as an intermediate representation enables us to reuse tools (e.g., evaluation met-

rics) from spoken language translation. We also observe striking similarities to spoken language MT in the experiments themselves. For example, low-resource optimizations have a similar impact, and multilingual models exhibit similar transfer effects. These findings validate our use of an intermediate text representation for signed languages to include them in NLP research.

7 Limitations

7.1 A word on top-n accuracy

In the translation of dictionary data, if a dictionary entry has been seen during training, assuming the model has enough capacity, it should memorize and predict it. However, evaluating the translation is tricky, so in §4.2 we resort to using top-n accuracy.

Paradoxically, high top-n accuracy on the test set does not guarantee good generalization and might be associated with overlap between the training and test sets. Conversely, claiming a model is terrible when it performs poorly on the test set is unjustified, as there might be no overlap between the training and test sets. If a model has seen all the words from a language, it should perform well on whatever dictionary test set. However, this is not the case in our low-resource setting.

7.2 Fingerspelling tokenization

Fingerspelling (Battison, 1978; Wilcox, 1992; Brentari and Padden, 2001) is an interesting linguistic phenomenon where a signed language geographically coexists with a spoken language. For words with no associated signs (e.g., names of people, locations, organizations, etc.), sign language users borrow a word of a spoken language by spelling it letter-by-letter with predefined signs for the letters of the alphabet of that language. The fingerspelling (manual) alphabet of a sign language draws on a closed set of hand shapes, which are supported by SignWriting.

As fingerspelling is usually applied on a character level (rarely extending to the level of multiple characters, such as “CH” or “SCH” for the finger alphabet of Swiss German Sign Language), the way BPE segmentation works (on subword level) does not apply perfectly. However, if we could detect fingerspelling during the segmentation/tokenization process, then force fingerspelled words to be split letter-by-letter, our models should be able to learn better the mappings between fingerspelling signs and spoken language letters.

7.3 Towards better multilingual models

As shown by Table 2, the data we use to train our models only contains many sentence pairs for American English and American Sign Language. For other language pairs, we train mainly on dictionary data.

At the time of writing, we find a multilingual parallel corpus created from translations of the Bible¹⁰ (Christodoulopoulos and Steedman, 2014), which, if aligned correctly, can be used to translate the ~15k American Sign Language biblical text to another 100+ spoken languages. We believe we could train better multilingual translation models (at least on the spoken language side) based on them.

7.4 Regression objective for positional numbers

In our experiments, positional numbers are treated as target factors (§5.3), contributing cross-entropy loss to the training process. However, we are aware that the positional numbers are, by nature, numeric values, so a regression objective/loss would possibly work better than the current cross-entropy loss, as it better reflects the numeric relationship between positional numeric values.

As for now, the target factor function we use is only implemented with a classification objective (cross-entropy loss). We envision that custom implementation of the regression objective might improve translation quality in this scenario.

7.5 Possibly flawed positional number evaluation

We note that using MAE for evaluating positional numbers (§4.3) is possibly flawed because the predicted symbol sequences can deviate from the gold symbol sequences. If this is the case, making a token-by-token comparison on the positional numbers is meaningless, as even the sequence length can mismatch.

7.6 Advanced SignWriting evaluation

Finally, we call for advanced and novel methods of SignWriting evaluation, considering its differences from spoken languages.

In our experiments, we separate the evaluation of FSW symbols and positional numbers. For symbols, we borrow BLEU and chrF2/chrF2++ from spoken language evaluation since FSW symbols are the basic graphemes in SignWriting that show

¹⁰<https://github.com/christos-c/bible-corpus>

many similar linguistic features as spoken language words. For positional numbers, MAE is used, and its limitation is discussed in §7.5.

From a broader perspective, FSW is merely a linearized specification of SignWriting, which means we can also evaluate on the original graphical form, as we do manually in §5.5. Moreover, we can exploit CV techniques to do an automatic comparative evaluation between predicted SignWriting graphics and gold SignWriting graphics.

Ideally, a cascading evaluation method is applied to SignWriting: we first evaluate the overall graphics of the signs, then the symbols within the signs, then the position of the symbols, then the factorized representation of the symbols. Finally, a thorough human evaluation is needed to gain better insight.

Note on reproducibility

We will release the source code and documentation to train our models, an API server with the trained models, and a demo Web application. This will allow others to see and consistently reproduce our results with minimal changes. We encourage the community to attempt to reproduce our results and publish the results.

A Extended introduction to SignWriting

SignWriting (Sutton, 1990) is a sign language writing system developed by Valerie Sutton¹¹ and currently managed by Steve Slevinski¹². SignWriting is very featural and visually iconic, both in:

- the shapes of the symbols, which are abstract pictures of hand shapes (Figure 6), orientation (Figure 7), body locations, facial expressions, contacts, and movement;
- the symbols’ two-dimensional spatial arrangement in an invisible “sign box” (Figure 8).

Outside each sign, the script is written linearly to reflect the temporal order of signs. Signs are mostly written vertically, arranged from top to bottom within each column, interspersed with special punctuation symbols (horizontal lines), and the columns progress left to right across the page. Within each column, signs may be vertically aligned to the center or shifted left or right to indicate body shifts.

A.1 Formal SignWriting in ASCII (FSW)

In 2012, Formal SignWriting in ASCII (FSW) specification (Slevinski, 2021) was released and documented in an Internet Draft submitted to the IETF.

The design of FSW is computerized so that it can be recognized and processed by programs. While signed languages are natural languages, FSW is a formal language handy in mathematics, computer science, and linguistics.

Although SignWriting is two-dimensional, FSW is written linearly like spoken languages. Each sign is written as first a box marker, then a sequence of symbols, and their relative position, as illustrated by Figure 3.

A.2 SignWriting in Unicode (SWU)

In 2017, SignWriting in Unicode (SWU) specification (Slevinski, 2021) was released, making SignWriting included in the Unicode Standard. The Unicode block for SWU is U+1D800 - U+1DAAF.

As illustrated in Figure 3, SWU is also written linearly. FSW and SWU are isomorphic and interchangeable, and both faithfully encode the complete information of SignWriting.

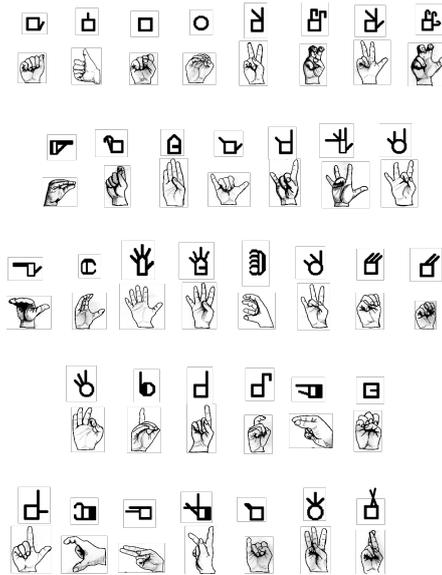

Figure 6: Hand shapes and their equivalents in SignWriting.

B Experimental setup

We performed all our experiments with Python 3.8.11 on an Nvidia Tesla V100 GPU (32GB GPU ram).

B.1 40k sign-to-en-us

Data includes:

- ~15k sentence pairs from 3 en-us puddles: Literature US, ASL Bible Books NLT, ASL Bible Books Shores Deaf Church,
- ~25k dictionary pairs from 3 en-us puddles: Dictionary US, LLCN & SignTyp, ASL Bible Dictionary,

which leads to:

- ~6k source vocabulary size (number of non-factorized symbols),
- ~2k target vocabulary size (determined by BPE).

Final model configuration:

- 6 layers + 8 heads + 512 embedding size (16 for each factor) (0.5 dropout) + 512 hidden size (0.5 dropout) + 2,048 feed forward size (0.5 dropout),
- initial learning rate 0.0001, decrease learning rate by a factor of 0.7 every 5 times validation score (BLEU) not improved,
- batch size 32 sentences, label smoothing 0.2, epochs 300,
- for testing, decoding with a checkpoint with the best validation score, beam size 5, alpha for length penalty 1.

Experiments were conducted with a custom version of Joey NMT (Kreutzer et al., 2019) to support source factors. Each model (~47 million parameters) finished training within 1 day.

B.2 100k sign-to-spoken

Data includes:

- ~17k sentence pairs from 3 en-us puddles (Literature US, ASL Bible Books NLT, ASL Bible Books Shores Deaf Church) and 1 pt-br puddle (Literatura Brasil),

- ~83k dictionary pairs from 3 en-us puddles (Dictionary US, LLCN & SignTyp, ASL Bible Dictionary), 2 pt-br puddles (Dicionário Brasil, Enciclopédia Brasil), 1 de-de puddle (Wörterbuch DE) and 1 fr-ca puddle (Dictionnaire Quebec),

which leads to:

- ~11k source vocabulary size (number of non-factorized symbols),
- ~2k target vocabulary size (determined by BPE).

A little change to the previous configuration to make training more efficient:

- batch size 4,096 tokens.

Experiments were conducted with a custom version of Joey NMT to support source factors. Each model (~50 million parameters) finished training within ~1.5 days and ~3 days, respectively.

B.3 100k spoken-to-sign

Data and model configurations are the same as **100k sign-to-spoken**, except that we use perplexity (Chen and Goodman, 1996; Sennrich, 2012) as validation score instead of BLEU.

Experiments were conducted with Sockeye (Hieber et al., 2020) for the convenience of ready-to-use target factor support. Each model (~60 million parameters) finished training within ~0.5 day.

C Data

Figure 9 visualizes the language pair distribution in SignBank. Table 7 contains an exhaustive list of all 21 language pairs used in this research. Listing 1 shows an example of FSW parsing and factorization.

A Multi-dimensional Evaluation of Tokenizer-free Multilingual Pretrained Models

Jimin Sun^{1,2} Patrick Fernandes¹ Xinyi Wang¹ Graham Neubig¹

¹Language Technologies Institute, Carnegie Mellon University ²Kakao Enterprise
{jamins2, pfernand, xinyiw1, gneubig}@cs.cmu.edu

Abstract

Recent works on tokenizer-free multilingual pretrained models show promising results in improving cross-lingual transfer and reducing engineering overhead compared to subword-based alternatives. However, previous work mainly focuses on reporting accuracy on a limited set of tasks and data settings, placing less emphasis on other important factors when tuning and deploying the models in practice, such as memory usage, inference speed, and finetuning data efficiency. We attempt to fill this gap by performing a comprehensive empirical comparison of multilingual tokenizer-free and subword-based models considering the various dimensions. Surprisingly, we find that subword-based models might still be the most practical choice in many settings, achieving better performance for lower inference latency and memory usage. Based on these results, we encourage future work in tokenizer-free methods to consider these factors when designing and evaluating new models.¹

1 Introduction

Several recent results (Clark et al., 2022; Xue et al., 2022) have excited the research community with the possibility of “tokenizer-free” models, character-level and byte-level models, as an alternative to more traditional subword-based models. Tokenizer-free models are especially appealing to practitioners as they can eschew the two-step processing pipeline of subword segmentation and reduce the corresponding difficulties in cross-lingual transfer (Hu et al., 2020; Maronikolakis et al., 2021; Rust et al., 2021; Wang et al., 2021) or domain adaptation (Sato et al., 2020; Liu et al., 2021) due to inconsistent subword units.

However, upon several attempts to apply tokenizer-free methods, our analysis reveals several practical difficulties in applying these methods.

¹We will release code to train and evaluate models upon de-anonymization.

This paper is a chronicle of some of the concerns we uncovered; we highlight some challenges with applying these models and propose best practices for future results reporting in this area.

Specifically, we perform experiments finetuning pretrained multilingual models, evaluating them with respect to finetuning data efficiency, inference time, and memory consumption. Based on these multiple dimensions, we come to the somewhat surprising conclusion that subword-based models, in particular mBERT (Devlin et al., 2019), might still be the most practical choice in most settings, as they perform best while maintaining a relatively low inference cost.

2 Tokenizer-free Multilingual Models

While multilingual pretrained models (Devlin et al., 2019; Lample and Conneau, 2019; Liu et al., 2020; Xue et al., 2021) have led to impressive performance improvements for low-resource languages through cross-lingual transfer, the standard word representation method in these models relies on subword segmentation (Sennrich et al., 2016; Kudo, 2018). In multilingual settings, subword tokenization can be sub-optimal as supporting hundreds of languages with various scripts and vocabularies causes segmentation mismatch between languages and over-segmentation in the lower-resourced languages (Wang et al., 2020).

To alleviate this problem, recent works propose removing the subword segmentation step by using characters or bytes as lexical units (Clark et al., 2022; Xue et al., 2022). In particular, these “tokenizer-free” methods have been applied to both encoder-only and encoder-decoder models. Tab. 1 presents an overview of the different tokenizer-free multilingual models with comparable subword models. Next, we briefly describe the two tokenizer-free models we consider in this work.

CANINE (Clark et al., 2022) is a character-level

Model	Params	Vocab (%)	Non-vocab	Architecture	Enc.	Dec.	Tokenization	↓sample?	Corpus	Langs
mBERT	178M	92M (52%)	86M	Enc-only	12	-	Subword	✗	Wikipedia	104
CANINE	132M	25M (19%)	107M	Enc-only	12	-	Character	✓	Wikipedia	104
mT5 (Small)	300M	256M (85%)	44M	Enc-dec	8	8	Subword	✗	mC4	101
ByT5 (Small)	300M	1.1M (0.3%)	298.5M	Enc-dec	12	4	UTF-8 bytes	✗	mC4	101

Table 1: Configuration of the pretrained models used. From left to right: number of parameters, number and ratio of vocabulary-related parameters, number of non-vocabulary parameters, architecture, encoder / decoder depth, tokenization scheme, whether downsampling was used, pretrained corpus, number of pretrained languages.

encoder suggested as an alternative to mBERT (Devlin et al., 2019). CANINE operates on raw characters and is pretrained using the masked language modeling objective. To compensate for the computational efficiency loss due to increased sequence length, CANINE uses convolutions to downsample the sequence before passing the representations to the transformer layers. The two weight variants of CANINE (CANINE-S, CANINE-C) have the same architecture but slightly different pretraining objectives using either subwords or characters at the last layer. As both variants performed similarly in our experiments and Clark et al. (2022), we only include CANINE-S for the main discussion, leaving CANINE-C results in § B.3.

ByT5 (Xue et al., 2022) is an encoder-decoder transformer model similar to the mT5 (Xue et al., 2021) model. ByT5 operates on the raw UTF-8 bytes of the input without any downsampling, leading to a longer sequence length while having a much smaller vocabulary size than mT5. Both ByT5 and mT5 are pretrained on the mC4 corpus² using the span reconstruction objective proposed by Raffel et al. (2020).

To keep the parameter count fixed between mT5 and ByT5, ByT5 allocates the parameters saved from the embedding layer to additional encoder layers. Although adding more depth to the encoder is a reasonable design choice, our results in § 4 show that ByT5 suffers from a much higher inference cost due to the deeper encoder, especially when input/output sequence lengths are longer.

3 Experimental settings

We conduct a multi-dimensional evaluation focusing on two aspects: finetuning data efficiency (§ 4.1) and inference cost (§ 4.2) to provide a better understanding of the practical applicability of tokenizer-free models. We finetune and evaluate

²<https://www.tensorflow.org/datasets/catalog/c4#c4multilingual>

two subword-based models (mBERT, mT5) and two tokenizer-free models (CANINE, ByT5), as mBERT-CANINE and mT5-ByT5 are directly comparable counterparts in terms of their pretraining corpus as shown in Tab. 1. For the T5 models, we consider only the small models of both mT5 and ByT5 as the focus of our work is in the practical implication of using multilingual pretrained models at relatively resource-constrained settings.

Specifically, we finetune the models on three multilingual natural language understanding tasks adopted from the XTREME benchmark (Hu et al., 2020). The three tasks we choose cover various input, output formats – sequence-level classification (XNLI), token-level classification (NER), and extractive question answering (TyDi QA-GoldP).

3.1 Tasks

XNLI The Cross-lingual Natural Language Inference (Conneau et al., 2018) is a sequence classification task in which the model predicts whether the hypothesis sentence is an entailment, contradiction, or neutral given the premise sentence. The task is provided in 15 languages.

NER Named Entity Recognition (NER) is a structured prediction task, where the model predicts a tag (location, person, organization) in IOB2 format for each token in the input sentence. We use the WikiAnn dataset (Pan et al., 2017) and select 20 out of 282 languages for multilingual training based on linguistic diversity and the language availability in the other two tasks we consider.

TyDi QA-GoldP The Typologically Diverse Question Answering (Clark et al., 2020) dataset is an extractive QA benchmark in 11 languages. While the original dataset includes two “primary” tasks (SelectP, MinSpan), the secondary GoldP task is the most widely adopted as it is compatible with other SQuAD-style QA tasks (Rajpurkar et al., 2016; Artetxe et al., 2020). For this reason, we mainly compare models on TyDi QA-GoldP

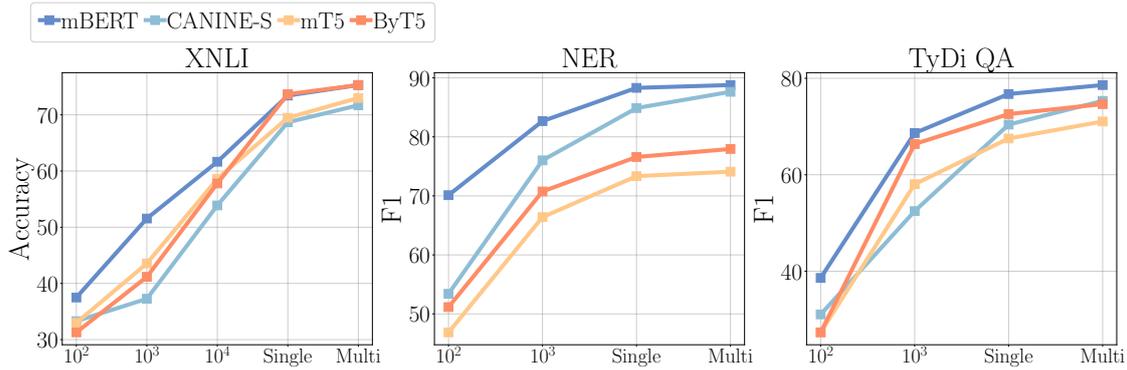

Figure 1: Average XNLI, NER, TyDi performance when each pretrained model is finetuned with varying numbers of in-language finetuning data (10^2 , 10^3 , 10^4), all in-language samples (Single), or the entire multilingual dataset (Multi). The exact numbers can be found in the Appendix (Tab. 2).

and discuss primary task results briefly through our replication experiment of Clark et al. (2022).

3.2 Details of Hardware and Measurements

We use a single Tesla V100 (32GB) GPU for all experiments regarding inference cost measurements. To obtain the peak GPU memory and inference latency, we randomly select 100 samples from the English test set for each task and measure the average cost of predicting one example at a time.

4 A Multi-dimensional Evaluation

4.1 Finetuning data efficiency

Most work presenting multilingual pretrained models evaluates downstream task performance under multilingual finetuning or zero-shot scenarios. In practice, however, downstream task datasets are often available in the language of interest. Thus, in addition to multilingual training, we compare models tuned on different data sizes *within* a single language to evaluate their finetuning data efficiency.

Specifically, we finetune the four pretrained models with varying numbers of task examples – 10^2 , 10^3 , 10^4 (when available), all target language samples (Single), and multilingual training (Multi) to incorporate situations where the task dataset is available in multiple languages. We experiment with four downstream task languages – English, Arabic, Russian, and Swahili – chosen based on both linguistic diversity and various pretraining resource conditions.³ While the controlled experiments are done on a subset of languages, we report the task performance in all languages for zero-shot evaluation, single language training, and multilin-

gual training in § B.3 for comprehensiveness.⁴

In Fig. 1, we report the models’ task performance averaged over languages under different finetuning settings. Notably, we find that mBERT achieves the highest score for most settings. The only exception is on XNLI Single and Multi, where ByT5 slightly outperforms mBERT. As the dataset size decreases, it becomes more evident that mBERT is the most sample efficient, especially in the most data-scarce scenarios where only 100 finetuning examples are available. The fact that mBERT outperforms mT5 and ByT5 on smaller datasets is quite surprising, as one might expect T5 models to generalize better in low-resource settings given their much larger pretraining corpus.

Interestingly, we find that CANINE performs poorly compared to mBERT in all three tasks, and the performance gap increases as fewer finetuning data are available. To explain this phenomenon, we hypothesize that character-level models have the additional burden of learning to compose characters into semantically meaningful units and thus require more data to learn task-specific higher-level semantics. These results align with the NER results on the CoNLL and MasakhaNER dataset in Clark et al. (2022), where mBERT outperformed CANINE in all languages except Amharic, a language not covered by mBERT’s vocabulary.

However, mBERT’s stronger performance in TyDi QA-GoldP was unexpected as CANINE performed better at the TyDi QA primary tasks in Clark et al. (2022). Through replication experiments to reconcile the contradictory findings, we found that mBERT outperforms CANINE also in the primary tasks when finetuned for more epochs with our codebase, suggesting that the previous

³The pretraining corpus sizes are noted in § B.4 (Tab. 8).

⁴Hyperparameters for all experiments are in Appendix A.

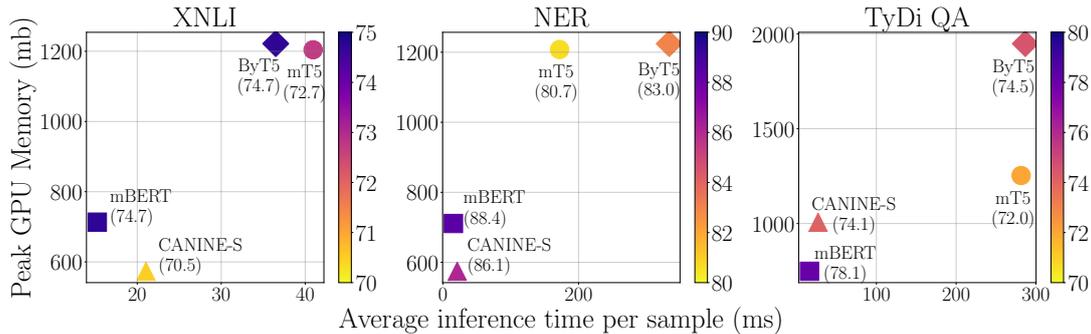

Figure 2: The inference cost of the four models (■: mBERT, ▲: CANINE, ●: mT5, ◆: ByT5) in each task. The x-axis denotes the average inference time while the y-axis shows the peak GPU memory consumption. Thus, models located near the bottom left corner are more cost efficient. The colors represent the model’s best task performance (XNLI: Accuracy, NER: F1, TyDi QA: F1). The numbers used to generate the plot can be found in § B.2 (Tab. 3).

mBERT baseline was potentially undertrained.⁵

For mT5 and ByT5, we find that the two models perform comparably in smaller datasets, while on larger sets, ByT5 consistently outperforms mT5 on all tasks. We note that the mT5-Small model could have been penalized in terms of capacity as 85% of the parameters are allocated to embeddings as shown in Tab. 1, leaving only 44M parameters for the non-vocabulary layers. This is even less than that of mBERT (86M), and drastically smaller compared to ByT5-Small, which assigns 298.5M parameters to the non-vocabulary layers. Also, given that the tasks concerned are not generation-heavy, the extra depth on the encoder (12 for ByT5 vs. 8 for mT5) might have favored ByT5 over mT5.

4.2 Inference cost

Another key concern in utilizing pretrained models for downstream applications is the inference cost, such as memory consumption and latency. In Fig. 2, we plot each model’s inference latency and peak memory consumption, color-coding their task performance to provide a comprehensive view of the trade-offs of deploying each model in practice.

In general, the encoder-only models, mBERT and CANINE, require much less memory and inference latency than mT5 and ByT5. Considering performance alongside inference cost, we find that mBERT is still the most practical choice among the four models, achieving the best performance while maintaining a relatively low inference cost.

While producing longer sequences than mBERT, CANINE does not necessarily incur higher memory or latency costs, as it has fewer parameters than mBERT. This helps CANINE, especially in sentence-level tasks (XNLI, NER) where inputs are

relatively shorter. However, for tasks with much longer inputs (TyDi QA), the computational overhead from the sequence length dominates the parameter reduction, leading to higher memory usage and slower inference for CANINE.

For mT5 and ByT5, inference costs vary according to the task’s input and output length. For tasks with shorter inputs and outputs like XNLI, ByT5 yields better performance than mT5 while retaining similar costs. However, for token-level prediction tasks like NER, ByT5 needs to generate tags autoregressively at the byte level, which drastically slows down the inference time. However, the additional cost is negligible in terms of memory consumption as the inputs are still relatively short. For TyDi QA, we observe an opposite pattern. As the input is a long passage, the extended input sequence significantly increases the memory consumption of ByT5, requiring more effort in tuning the batch size to fit into the GPU memory.

5 Related work

Large-scale NLP models have achieved remarkable performance in various natural language tasks, with the recent ChatGPT demonstrating near human-level language understanding capabilities. While achieving impressive results in standard benchmark settings, the applicability of these models have remained limited mainly due to practical considerations including their high energy consumption and environmental impact (Strubell et al., 2019). Both the NLP and computer vision communities have proposed evaluating models based on practical metrics, such as training/inference efficiency (Canziani et al., 2016; Dehghani et al., 2021; Zhou et al., 2021), energy usage (Henderson et al., 2020), robustness (Ribeiro et al., 2020; Kiela et al.,

⁵We include the finetuning code in our released codebase.

2021; Koh et al., 2021), and expected performance (Dodge et al., 2019). Similarly, a recent study by Liang et al. (2022) suggests a comprehensive evaluation suite for generative NLP models, including measures of robustness, fairness, and efficiency. Our multi-dimensional evaluation is an attempt to expand these evaluation protocols to *multilingual* settings and examine the trade-offs of various tokenization schemes.

6 Conclusion

In this paper, we present a multi-dimensional evaluation of tokenizer-free multilingual models focusing on their efficiency against finetuning dataset size and inference cost. Based on our experiments, we find that mBERT might still be the most cost-effective choice for many tasks, and show that the efficiency trade-offs of model design choices (tokenization, decoder availability) depend heavily on the task’s length statistics. Despite our findings, tokenizer-free models still have a significant advantage in reducing engineering effort and potentially increasing robustness to noisy data. We believe more work should be done in developing *efficient* tokenizer-free models, and encourage the community to consider these criteria of practical applicability when developing and evaluating tokenizer-free pretrained models.

7 Limitations

This paper mainly covers three NLP tasks, focusing on smaller-sized multilingual pretrained models. In future work, it would be interesting to run the multi-dimensional evaluation we suggest on a broader set of tasks and models. Although our results show that subword models are a more practical choice in some tasks, we note that other tasks or datasets may exist where tokenizer-free methods achieve better relative performance. For instance, tokenizer-free models have been reported to excel in word-level tasks, and noisy environments (Xue et al., 2022), and the conclusions we reached may be different in such settings. Moreover, we did not explore more complicated generation tasks like translation or summarization, where the difficulty in decoding and longer decode horizons could paint a different picture in a multi-dimensional evaluation.

Ethics Statement

We hope our results encourage the community to consider the practical concerns of running large lan-

guage models (LLMs) and designing tokenizer-free pretrained models. As the state-of-the-art LLMs are becoming more computationally extensive, it has become increasingly difficult for researchers and practitioners with less resources to utilize these models for downstream applications. We hope our multi-dimensional analysis can help researchers and practitioners with less computational resources decide which model to use in practice.

Acknowledgements

We acknowledge Kakao Enterprise for providing the compute resources for this work. We would like to thank Sanket Vaibhav Mehta, Daniel Fried, Saujas Vaduguru, and the anonymous reviewers for their valuable comments and feedback. Additionally, we would like to thank Jon Clark for answering questions related to the CANINE model. This work was supported in part by grant #2040926 from the National Science Foundation as well as the CMU-Portugal MAIA project.

A Tasks

For all tasks and models, we refer to the original papers' codebase for hyperparameters.⁶⁷⁸

XNLI For encoder-only models, the first token ([CLS]) is used to map the sentence representation to the label distribution. For encoder-decoder models, we generate the index of the label (e.g., '0') directly.

NER For encoder-decoder models, we follow the input-output format (e.g., input: 'tag: rick and morty are cool .', output: 'PER: rick \$\$ PER: morty') specified in the mT5 model's original codebase.

Abstract

Neural ranking (NR) has become a key component for open-domain question-answering in order to access external knowledge. However, training a good NR model requires substantial amounts of relevance annotations, which is very costly to scale. To address this, a growing body of research works have been proposed to reduce the annotation cost by training the NR model with weak supervision (WS) instead. These works differ in what resources they require and employ a diverse set of WS signals to train the model. Understanding such differences is crucial for choosing the right WS technique. To facilitate this understanding, we provide a structured overview of standard WS signals used for training a NR model. Based on their required resources, we divide them into three main categories: (1) only documents are needed; (2) documents and questions are needed; and (3) documents and question-answer pairs are needed. For every WS signal, we review its general idea and choices. Promising directions are outlined for future research.

1 Introduction

Open-Domain Question Answering (ODQA) aims to provide precise answers in response to the user’s questions by drawing on a large collection of documents (Voorhees et al., 1999). The majority of modern ODQA models follow the retrieve(-rerank)-read architecture: 1) given a question, a set of relevant documents are selected from a large document collection, and 2) the reader model produces an answer given this selected set and the question (Chen et al., 2017; Verga et al., 2021; Lee et al., 2021). Compared with parametric models without access to external knowledge, this architecture can better adapt to updated knowledge, offer easier interpretation and reduce hallucination (Zhu et al., 2021a; Shuster et al., 2021; Guo et al., 2022).

Conventional methods use sparse retrievers (SRs) such as TF-IDF and BM-25 in the first stage

Table 1: Overview of different weak-supervision signals, together with their required resources, that we can apply to train NR models for open-domain question-answering.

to match questions and documents via lexical overlap (Robertson and Walker, 1994), a process that may overlook semantically relevant documents with low lexical overlap with the question. Neural ranking (NR) models resolve this issue by encoding the questions and documents into dense vectors so that synonyms and paraphrases can be mapped to similar vectors through task-specific fine-tuning (Das et al., 2019; Karpukhin et al., 2020). However, training good NR models requires substantial amount of relevance annotations to perform competitively and NR models have been found to generalize poorly across domains (Thakur et al., 2021; Ren et al., 2022). In practice, collecting question-document relevance annotations is time-consuming. For a given question, an extensive annotation effort may be required to find the relevant documents. Repeating this annotation for every language and domain is not feasible (Shen et al., 2022c).

To reduce annotation costs, many techniques have been proposed to train NR models with *weak supervision (WS) signals* instead. This survey aims to provide a clear taxonomy to characterize these WS signals based on their required resources. There are three common resources that can be leveraged: (1) **Document** set, which is a bare minimum for building a ODQA system; (2) **Questions** without ground-truth relevance or answer annotations;

(3) **Question-Answer (QA) Pairs**, which are a set of already answered questions. Different applications have different levels of resource availability. For example, common domains such as e-commerce normally already have large amounts of question-answer pairs from customer services while smaller domains or low-resource languages can only have a document set without any existing questions. For each level of resource availability, we review the applicable WS signals. An overview can be seen in Table 1.

While there have been surveys that describe general neural information retrieval (IR) approaches (Mitra et al., 2018; Guo et al., 2020; Lin et al., 2021a; Zhu et al., 2021a; Guo et al., 2022), we focus specifically on the low-resource scenarios, which makes our contribution unique in this respect. The closest to our work is the BEIR benchmark for zero-shot cross-domain evaluation of IR models (Thakur et al., 2021) and its multiple related studies (Mokrii et al., 2021; Reddy et al., 2021; Wang et al., 2022; Ren et al., 2022). Nonetheless, these studies test specific algorithms but do not provide a holistic overview of how they are related. Our survey can be useful in that: (1) future WS research can use it as a reference book to compare with similar techniques. (2) It can serve as a practical guide for choosing the best WS signals to train NR models given different availability levels of resources. (3) As the retrieve(-rerank)-read paradigm is generic and has been increasingly popular across NLP tasks like machine translation (He et al., 2021) and intent detection (Mehri and Eric, 2021), it can have broader impact in many other applications. Therefore, although this survey illustrates with the use case of ODQA, *the introduced techniques are intended to go beyond specific applications.*

In the following sections we first lay out the necessary background knowledge (§2), then explain popular WS signals when different resources are available in sections 3 to 5. In conclusion, we highlight promising directions for future work (§6).

2 Background

Neural Ranking (NR) for ODQA Let Q , D and A denote the question, document and answer set. Given a question $q \in Q$, the NR model assigns a relevance score $\mathcal{R}(q, d)$ to each $d \in D$ and selects top- k document $D_{topk} \in D$ with the highest relevance scores. Afterwards, a reader will estimate the score $\mathcal{G}(a|q, D_{topk})$ to predict the final

answer $a \in A$ conditioned on both q and D_{topk} . The NR model can be implemented using various architecture with increasing model complexity. For computational efficiency, normally a bi-encoder architecture (Bromley et al., 1993) is first applied to pre-select top candidates from the whole document set, then a more complex cross-interaction model is applied to provide more accurate relevance scores only for the preselected candidates (Lee et al., 2021). The training objective for the NR model \mathcal{R} can be formalized as:

$$\min_{\mathcal{R}} \mathbb{E}_{q, d^+, d_{1 \sim n}^- \in Q \times D} \mathcal{L}(\mathcal{R}, q, d^+, d_{1 \sim n}^-) \quad (1)$$

where $Q \times D$ indicates the full set of question-document pairs, d^+ is a positive (relevant) document for q , $d_{1 \sim n}^-$ is the sampled n negative (irrelevant) documents and \mathcal{L} is the loss function. A common choice for \mathcal{L} is the contrastive loss:

$$\mathcal{L} = -\log \frac{e^{\mathcal{R}(q, d^+)}}{e^{\mathcal{R}(q, d^+)} + \sum_{j=1}^n e^{\mathcal{R}(q, d_j^-)}} \quad (2)$$

Neural Ranking with Weak Supervision In the standard supervised setting we need relevance annotations for $(q, d) \rightarrow \{+, -\}$ to train \mathcal{R} with Eq 1. Obtaining high-quality relevance annotations requires tremendous human labor and is expensive to scale to multiple domains (Del Tredici et al., 2021; Ram et al., 2022). Weak supervision (WS) is a widely-used approach to reduce such cost by leveraging supervision signals from e.g., heuristic rules, knowledge bases or external models (Zhang et al., 2021). WS signals are cheap to obtain but might contain significant noise which will affect the NR performance. Therefore, understanding their working mechanisms and pros and cons are important to obtain a good NR model. We group WS signals into 3 classes by the resources that they need: (1) *Documents*: only document collection D is needed; (2) *Documents + Questions*: document collection D and question set Q are needed; (3) *Documents + QA Pairs*: document collection D and QA pairs (Q, A) are needed. In the next section, we will present the three classes of WS signals and discuss their pros and cons.

3 Resource: Documents

This section discusses two main techniques to produce WS signals requiring only the document set: (1) self-contrastive learning and (2) question generation. This makes the minimum assumption about

Method	Pseudo Question
Perturbation	d with added perturbation
Summary	(Pseudo) summary of d
Proximity	Nearby text of d
Cooccurrence	Text sharing cooccurred spans with d
Hyperlink	Text with a hyperlink to/from d

Table 2: Given a document d , different heuristics to construct pseudo questions. Contrastive samples made from these heuristics serve as WS signals to train the NR model.

resource availability since having the document set is a prerequisite for building an ODQA system.

3.1 Self Contrastive Learning

Self contrastive learning relies on heuristics to construct pseudo question-document pairs $(q', d'^{+/-})$ from D , then uses them to supervise training of a NR model. The objective is:

$$\min_{\mathcal{R}} \mathbb{E}_{q', d'^+, d'_{1 \sim n}^- \in D} \mathcal{L}(\mathcal{R}, q', d'^+, d'_{1 \sim n}^-) \quad (3)$$

where \mathcal{L} is the ranking loss as in Eq 1. Since negative pairs can be easily constructed by random sampling, the main difficulty is to design good heuristics for constructing positive pseudo pairs (q', d'^+) . There are 5 popular heuristics to construct such positive pairs: perturbation-based, summary-based, proximity-based, cooccurrence-based and hyperlink-based. An overview is in Table 2.

Perturbation-based heuristics add perturbations to some text, then treat the perturbed text and the original text as a positive pair. The intuition is that *perturbed text should still be relevant to the original text*. Typical choices of perturbations include word deletion, substitution and permutation (Zhu et al., 2021b; Meng et al., 2021), adding drop out to representation layers (Gao et al., 2021), or passing sentences through different language models (Carlsson et al., 2021), among other.

Summary-based heuristics extract a summary from the document as the pseudo question based on the intuition that *questions should contain representative information about the central topic of the document*. The summary can be the document title (MacAvaney et al., 2017, 2019; Mass and Roitman, 2020), a random sentence from the first section of the document (Chang et al., 2020), randomly sampled ngrams (Gysel et al., 2018) or a set

of keywords generated from a document language model (Ma et al., 2021a).

Proximity-based heuristics utilize the position information in the document to obtain positive pairs based on the intuition that *nearby text should be more relevant to each other*. The most famous one is the inverse-cloze task (Lee et al., 2019), where a sentence from a passage is treated as the question and the original passage, after removing the sentence, is treated as a positive document. They can be combined with typical noise injection methods like adding drop-out masks (Xu et al., 2022), random word chopping or deletion (Izacard et al., 2021) to further improve the model robustness. Other methods include using spans from the same document (Gao and Callan, 2022; Ma et al., 2022), sentences from the same paragraph, paragraphs from the same document as positive samples (Di Liello et al., 2022), etc.

Cooccurrence-based heuristics construct positive samples based on the intuition that *sentences containing cooccurred spans are more likely to be relevant* (Ram et al., 2021). For example, Glass et al. (2020) constructs a pseudo question with a sentence from the corpus. A term from it is treated as the answer and replaced with a special token. Passages retrieved with BM25 which also contains the answer term are treated as pseudo positive documents. Ram et al. (2022) treat a span and its surrounding context as the pseudo question and use another passage that contains the same span as a positive document.

Hyperlink-based heuristics leverage hyperlink information based on the intuition that *hyperlinked text are more likely to be relevant* (Zhang et al., 2020; Ma et al., 2021b). For example, Chang et al. (2020) takes a sentence from the first section of a page p as a pseudo question because it is often the description or summary of the topic. A passage from another page containing hyperlinks to p is treated as a positive document. Yue et al. (2022a) replace an entity word with a question phrase like “what/when” to form a pseudo question. A passage from its hyperlinked document that contains the same entity word is treated as a positive sample. Zhou et al. (2022) build positive samples with two typologies: “dual-link” where two passages have hyperlinks pointed to each other, and “co-mention” where two passages both have a hyperlink to the same third-party document.

Input	Document Document + Answer Document + Answer + Question Type Document + Answer + Question Type + Clue
Question Generator	Rule-based Generator Prompt-based Generator Fine-tuned Generator [◊]

Table 3: Different choices for a question generation model setup. [◊] means minimal relevance annotations are needed.

3.2 Question Generation

Self contrastive learning relies on sentences already present in D . Question generation leverage a question generator (QG) to generate new questions *not found* in D , which can then be used to provide WS signals for the NR model. It often employs a filter Fil to filter poorly generated questions. The training objective is:

$$\min_{\mathcal{R}} \mathbb{E}_{q=QG(d^+) \& Fil(q, d^+) = 0} \mathcal{L}(\mathcal{R}, q, d^+, d_{1 \sim n}^-)$$

where the expectation is with respect to documents d^+ and $d_{1 \sim n}^-$ drawn from D , the q are generated from d^+ , $Fil(q, d^+) = 0$ requires that these questions not be discarded by Fil , and \mathcal{L} is the standard ranking loss. There are various ways of designing the question generator and filter. We will cover the popular choices in the following section. An overview can be seen in Table 3.

Choices of Input A variety of information can be provided as input for the QG. The most straightforward approach is answer-agnostic which provides only the document (Du and Cardie, 2017; Kumar et al., 2019). In this way, the model can choose to attend to different spans of the document as potential answers and so generate different, corresponding questions. A more common method is answer-aware where an answer span is first extracted from a document, then the QG generates a question based on both the document and answer (Alberti et al., 2019; Shakeri et al., 2020). Finer-grained information can also be provided such as the question type (“what/how/...”) (Cao and Wang, 2021; Gao et al., 2022) as well as additional clues (such as document context to disambiguate the question) (Liu et al., 2020). Adding more information reduces the entropy of the question and

makes it easier for the model to learn, but also increases the possibility of error propagation (Zhang and Bansal, 2019). In practice, well-defined filters should be applied to remove low-quality questions.

Choices of Question Generator There are three popular choices for the question generator. (1) Rule-based methods (Pandey and Rajeswari, 2013; Rakangor and Ghodasara, 2015) rely on hand-crafted templates and features. These are time-consuming to design, domain-specific, and can only cover certain forms of questions. (2) Prompt-based methods relying on pre-trained language models (PLMs). Documents can be presented to a PLM, with an appended prompt such as “Please write a question based on this passage” so that the PLM can continue the generation to produce a question (Bonifacio et al., 2022; Sachan et al., 2022; Dai et al., 2022). (3) Fine-tuned generators that are trained on annotated question-document pairs. When in-domain annotations are not enough, we can leverage out-of-domain (OOD) annotations, if any, to fine-tune the QG. The first two QGs require no training data, but their quality is often inadequate. In practice, we should only consider them when *there is a complete lack of high-quality supervised data for fine-tuning the QG*. When target-domain questions are available, we can also apply semi-supervised techniques such as back-training to adapt the QG to the target domain (Zhao et al., 2019; Kulshreshtha et al., 2021; Shen et al., 2022a).

Choices of Filter Filtering is a crucial part of QG since a significant portion of generated questions could be of low quality and would provide misleading signals when used to train the NR model (Alberti et al., 2019). A typical choice is filtering based on round-trip consistency (Alberti et al., 2019; Dong et al., 2019), where a pre-trained QA system is applied to produce an answer based on the generated question. A question is kept only when the produced answer is consistent with the answer from which the question is generated. We can also relax this strict consistency requirement and manually adjust an acceptance threshold based on the probability from the pre-trained QA system (Zhang and Bansal, 2019; Lewis et al., 2021), LM score from the generator itself (Shakeri et al., 2020; Liang et al., 2020), or an entailment score from a model trained on question-context-answer pairs (Liu et al., 2020). Influence functions (Cook and Weisberg, 1982) can be used to estimate the

effect on the validation loss of including a synthetic example (Yang et al., 2020), but this does not achieve satisfying performances on QA tasks (Bartolo et al., 2021). Bartolo et al. (2021) propose filtering questions based on ensemble consistency, where an ensemble of QA models are trained with different random seeds and only questions agreed by most QA models are selected. When minimal target-domain annotation is available, we can also learn to reweight pseudo samples based on the validation loss (Sun et al., 2021), or use RL to select samples that lead to validation performance gains (value estimation) (Yue et al., 2022b).

3.3 Discussion

If the heuristics or QG are properly designed, NR models trained from their supervision can even match the fully-supervised performance (Wang et al., 2022; Ren et al., 2022). The biggest challenge is the difficulty to pick the most suitable heuristics or QG when we face a new domain. A general solution is to automatically select good pseudo pairs with reinforcement learning (RL) when minimal target-domain annotations are available (Zhang et al., 2020), so as avoiding the need to manually fixing the WS signals, but this would bring significant computational overhead. In practice hyperlink-based approaches often perform the best among the heuristics as they have additional reference information to leverage, which makes them most similar to the actual relevance annotations. However, hyperlink information is not available in most domains and thereby limits its use cases (Sun et al., 2021). QG-based WS signals are often preferred over heuristics-based ones as they can produce naturally-sound questions themselves without relying on the chance to find good pseudo questions in the documents. Nonetheless, obtaining a high-performing QG can also be non-trivial. One big challenge comes from the one-to-many mapping relations between questions and documents. Under this situation, standard supervised learning tends to produce safe questions with less diversity and high lexical overlap with the document. For example, Shinoda et al. (2021) found that QG reinforces the model bias towards high lexical overlap. We will need more sophisticated training techniques such as latent-variable models (Shen and Su, 2018; Xu et al., 2020; Li et al., 2022) and reinforcement learning (Yuan et al., 2017; Zhang and Bansal, 2019; Shen et al., 2019a) to alleviate the

model bias towards safe questions.

4 Resource: Documents + Questions

This section includes WS signals that require additional access to a question set Q . In practice, annotating question-document relations usually requires domain experts to read long documents and careful sampling strategies to ensure enough positive samples, while unlabeled questions are much easier to obtain either through real user-generated content or simulated traffic. Therefore, it is common to have a predominance of unlabeled questions. The crucial point is to establish the missing relevance labels. Suppose a WS method can provide the missing label $WS(q, d)$ for a question-document pair (q, d) , then we can use it to supervise the NR model by:

$$\min_{\mathcal{R}} \mathbb{E}_{q \in Q, d \in D} \mathcal{L}(\mathcal{R}(q, d), WS(q, d)) \quad (4)$$

where \mathcal{L} is the loss function that encourages similarity between $\mathcal{R}(q, d)$ and $WS(q, d)$.

There are three popular types models that can provide such WS signal here: (1) sparse retriever, (2) pre-trained language model and (3) supervised teacher model.

Sparse Retriever (SR) Recent research finds that NR and SR models are complementary. NR models are better at semantic matching while SRs are better at capturing exact match and handling long documents (Chen et al., 2021; Luan et al., 2021). SRs are also more robust across domains (Thakur et al., 2021; Chen et al., 2022). This motivates the use of unsupervised sparse retrievers like BM25 as WS signals. For example, Dehghani et al. (2017); Nie et al. (2018) train a NR model on samples annotated with BM25. Xu et al. (2019) apply four scoring functions to auto-label questions and documents with: (1) BM25 scores, (2) TF-IDF scores, (3) cosine similarity of universal embedding representation (Cer et al., 2018) and (4) cosine similarity of the last hidden layer activation of pre-trained BERT model (Devlin et al., 2019). Both papers observe that the resulting model outperforms BM25 on the test sets. Chen et al. (2021) further show that distilling knowledge from BM25 helps the retriever to better match rare entities and improves zero-shot out-of-domain performance.

Pre-trained Language Model (PLM) As PLMs already encode significant linguistic knowledge, there have also been attempts at using prompt-based PLMs to provide WS signals for question-

document relations (Smith et al., 2022; Zeng et al., 2022). Similar as in question generation, we can use prompts like “Please write a question based on this passage”, concatenate the document and question, then use the probability assigned by the PLM to auto-label question-document pairs. To maximize the chances of finding positive document, normally we first obtain a set of candidate documents by BM25, then apply PLM to auto-label the candidate set (Sachan et al., 2022). This can further exploit the latent knowledge inside PLMs that has been honed through pre-training, so it often shows better performance compared with weak supervision only using BM25 (Nogueira et al., 2020; Singh Sachan et al., 2022).

Supervised Teacher Model A very common choice is using a supervised teacher model to provide WS signals. The teacher model is “supervised” because it is explicitly fine-tuned on annotated question-document pairs. When in-domain annotations are not sufficient, we can leverage out-of-domain (OOD) annotations, if available, to train the teacher model. The teacher model usually employs a more powerful architecture such as with more complex interactions or larger sizes. It may not be directly applicable in downstream tasks due to the latency constraints, but can be useful in providing WS signals for training the NR model. For example, previous research has shown that models with larger sizes or late/cross-interaction structures generalize much better on OOD data (Pradeep et al., 2020; Lu et al., 2021; Ni et al., 2021; Rosa et al., 2022; Muennighoff, 2022; Zhan et al., 2022). After training a teacher model on OOD annotations, applying it to provide WS signals through target-domain question and document collections can significantly improve the in-domain performance of the NR model (Hofstätter et al., 2021; Lin et al., 2021b; Lu et al., 2022). Kim et al. (2022) further show that we can even use the same architecture and capacity to obtain a good teacher model. They expand the question with centroids of word embeddings from top retrieved passages (using BM25), and then use the expanded query for self knowledge distillation. Similar ideas of reusing the same architecture to provide WS signals have also been explored by Yu et al. (2021a); Kulshreshtha et al. (2021); Zhuang and Zuccon (2022).

Discussion The three WS signals listed above work directly on actual questions instead of pseudo

pairs as in §3 so that the NR model can adapt better to the target-domain question distribution. The bottleneck is the quality of the WS signals. SRs and PLMs are unsupervised, which could be more robust when we face a completely different domain (Dai et al., 2022). Otherwise, if we already have certain amounts relevance annotations from the target or similar domains, usually using a supervised teacher model is preferred. Nevertheless, these WS signals inevitably contain noise, and can harm the downstream performance if the noise is significant. There are two main strategies to reduce the noise effects: (1) Apply less strict margin-based loss such as the hinge loss (Dehghani et al., 2017; Xu et al., 2019) and MarginMSE loss (Hofstätter et al., 2020; Wang et al., 2022), then models have fewer chances of overfitting to the exact labels, and (2) Apply noise-resistant training methods such as confidence-based filtering (Mukherjee and Awadallah, 2020; Yu et al., 2021b) and meta-learning-based refinement (Ren et al., 2018; Zhu et al., 2022). Another potential issue is that the amount of training data in this section relies on the amount of questions we have. Unlike the document set which we can obtain for free, the question set takes time to collect and are often orders of magnitudes smaller. If no sufficient questions are available, we can use synthetic questions from question generation, then apply same WS signals in this section, which has been shown to perform on par with using real questions in certain domains (Wang et al., 2020, 2022; Thakur et al., 2022).

5 Resource: Documents + QA Pairs

Many domains have large numbers of already answered questions from customer services, technical support or web forums (Huber et al., 2021). These QA pairs can provide richer information than only unlabeled questions. However, most answers are based on personal knowledge, derived from experience, and do not include a reference to any external document. This prevents their direct use as training data for the NR model. This section introduces three standard methods that exploit QA pairs to provide WS signals despite this difficulty: (1) Answer as document, (2) Answer-document mapping and (3) Latent-variable models.

5.1 Answer as a Document

As a straightforward way to leverage QA pairs, this method directly treats QA pairs as positive samples

and does not distinguish between documents and answers (Lai et al., 2018). These QA pairs can provide direct WS signals to train the NR model:

$$\min_{\mathcal{R}} \mathbb{E}_{q, a^+, a_{1 \sim n}^- \in Q \times A} \mathcal{L}(\mathcal{R}, q, a^+, a_{1 \sim n}^-) \quad (5)$$

where $(q, a^+) \in Q \times A$ are question-answer pairs in the target domain, $a_{1 \sim n}^-$ are sampled n negative answers and \mathcal{L} is the standard ranking loss.

Though simple, this has been a common practice to “warm up” the NR model when no sufficient relevance annotations are available. For large-sized models, this can be crucial to fully leverage the model capacity since we often have orders of magnitude more QA pairs than relevance annotations (Ni et al., 2021; Oğuz et al., 2021). However, the style, structure and format differ between the document and the answer. The answer is a direct response to the question, and so it is easier to predict due to its strong semantic correlation with the question. Whereas the document can be implicit and may contain fewer obvious clues that can imply an answer; deep text understanding is required to predict the relevance between questions and documents (Zhao et al., 2021; Shen et al., 2022b). Therefore, this approach may be insufficient to reach satisfying results as a standalone method.

5.2 Answer-document Mapping

This approach leverages an additional mapping function to automatically link answers to the corresponding documents. The NR model can get WS signals from the linked answers:

$$\min_{\mathcal{R}} \mathbb{E}_{q, a \in (Q, A), d_{1 \sim n}^- \sim D} \mathcal{L}(\mathcal{R}, q, M(a), d_{1 \sim n}^-)$$

where $(q, a) \in (Q, A)$ are question-answer pairs, M is a mapping function from an answer to its corresponding document, and \mathcal{L} is the standard ranking loss. The mapping function is based on hand-crafted heuristics. For long-form descriptive answers, a popular way is to map them to documents with highest ROUGE scores (Lin, 2004) since the answers can be considered as summaries of the original documents (Fan et al., 2019). For short-span answers, a popular way is to map them to top-ranked documents retrieved using BM25 that contain the answer span (Karpukhin et al., 2020; Sachan et al., 2021; Christmann et al., 2022).

Answer-document mapping was widely adopted for constructing large-scale datasets in information retrieval (Joshi et al., 2017; Dunn et al., 2017; Elgohary et al., 2018). This can work well if the

Distribution of $\mathcal{R}(z q)$	Optimization Method
Categorical	Top- k approximation
Multinomial	EM algorithm
	Learning from attention

Table 4: Distribution assumptions made about the neural ranker and corresponding optimization methods, suppose we train the NR model following Equation 6.

mapping has high accuracy, which is often difficult to achieve. Frequent answers or entities might lead to false positive mappings. It is also difficult to find positive documents for boolean and abstractive answers using only heuristics-based mapping functions (Izacard and Grave, 2021). Models can easily overfit to the biases introduced via such mapping function (Du et al., 2022).

5.3 Latent-Variable Model

We can still train the NR model on question-document pairs as in Answer-Document Mapping. However, instead of relying on a heuristic-based mapping function, we can treat this mapping as a “latent variable” within a probabilistic generative process (Lee et al., 2019; Shen, 2022). By this means, the NR model \mathcal{R} gets WS signals from the QA reader \mathcal{G} by maximizing the marginal likelihood:

$$\max_{\mathcal{R}, \mathcal{G}} \mathbb{E}_{q, a \in (Q, A)} \log \sum_{z \sim Z} \mathcal{R}(z|q) \mathcal{G}(a|q, z) \quad (6)$$

where Z indicates all possible document combinations. Directly optimizing over Eq 6 is infeasible as it requires enumerating over all documents. A closed-form solution does not exist due to the deep neural network parameterization of \mathcal{R} and \mathcal{G} . The following section explains popular optimization options. An overview can be seen in Table 4.

Top- k approximation A popular approach is to assume a categorical distribution for $\mathcal{R}(Z|q)$; that is, to assume for each question only a single document is selected and the answer is generated from that one document. Eq 6 can be approximated by enumerating over only the top- k documents, assuming the remaining documents having negligibly small contributions to the likelihood:

$$\max_{\mathcal{R}, \mathcal{G}} \mathbb{D}_{q, a \in (Q, A)} \log \sum_{z \sim E_{topk}} \mathcal{R}(z|q) \mathcal{G}(a|q, z)$$

This has been a popular choice in end-to-end training of text generation models (Lee et al., 2019; Shen et al., 2019b; Guu et al., 2020; Lewis et al.,

2020; Shuster et al., 2021; Ferguson et al., 2022). Despite its simplicity, the top- k approximation has two main drawbacks. (1) The approximation is performed on the top- k documents obtained from the NR model. If the NR model is very weak at the beginning of training, these top- k documents can be a bad approximation to the real joint likelihood and the model might struggle to converge. (2) The assumption that document follow a categorical distribution might be problematic especially if the answer requires evidence from multiple documents (Wang and Pan, 2022).

Expectation–Maximization (EM) algorithm

To address the second drawback of the top- k approximation approach, we can assume a multinomial distribution for $R(Z|q)$ so that an answer can be generated from multiple documents. The cost of this relaxation is the increased difficulty of optimization. Approximating the joint likelihood from top- k samples becomes infeasible due to the combinatorial distribution of document. Singh et al. (2021) propose optimizing it with the EM algorithm under an independent assumption about the posterior distribution of $\mathcal{R}(z|q)$:

$$\begin{aligned} \max_{\mathcal{R}, \mathcal{G}} \mathbb{E}_{q, a \in (Q, A)} [\log \sum_{z \in D_{topk}} \mathcal{R}(z|q) \\ \times SG(\mathcal{G}(a|q, z)) + \log \mathcal{G}(a|q, D_{topk})] \end{aligned} \quad (7)$$

where SG means stop-gradient (gradients are not backpropagated through \mathcal{G}). As can be seen, the training signal for the NR model is essentially the same as in the *Top-k Approximation* case, except that the reader is trained by conditioning on all top- k documents to generate the answer. Singh et al. (2021) also find that Eq 7 is quite robust with respect to parameter initialization. Similarly, Zhao et al. (2021) apply the hard-EM algorithm to train the NR model, which only treats documents with the highest likelihood estimated by the reader as positive. Izacard et al. (2022) further experiment with using the leave-one-out perplexity from the reader to supervise the ranker.

Learning from attention Another way to optimize the NR model in Eq 6 is to leverage attention scores from the reader \mathcal{G} . The assumption is that when training \mathcal{G} to generate the answer, its attention score is a good approximation of question-

document relevance. The training objective is:

$$\begin{aligned} \min_{\mathcal{R}, \mathcal{G}} \mathbb{E}_{q, a \in (Q, A)} \sum_{z \sim E_{topk}} \mathcal{L}(A_z | \mathcal{R}(z|q)) \\ - \log \mathcal{G}(a|q, Z = D_{topk}) \end{aligned} \quad (8)$$

where \mathcal{G} is trained to generate the right answer based on the question and the top- k document, same as in the EM algorithm. A_z is the attention score of \mathcal{G} on the document z . \mathcal{L} is the loss function to encourage the similarity between distributions of the attention scores and retrieving scores.

Izacard and Grave (2021) propose a training process that optimizes \mathcal{R} and \mathcal{G} iteratively. \mathcal{R} is trained to minimize KL divergence between relevance and attention scores. (Lee et al., 2021) jointly optimize \mathcal{R} and \mathcal{G} and apply a stop-gradient operation on \mathcal{G} when updating \mathcal{R} . Sachan et al. (2021) use retriever scores to bias attention scores on the contrary. These can be considered as first-order Taylor series approximations of Eq. 6 by replacing $\mathcal{R}(Z|q)$ with attention scores (Deng et al., 2018).

Discussion Training with latent-variable models can perform close to fully supervised models under certain scenarios (Zhao et al., 2021; Sachan et al., 2021). The main challenge is the training difficulty. In practice, we can often initialize the NR model using the *answer as document* or *answer-document mapping* to make the training more stable. If not enough QA pairs are available, we can use heuristics like masked salient entities (Guu et al., 2020) to form pseudo pairs, then apply the same WS techniques in this section. Combining supervision signals from various various optimization techniques such as learning from attention and EM algorithm can also be beneficial (Izacard et al., 2022). If the independence assumption made by Eq 7 does not hold, we need to resort to more complex optimization algorithms. A potential direction is to apply a Dirichlet prior over $R(z|q_i)$, which is a conjugate distribution to the multinomial distribution (Minka, 2000), with the result that the sampled document are not independent individuals but a combination set. Eq 6 can then be estimated by rejection sampling (Deng et al., 2018) or a Laplace approximation (Srivastava and Sutton, 2017) so as to avoid the independence assumption about the posterior distribution. Nonetheless, this will further increase the training complexity, which is already a key bottleneck for training the NR model.

6 Conclusions

We review standard WS signals used for training NR models in ODQA and provide a structured way of classifying them according to the required resource. For WS signal, we discuss different options and summarize the pros and cons. As a final wrap-up, we list promising directions that we believe worth exploring further: (1) *How to select the most suitable technique for a given scenario?* Despite the wide range of applicable techniques, it is non-trivial to decide how to select the best one except for an empirical experimentation. (2) *To which extent are these techniques complementary?* Existing work compares performance only between similar types of methods but not across the whole range of techniques and resources available. This makes it hard to decide whether different approaches could potentially complement each other and how they should be combined effectively. (3) *Do methods work across languages?* The vast majority of current research is conducted on English datasets. Even though all described methods in this survey have no explicit restrictions on languages they can be applied to, it is likely that their performance will vary across languages, especially for the methods relying on handcrafted heuristics.

Limitations

This survey covers introductions and related work of major WS algorithms used for neural ranking. Due to the space limit, most methods included in this paper are brief. Readers might not have a good understand on all the introduced methods. Interested readers can refer to existing surveys about general knowledge in QA (Zeng et al., 2020; Zhu et al., 2021a; Roy and Anand, 2021; Rogers et al., 2021; Pandya and Bhatt, 2021). Furthermore, we did not provide points to existing ODQA datasets and the performance of recent models. The conclusions in this survey also come from summaries of previous works. The lack of datasets including various resources needed for different WS algorithms prevents a comprehensive, fair comparison across algorithms. We hope future research can work on the creation of more datasets with various availabilities of resources in different domains to enable this comparison. Lastly, we aim to create a big picture from the technology level, so we did not strictly limit our references only to the application of ODQA. The connection to specific ODQA applications might be loose, readers would need

to extract useful information for the specific use cases.

Abstract

Recent work has shown that an answer verification step introduced in Transformer-based answer selection models can significantly improve the state of the art in Question Answering. This step is performed by aggregating the embeddings of top k answer candidates to support the verification of a target answer. Although the approach is intuitive and sound, it still shows two limitations: (i) the supporting candidates are ranked only according to the relevancy with the question and not with the answer, and (ii) the support provided by the other answer candidates is suboptimal as these are retrieved independently of the target answer. In this paper, we address both drawbacks by proposing (i) a double reranking model, which, for each target answer, selects the best support; and (ii) a second neural retrieval stage designed to encode question and answer pair as the query, which finds more specific verification information. The results on well-known datasets for Answer Sentence Selection show significant improvement over the state of the art.

1 Introduction

In recent years, automated Question Answering (QA) research has received a renewed attention thanks to the diffusion of Virtual Assistants. For example, Google Home, Siri and Alexa provide general information inquiry services, while many other systems serve customer requests in different application domains. Retrieval-based QA is enabled by two main tasks: (i) Answer Sentence Selection (AS2), which, given a question and a set of answer-sentence candidates, consists in selecting sentences (e.g., retrieved by a search engine) that correctly answer the question; and (ii) Machine Reading (MR), e.g., (Chen et al., 2017), which, given a question and a reference text, finds an exact text span that answers the question. Deploying MR

*Work done while the author was an intern at Amazon Alexa

q :	What causes heart disease?
c_1 :	Cardiovascular disease (also called heart disease) is a class of diseases that involve the heart or blood vessels (arteries, capillaries, and veins).
c_2 :	The causes of cardiovascular disease are diverse but atherosclerosis and/or hypertension are the most common.
c_3 :	Cardiovascular disease refers to any disease that affects the cardiovascular system , principally cardiac disease, vascular diseases of the brain and kidney , and peripheral arterial disease.

Table 1: A question with answer candidates.

systems in production is challenging for efficiency reasons, while AS2 models can efficiently target large text databases. Indeed, they originated from TREC QA tracks (Voorhees and Tice, 1999), which dealt with real-world retrieval systems since the first edition. Another limitation of MR is the focus on factoid answers: although it can in principle provide longer answers, the datasets developed for the task mainly contains short answers and in particular named entities. In contrast, as AS2 processes entire sentences, its inference steps always involve sentences/paragraphs, which make the approach agnostic to both factoid and not factoid classes.

Garg et al. (2020) proposed the TANDA approach, which basically uses two stage of fine-tuning on pre-trained Transformer models (using a general dataset, ASNQ, and the target dataset), obtaining impressive improvement over the state of the art for AS2, measured on the two most used datasets, WikiQA (Yang et al., 2015) and TREC-QA (Wang et al., 2007). The approach above, based on pointwise rerankers, was significantly improved by the Answer Support-based Reranker (ASR) (Zhang et al., 2021), which adds an answer verification step similar to the one operated by fact checking systems, e.g., see the FEVER challenge (Thorne et al., 2018).

More specifically, given a question q , and a target answer, t , to be verified, which is taken from a ranked set of answer candidates (c_1, \dots, c_k),

ASR concatenates transformer-based embeddings of (q, c_i) with the max-pooling vector produced by the top k embeddings of (t, c_i) , where the c_i are selected by an initial answer reranking model (e.g., TANDA). For example, Table 1 reports a question, $q = \textit{What causes heart disease?}$, with some candidate answers, c_1, c_2 , and c_3 . Selecting the correct answer c_2 is difficult, without the information: *cardiovascular disease* is also called *heart disease*. This information is provided by c_1 . Thus, to compute the correctness probability of c_1 , they exploit the representation of c_2 , similarly to the way claims are supported in the fact verification.

ASR reduced the error of TANDA by 10% (relative), both on WikiQA and TREC-QA datasets. However, ASR shows two important limitations: first, when attempting the verification step of t , the k candidates, used in the max-pooling operation, are ranked only based on the question, i.e., independently of t . Second, the support for each t is provided by other answer candidates, which again are retrieved independently of t , i.e., t is not part of the query used for searching relevant documents.

In this paper, we provide new answer verification models, which are more efficient and accurate than ASR. We introduce a new architecture, Double Answer Reranking (DAR), which uses two models for reranking target answers and supporting candidates, respectively. Given t , the first, support reranker (SR), sorts (q, t, c_i) triplets with respect to i , in order to find the best support for t , i.e., $s_t = c_i$, while the second, answer reranker (AR), orders (q, t, s_t) triplets with respect to t , thus ranking all target answers.

Additionally, we improve the quality of supports using a second retrieval stage that searches for passages relevant to (q, t) . This is important as standard answer candidates provide only information relevant to q , thus they not necessarily provide useful context for assessing t . As formulating an effective query for retrieving a question/answer pair is a new problem, and can be challenging, we exploit deep passage retrieval (DPR) (Karpukhin et al., 2020). This enables us to automatically produce embeddings for (q, t) as the target query of a neural retrieval model. As DAR is efficient, it can process many candidates from DPR, making Double Retrieval (DR) effective.

The results derived on three well-known AS2 datasets, WikiQA (Yang et al., 2015), TREC (Wang et al., 2007), and SelQA (Jurczyk et al., 2016) and

a popular multi-hop QA dataset, HotpotQA (Yang et al., 2018), show consistent and significant improvement over the state of the art. For example, DAR improves TANDA by 13.6% (relative error reduction), achieving the same accuracy of the computational expensive ASR verification approach (84.36%) while DAR-DR improves the AS2 state of the art, reducing the error by an additional 8%.

We will release the datasets augmented with DPR retrieval (support candidates) for each (q, a) of each of the datasets above.

2 Related work

We focus our research on QA systems based on Information Retrieval. Since early versions, e.g., TREC QA tracks (Voorhees and Tice, 1999), these systems have been based on a search engine, which retrieves documents relevant to the asked questions, followed efficient and accurate passage rerankers to select text that most likely contains the answer. This research was revived introducing the task of answer sentence reranking (Wang et al., 2007).

In recent work, the probability, $p(q, c_i)$, for a passage/sentence, c_i , to be correct for q is estimated using neural networks, e.g., encoding q and c_i text, separately with a CNN (Severyn and Moschitti, 2015). Also designing attention mechanisms, e.g., Compare-Aggregate (Yoon et al., 2019), inter-weighted alignment networks (Shen et al., 2017). The state of the art is achieved with pre-trained Transformers, e.g., (Garg et al., 2020).

A number of researchers has proposed more than one candidate for the inference stage, e.g., using pairwise model, i.e., binary classifiers of the form $\chi(q, c_i, c_j)$, which determine the partial rank between c_i and c_j . For example, (Laskar et al., 2020; Tayyar Madabushi et al., 2018; Rao et al., 2016) use a pairwise loss and encoding. However, these methods have been largely outperformed by the pointwise models based on Transformers.

Bonadiman and Moschitti (2020) designed several joint models that improved early neural models for AS2 but failed to improve Transformer-based models. Jin et al. (2020) used the relation between candidates in Multi-task learning approach for AS2 but as they did not exploit transformer models, their results are rather lower than the state of the art. Very recently, Zhang et al. (2021) proposed ASR, a model based on a pointwise reranker fed with the embeddings refined by a pairwise approach. This significantly improved the state of the art, there-

fore, we analyzed ASR and specifically compare our models with it.

Very different approaches to QA systems than above use MR to extract answers from entire documents. As they have been mainly developed to find answers in a paragraph or in a text of limited size, they are rather inefficient at processing hundreds of documents, while AS2 methods can do this with high efficiency. [Chen et al. \(2017\)](#); [Hu et al. \(2019\)](#); [Kratzwald and Feuerriegel \(2018\)](#) proposed solutions for reliably performing inference with MR models on multiple documents. Still, the efficiency drawback was not solved. Finally, multihop QA uses multiple retrieval stages ([Xiong et al., 2020](#); [Qi et al., 2019](#)) but the answers are just entities.

3 Baseline models for AS2

A general problem formulation for AS2 is the following: given a question q , a subset of its top- k ranked answer candidates, and a target answer $t \in C_k$, train a function, $f : Q \times C^k \rightarrow \mathbb{R}$ such that $f(q, t, c_1, \dots, c_{k-1})$ provides the probability of t to be correct. In this section, we describe our re-implementation of baselines, and the state-of-the-art model for AS2, namely, ASR ([Zhang et al., 2021](#)). More complex models are built on top of simpler ones, thus providing an ablation study.

3.1 Simple binary classifier (SBC)

This approach does not model dependencies between candidates, thus, we simply estimate $p(q, t)$, where $t = c_i, i = 1, \dots, k$ with a transformer-based model. Following ([Garg et al., 2020](#)), we set the input as $q = \text{Tok}_1^q, \dots, \text{Tok}_N^q$ and $t = \text{Tok}_1^t, \dots, \text{Tok}_M^t$, where we start and end the input with [CLS] and [EOS] tags, respectively, and separate sentences with [SEP]. The rest follows the standard transformer logic. We use [CLS] to represent the embedding \mathbf{E} of (q, t) , and we use a softmax to model the probability of the question/candidate pair classification, as $p(q, t) = \text{softmax}(W \times \tanh(E(q, t)) + B)$. We fine-tune this model with log cross-entropy loss: $\mathcal{L} = -\sum_{l \in \{0,1\}} y_l \times \log(\hat{y}_l)$ on pairs of text, where y_l is the correct and incorrect answer label, $\hat{y}_1 = p(q, t)$, and $\hat{y}_0 = 1 - p(q, t)$. We start training from TANDA-RoBERTa (base or large), i.e., RoBERTa fine-tuned on ASNQ ([Garg et al., 2020](#)).

3.2 Pairwise Classifier (PC)

We use the previous TANDA-RoBERTa model similarly to what is done for a multiple-choice QA ([Zellers et al., 2018](#)). We proceed as in the previous section obtaining the CLS representation for each (q, c_i) pairs. Then, for each t , we concatenate the embedding of (q, t) with all the embeddings (q, c_i) , where $c_i \neq t$. This way, (q, t) is always in the first position. We train the model again using binary cross-entropy loss. At classification time, we select one candidate t at a time, set it in the first position, followed by all the others, classify all k target answers, and rerank them based on these scores.

3.3 All Candidate Multi-classifier (ACM)

We concatenate the question text with the text of all k answer candidates, i.e., $(q[\text{SEP}]_{c_1}[\text{SEP}]_{c_2} \dots [\text{SEP}]_{c_k})$, and provide this input to the same TANDA-RoBERTa model used for SBC. We use the final hidden vector E corresponding to the first input token [CLS] in a classification layer with weights $W \in \mathbb{R}^{k \times |E|}$, and train the model using a standard cross-entropy classification loss: $y \times \log(\text{softmax}(EW^T))$, where y is a one-hot vector representing labels for the k candidates, i.e., $|y| = k$. The scores for the candidate answers are calculated as $p(\{c_1, \dots, c_k\}) = \text{softmax}(EW^T)$. Then, we rerank c_i according to their probability.

3.4 Answer Support Reranker (ASR)

The previous models have been shown to be outperformed by ASR ([Zhang et al., 2021](#)), described in Figure 1. ASR consists of five main components: (i) the primary retrieval, which recuperates documents relevant to a question and produces answer sentence candidates, (ii) an SBC, which provides the embedding of the input (q, t) . This is built with the TANDA approach applied to RoBERTa pre-trained transformer ([Garg et al., 2020](#)). (iii) The joint representation of the pairs, $(t, c_i), i = 1, \dots, k, t \neq c_i$, where t and c_i are the top-candidates reranked by SBC, is obtained with a max-pooling operation over the k pairs, (t, c_i) . (iv) The *Answer Support Classifier* (ASC) classifies each (t, c_i) in four classes: (0) both answer correct, (1) t is correct while c_i is not, (2) vice versa, and (3) both incorrect. This multi-classifier is trained end-to-end with the rest of the network in a multi-task learning fashion, using its specific cross-entropy loss, computed with

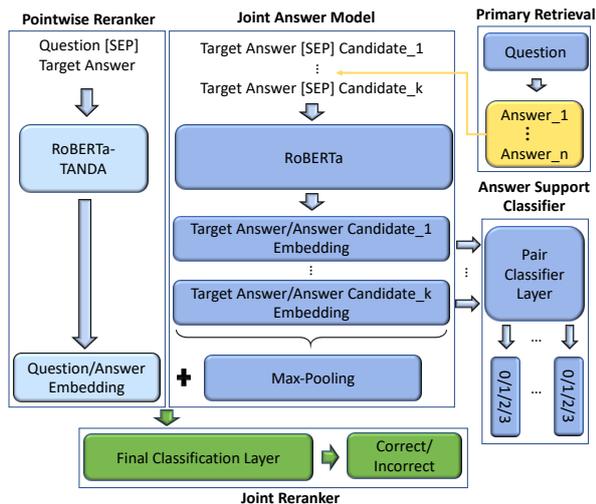

Figure 1: Answer Support-based Reranker (ASR)

the labels above. (v) The *Final Classification Layer* takes in input the concatenation of the SBC embedding with the max-pooling embedding. Thus, the classifier scores t with respect to q , also using the other candidates.

ASC uses pre-trained RoBERTa-base (Liu et al., 2019), to generate $[CLS] \in \mathbb{R}^d$ embedding of $(q, t) = E_t$. \hat{E}_i is the $[CLS]$ output of another RoBERTa-base Transformer applied to answer pairs, i.e., (t, c_i) . Then, E_t is concatenated to the max-pooling tensor from $\hat{E}_1, \dots, \hat{E}_k$, that is, $V = [E_t : \text{Maxpool}([\hat{E}_1, \dots, \hat{E}_k])]$, where $V \in \mathbb{R}^{2d}$ is the final representation of the target answer t . Finally, we apply a binary classification layer: $p(y_i|q, t, c_1, \dots, c_{k-1}) = \text{softmax}(WV + B)$, where $W \in \mathbb{R}^{2d \times 2}$ and B are parameters to transform the representation of the target answer t from dimension $2d$ to dimension 2, which represents correct or incorrect labels.

4 Double Reranking and Retrieval

ASR is the state of the art for joint modeling candidates. However, it suffers from three main limitations: (i) it needs to limit k otherwise the complexity may be too high, this means that it may not be able to process all available supporting candidates, (ii) the top k candidates are the best answer ranked by TANDA, which does not guarantee that these are also the best supports, and (iii) answer candidates may be good supports but they were not retrieved for this purpose. We address the above drawbacks proposing: (i) double reranking functions, which can efficiently rank supports as well as the best target answers, and (ii) a second stage of retrieval that

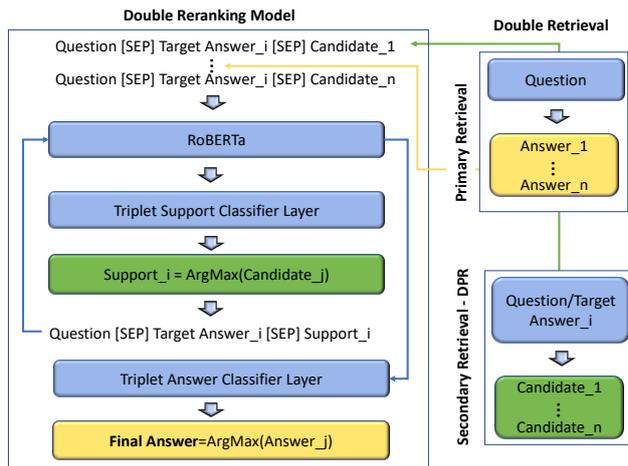

Figure 2: Double Answer Reranker and Retrieval (DAR-DR)

performs support retrieval using a representation of the target answer and question pairs.

4.1 Double Answer Reranking (DAR)

The architecture, shown in Fig. 2, is much simpler than ASR: it just uses one RoBERTa transformer to encode triplets, question, target answer, candidate, i.e., (q, t, c_i) , rather than encoding (q, t) and (t, c_i) with two separate transformer models. Then two classification layers operate two different types of ranking of the same triplets: the first, Support Reranker (SR), given t , learns to rank the best support, c_i higher. The second, Answer Reranker (AR), given the best support, i.e., $s_t = \arg\max_{i:c_i \neq t} SR(q, t, c_i)$, learns to rank the best answer producing, $f = \arg\max_{t \in C_k} AR(q, t, s_t)$, as the final output.

Training DAR Training SR and AR is challenging as, for the former, labels are typically not available in standard datasets. Additionally, defining a support, i.e., a piece of knowledge improving the accuracy of another classifier is not a well-understood problem. Thus, we use feedback from AR directly, i.e., a high relevant support is the one that produces the highest score in AR, if the answer is correct, and the lowest score, otherwise. We train SR and AR, at the same time, in a multi-task learning fashion, also considering that the triplets ranked by SR and AR are essentially the same: learning the different roles of SR and AR boils down from selecting a subset of triplets for their training, along with the appropriate loss function.

SR learns to rank the best supports higher. This can be enforced by requiring that s_t produces

the highest score, $AR(q, t, s_t)$, among c_i scores, $\{AR(q, t, c_i)\}_i$, if t is correct, and the lowest score, otherwise. We enforce this property with a loss function: given a training example, (q, C_k) , $C_k = \{c_1, \dots, c_k\}$, where c_i are associated with training label $l_i \in \{+1, -1\}$, we (i) select the best support, according to the current AR model, $s_t = \arg\text{-max}_{i:c_i \neq t} l_i \times AR(q, t, c_i)$, and (ii) use the following ranking loss function to train SR:

$$L(q, c_1, \dots, c_n) = -\log \frac{e^{\text{sim}(q, s_t)}}{\sum_{i=1}^n e^{\text{sim}(q, c_i)}}. \quad (1)$$

This pushes the support that provides the highest confidence score for AR in the top of the rank.

In contrast, we train AR as a standard binary classifier with the cross-entropy loss using all triplets, i.e., $(q, t, c_i) \forall t, c_i, t \neq c_i$.

4.2 Double Retrieval (DR) with DPR

The right side of Fig. 2 shows two retrieval steps: the first one is the traditional retrieval stage which, given an initial q , recuperates relevant documents, and splits them in answer sentence candidates. This step is typically carried out to build all AS2 datasets. However, if the objective is to retrieve items supporting a target t , the appropriate query should be built with the whole pair (q, t) . For this reason, we propose a secondary retrieval step using (q, t) . We note that (i) DAR approach does not limit the number of initial support to a fixed k as ASR does, either in training or in testing. This makes it suitable to work with more supporting items than those available from the first retrieval step. (ii) Since the semantics of (q, t) is difficult to define, neural retrieval fed with the embedding of the pair above is a promising choice.

Embeddings for support retrieval We adapted the Dense Passage Retrieval (DPR) by Karpukhin et al. (2020) for our task of support retrieval. We built two encoders $E_Q(\cdot)$ for the pairs (q, t) , and $E_P(\cdot)$ for text passages p (typically they are larger than a single sentence). The encoders map the input to a d -dimensional real-valued representation, while an indexing process computes representations for all text using $E_P(\cdot)$. The retrieval of relevant content for (q, t) is done in two steps: (i) we compute the (q, t) representation using $E_Q(\cdot)$; and (ii) we then retrieve M passages that have vector representations the most similar to the pair representation, in terms of dot product:

$$\text{sim}(q, p) = E_Q(q, t)^\top E_P(p). \quad (2)$$

The encoder is trained to make the dot-product similarity corresponding to the expected ranking. Thus, for training our DPR, we use again the ranking loss in Eq. 1, where the label of p is positive if a support is part of the paragraph, i.e., $s_t \in p$.

4.3 Double Ranking and Retrieval

The combination DAR-DR needs to consider the fact that AS2 datasets do not have annotated supports. For standard datasets, we consider candidates as potential supports, where the candidates are also annotated as correct or incorrect answers. In contrast, when we retrieve new support using the (q, t) query, no label is available. However, our DAR approach does not require support labels, thus we can still train our entire DAR-DR model, by simply considering two sets: initial candidates C , on which we can train AR, and a set S containing new supports retrieved by DPR. SR can be trained on $C \cup S$, using the ranking loss (Eq. 1), which only need to estimate the best support. Again, we find it with $s_t = \arg\text{-max}_i AR(q, t, c_i)$, where $t \in C$ and $c_i \in C \cup S \setminus t$.

5 Experiments

We compare our models with several baselines we implemented from previous work, and ASR, which is the current state of the art for AS2. For the evaluation, we used three different datasets traditionally used for AS2. Finally, we provide error analysis and model discussion.

5.1 Datasets

WikiQA is a QA dataset (Yang et al., 2015) containing a sample of questions and answer-sentence candidates from Bing query logs over Wikipedia. The answers are manually labeled. Some questions have no correct answers (*all-*), or only correct answers (*all+*). Table 2 reports the corpus statistics without *all-* questions, and without both *all-* and *all+* questions (*clean*). We follow the most used setting: training with the *noall-* mode and then answer candidate sentences per question in testing with the *clean* mode.

TREC-QA is another popular QA benchmark by Wang et al. (2007). Since the original test set only contain 68 questions and previous method already achieved ceiling performance (Zhang et al., 2021), we combined train., dev. and test sets, removed questions without answers, and randomly re-split into new train., dev. and test sets, which

	Train		Dev		Test	
	#Q	#A	#Q	#A	#Q	#A
no all-	873	8,672	126	1,130	243	2,351
clean	857	8,651	121	1,126	237	2,341

Table 2: WikiQA dataset statistics

contains 816, 204 and 340 questions, and 32,965, 9,591, and 13,417 question-answer pairs for the train., dev. and test sets, respectively.

SelQA is another benchmark for Selection-Based QA (Jurczyk et al., 2016), which composes about 8K factoid questions for the top-10 most prevalent topics among Wikipedia articles. We used the original splits for answer selection filed, which contain 5529 questions for train set, 785 questions for dev. set and 1590 questions for test set. SelQA is a large-scale dataset and it is more than 6 times larger than WikiQA in number of questions.

HotpotQA is a popular benchmark for multi-hop QA (Yang et al., 2018), which contains about 100,000 crowd-sourced questions that require reasoning over separate Wikipedia paragraphs. Each question not only has gold answer phrase but also has two supporting documents that contain the necessary evidence to infer the answer. To make it suitable for the AS2 task, we split paragraph into sentences, and label the sentences containing the gold answer phrase as correct answer, while considering the others as incorrect. For evaluation, we use the official dev-set-distractor as our test set.

5.2 Training and testing details

Metrics The performance of QA systems is typically measured with Accuracy in providing correct answers, i.e., the percentage of correct responses, which also refers to Precision-at-1 (P@1) in the context of reranking. We also use Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) evaluated on the test set, using the entire set of candidates for each question (this varies according to the dataset), to have a direct comparison with the state of the art.

Models We use the pre-trained RoBERTa-Base (12 layer) and RoBERTa-Large-MNLI (24 layer) models, which were released as checkpoints for use in downstream tasks¹.

Reranker training We adopt Adam optimizer (Kingma and Ba, 2014) with a learning rate of 2e-5

for the transfer step on the ASNQ dataset (Garg et al., 2020), and a learning rate of 1e-6 for the adapt step on the target dataset. We apply early stopping on the development set of the target corpus for both fine-tuning steps based on the highest MAP score. We set the max number of epochs equal to 3 and 9 for the adapt and transfer steps, respectively. We set the maximum sequence length for RoBERTa to 128 tokens.

ASR training Again, we use the Adam optimizer with a learning rate of 2e-6 for training the ASR model on the target dataset. We utilize one Tesla V100 GPU with 32GB memory and a train batch size of eight. We use two transformer models for ASR: a RoBERTa Base/Large for PR, and one for the joint model (see Fig. 1). We set the maximum sequence length for RoBERTa to 128 tokens and the number of epochs as 20. We select the best k chosen in (Zhang et al., 2021).

DAR implementation and training For training the DAR model, we also use the Adam optimizer but with a different learning rate, 5e-6. We utilize two Tesla A100 GPUs with 40GB memory and a train batch size of 128. DAR only needs one transformer model: a RoBERTa Base/Large (see Fig. 2). The maximum sequence length and the number of epochs are the same with ASR training, which are 128 and 20 separately.

DPR implementation and training We utilize the same training configuration of the original DPR in Karpukhin et al. (2020). Then, we used it to build a large index having up to 130MM passages extracted from 54MM documents of Common-Crawl². We selected English Web documents of 5,000 most popular domains, including Wikipedia, from the recent releases of Common Crawl of 2019 and 2020. We then filtered pages that are too short or without proper HTML structures, i.e., having title and content. To retrieve to N candidates, we input our DPR with (q, t) pairs as query to retrieve top 1000 passages.

DAR-DR implementation and training The training configuration is similar to DAR training with the different steps highlighted in Sec. 4.2. For each (q, c_i) of our datasets, we used our DPR for retrieving 1000 supporting paragraphs, which are then split into sentences, s . We rank s according to a $E_Q(q, t) \cdot E_P(s)$, where $E_P(s)$ provides the

Table 3: Performance of different models using RoBERTa base Transformer on WikiQA, TRECQA, SelQA and HotpotQA. RER is the relative error reduction on P@1. The difference between P@1 of DAR and DAR-DR and P@1 of all the other systems is statistically significant at 95%.

embedding representation of each s , even though we trained $E_P(\cdot)$ for passages. We select the top 10 sentences as support for all the experiments with DAR-DR. It should be noted that all datasets for retrieval-based QA are based on candidates retrieved with an initial search engine, e.g., Bing, Google, TREC systems. This constitutes the first standard retrieval in our DR approach.

5.3 Comparative/ablated results

We design a set of baselines (see Sec. 3), which also constitute the best ablation systems of our most complex architecture DAR-DR. Indeed, **SBC** is our reimplementation of TANDA, which corresponds to the basic system (or basic component) of our architecture, it uses only one reranker and no joint inference. **PC** is the simplest joint model, which still uses only one classifier as SBC but applied to pairs of answers. **ASR** (ours) is our reimplementation of ASR, which uses an SBC model, a PC model, and an internal SR (called ASC) model as in DAR, used just for classification, no ranking. **ASR-Rank** extends ASR using the top 3 candidates re-ranked by ASC category 0 score (see Sec. 3.4), instead of using the standard TANDA rank. We introduced, ASR-Rank to show an approach similar to DAR. **ACM** is a joint model over all k candidates (theoretically more expressive than just joint models over pairs). **DAR** uses two rerankers as ASR-Rank but only one transformer and our approach to train them. Finally, **DAR-DR** adds to DAR new candidates retrieved by DPR.

Main results Table 3 reports P@1, MAP and MRR of models on WikiQA, TREC-QA, SelQA and HotpotQA datasets. TANDA and ASR rows report the results obtained by Garg et al. (2020) and Zhang et al. (2021), respectively, which certify the alignment between our and previous work setting and implementation. We note that:

- (i) P@1, MAP and MRR correlate well, thus, we can focus our analysis on P@1, which typically provides the QA performance. The AS2 model P@1 numbers are in the lower 80s% for all datasets but HotpotQA. This means that absolute improvements are not expected to be large, thus we also report the relative error reduction (RER) for P@1, which better shows model differences.
- (ii) Our SBC and ASR replicate the performance reported in previous work (WikiQA and TREC-QA), which are the previous state of the art.
- (iii) We confirm that ASR, using candidate pairwise information greatly improves on single answer classification models, e.g., we observe a relative error reduction of 13.64% (from 81.89 to 84.36) over TANDA and SBC, which do not use the information from other candidates.
- (iv) Our proposed model DAR significantly reduces the error of QA systems with respect to ASR by 4.58% (from 84.36 to 85.19), 2.55% (from 90.88 to 91.18), 14.47% (from 93.14 to 94.15), and 1.44% (from 67.95 to 68.44) on WikiQA, TREC-QA, SelQA, and HotpotQA, respectively. It is interesting to note that DAR only uses the half of the parameters of ASR (125M vs. 250M). The combination between the two rerankers for answer and support generates more selective information than max-pooling pairwise embeddings.
- (v) To verify that the unique feature of DAR of effectively combining training examples and their losses is a key element, we implemented ASR-Rank, which also selects supporting candidates for ASR, using its internal answer pair classifier, $ASC(t, c_i)$. The results derived on WikiQA and TREC-QA show no difference between ASR and ASR-Rank, while the latter underperforms on SelQA. This shows that the improvement produced by DAR is not about selecting the best support in absolute, but it is about selecting the support that

Roberta Large	WikiQA				
	P@1	RER	MAP	MRR	Param.
SBC	0.8724	0.00%	0.9151	0.9266	355M
ASR	0.8971	19.36%	0.9280	0.9399	710M
DAR	0.8889	12.93%	0.9230	0.9362	355M
DAR-DR	0.8930	16.14%	0.9241	0.9375	355M

Table 4: Results on WikiQA using RoBERTa Large.

can produce the highest confidence in the answer selector (see Sec. 4.1).

(vi) DAR-DR introduces 10 additional supports to DAR processing, retrieved with our modified DPR approach. These new candidates do not have any label indicating if they are good or bad support. They are automatically ranked with the DAR approach. The results show an RAR of 2.27%, 4.93%, and 9.88%, on WikiQA, TREC-QA, and SelQA, respectively. Suggesting that retrieving supporting candidates for (q, t) can be very effective. HotpotQA does not benefit from retrieving candidates external to the dataset as the original candidate set always contains at least one correct support by construction, thus no additional retrieval is needed.

(vii) Finally, we perform randomization test (Yeh, 2000) to verify if the models significantly differ in terms of prediction outcome. Specifically, for each model, we compute the best answer for each question and derive binary output based on the ground truth. We then follow the randomization test to measure the statistical significance between two models. We use 100,000 trials for each calculation. The test show statistical significant difference of DAR and DAR-DR vs. all the other models over all datasets but HotpotQA, with $p < 0.05$, and between DAR and DAR-DR on SelQA.

Results with large models We experimented with SBC, ASR, DAR and DAR-DR models implemented on a larger transformer, i.e., RoBERTa Large, on WikiQA. Table 4 reports the comparative results: SBC and ASR replicate the results by Zhang et al. (2021), i.e., a P@1 of 87.24% and 89.71%, respectively; the latter is the state of the art on WikiQA with a P@1 of 89.71%. Both DAR and DAR-DR improve SBC up to 20% RAR. However, even DAR-DR is behind ASR, by about 3.21% of RER. This different outcome with respect previous results on the RoBERTa base can be explained by looking at the column reporting model parameters. As before, ASR uses the double of parameters of DAR, however, in this case the number of parameters is 710M, which is a large number in absolute:

q : what is the measurements of saturn 's moons?
c_1 : The rings of Saturn are made up of objects ranging in size from microscopic to hundreds of meters, each of which is on its own orbit about the planet.
c_2 : Saturn has 62 moons with confirmed orbits , 53 of which have names and only 13 of which have diameters larger than 50 kilometers.
c_3 : The moons of Saturn (also known as the natural satellites of Saturn) are numerous and diverse ranging from tiny moonlets less than 1 kilometer across to the enormous Titan which is larger than the planet Mercury.
c_4 : Saturn has seven moons that are large enough to be ellipsoidal due to having planetary mass , as well as dense rings with complex orbital motions of their own.

Table 5: A question with answer candidates; c_2 and c_3 are correct.

although DAR is a better model, it can hardly improve a model with 355M parameters more.

5.4 Model discussion and error analysis

Tab. 5 shows a question with the rank provided by SBC. The top-1 answer, c_1 is incorrect, as it refers to objects of Saturn’s rings, instead of targeting its moons. SBC probably got tricked by the phrase *ranging in size*. ASR also selected c_1 using the support of the top 3 candidates selected by SBC, i.e., c_2 , c_3 , and c_4 . These candidates support c_1 as they provide more context, e.g., *moon*, which is not in c_1 but it is required in the question. The main problem of ASR is the fact that correct answers also tend to support imperfect but reasonable answers such as c_1 . In contrast, for each t , DAR learns to select the best support: in the example, it selects the correct answer c_2 using c_4 as support. This probably provides phrases such as *seven moons that are large enough* supporting c_2 phrases such as *have diameters larger than*.

In Tab. 6, we see an example, in which SBC ranks an incorrect answer at the top. It probably prefers c_1 to the correct answer c_2 because it matches the main question entity and verb, i.e., *Family Guy* and *premier*, while c_2 does not contain explicit reference to the main entity. Also ASR and DAR cannot select c_2 , as the available supports, c_1 and c_3 , do not provide any useful information. In contrast, DAR-DR can use new retrieved support, i.e., s_1 , which contains the main entity and reinforces the information in c_2 , i.e., *22 millions*.

See Appendix for more discussion.

6 Conclusion

In this paper, we propose, DAR, a transformer architecture based on two reranking heads: (i) the answer reranker (AS2 model) and the answer support

q:	How many viewers did "Family Guy" premier to?
c₁:	Family Guy officially premiered after Fox's broadcast of Super Bowl XXXIII on January 31, 1999, with "Death Has a Shadow."
c₂:	The show debuted to 22 million viewers, and immediately generated controversy regarding its adult content.
c₃:	At the end of its first season, the show was #33 in the Nielsen ratings, with 12.8 million households tuning in.
s₁:	Family Guy has been around since 1999 with 11 seasons to date, the viewing rates have dropped from over 22 millions to 7 million.

Table 6: Example with c_2 correct.

reranker. We optimize the latter imposing a loss function that penalizes non optimal support for the target answer, thus avoiding the need of defining and manually labeling supporting data. Additionally, we introduce a second retrieval stage based on DPR, where we optimize the score function between answer/question pair and the retrieving passage. The experiments with four well-known datasets show consistent improvement of DAR over the state of the art, and the potential benefit of the secondary retrieval, achieving up to 14.47 of relative error reduction (on SelQA). We will release software, models, and the DPR retrieved data for all datasets for fostering research in this field.

Limitations

We propose a new QA architecture that operate a second retrieval. This can make the approach slower than a standard QA system using only one retrieval but, at the same time, it enables the possibility to retrieve critical information. The latter can be used to verify question/answer pairs or also complement the information need of the user. This is clearly a future direction for QA/personal assistant systems. As we explain in the paper, we designed a DPR model which can specifically retrieve supporting items (no just answer candidates), as we can query DPR with the pair (question, answer to be verified). This is a major novelty with respect to systems that can only retrieve text relevant to the question.

Our new approach uses only one support to verify answer correctness. This may be seen as lack of exploration of the model potential. However, using one support only requires a classifier of the form $SR(q, t, s_i)$. If we use more supports, for example two, we will have a classifier of the type $SR(q, t, s_i, s_j)$. This means that to find the arg-max we would need to iterate over k^2 , where k is the number of candidates (so in general k^n with n the number of supports we want to use). This is much

less efficient than our approach. Although, approximated solutions more efficient than $O(k^n)$ can be surely designed, in this paper, we have focused on a rather efficient version, which has also shown to improve the state of the art.

A Deeper Discussion

A.1 Double Retrieval

The complete architecture DAR-DR can operate a second retrieval, which can make the approach slower than a standard system using only one retrieval but, at the same time, it enables the possibility to retrieve critical information. The latter can be used to verify question/answer pairs or also complement the information need of the user. This is clearly a future direction for QA/personal assistant systems. As we explain in the paper, we designed a DPR model which can specifically retrieve supporting items (no just answer candidates), as we can query DPR with the pair (question, answer to be verified). This is a major novelty with respect to

systems that can only retrieve text relevant to the question.

It should be noted that we apply two answer sentence retrieval steps: (i) the standard one, which is contained in all datasets for AS2 based QA systems. See our description of WikiQA, TREC, SelQA, and HotpotQA. For example, WikiQA uses Bing to retrieve passages. (ii) Our innovative retrieval based on our new DPR model. This takes (q, a) as query and returns passages that have higher probability to be good support for a with respect to q .

Our DAR-DR aims to be an end-to-end system, AS2 tasks are defined using retrieval systems. We also operate the second retrieval. In other words, a DAR-DR system deployed in production will always performs 2 stages of retrieval to provide answers to users.

A.2 AS2 Tradition

Please note that the AS2 research our paper builds on has been contributed for more than 20 years. It started in TREC competitions (QA track 1999). It has been revived in 2007 with the specialization of passage reranking in answer sentence selection (AS2): see for example the systems based on TREC data [https://aclweb.org/aclwiki/Question_Answering_\(State_of_the_art\)](https://aclweb.org/aclwiki/Question_Answering_(State_of_the_art)). Also note that TANDA by Garg et al, 2020 is simply a transformer fined-tuned in two steps (i) on ASNQ dataset proposed by the same authors, and (ii) on the target dataset.

A.3 Ablation study

The baseline models we implemented and compared to are ablated versions of our systems, sometimes including different alternatives (instead of just excluding some features). Sec. 5.3 explains how the different models we test constitute an excellent ablation study.

A.4 Usefulness of reporting result with Relative Error Reduction

The relative error reduction is suitable for reporting the performance in our setting since we are improving state-of-the-art systems with performance ranging from $\sim 81\%$ to $\sim 97\%$ (depending on the measure and datasets). Reporting absolute (or also relative) improvement does not capture the complexity of the task. For example, improving a system from 30% to 31% (margin of improvement 70%) is completely different than improving a system from 98% to 99%, where the margin of im-

provement is 2%. Relative error reduction, which we use, accounts for such difficulties. In any case, whatever lens one uses, the results are statistical significant, showing that we improve the state of the art.

A.5 Model Effectiveness

We report the number of model parameters on the Table 4, which shows that our solution uses half of the parameters of previous state of the art, ASR (indeed that uses two transformer models: instead of our DAR only uses one).

A.6 Multiple supports

Using one support only requires a classifier of the form $SR(q, t, s_i)$. If we use more supports, for example two, we will have a classifier of the type $SR(q, t, s_i, s_j)$. This means that to find the arg-max we would need to iterate over k^2 , where k is the number of candidates (so in general k^n with n the number of supports we want to use). This is much less efficient than our approach. Although, approximated solutions more efficient than $O(k^n)$ can be surely designed, in this paper, we have focused on a rather efficient version, which has also shown to improve the state of the art.

Moreover, although it may happen that to verify information multiple pieces are required, this situation is rather rare in general open QA, as the web contains the needed information in a redundant fashion. This means we can most times retrieve a compact version of an answer *why should it be available only in a fragmented way?*

For other more specific application scenarios, e.g., deriving answers from several axioms and logic formulas (expressed in text format), combinations of different supports, composing different retrieved pieces may be required. However, this scenario is out of the scope of our paper: it can be an interesting new research.

A.7 Comparison with (Zhang et al., 2021)

(Zhang et al., 2021) is a great work which outperforms the previous state of the art in AS2, i.e., TANDA, which seemed very difficult to improve. Our contributions:

- We defined a new techniques to automatically learn to rank support without using any annotation, which is for example used in hotpotQA.

- Our approach outperforms (Zhang et al., 2021) on base architectures. With respect to LARGE, we did not have the language models comparing with the same number of parameters but using 355M parameters less, our approach provide close results.
- Our RoBERTa-base model only use half of the parameters of (Zhang et al., 2021), which these days of energy crisis is absolutely important results.
- Most importantly, we defined a new paradigm for QA (and answer verification), which uses double retrieval, our support reranker can be used to select support obtained with a second stage of retrieval. This to our knowledge is completely new for answer sentence selection.

Our approach improves all previous techniques in a fair comparison, which means similar number of parameters. In case of RoBERTa based, our approach outperforms models with the double of parameters. Specifically, only using 130M parameters, it outperforms an architecture of 260M parameters, i.e., architectures having 130M parameters more. The fact that our approach does not perform an architecture of 710M parameters, i.e., a model that used 355M more than ours, is not a limitation. We show these unfair experiments (for our approach) because they provide strong evidence about the effectiveness of our approach. The lower performance on HotpotQA is expected as the related task is not answer sentence selection, for which our approach was built. Indeed, HotpotQA focused on entities and annotated data such that two paragraphs complement each other, which is a more restrictive assumption than our approach. For the sake of generality, we showed that our approach can also work well for this rather different setting.

Evaluating the Diversity, Equity and Inclusion of NLP Technology: A Case Study for Indian Languages

Simran Khanuja*

partha@google.com

Abstract

In order for NLP technology to be widely applicable, fair, and useful, it needs to serve a *diverse* set of speakers across the world’s languages, be *equitable*, i.e., not unduly biased towards any particular language, and be *inclusive* of all users, particularly in low-resource settings where compute constraints are common. In this paper, we propose an evaluation paradigm that assesses NLP technologies across all three dimensions. While diversity and inclusion have received attention in recent literature, equity is currently unexplored. We propose to address this gap using the Gini coefficient, a well-established metric used for estimating societal wealth inequality. Using our paradigm, we highlight the distressed state of current technologies for Indian (IN) languages (a linguistically large and diverse set, with a varied speaker population), across all three dimensions. To improve upon these metrics, we demonstrate the importance of region-specific choices in model building and dataset creation, and more importantly, propose a novel, generalisable approach to optimal resource allocation during fine-tuning. Finally, we discuss steps to mitigate these biases and encourage the community to employ multi-faceted evaluation when building linguistically diverse and equitable technologies.

1 Introduction

NLP has seen large advances in recent years driven by the rapid progress in transfer learning (Ruder et al., 2019; Devlin et al., 2019). The benefits of these advances, however, are not equally distributed across the world’s languages (Joshi et al., 2020) and users. While linguistic diversity and inclusion have evolved to be a pressing concern today, measures to quantify these are still lacking. The progress of any field is tightly coupled with

its evaluation paradigm and the community is incentivized to work on highly visible metrics and benchmarks. In order for users around the world to reap the benefits of NLP technology, we must move from an evaluation that focuses on optimizing raw performance on available test data to a more holistic user-centric evaluation (Ethayarajh and Jurafsky, 2020; Ruder et al., 2021). In this paper, we attempt to do so by defining an evaluation framework along three dimensions: diversity, equity, and inclusion.¹

Diversity is important as NLP technology should be available to speakers of any language (European Language Resources Association, 2019). To this end, recent work (Blasi et al., 2022) quantifies diversity of NLP technology across the world’s languages by weighing normalized task performance for each language based on its speaker population.

Equity is key as we should aim to develop technology that does not discriminate against speakers of any particular language (Kaneko and Bollegala, 2019). State-of-the-art multilingual models in fact have been shown to perform much better in languages with access to many pre-training resources (Hu et al., 2020). To measure such performance inequity across languages, we propose to use the Gini coefficient (Dorfman, 1979), a measure that has been used to represent the income inequality within social groups.

Finally, inclusion is a concern as the fact that NLP technology is performant in a given task and language does not mean that it is usable by all. State-of-the-art models are becoming larger and larger (Fedus et al., 2021) and the low-resource settings of many languages often coincide with constraints on computational resources (Ahia et al., 2021). The value a technology provides to a user thus also needs to consider how easily such technol-

*Equal contribution.

[†]Work done at Google Research.

¹We focus on assessing these dimensions on the *language level*. Prior work on equity focuses mainly on subpopulations *within* a language (Katell et al., 2020).

ogy can be deployed in practice. [Ma et al. \(2021\)](#) quantify this based on a model’s runtime efficiency, considering factors like throughput and memory.

Our proposed paradigm is language and model agnostic making it applicable to an arbitrary set of languages and models. We apply our paradigm to highlight the distressing state of current technologies for Indian (IN) languages. India is a multilingual society with 1369 rationalized languages and dialects being spoken across the country ([Chandramouli, 2011](#)). Of these, 22 scheduled languages² spoken by almost 97% of the population hold an official recognition and 121 languages have more than 10,000 speakers. Additionally, 21.92% of its population lives below the poverty line ([RBI, 2021](#)). Serving this large varied population justly requires a multi-faceted effort and basing our case study on IN languages directs the way forward.

We evaluate a range of state-of-the-art models and transfer settings ([Hu et al., 2020](#)) across four standard downstream tasks: *Named Entity Recognition* (NER), *Part-of-Speech Tagging* (POS), *Natural Language Inference* (NLI) and *Question Answering* (QA). We observe that region-specific choices, i.e., a) region-specific pre-trained models ([Kakwani et al., 2020](#); [Khanuja et al., 2021](#)) and b) Hindi as the transfer language during fine-tuning, generally yield the best results. In terms of efficiency, we find that smaller models are preferable for easier, syntactic tasks while larger models have the edge on more complex, semantic tasks.

Our findings, however, also highlight that we are still a long way from building perfectly inclusive and equitable NLP technology. Towards bridging this gap, we explore how we can most effectively annotate data for the remaining languages. Past work ([Lin et al., 2019](#); [Ahuja et al., 2022](#)) has relied on heuristic and feature-based approaches to source language selection. In our work, we propose a novel, fully computational approach to model the space of source and target languages, and derive the optimal allocation of a fixed annotation budget to maximize performance on our proposed metrics in a multi-source setting.

Our contributions are the following: **1)** We propose a holistic evaluation paradigm that assesses NLP technology based on their diversity, equity,

and inclusion. **2)** Using this paradigm, we evaluate model capabilities for IN languages and quantify their shortcomings. **3)** We propose a novel approach to select data for fine-tuning these models with the objective of maximizing performance on the proposed metrics. **4)** We discuss steps that must be taken to mitigate these biases and call upon the community to incorporate our evaluation paradigm when building models to track progress towards building linguistically inclusive and diverse technologies.

2 Background and Related Work

Multilingual Models Transformer-based language models (LMs) ([Vaswani et al., 2017](#)) trained on massive amounts of text from multiple languages have enabled the inclusion of an unprecedented number of languages in NLP technologies ([Conneau et al., 2020](#); [Devlin et al., 2018](#)). However, previous research has shown that these models do not serve all languages equally, with resource-poor languages in the long tail suffering the most ([Hu et al., 2020](#); [Lauscher et al., 2020](#)). These models go through a critical step of fine-tuning for the downstream task before being deployed. Several recent works focus on optimal fine-tuning strategies that mitigate transfer gaps and improve overall performance across target languages. [Lin et al. \(2019\)](#) propose a tool that chooses optimal transfer languages based on linguistic features. [Lauscher et al. \(2020\)](#) demonstrate the effectiveness of investing in few-shot in-language training examples. Recently, [Debnath et al. \(2021\)](#) show that investing in an equal number of fine-tuning instances across target languages performs best. These past approaches however, have all been heuristically designed based on the knowledge and intuition of the experimenter.

User-centric Evaluation At its core, the need for language diversity in technologies is tied to the people it serves. Previous work ([Ethayarajh and Jurafsky, 2020](#); [Ma et al., 2021](#)) has highlighted the need for transparent and user-centric leaderboard evaluation, reporting practically relevant statistics such as model size, energy efficiency, and inference latency. It is common for speaker populations of under-represented languages to operate in resource-constrained settings. Therefore, in addition to evaluating *linguistic* diversity, we follow [Ma et al. \(2021\)](#) in computing model efficiency, which serves to assess the *inclusivity* of these technologies. With regards to linguistic di-

²Assamese, Bengali, Bodo, Dogri, Gujarati, Hindi, Kashmiri, Kannada, Konkani, Maithili, Malayalam, Manipuri, Marathi, Nepali, Oriya, Punjabi, Tamil, Telugu, Sanskrit, Santali, Sindhi, Urdu

iversity, Ruder et al. (2021) highlight the need for more fine-grained evaluation across languages and introduce language-specific leaderboards. Blasi et al. (2022) quantify the value of NLP technology weighed by speaker population and determine utilities of several technologies across the world’s languages. Choudhury and Deshpande (2021) propose strategies for fair and efficient model selection depending on one’s application, based on the principles of fairness in economics and social choice theory.

Indian Languages The research community has actively been contributing to the advancement of IN NLP by collecting and open-sourcing data (Kakwani et al., 2020; Ramesh et al., 2021; Abraham et al., 2020; Roark et al., 2020; Kunchukuttan et al., 2017; Khanuja et al., 2020a), building region-specific multilingual models (Khanuja et al., 2021; Kakwani et al., 2020; Ramesh et al., 2021) and creating evaluation benchmarks (Kakwani et al., 2020; Khanuja et al., 2020b)³ Several of these efforts have been undertaken by AI4Bharat⁴, a non-profit open-source community that has additionally been working on developing resources for IN signed languages (Sridhar et al., 2020) and creating keyboards for IN scripts. Recently, Google Research India launched a question answering (QA) challenge named ChAII⁵. Microsoft Research India has also made significant contributions to IN NLP with several efforts directed towards code-mixed language processing⁶ and building tools and datasets for under-represented languages in India⁷.

3 Diversity, Equity and Inclusion (DEI)

There is increasing awareness in society to promote diversity, equity and inclusion in our workforce, wherein such measures have recently been enforced by law (Constitution, 2021). In the social construct, *diversity* is defined as “the practice of including the many communities, identities, races, ethnicities, backgrounds, abilities, cultures, and beliefs of the people, including underserved communities”, *equity* refers to “the consistent and systematic fair, just, and impartial treatment of all individuals” and *inclusion* means “the recognition, and use of the

⁵<https://www.kaggle.com/c/chaii-hindi-and-tamil-question-answering>

⁶<https://www.microsoft.com/en-us/research/project/melange>

⁷<https://www.microsoft.com/en-us/research/project/ellora>

talents and skills of employees of all backgrounds” (Constitution, 2021). Given the ubiquitous use of technology in our daily lives, we as technology makers hold the responsibility of making sure all voices are heard and equally represented in the technology we serve. Given that our research community is incentivized to work on highly visible metrics and benchmarks, an important first step is to encourage evaluation along these dimensions. Previous work mainly focused on average performance (as measured by accuracy or F1 for NLU tasks), which is not indicative of differences in DEI. Hence, while models claim state of the art based on an increase in average performance, this increase may only be due to making the “rich richer” (see Table 4).

We propose an evaluation paradigm for current NLP technology that operationalizes the well-established diversity, equity and inclusion pillars on a language level: we quantify diversity based on the value diverse speaker populations derive from a technology, equity based on egalitarian performance across speaker populations, and inclusion based on a technology’s accessibility. We employ metrics of Blasi et al. (2022) and Ma et al. (2021) to measure diversity and inclusion respectively and propose a new metric to quantify equity. We describe the metrics in more detail below:

3.1 Diversity: Utility, Demand and the Global Metric

The global metric introduced by Blasi et al. (2022) helps quantify linguistic diversity. Formally, this metric is composed of the utility of a technology weighed by its demand. The utility u_1 of a system for a task and language is its performance normalized by the best possible performance (typically, human-level performance) afforded by the task:

$$u_1 = \frac{\text{performance}_1}{\text{theoretical max performance}}$$

Demand d_1 is characterized by taking into consideration demographic and linguistic perspectives. Under the demographic perspective, the demand for a given technology in a language is estimated to be proportional to the number of speakers of the language itself n_1 ($d_1 \propto n_1$). Under the linguistic perspective, the demand across languages is identical ($d_1 \propto 1$). These two alternatives, as well as any intermediate combination of them, are parameter-

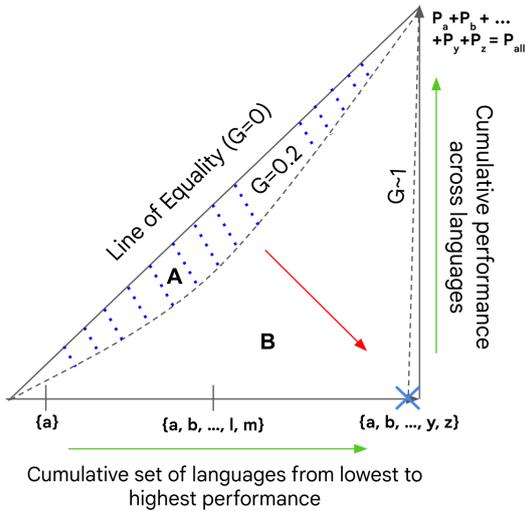

Figure 1: *Graphical Representation* of the Gini coefficient (G), given by $A/(A + B)$ when $G = 0.2$. Each point on the graph depicts the proportion of the total (cumulative) performance P_{all} (e.g., accuracy, F1, etc) that is achieved by the bottom $n\%$ of languages combined. Assume we have a language set $\{a, b, \dots, y, z\}$ with performances $P_a \leq P_b \dots \leq P_y \leq P_z$ and $P_a + P_b \dots P_y + P_z = P_{all}$. When all languages perform the same, i.e., $P_a = P_b = \dots = P_y = P_z$, $G = 0$, as represented by the line of equality, i.e., the bottom $n\%$ of languages also account for $n\%$ of the total performance. The value of G increases as the disparity in performance between all languages increases, and approaches unity in the case of perfect inequality (here, this would mean $P_a = P_b = \dots = P_y = 0$ and $P_z = P_{all}$), i.e., the model / application supports only one language. See §3.2 for details.

ized through a single exponent τ :

$$d_1^{(\tau)} = \frac{n_1^\tau}{\sum_{l' \in L} n_{l'}^\tau}$$

where $\tau = 1$ corresponds to a demographic notion of demand and $\tau = 0$ to a linguistic one. The global metric can now be defined as:

$$M_\tau = \sum_{l \in L} d_1^{(\tau)} \cdot u_l$$

In essence, $M_\tau = 0$ means that no user benefits from language technology and $M_\tau = 1$ corresponds to each language user enjoying perfect technology. Given our people-centric aim to measure benefit for all speakers, we employ the demographic notion of demand ($M_{\tau=1}$).

3.2 Equity: Gini Coefficient

While diversity accounts for a language’s speaker population, it does not take into account inequal-

ities in the performance across languages. While several past works have highlighted transfer gaps in performance across languages (Hu et al., 2020), none have quantified this dispersion.⁸ Traditionally used measures of statistical dispersion like standard deviation or calculating range are sub-optimal choices as they are scale-dependant, unbounded and highly sensitive to outliers, which makes them unsuitable for data that does not approach a normal distribution (De Maio, 2007).

Beyond these measures, several nuanced metrics have been introduced to quantify disparity in income distributions. The choice of income inequality indicator is of significant importance since it has implications in measuring health, state-level mortality, etc. (De Maio, 2007). The Gini coefficient (Dorfman, 1979) has been most commonly used for this purpose (De Maio, 2007).

Hurley and Rickard (2009) lay out six desirable attributes of a measure of sparsity, drawing from past literature (Dalton, 1920; Rickard and Fallon, 2004) and prove the Gini coefficient to be the only measure having all six, among a varied set of alternatives. Briefly, these properties and their relevance in measuring linguistic disparity across tasks include: i) *Robin Hood*: a drop in high-performant and gain in low-performant languages should lead to higher equity; ii) *Scale Invariance*: no change in relative performance should lead to no change in equity, regardless of changes in absolute values; iii) *Rising Tide*: adding a constant value to each language’s performance should increase equity; iv) *Cloning*: equity must remain invariant under cloning, i.e., if two identical distributions are combined, the equity remains unchanged; v) *Bill Gates*: if one language hypothetically gains infinite performance, equity should tend to zero; vi) *Babies*: adding languages with zero performance in the distribution should decrease equity.

Given that the Gini coefficient satisfies all of these attributes (Hurley and Rickard, 2009), we propose to use the same in pursuit of quantifying the inequalities amongst languages with regard to downstream tasks in NLP. A pictorial representation of the Gini coefficient for this setting can be found in Figure 1. Downstream task performance closely follows the highly skewed data distributions on which massively multilingual models are pre-trained. By including the Gini coefficient mea-

⁸Hu et al. (2020) only considered the difference between English and other languages as cross-lingual transfer gap.

sure in our evaluation, we aim to incentivize model builders to invest in equitable performance, despite data differences. Details on how the Gini coefficient is calculated are given in Appendix A.3.

3.3 Inclusion: Efficiency Score

Language technology is only beneficial if it can be deployed and accessed by users in a region. We employ efficiency to quantify inclusion as user devices are resource-constrained in many low-resource settings. Following work on user-centric evaluation (Ethayarajh and Jurafsky, 2020; Ma et al., 2021), we propose to incorporate efficiency into model performance based on throughput and memory, each of which are defined below.⁹

Throughput Number of instances the model can process per second on a CPU, assuming that GPUs are rarely used for deployment at scale in resource-constrained environments.

Memory Saved The size of the model is considered to be a measure of how expensive a model is to use in practice. Since we wish to minimize this metric, *memory used* is transformed into *memory saved* by subtracting it from a maximum available memory of 16 GB (Ma et al., 2021). We show the memory and throughput values for our models in Appendix A.1.

Following Ma et al. (2021), to calculate the efficiency score we first convert each metric into units of performance, by calculating the average marginal rate of substitution (AMRS) for each metric M (i.e., throughput and memory). $\text{AMRS}(M, \text{perf})$ tells us the rate at which model creators, as a group, are trading off M for a one-point increase in perf while keeping utility constant. For example, if AMRS of “memory saved” with respect to accuracy were 0.5 GB, then each GB of memory saved would on average be worth 2 points of accuracy. Dividing M by $\text{AMRS}(M, \text{perf})$ converts it to units of performance. Details on how one can calculate $\text{AMRS}(M, \text{perf})$ can be found in Appendix A.1. For a model x_i , $\text{Efficiency}(x_i)$ is then defined as :

$$\text{Efficiency}(x_i) = \sum_M w_M * \frac{M(x_i)}{\text{AMRS}(M, \text{perf})}$$

⁹Ma et al. (2021) additionally consider fairness and robustness, both of which are highly contextual and difficult to define in the context of multilingual models at present. Hence, we focus on model aspects that are objectively measurable.

where we choose $w_{\text{perf}} = 0.5$, $w_{\text{throughput}} = 0.25$ and $w_{\text{memory}} = 0.25$ as default weights. In practice, these weights can be adjusted based on user requirements and existing constraints.

4 Egalitarian Annotation Budget Allocation

Model development involves not just the design of an architecture or training but also data annotation. The proposed dimensions thus cannot only be used to assess models but can also inform how data should be annotated across many languages. As fine-tuning on a few labeled examples in the target language has shown to improve zero-shot transfer performance, we study how to allocate an annotation budget across a number of source languages S in order to optimize for inclusion and equity across a set of target languages T . Previous work employs a feature-based approach to select a single source language to maximize performance on a target language (Lin et al., 2019) or labels examples across all source languages equally (Debnath et al., 2021). We propose a fully computational approach for modeling the space of source and target languages for a multi-source multi-target language setting. This is done by empirically estimating performance of language $t \in T$ on a held-out set when fine-tuned on x labeled instances of language $s \in S$, $\forall (s, t)$ pairs, which follows a power-law distribution (Rosenfeld et al., 2019). We now seek to find the optimal allocation $\{x_s : s \in S\}$ subject to $\sum_{s \in S} x_s \leq X$ (details in Appendix A.5).

We follow a simple greedy approach to solve this constrained optimization problem as shown in Table 10. Specifically, at each step we allocate a sample to the source language conferring the highest marginal gain to all target languages, which is quantified by the summation of the increase in the global metric and the reduction in Gini.¹⁰ At present, we assign equal weight to each metric but this can be changed according to user preferences.

5 Experiments

5.1 Experimental setup

Languages We base our case study on the 22 scheduled languages of India spoken by 97% of its population. We also include English, since it has a sizeable population of 128.5M speakers (Table 1).

¹⁰Future work may consider more complex approaches that consider language relatedness based on work on transfer relationship learning (Zamir et al., 2018; Song et al., 2019).

Language	as	bn	brx	doi	en	gu	hi	kn	kok	ks	mai	ml
Speakers (in M)	23.6	107.4	1.6	2.8	128.5	60.3	691.6	58.8	2.6	7	14.3	35.6
Language	mni	mr	ne	or	pa	sa	sat	sd	ta	te	ur	-
Speakers (in M)	2.2	99.1	3.4	42.6	36.1	3.1	7.7	3.1	76.6	94.5	63.2	-

Table 1: The number of speakers (in millions) for each of the 22 scheduled languages and English. We take the sum total of first, second and third language speakers for each language.

Task	Dataset	Test Langs.	HP
NER	WikiAnn (Pan et al., 2017; Rahimi et al., 2019)	bn, en, gu,	97.6
		hi, ml, mr, pa, ta, te, ur

NLI	XNLI (Conneau et al., 2018)	en, hi, ur	92.8
QA	XQuAD (Artetxe et al., 2019); TyDiQA-GoldP (Clark et al., 2020)	bn, en, hi, te	91.2;
			90.1

Table 2: *Finetuning Tasks and Datasets*. HP denotes the human performance for each task. For QA, HP is 91.2 F1 for XQuAD and 90.1 F1 for TyDiQA.

Language	NER	POS	NLI	QA
English	20,000	21,261	392,702	88,602
Hindi	5,000	13,305	392,702 (-tran)	88,602 (-tran)

Table 3: *Number of training instances for English and Hindi*. (-tran) denotes that the English fine-tuning set has been translated to Hindi.

Tasks We select tasks from the XTREME (Hu et al., 2020) benchmark. Dataset details and the human performance (HP) for each task can be found in Table 2. For each task, we only evaluate on IN language test sets.

Models Model selection is motivated by two key factors that we wish to explore in our study: **i)** general vs region-specific choices; and **ii)** model efficiency. We choose IndicBERT (Kakwani et al., 2020), MuRIL (Khanuja et al., 2021) and XLM-R (Conneau et al., 2020), the first two being region-specific models and the third being a state-of-the-art model trained on 100+ languages. We consider both the base and large versions for MuRIL and XLM-R. IndicBERT follows the ALBERT architecture (Lan et al., 2019) and is hence much smaller than the base versions of both models. IndicBERT is trained on 11, MuRIL on 16, and XLM-R on 15 IN languages (details in Appendix A.2).

Task	Model	Baseline F1/Accuracy \uparrow	Diversity $M_{\tau=1} \uparrow$	Equity Gini Coeff. \downarrow	Inclusion Efficiency \uparrow
NER	MuRIL _{base}	77.6	69.6	0.59	69.1
	XLM-R _{large}	68.0	61.2	0.60	44.4
	MuRIL _{large}	77.7	68.2	0.59	63.1
POS	MuRIL _{base}	75.0	54.7	0.76	52.5
	XLM-R _{large}	79.2	60.3	0.75	48.0
	MuRIL _{large}	77.3	58.6	0.76	51.8
NLI	MuRIL _{base}	74.1	45.5	0.88	58.7
	XLM-R _{large}	78.7	46.6	0.88	57.3
	MuRIL _{large}	78.6	47.4	0.88	57.8
QA	MuRIL _{base}	76.1	53.8	0.83	77.8
	XLM-R _{large}	75.7	56.6	0.83	76.3
	MuRIL _{large}	77.7	57.9	0.83	75.7

Table 4: *DEI Results compared to baseline F1/accuracy performance*. Here, we compare models' accuracy/F1 performances (usually reported as the evaluation metric) to their DEI metrics. We observe that while performances may significantly vary, DEI metrics (especially equity) don't change as much, indicating that multilingual models make the rich "richer" to increase average performance but may not be moving towards being truly multilingual and equitable across languages. More discussions in Section 5.2.

Fine-tuning We initially fine-tune the selected models using training data in English (EN) given the availability of labeled data across tasks. However, past works highlight that this choice is sub-optimal and one can obtain better performance by transferring from closely related languages (Lauscher et al., 2020; Cotterell and Heigold, 2017; Dong et al., 2015; Turc et al., 2021). To examine this effect in our case study, we additionally fine-tune models on Hindi (HI) because **i)** 15 out of 22 languages belong to the same language family as HI (Indo-Aryan); **ii)** we have training data available for all tasks in HI¹¹; and **iii)** HI has the highest speaker population, which may lead to higher demographic utility and is a future-safe choice to obtain annotations for any task. Table 3 summarizes training data statistics for EN and HI.

¹¹Training sets for NLI and QA have been machine-translated from English, which has been shown to perform similar to human-generated train sets (Turc et al., 2021).

Metric	Train Lang.	Model	NER	POS	NLI	QA	Average
$M_{\tau=1} \uparrow$ (Diversity)	English	MuRIL _{base}	69.6	54.7	45.5	53.8	55.9
		XL _M -R _{large}	61.2	60.3	46.6	56.6	56.2
		MuRIL _{large}	68.2	58.6	47.4	57.9	58.0

Table 5: *Region-specific fine-tuning results.* Note that the metrics are computed considering all 23 languages as detailed in Section 5.1. Region-specific fine-tuning helps, but disparities along DEI axes persist. More discussions in Section 5.2.

5.2 Zero-shot transfer results

How do DEI metrics compare to baseline standard performance metrics (F1/Accuracy)?

We report results of the best-performing models in Table 4. While average performance is similar across tasks, there are stark differences in DEI metrics. The diversity metric helps discern whether the change in performance is more skewed towards languages with a relatively high or low speaker population. For example, for POS, MuRIL_{base} and XL_M-R_{large} have a 4.2% difference in performance but a 5.9% difference in $M_{\tau=1}$. This indicates that the difference is more pronounced for languages with large speaker populations. Similarly, for NLI, the difference in performance and $M_{\tau=1}$ is 4.6% and 1.1% respectively, which also highlights a lack of test data to quantify larger differences in diversity. With regards to equity, we observe that even though major differences exist compared to average performance, the Gini coefficient remains relatively unchanged, indicating that while overall performance has increased, the disparity in performance amongst languages has not yet been addressed by any model. Regarding efficiency or inclusion, while MuRIL_{large} beats MuRIL_{base} in performance, MuRIL_{base} is more efficient to use, across all tasks.

Where are we today w.r.t DEI of NLP technology? We report results of best-performing models (fine-tuned on EN and HI) in Table 5 (detailed results with XL_M-R_{base} and IndicBERT in Table 13). Overall, the diversity metric is highest

Metric	Budget	Model	Fine-tuning Strategy			
			English	Hindi	Egalitarian	Greedy
$M_{\tau=1} \uparrow$	1,000	XL _M -R _{large}	54.0	66.2	65.4	65.3
		MuRIL _{large}	60.4	71.3	74.1	73.6
		XL _M -R _{large}	59.4	74.4	75.4	75.7
	5,000	MuRIL _{large}	65.4	74.8	78.2	78.3
		XL _M -R _{large}	59.0	-	77.6	77.6
		MuRIL _{large}	70.5	-	79.6	79.9
Gini Coeff. \downarrow	1,000	XL _M -R _{large}	0.6	0.6	0.59	0.59
		MuRIL _{large}	0.6	0.6	0.58	0.58
		XL _M -R _{large}	0.6	0.59	0.59	0.59
	5,000	MuRIL _{large}	0.59	0.59	0.58	0.58
		XL _M -R _{large}	0.61	-	0.59	0.59
		MuRIL _{large}	0.59	-	0.58	0.58

Table 6: *Performance on NER under different annotation budgets.* We observe that the greedy approach (§4) performs best across all metrics. Note that the HI train set has 5,000 examples only. Details in §5.3.

for MuRIL_{large}, when fine-tuned on HI. We also observe that the diversity metric increases with region-specific choices, both in pre-training and fine-tuning. The Gini coefficient remains relatively high at around 0.76 even for the best models, which highlights the disparity in performance even among languages within a single region.¹² With regards to efficiency, averaging across languages and tasks, MuRIL_{base} performs best.

What is the way forward? Overall, the absolute values of the global metric and the Gini coefficient indicate that there lies great potential in both increasing the utility of our models and making them more equitable. Since model performances partially reflect the amount of raw data used in pre-training (Lauscher et al., 2020), creating equitable unlabeled data resources would alleviate these issues. However, this is an ambitious undertaking that is extremely resource intensive and can certainly not be achieved for 6500 languages in the near future. We thus investigate how limited amounts of data can be used to maximally improve utility and equity during fine-tuning.

5.3 Few-shot results

Problem Formulation For few-shot fine-tuning, we focus on NER where sufficient labeled training data for seven IN languages is available. We employ the source languages $S = \{\text{bn, en, hi, ml, mr, ta, ur}\}$ and seek to optimize metrics on the target languages $T = \{\text{bn, en, gu, hi, ml, mr, pa, ta, te, ur}\}$. In

¹²For comparison, for OECD countries from 2008–2009, the Gini coefficient on income for the entire population ranged between 0.34 and 0.53 while the Gini coefficient for the entire world has been estimated to be between 0.61 and 0.68 (Hillebrand et al., 2009; Klugman and Nations, 2010).

each setting, we have a limited annotation budget, which we can divide among the source languages. We compare against several competitive baselines: **i)** using only examples from EN or HI respectively; **ii)** distributing the annotation budget in an egalitarian (uniform) way across all source languages (Debnath et al., 2021); and **iii)** our novel greedy approach proposed in §4. For the greedy approach, we illustrate the best-fit curves for each (s, t) pair in Appendix A.5 (Table 11).

Results We show the results under various annotation budgets in Table 6. Overall, we find that our method yields a higher global metric under most budgets (5 of 6 cases) and also yields a lower Gini coefficient under *all* budget schemes. The optimal allocations for each budget are shown in Table 12. As we can see, the greedy algorithm converges to a solution that is close to uniform. This provides further evidence for the benefits of an egalitarian distribution of annotation budget in order to maximize performance across all languages as the expected marginal gain for languages that have been under-represented during training will be highest. Both the egalitarian and greedy approaches significantly outperform fine-tuning on EN or HI. For instance, our greedy approach outperforms fine-tuning on 10,000 EN examples by 1–3% with a budget of only 1,000 examples.

6 Discussion

Building evaluation datasets Having uncovered the linguistic inequity and exclusivity of current NLP technologies, we seek to identify practical measures we can take in order to mitigate these biases. As a first step, it is paramount to build representative evaluation sets for all languages as they are required to accurately measure diversity and equity. Out of the 23 languages in our case study, most do not have evaluation data across tasks despite holding official recognition and being spoken by 97% of the population. In light of the benefits of an egalitarian data distribution during few-shot learning, we also recommend the collection of small amounts of data across many languages for training, in order to maximize marginal gain. These datasets should be collected at the grass-roots level, involving the community they need to serve to capture culturally relevant phenomenon. A prime example of this is the Masakhane organisation¹³ steering efforts towards data collection in

¹³<https://www.masakhane.io/>

African languages, involving the local community. Incentivizing rural, low-income workers to provide for such data also serves as a viable source of supplementary income, and does not degrade dataset quality (Abraham et al., 2020).

Trading off multilinguality and regionality

From a modeling perspective, multilingual pre-trained models have been instrumental to NLP systems supporting an unprecedented number of languages, because of their zero-shot transfer capabilities. However, while these are a big step towards linguistic inclusion, they are subject to limitations such as highly skewed pre-training distributions and limited transfer to under-represented languages (Hu et al., 2020; Lauscher et al., 2020), a bias towards the source language, and sub-optimal tokenization (Wang et al., 2021). A way to combat these issues is to make region-specific choices, both in pre-training and fine-tuning, as observed in §5.2. Localizing the problem also enables one to incorporate linguistic expertise (Nzeyimana and Niyongabo Rubungo, 2022) and provide support for culturally relevant phenomena like transliteration or code-mixing. Despite this, we must be wary of excessive fragmentation in pre-training as it leads to higher maintenance costs and there is a possibility that these benefits will be overcome with advances in compute and model capacity in the near future. Optimal fine-tuning however, is promising, as evidenced in §5.3 where we observe significant gains in moving away from the zero-shot paradigm.

7 Conclusion

We have proposed a framework for the evaluation of NLP technology based on diversity, equity, and inclusion and proposed the Gini coefficient to quantify equity. We have assessed to what extent several modeling and data choices affect the value NLP technology confers to speakers of Indian languages. We have also proposed an algorithmic method for resource allocation for task-specific fine-tuning, which outperforms a purely egalitarian distribution of data labeling. Finally, we highlight the importance of building representative evaluation sets from the grass-roots level to enable tracking progress, and discuss how even with the best modeling strategies, we have a long road ahead in building inclusive, equitable systems. While region-specific choices help to a certain extent, building a single global multilingual model without compro-

missing on the three metrics is something we should move towards in the future. We sincerely hope our evaluation paradigm aids in tracking the community’s progress in building linguistically diverse technologies.

Limitations

We do not consider the inequalities that may exist within subgroups in a language given the lack of fine-grained evaluation data. In multilingual countries like India, each language is composed of several dialects (Hindi alone is composed of 58 dialects (Chandramouli, 2011)). As disparities exist along multiple axes such as caste, gender, religion and so on (Sambasivan et al., 2021), it is imperative to go beyond the language level. We only consider pre-trained language models for our experiments given their massive language coverage and zero-shot transfer capabilities. There have been efforts to build language-specific, task-specific models which we do not include in our study. Our greedy data allocation method is a strong baseline that outperforms standard approaches such as selecting a single source language or uniform selection. It can be improved by incorporating notions of language similarity, which requires more complex methods (Song et al., 2019).

A Appendix

A.1 Efficiency

We report the throughput and memory for each model and task in Table 7. For NLI, POS and NER, the maximum sequence length is 128 and for QA it’s 384.

As detailed in Section 3.3, we need to calculate the AMRS for each metric M (throughput and memory saved), to calculate the efficiency score. As described in (Ma et al., 2021), each model has properties (or *goods*) that inform its utility. Here, these goods are throughput, memory saved, and performance. A model is a point in this space of goods and an indifference curve is a set of points

that provide the same utility (for different values of these properties). These curves are monotonically negatively sloped, i.e., for a model with higher accuracy to be on the same curve as one with a lower accuracy, it will have to use up more memory or have lower throughput. For a given indifference curve, the rate at which this trade-off is made, is called the marginal rate of substitution (MRS).

To calculate MRS, and consequently AMRS, (Ma et al., 2021) make two key assumptions: **i)** All models lie on the same indifference curve; **ii)** if $M(x_i) > M(x_{i+1})$ and $\text{perf}(x_i) > \text{perf}(x_{i+1})$, then there exists a model $(\text{perf}(x_{i+1}), M(x_i) + (M(x_i) - M(x_{i+1})))$ on the same indifference curve as x_i . For our case study, we believe that assuming regional and global models to lie on the same indifference curve would be inaccurate, since models with the same capacity (size and architecture) have been trained on a different set of languages. In the case of (Ma et al., 2021), they only consider models pre-trained on English. Here, we assume that regional models (trained on 15-17 languages) would be strictly better on all dimensions and hence lie on a different indifference curve as compared to global models (trained on 100+ languages). Hence, we assume IndicBERT, MuRIL_{base} and MuRIL_{large} to lie on one indifference curve and XLM-R_{base} and XLM-R_{large} to lie on another. The second assumption holds in our case as well.

For a model x_i , Efficiency(x_i), MRS, and AMRS are given by :

$$\text{Efficiency}(x_i) = \sum_M w_M * \frac{M(x_i)}{\text{AMRS}(M, \text{perf})}$$

$$\text{AMRS}(M, \text{perf}) = \overline{\text{MRS}}$$

$$\text{MRS} = \left\{ \left| \frac{M(x_i) - M(x_{i+1})}{\text{perf}(x_i) - \text{perf}(x_{i+1})} \right| \mid 1 \leq i < n \right\}$$

A.2 Pre-training Languages

In Section 5.1, we choose IndicBERT, MuRIL and XLM-R as pre-trained multilingual models to base our analysis upon. IndicBERT is trained on 11 IN languages that include Assamese (as), Bengali (bn), Gujarati (gu), Hindi (hi), Kannada (kn), Malayalam (ml), Marathi (mr), Oriya (or), Punjabi (pa), Tamil (ta), Telugu (te). XLM-R includes 15 IN languages in training with the addition of Nepali (ne), Sanskrit (sa), Sindhi (sd) and Urdu (ur) over IndicBERT and MuRIL is trained on 16 IN languages, with the addition of Kashmiri (ks) over XLM-R.

Model	Metric	NER	PoS	NLI	QA
IndicBERT	Memory Saved	15.9GB			
	Throughput	22.6	20.2	22.9	10.5
	Perf (EN)	41.3	71.6	69.7	52.4
XLM-R _{base}	Memory Saved	15GB			
	Throughput	24.4	23.2	26.4	14.9
	Perf (EN)	61.7	82.2	77.1	72.1
MuRIL _{base}	Memory Saved	15.1GB			
	Throughput	23.8	23.1	26.2	15.7
	Perf (EN)	74.9	80.3	78.9	77.5
XLM-R _{large}	Memory Saved	13.9GB			
	Throughput	9.4	10.0	10.4	4.1
	Perf (EN)	64.6	83.7	81.8	81.4
MuRIL _{large}	Memory Saved	14.1GB			
	Throughput	9.8	9.9	10.5	4.2
	Perf (EN)	71.8	83.4	82.8	83.0
AMRS (Regional)	Throughput	1.7	3.4	2.2	1.1
	Memory	0.1	0.3	0.2	0.1
AMRS (Global)	Throughput	3.7	7.1	3.3	1.2
	Memory	0.3	0.5	0.2	0.1

Table 7: The throughput is given by the number of instances processed per second by the fine-tuned models on CPU.

A.3 Gini Coefficient

The Gini coefficient is mathematically computed based on the Lorenz curve, which plots the relation between population size and the cumulative income earned by that population as shown in Figure 1. To plot the Lorenz curve, individuals are sorted in increasing order of income (x-axis) and their cumulative wealth is plotted on the y-axis. In essence, a point (x, y) indicates that the bottom x% of the population holds y amount of wealth. The line at 45 degrees represents perfect equality of incomes. The Gini coefficient G is then calculated as the ratio of the area that lies between the line of equality and the Lorenz curve (A in Figure 1), over the total area under the line of equality (A + B in Figure 1). If G = 0, every person in the population receives an equal percentage of income and if G = 1, a single person receives 100% of the income. Since the axes scale from 0 to 1, A + B = 0.5. In essence, if the Lorenz curve is represented by the function Y = L(X) then G can be given as:

$$G = \frac{A}{A + B} = 2A = 1 - 2B = 1 - 2 \int_0^1 L(X) dX$$

For a population with values y_i , $i = 1 \dots n$, that are indexed in non-decreasing order ($y_i \leq y_{i+1}$):

$$G = \frac{1}{n} \left(n + 1 - 2 \frac{\sum_{i=1}^n (n + 1 - i) y_i}{\sum_{i=1}^n y_i} \right)$$

For comparison, for OECD countries from 2008–2009, the Gini coefficient on income for the entire

Metric	Train Lang.	Model	NER	PoS	NLI	QA	Average
Gini Coeff. ↓	English	IndicBERT	0.155	0.107	0.051	0.091	0.101
		XLM-R _{base}	0.095	0.067	0.058	0.048	0.067
		MuRIL _{base}	0.047	0.086	0.048	0.03	0.052
		XLM-R _{large}	0.084	0.06	0.049	0.026	0.055
		MuRIL _{large}	0.051	0.086	0.051	0.027	0.057
	Hindi	IndicBERT	0.173	0.073	0.004	0.041	0.073
		XLM-R _{base}	0.067	0.037	0.039	0.046	0.047
		MuRIL _{base}	0.062	0.032	0.036	0.012	0.035
		XLM-R _{large}	0.057	0.04	0.033	0.029	0.04
		MuRIL _{large}	0.065	0.057	0.033	0.014	0.042

Table 8: *Gini Coefficient* for all models calculated only across languages having evaluation sets for each task.

Task	Batch Size	Learning Rate	No. of Epochs	Warmup Ratio	Max. seq. Length
NER	32	2e-5	10	0.1	128
POS	32	2e-5	10	0.1	128
NLI	64	2e-5	3	0.1	128
QA	32	3e-5	2	0.1	384

Table 9: Hyperparameter details for each fine-tuning task

population ranged between 0.34 and 0.53. The Gini coefficient on income for the entire world has been estimated to be between 0.61 and 0.68 (Hillebrand et al., 2009; Klugman and Nations, 2010). In our experiments on Indian languages, state-of-the-art models achieve an average Gini coefficient of 0.77, which highlights the disparity in performance even among languages within a single region.

As mentioned in Section 5.2, calculating the Gini coefficient across all 23 languages doesn’t reflect the dispersion in performances across languages for which we have test sets. To compare between baselines, we additionally report the Gini coefficient evaluated only across those languages for which we have test sets as shown in Table 8. We observe that region-specific choices (MuRIL_{base} fine-tuned on HI) lead to the lowest value, similar to what we observe with the global metric.

A.4 Fine-tuning Details

We fine-tune all models using the hyperparameters mentioned in Table 9 for each task and model consistently throughout the paper. We make use of the XTREME codebase¹⁴ to finetune these models using a NVIDIA A100 GPU. We make an exception for IndicBERT when fine-tuning on NER, where we fine-tune for 15 epochs instead of 10, to reach convergence.

A.5 Budget Allocation

In Section 4, we describe an empirical budget allocation scheme for fine-tuning of pre-trained models

¹⁴<https://github.com/google-research/xtreme>

that can jointly optimize on our proposed metrics. We follow a greedy approach to solve this problem, as shown in Table 10. In this paper, we solve this for one task, namely NER, but the methodology proposed is generally extensible to any task and combination of languages since it is purely empirical. We select seven source languages for which we have enough training data and fine-tune MuRIL_{large} and XLM-R_{large} for each of these source languages independently, for two epochs. During fine-tuning, we evaluate on each of our target languages after every 10 steps of training. Given our batch-size is 32, we gather data-points at a step size of 320 training instances. Consequently, say we have 5000 training instances for a source language, we gather approximately 30 sample points for that source language and any target language. Using these, we plot best-fit curves for $\forall(s, t)$ pairs using the *scipy.optimize.curve_fit* package. Given a function, $f(x)$, *curve_fit* uses non-linear least squares to fit $f(x)$ to the observed data-points. We define $f(x)_{s,t} = a_{s,t} + b_{s,t} * x^{-c_{s,t}}$, because the relation between model performance and training data follows a power-law distribution (Rosenfeld et al., 2019). The best-fit curves for each source and target pair are shown in Table 11. The visualizations of the best-fit curves for a sample training language (Tamil) are shown in Figures 2, 3. Having determined constant values $\{a_{s,t}, b_{s,t}, c_{s,t}\} \forall(s, t)$ independently, we proceed with finding the optimal allocation using the algorithm described in Table 10. We solve this for three different budgets, i.e., 1,000; 5,000 and 10,000 and the optimal allocations for each budget are shown in Table 12.

Greedy Algorithm

- 1: **Input:** Fine-tuning labeled data $\forall s \in S$. A fixed budget of labeled data instances X
 - 2: **Initialize:** Set the total number of allocated instances to zero, i.e., $\text{allocated} = 0$, the number of allocated samples for each source language to zero, i.e. $\text{samples}[s] = 0 \forall s \in S$, the current global metric for each source language to $-\text{inf}$, i.e. $\text{current_gm}[s] = -\text{inf} \forall s \in S$ and the current gini coefficient for each source language to 1, i.e. $\text{current_gini}[s] = 1 \forall s \in S$
 - 3: **while** $\text{allocated} < X$ **do**
 - 4: $\text{highest_marginal_gain} = 0$
 - 5: **for** s in S **do**
 - 6: $\text{gm}_s = \sum_{t \in T} d_t^{(r)} * (a_{s,t} + b_{s,t} * (\text{samples}[s] + 1)^{-c_{s,t}})$
 - 7: $\text{gini}_s = F[\text{abs}(\text{performance}_{s,t}(\text{samples}[s] + 1)) \forall t \in T]$
 - 8: $\Delta \text{gm}_s = \text{gm}_s - \text{current_gm}[s]$
 - 9: $\Delta \text{gini}_s = \text{current_gini}[s] - \text{gini}_s$
 - 10: $\text{marginal_gain} = \alpha * \Delta \text{gm}_s + \beta * \Delta \text{gini}_s$
 - 11: **if** $\text{marginal_gain} > \text{highest_marginal_gain}$ **do**
 - 12: $\text{highest_marginal_gain} = \text{marginal_gain}$
 - 13: $\text{best_language} = s$
 - 14: $\text{best_gm} = \text{gm}_s$
 - 15: $\text{best_gini} = \text{gini}_s$
 - 16: **end if**
 - 17: **end for**
 - 18: $\text{samples}[\text{best_language}] = \text{samples}[\text{best_language}] + 1$
 - 19: $\text{allocated} = \text{allocated} + 1$
 - 20: $\text{current_gm}[\text{best_language}] = \text{best_gm}$
 - 21: $\text{current_gini}[\text{best_language}] = \text{best_gini}$
 - 22: **end while**
-

Table 10: A greedy approach to solve the constrained optimization for the budget allocation problem as described in Appendix A.5.

Abstract

Traditional systems designed for task oriented dialog utilize knowledge present only in structured knowledge sources to generate responses. However, relevant information required to generate responses may also reside in unstructured sources, such as documents. Recent state of the art models such as HyKnow (Gao et al., 2021b) and SEKNOW (Gao et al., 2021a) aimed at overcoming these challenges make limiting assumptions about the knowledge sources. For instance, these systems assume that certain types of information, such as a phone number, is *always* present in a structured knowledge base (KB) while information about aspects such as entrance ticket prices, would always be available in documents.

In this paper, we create a modified version of the MutliWOZ-based dataset prepared by (Gao et al., 2021a) to demonstrate how current methods have significant degradation in performance when strict assumptions about the source of information are removed. Then, in line with recent work exploiting pre-trained language models, we fine-tune a BART (Lewis et al., 2020) based model using prompts (Brown et al., 2020; Sun et al., 2021) for the tasks of querying knowledge sources, as well as, for response generation, without making assumptions about the information present in each knowledge source. Through a series of experiments, we demonstrate that our model is robust to perturbations to knowledge modality (source of information), and that it can fuse information from structured as well as unstructured knowledge to generate responses.

1 Introduction

Most existing work on task-oriented dialog systems assumes that the knowledge required for completing a task (eg: booking a restaurant reservation), resides in structured knowledge sources. Thus, typical task-oriented dialog systems require generating a *belief state*, that can be used to query a knowledge

base to fetch entity results; these results are then used to generate responses. Recognizing that information is not always present in structured resources, recently methods that can additionally use unstructured knowledge (eg: document collections), have also been developed (Kim et al., 2020; Gao et al., 2021a). However, current state-of-the-art models designed for such tasks make limiting assumptions about the nature of knowledge sources, that make them unsuitable for use in real-world settings.

Limitations of existing methods: First, current task-oriented dialog systems designed to reason over hybrid knowledge sources assume that a knowledge base and the unstructured knowledge source encode separate pieces of information about entities (eg: the zip-code is always in structured knowledge, ticket prices are always available in unstructured text) (Kim et al., 2020; Zhang et al., 2021). This is not reflective of real-world knowledge, where independent information systems are often fused to enable applications.

Second, existing systems are trained to learn the source of different pieces of information, thus, making them unsuitable for situations where any field that was previously in a structured knowledge source is now available in an unstructured knowledge source (and vice versa). In effect, a simple change in the modality of information can result in a failure of the model to utilize the information present in knowledge, as existing models memorize the source of every piece of information.

Third, such systems assume that each knowledge grounded response can contain information from only *one* source type (Kim et al., 2020; Gao et al., 2021a; Zhang et al., 2021) – either structured or unstructured knowledge. This is an artificial constraint imposed to make modelling easier, but real-world conversations can routinely require systems to fuse information from more than one knowledge type (eg: See Dialog turn 4 in Figure 1).

Contributions: In this paper, we present our work

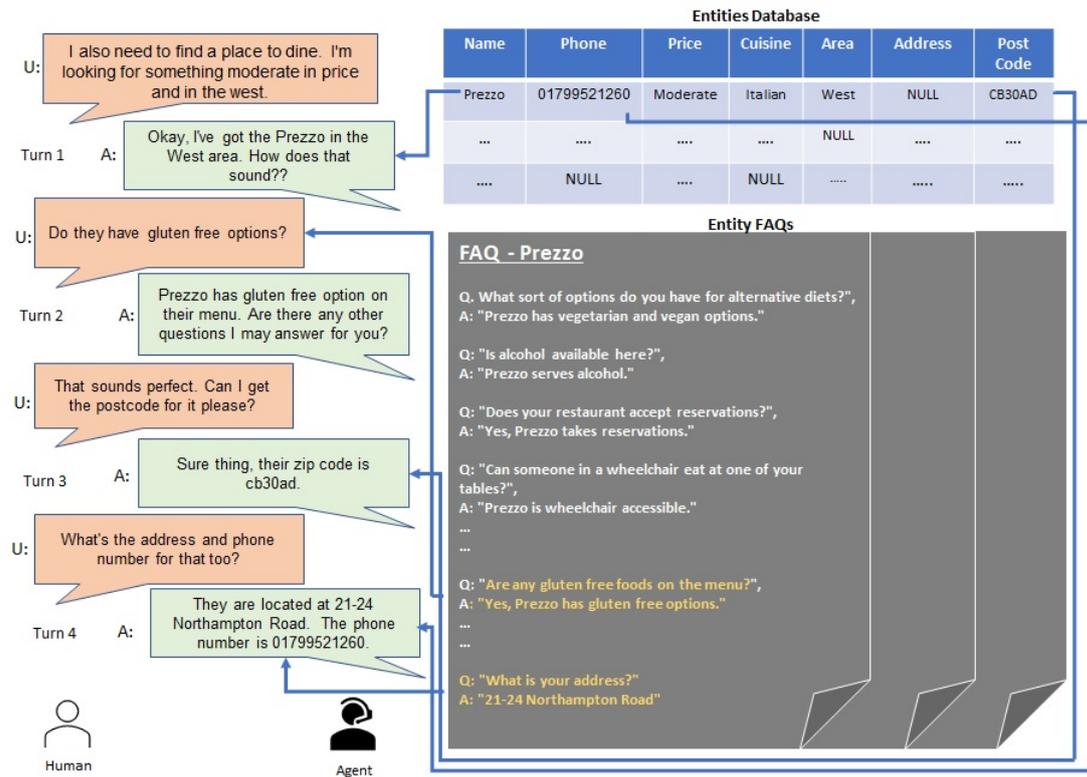

Figure 1: Example of a dialog requiring the use of data from two different sources. Agent Turn 4, requires incorporating information from both structured (DB Table) and unstructured data (a document consisting of FAQs for the entity).

aimed at removing each of these strict assumptions from task-oriented dialog systems. Current methods for joint-reasoning in task oriented dialogs have been developed using an augmented version of MultiWOZ 2.1 which contains additional dialog turns based on new unstructured information (Gao et al., 2021a). Unfortunately, no attempt has been made to distribute information across knowledge sources. We therefore create a modified version of this dataset (called HYBRIDTOD) that optimally redistributes information across structured and unstructured knowledge so that most dialogs in the train dataset are affected by this change.

A trivial method of redistributing information across structured and unstructured knowledge sources would be to arbitrarily move structured fields for some entities to the unstructured knowledge source. However, since the universe of entities in the dataset is very large and not all entities are directly referred to in the dialogs, such a method of redistributing information may not be as effective if the dialogs do not use the slot-values that have been redistributed. We therefore, develop an automated graph based approach which uses the max-cut of the graph to optimally redistribute infor-

mation from structured to unstructured knowledge sources.

Lastly, in line with recent work exploiting pre-trained language models, we fine-tune BART (Lewis et al., 2020) using prompts for the tasks of querying knowledge as well as response generation without making assumptions about the information present in each knowledge source. Specifically, we do Prompt+LM finetuning (Liu et al., 2021a) in which both the prompt and model parameters are trainable (Ben-David et al., 2021; Liu et al., 2021b; Han et al., 2021). Through a series of experiments, we demonstrate that our model is robust to perturbations to knowledge modality (source of information), and it can fuse information from structured as well as unstructured knowledge to generate responses.

In summary we make the following contributions¹: (1) We prepare a new version of the MultiWOZ-DSTC9 combined dataset (Kim et al., 2020; Gao et al., 2021a) called HYBRIDTOD to study the reasoning on hybrid knowledge sources for task oriented dialog systems. (2) We demon-

¹The constructed dataset and code used is available at <https://github.com/mayank31398/HybridToD>

Slot Type	Slot Values	Question Template	Answer Template
price	cheap	What is the price range?	It has \${price} pricing.
	expensive	How costly is \${restaurant name}?	\${restaurant name} is \${price}
cuisine	Italian	What is the cuisine?	\${restaurant name} caters for \${cuisine} cuisine.
	Thai	What type of food is served here?	You can find \${cuisine} food here

Table 1: Examples of templates used for moving slot values from the structured to the unstructured knowledge source.

strate that our model (referred to as JOINTLM) is also able to fuse information from both knowledge modalities and beats existing state-of-the-art systems on standardized metrics. (3) We present detailed ablation studies demonstrating the value of our modelling choices.

2 Related Work

Modeling Task Oriented Dialogs: Multiple flavours of this problem have been defined to address different aspects of modeling - eg: belief state tracking to assess whether a model is able to correctly decode the query needed given a current conversational context (Dey and Desarkar, 2021; Li et al., 2021; Yang et al., 2021), generating responses given belief states to assess whether a model is able to correctly predict the knowledge attributes to be used in a response (Yang et al., 2021; Chen et al., 2019; Gao et al., 2020; Mohapatra et al., 2021), end-to-end modeling of dialog systems where models are assessed on the correctness of the response generated including the values used from the knowledge base (Bordes et al., 2017; Raghu et al., 2021b), etc. Recent work that assumes that belief state annotations are latent and not available for training have also been developed (Raghu et al., 2021a).

Knowledge Grounded Dialog: Dialog systems that generate responses on information grounded in external knowledge have also been developed. Unlike, work on task oriented dialogs, which primarily focuses on using structured knowledge to complete a ‘goal’ or accomplish a ‘task’ (eg: POI recommendation for in car navigation (Eric et al., 2017), restaurant, hotel or flight booking (El Asri et al., 2017), etc), most existing knowledge grounded systems are designed to address informational needs of users (eg: answering queries based on collections of documents, making response recommendations to contact center agents). Finally, contemporaneous to our work, knowledge grounded response generation tasks that combine information from hybrid knowledge sources have also been proposed

(Nakamura et al., 2022). Here, unlike task oriented dialog systems, which require the retrieval of an entity to make recommendations or accomplish a task, in such tasks, the goal is to answer an informational seeking query in a chat-conversation. Models are required to use the dialog context to fetch related tables (often flattened and encoded as independent table cells), along with documents to generate a response.

3 The HYBRIDTOD Dataset

The dataset prepared by (Gao et al., 2021b) (referred to as the SEKNOW-MULTIWOZ dataset in this paper) is the only publicly available task-oriented dialog dataset in which the dialogs are grounded on two types of knowledge sources: structured and unstructured (FAQs). However, SEKNOW-MULTIWOZ is not indicative of a real-world setting due to two major limitations: (1) It has a strict, slot-type to knowledge-source type mapping. For example, the slot-type ‘cuisine’ is always in the structured source while ‘timings’ of operation would always be mentioned in unstructured documents, and (2) an agent response contains information from only one source (i.e., either from structured or unstructured). To alleviate these limitations, we systematically modify the knowledge sources in SEKNOW-MULTIWOZ to construct a new dataset that we refer to as HYBRIDTOD.

Dataset Construction: We first create an undirected graph $G = (V, E)$ where each vertex $v \in V$ is a unique slot-value and an edge $e \in E$ exists between two vertices, if the slot values represented by these vertices occur together in a training dialog utterance. For instance, in Figure 1 nodes associated with slot-values “21-24 Northampton Road” and phone number “01799521660” would have an edge between them due to Turn 4. Similarly, vertices corresponding to the values for slot-type ‘cuisine’ *Italian* and the slot-type ‘address’ *21-24 Northampton Road* would have had an edge between them if the utterance at Turn 4 was instead, “It is an *Italian restaurant located at 21-24 Northampton*

Domain	Context-Response pairs			Number of entities
	train	validation	test	train/validation/test
hotel	19370	2316	2295	33
restaurant	19716	2162	2188	110
attraction	8192	1226	1246	79
total	47278	5704	5729	222

Table 2: Number of context-response pairs in the dataset

Domain	SEKNOW-MULTIWOZ	HYBRIDTOD
hotel	10.97	6.79
restaurant	8.12	5.25
attraction	9	6.38

Table 3: Average number of slot values by domain in the structured knowledge source for each dataset.

Road". Our goal is to move some of the slot-values (vertices) in G that are originally in the structured knowledge source to the unstructured knowledge source so as to alleviate some of the limitations of the original dataset.

In order to identify which vertices to move, we create a maxcut of the graph G using the Max-CutBM algorithm (Boumal et al., 2016). A maxcut results in a graph in which the most number of edges from the original graph are ‘cut’. After the application of MaxCut, all slot values in one graph partition are retained in the structured knowledge source, while the others are converted to text QA pairs using templates and included as part of the unstructured document associated with that entity. The templates for the restaurant slot types ‘price’ and ‘cuisine’ are shown in Table 1 for illustration. Since the edges of the graph are based on slot-value mentions in dialog utterances, applying a maxcut modifies the knowledge source in a way that it affects most dialog turns in the dataset; in other words, the max-cut ensures the maximum possible utterances in the dataset have information fused from both knowledge sources.

Since we move slot values from one partition of the graph to the unstructured knowledge source, a slot type can now have some values in structured knowledge and some in unstructured knowledge (as an FAQ). We find that our approach ends up modifying each entity referred to in the dataset, and that slot-values of the same type are now distributed across different types of knowledge.

Domain	SEKNOW-MULTIWOZ	HYBRIDTOD	UNSTRUCTURED TOD
hotel	36.52	40.58	46.48
restaurant	14.96	17.83	22.7
attraction	0	2.62	8

Table 4: Average number of FAQs for each domain in the unstructured knowledge source.

For experimentation, we also create a version of the dataset with all slot values² moved from the structured to the unstructured knowledge source. We refer to this dataset as UNSTRUCTURED TOD. To construct HYBRIDTOD and UNSTRUCTURED TOD dataset, we only consider dialogs from 3 domains: hotel, restaurant and attraction. We omit dialogs from other domains as they do not have associated knowledge. For example, the taxi domain only contains the information that the slot-type *phone* should match the regular expression $[\"^[0-9]{10}\$\"]$, but does not contain any instance of phone numbers present in the train dialogs.

Dataset Statistics: The number of context-response pairs (spread across the 3 domains: hotel, restaurant and attractions) for HYBRIDTOD are shown in Table 2. We also show the entity distribution by domain-type. The restaurant domain dominates the knowledge sources, occupying almost half of the total entities and the other half is constituted by hotel and attraction domains. Tables 3 and 4 show the distribution of entity slot-values in structured knowledge sources and FAQs in the unstructured knowledge source for each domain in the datasets. As can be seen, the average number of slot-values presented in structured knowledge are lesser in HYBRIDTOD as compared to SEKNOW-MULTIWOZ and correspondingly the number of FAQs in HYBRIDTOD are higher as compared to SEKNOW-MULTIWOZ. We present the detailed slot-type distribution of SEKNOW-MULTIWOZ and HYBRIDTOD in the appendix. We find that approximately 50% slot-values are moved to unstructured knowledge from the structured sources for each slot-type.

Limitations of the Dataset: Information about entities is only redistributed from the structured knowledge source to the unstructured knowledge source. In effect, information that was previously in unstructured knowledge sources continues to remain there. Redistributing information from unstructured documents to structured documents would require annotations to be able to extract facets to be converted to slot-types.

We describe our model, JOINTLM in the next section.

²The entity name is also a slot type but we always retain it in both knowledge sources.

4 JOINTLM

The problem of utilizing information and responding to users in task-oriented dialogs can be broken down into parts: (i) Querying Knowledge Source (structured and/or unstructured) to return entities (ii) Generating Responses (eg:sharing information about entities, requesting for more details from the user, etc).

We represent the dialog context as $c = (u_1, r_1, \dots, u_n)$, where (u_i, r_i) represent the user and the system response utterance at i^{th} turn respectively. We represent the entity e required for generating the response as the concatenation of its slot-values (from structured KB), represented as e^s , and FAQs from the unstructured knowledge source, represented as e^{us} :

$$\begin{aligned} [e^s] &= \langle struct \rangle \langle slot \rangle slot_1 \langle val \rangle value_1 \\ &\quad \langle slot \rangle slot_2 \langle val \rangle value_2 \dots \\ [e^{us}] &= \langle unstruct \rangle \langle doc \rangle document_1 \\ &\quad \langle doc \rangle document_2 \dots \\ [e] &= [e^s] [e^{us}] \end{aligned}$$

where $\langle struct \rangle$, $\langle unstruct \rangle$ are special tokens to demarcate the start of structured knowledge and unstructured knowledge of an entity respectively. $\langle slot \rangle$, $\langle val \rangle$ demarcate the slot-type and its value and $\langle doc \rangle$ denotes the start of a document from unstructured knowledge. We train JOINTLM to jointly model two tasks: entity retrieval and response generation. We use a hyperparameter α to weigh the two tasks during training, where α denotes the number of training samples used for entity retrieval task. Note that $\alpha = 0.5$ denotes equal number of examples for both the tasks.

4.1 Entity Retrieval

As discussed, prior to generating a response, we need to retrieve the relevant entity required to generate the response. We represent the inputs to the language model (LM) for this task as:

$$\begin{aligned} &\langle entity_retrieval_task \rangle \langle u \rangle u_1 \langle r \rangle r_1 \dots \\ &\langle u \rangle u_n \langle entity \rangle [e_j] \end{aligned}$$

where, $e_j \in \mathcal{E}$, the set of all entities, $\langle entity_retrieval_task \rangle$ and $\langle entity \rangle$ are special tokens for task prompting and demarcating the start of an entity. We train the model to generate the special tokens $z_j = \langle relevant \rangle$ or $z_j = \langle irrelevant \rangle$

for each entity e_j given the context c . We choose the best entity e as:

$$e = \underset{e_j}{\operatorname{argmax}} p(z_j = \langle relevant \rangle | c, e_j) \quad (1)$$

During training we use a subset of the entities in \mathcal{E} for creating the positive and negative set of entities. However, at inference time, we evaluate on all the entities in \mathcal{E} .

4.2 Response Generation

After scoring all entities, we use the context and the best entity e (the entity with the highest score for the $\langle relevant \rangle$ token) and generate response using the same LM. We represent the inputs for this task as:

$$\begin{aligned} &\langle response_task \rangle \langle u \rangle u_1 \langle r \rangle r_1 \dots \\ &\langle u \rangle u_n \langle entity \rangle [e] \end{aligned}$$

where $\langle response_task \rangle$ is a special token to prompt this task. We train the model to generate the response token-by-token.

4.3 Training details

We train our model to minimize $\sum_{(c,r)} \mathcal{L}(\theta, c, r)$, where

$$\begin{aligned} \mathcal{L}(\theta, c, r) &= -\alpha \log p_\theta(z_j | c, e_j) \\ &\quad - (1 - \alpha) \log p_\theta(r | c, e_j) \end{aligned}$$

The first term in the above objective represents the log-likelihood of retrieving the relevant entity and the second term is the log-likelihood of generating the response. Note that the term α (percentage of samples for each task) can be adjusted by changing the number of examples for the two tasks in a given batch of fixed size.

To train our model, we use early stopping with $patience = 5$ for the above objective on the validation set to prevent overfitting of our model. The loss was optimized using AdamW optimizer (Loshchilov and Hutter, 2017). We use a batch-size of 8 examples, with 4 examples for entity retrieval and 4 for response generation per batch. For the 4 examples for entity retrieval, 2 are positive and 2 are negative examples (effectively our batch is $2 + 2 + 4$). We use equation 1 during inference to pick the highest scored relevant entity.

Train Dataset	Test Dataset	Model	Bleu-1	Bleu-4	slot-values

5 Experiments

Our experiments are aimed at answering the following questions: (1) How does JOINTLM perform compared to the baseline when trained and tested on HYBRIDTOD? (2) How does the change in slot-value distribution across structured and unstructured sources affect the performance of the models? (3) Is joint training of PromptLM for the two tasks of entity retrieval and response generation helpful? (4) How does JOINTLM compare with natural baselines for entity retrieval?

Experimental Setup: Task oriented dialog systems have to identify relevant entities (e.g. restaurants) from associated knowledge sources needed to generate a response. In order to identify these relevant entities, existing datasets provide the belief state annotations during training. Additionally, in our work for each dialog context, we associate a set of (positive) entities that exactly match the requirements present in the dialog context and a set of (negative) entities that do not match by an automated method. Note that the text snippets in the unstructured corpus do not have any annotations.

For all of our experiments, we use BART (Lewis et al., 2020) encoder-decoder based language model and finetune the pretrained model on the three datasets i.e, SEKNOW-MULTIWOZ (Gao et al., 2021a), HYBRIDTOD and UNSTRUCTURED-TOD datasets.

Baseline: We use the current state-of-the-art model for joint reasoning, SEKNOW (Gao et al., 2021a) model as our baseline. SEKNOW is designed to use belief state annotations – specifically, SEKNOW is trained to generate the belief state given the dialog context. These belief states are then used to query

the knowledge sources and generate a delexicalised response using the context and the generated belief state. The slot-values in the delexicalised response are then populated using an unordered set of entities returned by the belief state query on the structured knowledge source.

5.1 Evaluation Metrics

We report BLEU scores for assessing response generation performance and slot-value precision, recall and $F1$ for comparing the slot-value filling performance against the baseline. As described previously, since no new slot types were created from unstructured documents, the slot-value metrics are computed only using the slot-types that were originally present in the structured knowledge source.

We also report success@k for entity retrieval baselines to assess the performance of systems on the entity selection task. We define success@k as 1 if the top-k scored entities contain a relevant entity for response generation and 0 otherwise. However, note that it is not possible to measure success@k on SEKNOW since it generates the response using an unordered set of entities returned by the belief state query. We thus compare the two models only based on their performance on response generation.

5.2 Results

Knowledge-Source Memorization: We train and test both JOINTLM and the baseline model, SEKNOW on HYBRIDTOD and observe that JOINTLM outperforms SEKNOW by 13 points on slot-value F1 score (Row 1, Table 5). Also, the performance of SEKNOW drops from 48.31 (Row

Train Dataset	Test Dataset	Model	success@1	success@5	Bleu-1	Bleu-4	prec.	recall	F1
HYBRIDTOD	HYBRIDTOD	JOINTLM	84.50	86.57	30.59	8.67	50.56	45.83	48.08
		SEPLM	79.79	85.64	29.96	8.66	47.08	42.53	44.69
		TF-IDF	28.31	34.49	-	-	-	-	-

Table 7: Performance of models on the entity retrieval task.

1, Table 6) when trained/tested on the SEKNOW-MULTIWOZ dataset to 35.14 (Row 1, Table 5) when trained/tested on HYBRIDTOD dataset. This severe drop in performance is indicative of the fact that SEKNOW learns the source of slot-values and is unable to use information when the source of the particular slot-value can be varying (structured/unstructured) across entities.

Generalization of JOINTLM: To assess the generalization performance of the models, we train all the models on HYBRIDTOD and test on other datasets which have different slot-value distributions. As can be seen from Table 5, when trained on HYBRIDTOD, JOINTLM outperforms SEKNOW on all three dataset settings, SEKNOW-MULTIWOZ, HYBRIDTOD and UNSTRUCTURED-TOD across all response generation metrics. We also notice that JOINTLM trained on HYBRIDTOD is robust to change in the knowledge modality during inference (slot-value F1 stays at approx. 48). This is not the case for SEKNOW which exhibits large drop (31% from SEKNOW-MULTIWOZ to HYBRIDTOD and 45% from SEKNOW-MULTIWOZ to UNSTRUCTURED-TOD) in slot-value F1, as the distribution of slot-types changes in different datasets (Table 5).

We also train the models on SEKNOW-MULTIWOZ, and test on the other datasets and notice that JOINTLM outperforms SEKNOW on both HYBRIDTOD and UNSTRUCTURED-TOD (Table 6). However, SEKNOW has better slot-value F1 than JOINTLM on HYBRIDTOD. We hypothesize that this is because the belief state labels are more informative and provide a very strong signal for SEKNOW on SEKNOW-MULTIWOZ and this has the effect of SEKNOW learning the knowledge modality which is not the case for JOINTLM. This suggests that JOINTLM has better generalization performance.

5.3 Model Ablation Study

To study the importance of joint-training of our model, we also train a model without prompts using entity annotations, where two different BART (Lewis et al., 2020) models are trained for retrieval and generation. We call this model SEPLM. This

Dialog context

User: Suggest me some *Turkish* restaurants in Cambridge.

Agent: Yes there is a *Turkish* restaurant in Cambridge with two different locations, would you like the addresses?

User: I would like if its located in the *center* of the city price one located in the center of city and I don't care about the pricing.

Response

Ground truth response: I have two *Turkish* restaurants, both in the *center* and both *expensive*. May I recommend *Meze Bar*?

	SEKNOW	JOINTLM
SeKnow-MultiWOZ	I found a restaurant at <i>196 Mill Road City Centre</i> . Their phone number is <i>01223362372</i> .	<i>Meze Bar</i> is a <i>Turkish</i> restaurant in the <i>expensive</i>
HybridToD	I found a restaurant at <i>196 Mill Road City Centre</i> . Their phone number is {null}.	price range. Their address is <i>196 Mill Road City</i>
UnstructuredToD	I found a restaurant at {null}. Their phone number is {null}.	<i>Centre</i> .

Table 8: Response generated by SEKNOW and JOINTLM on the three datasets.

model is trained on HYBRIDTOD and is compared against JOINTLM on both entity retrieval and response generation (Table 7). We observe that JOINTLM outperforms SEPLM in both the tasks with a 5 points difference in success@1 and a 3 points difference in slot-value F1. This confirms that the joint modeling of the 2 tasks using prompting yields a better model than learning a separate model for the 2 tasks at hand. For a detailed evaluation on all other dataset combinations, please refer to the Appendix. For comparison with a non-neural entity retrieval baseline, we also report the success scores BM25 based TF-IDF retriever which are significantly worse than the neural retrievers used for JOINTLM and SEPLM. These experiments highlight the benefit of joint modeling of the two tasks.

5.4 Qualitative Study

In Table 8, we show the responses generated for a sample dialog by JOINTLM and SEKNOW on the three datasets used for our experiments. It should be noted that JOINTLM generates the same response for all the three datasets. However, SEKNOW is not able to populate the required slot-values for this entity (*Meze Bar*) in the response in HYBRIDTOD and UNSTRUCTURED-TOD when those slot-values are no longer available in the structured source.

6 Conclusion

In this paper we presented a new dataset, HYBRID-TOD that requires reasoning over both structured and unstructured knowledge sources to generate responses to dialogs. Unlike existing task-oriented dialog datasets, it does not restrict slot-types to specific knowledge sources. Through our experiments we demonstrated how existing methods do not adapt well to changing distributions of slot-type sources and that our model JOINTLM (trained using entity annotations rather than belief state), not only generates better responses by reasoning over both knowledge sources, it also learns a better retriever for entities. In future work, we also plan to train our models without using any annotations i.e without any supervision on entity label information.

7 Limitations

Our dataset and model are not intended to be directly used in a real-world system as they have some inherent limitations. As mentioned in Section 3, we only redistribute slot types from structured knowledge sources to unstructured knowledge sources. Due to a lack of resources we are unable to annotate unstructured documents – our dataset has a bias that certain information will always appear in unstructured information. In addition, we rely on a pre-trained language model, BART, to generate responses. We have not assessed to what extent the generated responses could exhibit any form of social bias or toxic language (when prompted). We do not recommend that our system be used in a real-world deployed chatbot without further study. Lastly, this work has been assessed only on English language data using a pretrained language model developed for English.

8 Acknowledgement

The authors would like to thank Raunak Sinha for his contributions on the scripts for the development of the dataset.

A Appendix

A.1 Additional Results

We present additional results for the comparison of JOINTLM, SEPLM and SEKNOW (Gao et al., 2021a) when trained on HYBRIDTOD and tested on the other datasets (Table 9). We see that JOINTLM outperforms SEPLM and SEKNOW on all the datasets demonstrating the importance of joint modeling.

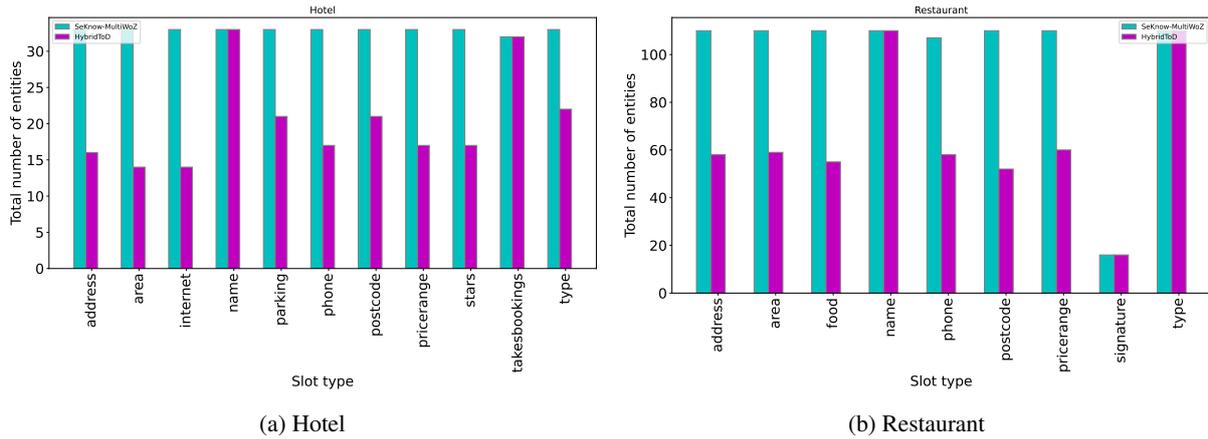

Figure 2: Figures 2a and 2b show the slot-value distribution by slot-types in the hotel and restaurant domains the three datasets.

Train Dataset	Test Dataset	Model	Bleu-1	Bleu-4	slot-values		
					prec.	recall	F1
HYBRIDTOD	SEKNOW-MULTIWOZ	JOINTLM	30.63	8.60	50.48	45.37	47.79
		SEPLM	30.03	8.63	47.26	42.76	44.89
		SEKNOW	29.20	7.83	43.16	28.65	33.14
HYBRIDTOD	HYBRIDTOD	JOINTLM	30.59	8.67	50.56	45.83	48.08

		SEKNOW	27.43	6.68	42.96	19.62	27.11

Table 9: All models trained on HYBRIDTOD and evaluated on the rest of the datasets

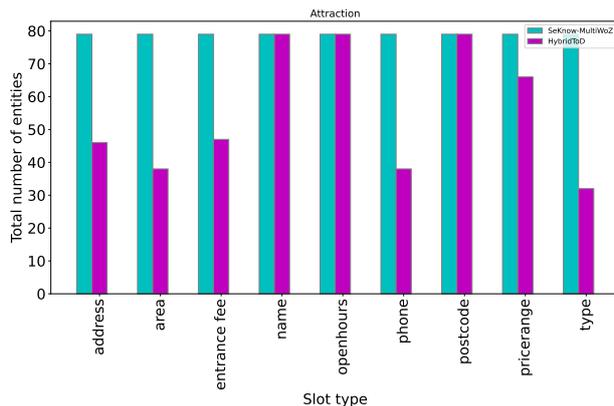

Figure 3: This figure shows the slot-value distribution by slot-types in the attraction domains in the three datasets.

A.2 Additional Dataset Statistics

We present the detailed slot-type distribution of SEKNOW-MULTIWOZ and HYBRIDTOD in Figure 2 and 3. We find that approximately 50% slot-values are moved to unstructured knowledge from the structured sources for each slot-type. The bar-graphs show the number of entities with a particular slot-type.

A.3 Hyperparameters and Training Details

For all our experiments, we use BART (Lewis et al., 2020) model from the HuggingFace Transformers library (Wolf et al., 2020). To train the BART model, we use early stopping with *patience* = 5 on the validation set to prevent overfitting of both the entity retriever and the response generator. We use learning rate = 10^{-5} with AdamW optimizer (Loshchilov and Hutter, 2017). We use a batch-size of 8 examples, with 4 examples for entity retrieval and 4 for response generation per batch. For the 4 examples for entity retrieval, 2 are positive and 2 are negative examples (effectively our batch is 2 + 2 + 4). All the experiments are conducted on a single A100 80GB GPU.

Revisiting Offline Compression: Going Beyond Factorization-based Methods for Transformer Language Models

Mohammadreza Banaei^{*1}, Klaudia Bałazy^{*2}, Artur Kasymov²
Rémi Lebret¹, Jacek Tabor², Karl Aberer¹

¹EPFL, ²Jagiellonian University

Abstract

Recent transformer language models achieve outstanding results in many natural language processing (NLP) tasks. However, their enormous size often makes them impractical on memory-constrained devices, requiring practitioners to compress them to smaller networks. In this paper, we explore offline compression methods, meaning computationally-cheap approaches that do not require further fine-tuning of the compressed model. We challenge the classical matrix factorization methods by proposing a novel, better-performing autoencoder-based framework. We perform a comprehensive ablation study of our approach, examining its different aspects over a diverse set of evaluation settings. Moreover, we show that enabling collaboration between modules across layers by compressing certain modules together positively impacts the final model performance. Experiments on various NLP tasks demonstrate that our approach significantly outperforms commonly used factorization-based offline compression methods.¹

1 Introduction

The recent trend of pre-training Transformer (Vaswani et al., 2017) language models on enormous unsupervised corpus has led to outstanding performances on many downstream tasks. For downstream tasks, these pre-trained models are then either fine-tuned (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019) or the *prompting* paradigm (Brown et al., 2020) is used (especially in the so-called Large Language Models), which avoids having a different model per task (Lieber et al., 2021; Rae et al., 2021; Smith et al., 2022; Thoppilan et al., 2022). In each of the two paradigms, it has been shown

that increasing the scale of language models generally leads to better performance on a range of downstream tasks (Devlin et al., 2019; Brown et al., 2020). Indeed, for autoregressive language models, Kaplan et al. (2020) demonstrated a power-law relationship between the number of parameters and the respective performance. Wei et al. (2022) further showed that certain abilities of language models emerge only when the number of its parameters passes certain thresholds, providing an incentive to scale these models further.

Although scaling up these language models make them empirically powerful across many diverse tasks, it makes them infeasible to train for many NLP practitioners due to huge pre-training costs. More importantly, even using the available pre-trained models for inference is becoming more challenging (especially for memory-constrained applications like edge devices), with recent models having hundreds of billions of parameters (Zhang et al., 2022).

With the rise of NLP model sizes, there have been many efforts to compress transformer language models without compromising their performance. Although being inherently different, many of these efforts rely on knowledge distillation (Hinton et al., 2015) to help the compressed model (i.e., the student model) better imitate the parent model (i.e., the teacher model). However, these approaches often need costly distillation on upstream or downstream tasks (Sanh et al., 2019) as well as expensive data augmentation techniques (Jiao et al., 2019) to help improve the compressed model performance. These approaches become even less feasible when enormous language models are being distilled.

Another line of research focuses on computationally-cheap methods (i.e., offline compression) where a smaller model can be achieved from a pre-trained model without it being necessarily fine-tuned over a downstream

¹Our code is public: github.com/MohammadrezaBanaei/auto-encoder-based-transformer-compression

or upstream task. These offline methods include weight pruning (Li et al., 2016; Han et al., 2015), weight quantization (Zhou et al., 2016; Hubara et al., 2016), tensor factorization (Lan et al., 2019; Winata et al., 2019; Bałazy et al., 2021; Cordonnier et al., 2020) and hybrid approaches (Wang et al., 2019; Mao et al., 2020).

This paper proposes a novel offline factorization-based method for compressing transformer language models. The paper’s main goal is to propose an offline method that produces a competitive language model (compared to the original model perplexity) before any fine-tuning is performed. Similar to Bałazy et al. (2021), we use an autoencoder model (see Figure 1a) to compress different modules’ weights. However, unlike the previous work, our approach is not limited to the token embeddings (a.k.a. word embeddings) and can be applied to other transformer modules as well. We also propose and thoroughly investigate the impact of various enhancements for the approach of obtaining the compressed model. It is worth noting that although the experiments and ablation studies are only done BERT_{BASE} model, our

In Section 4 we demonstrate that applying small changes to the autoencoder architecture (e.g., introducing non-linearity to the decoder) and its loss objective results in superior performance to the Singular Value Decomposition (SVD) baseline as measured by model perplexity and its performance on the downstream tasks. Moreover, inspired by the redundancies present across self-attention heads (Cordonnier et al., 2020), in Section 4.2 we show that the compressed models perform in general better when compressing certain modules from different layers together.

Additionally, in Section 4.6 we investigate the effectiveness of a (parameter) sensitivity-based² compression by incorporating fisher information (Pascanu and Bengio, 2013) in the loss objective. We later show that incorporating these weights significantly improve the compressed language model performance (i.e., perplexity).

Finally, in Section 4.7 and in Section 4.8 we discuss the performance of our approach in comparison to various offline-compression baselines and demonstrate that our method provides the best or competitive quality of the compressed model.

Our main contribution can be summarized as

²We call it sensitivity as it measures how sensitive the model performance is to the reconstruction error of a certain parameter.

follows:

- We propose a novel autoencoder-based framework for low-cost compression of transformer language models and conduct an extensive ablation study on its different aspects.
- We show that enabling collaboration across layers by compressing different layers modules together boosts the performance.
- We demonstrate that our approach significantly outperforms other commonly used offline-compression methods on various NLP downstream tasks.³

2 Related work

Deep transformer language models have gained increasing attention in recent years since the seminal work of Devlin et al. (2019). Many recent efforts demonstrate that scaling up these language models’ parameters generally results in better performance on a range of downstream tasks (Devlin et al., 2019; Brown et al., 2020; Kaplan et al., 2020). This empirical observation resulted in recent language models having over a thousand times more parameters (Lieber et al., 2021; Rae et al., 2021; Smith et al., 2022) than the BERT_{BASE} model (Devlin et al., 2019). Although empirically powerful, these models are becoming harder to use for memory-constrained applications, which led to many efforts toward language model compression in recent literature.

Although many recent efforts for language model compression take advantage of distillation (Hinton et al., 2015) techniques to better imitate the uncompressed model (i.e., the teacher model) behavior, this paper focuses mainly on *offline* compression methods. By *offline*, we refer to approaches that do not need fine-tuning the whole model on a downstream/upstream dataset. In the case of language model compression, these methods aim to output a compressed model without losing too much performance (measured by perplexity) that can then be fine-tuned (with or without distillation) or prompted for a certain downstream task. It is worth noting that these methods can still be combined with distillation techniques, but starting the finetuning from a better compressed

³It is worth noting that although the experiments and ablation studies in this paper are only done on the BERT_{BASE} model, our proposed approach can potentially be used for any transformer-based architecture.

language model would generally reduce its costs of training (e.g., by improving convergence time).

Offline compression methods, while being diverse, can be roughly categorized into few paradigms, namely weight pruning (See et al., 2016; Li et al., 2016; Han et al., 2015; Fan et al., 2019; Michel et al., 2019; Voita et al., 2019), quantization (Gong et al., 2014; Hubara et al., 2016; Zhou et al., 2016), tensor factorization (Lan et al., 2019; Winata et al., 2019; Bałazy et al., 2021; Cordonnier et al., 2020; Panahi et al., 2021; Ren et al., 2022) and hybrid approaches (Wang et al., 2019; Mao et al., 2020).

This paper primarily focuses on the effectiveness of low-rank factorization-based approaches in recent literature (Lan et al., 2019; Panahi et al., 2021; Ren et al., 2022) as an *offline* compression method. Lan et al. (2019) proposed a SVD-based (Halko et al., 2011) technique to compress the token embedding module. Later works have shown that more complex architectures like autoencoders can result in better compression quality than SVD methods (Lioutas et al., 2020; Bałazy et al., 2021). By taking advantage of the autoencoder, we are able to more easily enforce different properties by either changing its training objective or architecture (e.g., preserving l_2 norm in reconstructed embeddings). Bałazy et al. (2021) emphasized on the importance of *direction* in token embedding compression, and in this work we demonstrate its potential importance for other transformer modules as well in different compression ratios.

Moreover, Cordonnier et al. (2020) showed the significance of redundant information in self-attention heads and compressed different heads (in a certain layer) together to improve compression performance. Following a similar idea, we later show that compressing heads from different layers together would generally further boost the compression quality.

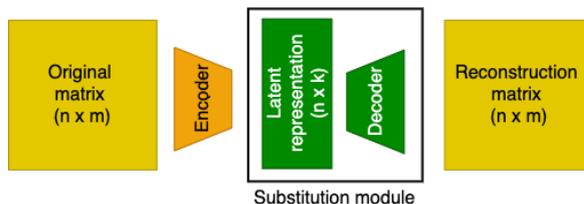

Hsu et al. (2022) proposed a weighted SVD (using Fisher Information) (Pascanu and Bengio, 2013) to outperform the classical SVD. We further investigate the benefits of a non-uniform compression (i.e., a weighted reconstruction loss in the autoencoder loss objective) in Section 4.6 by analyzing different weighting schemes for parameters.

Moreover, Ren et al. (2022) proposed using tensor decomposition techniques to compress language models to relatively high compression ratios while using a two-stage distillation technique.

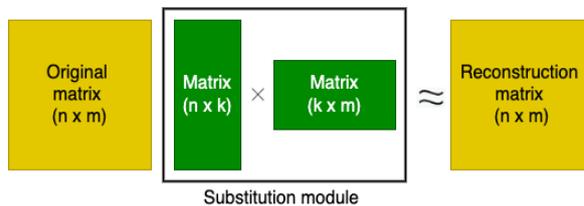

Moreover, Panahi et al. (2021) proposes using the Kronecker product as an alternative for the factorization of transformer modules. Appendix A.7 discusses using Tucker (De Lathauwer et al., 2000) or Kronecker-based methods as an offline approach. It is worth noting that models with relatively high compression ratios become highly dependent on distillation techniques to perform reasonably on downstream tasks. For instance, Ren et al. (2022) claims that even randomly initializing the compressed BERT nearly achieves identical performance compared to tensor decomposition from a pre-trained model.

3 Model

Our offline compression approach is based on the an autoencoder neural network architecture, similar to Lioutas et al. (2020) and Bałazy et al. (2021). However, in this work, we focus on compressing all the transformer weight matrices rather than just the token embedding matrix. Furthermore, we are exploring many more compression improvements using autoencoder as well as investigating architecture-independent techniques.

(a) Autoencoder-based compression with customizable objective function. Our approach minimizes the root mean square error (RMSE) and cosine distance between the original and reconstruction matrix. In this setting, the original matrix’s latent representation and the decoder form the substitution module.

(b) Classical matrix-factorisation-based compression with root mean square error (RMSE) minimization objective. Two smaller matrices, approximating the target matrix after multiplication, form the substitution module.

Figure 1: A high-level view of the matrix compression approaches using classical matrix-factorization and autoencoder model that is leveraged in this work. The purpose of the compression is to provide a parameter-efficient substitution module to replace the original matrix in the considered model.

The autoencoder architecture consists of encoder function $h(\cdot)$ that maps model input $x \in \mathbb{R}^m$ to some latent representation $l \in \mathbb{R}^k$. The second element of the architecture is the decoder function $g(\cdot)$ responsible for mapping $l \in \mathbb{R}^k$ into the approximation $\tilde{x} \in \mathbb{R}^m$ of the input x .

Let us assume that we want to compress the matrix $A \in \mathbb{R}^{(n \times m)}$. Using the gradient-descent algorithm, we train the autoencoder model to produce the appropriate approximation \tilde{A} of the original matrix. As a compressed module, we understand the hidden representation $h_\Psi(A) \in \mathbb{R}^{(n \times k)}$ together with the decoding module $g_\Phi(\cdot)$. In this setting, the formula for the *compression ratio* of the original module can be expressed as:

$$\frac{n \cdot m}{(n \cdot k) + |\Phi|}, \quad (1)$$

which is the ratio of the original matrix size to the hidden representation size and the number of parameters in the decoder module $|\Phi|$. We illustrated the approach of compressing a matrix using the autoencoder model in Figure 1a.

Our approach to offline compression based on the autoencoder offers flexibility in performing the ablation study as we are able to easily modify its elements, for example, decoder module complexity level or the loss function components. By using an autoencoder architecture with a linear decoder and the RMSE cost function, we can obtain the equivalent approximation as provided by a simple matrix factorization. An illustrative comparison of our compression method with the classical matrix factorization approach is shown in Figure 1.

Following Bałazy et al. (2021), we train our autoencoder with the multi-objective cost function consisting of l_2 norm loss and cosine distance loss:

$$\Psi_\beta(X, \tilde{X}) = (1 - \beta) \cdot L_2(X, \tilde{X}) + \beta \cdot CD(X, \tilde{X}), \quad (2)$$

where X represents the original matrix, \tilde{X} is the reconstructed matrix, $L_2(X, \tilde{X})$ represents the root mean square error (RMSE) loss function, and $CD(X, \tilde{X})$ is the mean cosine distance loss for all pairs of vectors (rows) of the original and reconstructed matrices. The β hyperparameter ($0 \leq \beta \leq 1$) is responsible for determining the weight we would like to assign to the different components of the loss function.

4 Experiments

This section describes our motivations and the results of various analyses and experiments that we

conducted to investigate the topic of offline compression thoroughly.

We performed our experiments for different weight matrices in the transformer architecture, as each type of weight matrix may have different characteristics, and a given compression method may or may not be appropriate. The analyses described below are performed for token embedding, self-attention (keys, queries, values), and output-dense weight matrices.

We focus our study on the BERT_{BASE} model (Devlin et al., 2019), but the same methods could be applied to other transformer architectures. All experiments are conducted for three compression ratios (3, 10, and 25) to investigate the differences given the different number of available parameters. All experimental settings of the various studies presented in the following sections are included in Appendix A.

We evaluate the quality of our compressed models on the masked (Devlin et al., 2019) language modeling task (using the WikiText-103 test dataset (Merity et al., 2016)) and multiple datasets from the GLUE benchmark (Wang et al., 2018).

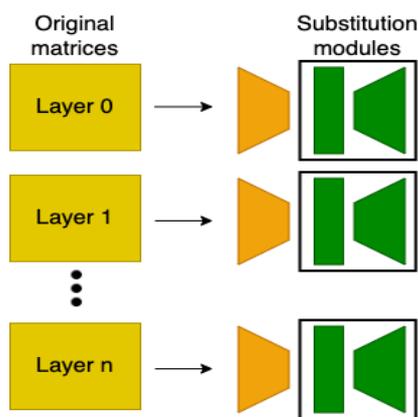

4.1 Cosine distance objective

First, we investigate whether including the direction component in the compression objective has a positive effect on the compression of weight matrices other than token embeddings in the transformer model. Bałazy et al. (2021) demonstrated that supplementing the loss function with the cosine distance between pairs of rows of the original and reconstructed matrix produces noticeably better compression results for the token embeddings matrix. Unfortunately, their study does not examine other matrices in the transformer, whereas because of the different nature of these matrices, we believe it is worth investigating.

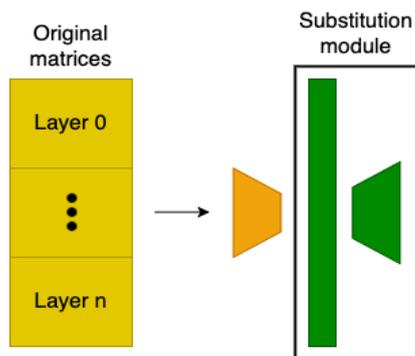

Results In Table 3 and Table 4 (in Appendix A.1), we present the effect of adding the cosine distance component to the cost function for the keys and output-dense matrices from the BERT_{BASE} model. It seems that for matrices other than token embeddings, considering the direction of vectors (rows in the matrix) in most cases may have a positive impact on the final results of the compressed model. However, the benefits of using this component are not as significant as in the case of the token embeddings matrix. Indeed, there are some examples where minimizing only Euclidean distance or

adding only a small proportion of cosine distance provides the best results. We suppose this behavior is the consequence of the token embeddings matrix nature, where the rows represent specific tokens used to construct the words. It seems that the representation of the part or entire word is largely encoded in the vector direction. This characterization does not necessarily apply to other matrices though often there is a subtle benefit from adding a cosine distance component to the reconstruction objective.

4.2 Concatenated and separated weight matrices

(a) Separated matrices compression mode. All substitution modules have separate decoder.

(b) Concatenated matrices compression mode. All substitution modules share the decoder module that enables collaboration between layers.

Figure 2: Separated and concatenated weight matrices compression. We demonstrate that compressing concatenated matrices from all layers provides a better-performing substitution module. In the concatenated setting, the substitution modules share a decoder that allows for cross-layer collaboration and provides the potential to further eliminate redundant information.

This section investigates whether compressing separately each weight matrix from the considered model is the best possible strategy. Our in-

tuition is that compressing together the same type of weight matrices from different layers may bring certain advantages. First, it could allow for minimizing redundant information in the model weights, and second, it could enable collaboration between compressed modules across different layers. Suppose that the neural network model consists of n layers (l_0, l_1, \dots, l_{n-1}). Each layer l_i encapsulates a particular weight matrix W_{l_i} . Conventionally, each W_{l_i} matrix is considered separately during the compression process. In the concatenated mode, we propose compressing a single matrix $W = [W_{l_0}, W_{l_1}, \dots, W_{l_{n-1}}]$ resulted from concatenating all W_{l_i} matrices. Given the proposed compression process, the compressed weight matrices share a common decoder as illustrated in Figure 2.

Results Experiments discussed in this section demonstrate that compressing concatenated weight matrices performs better than compressing each matrix separately in terms of the compressed model performance as well as the compression process time. Figure 3 presents the performance achieved by models with compressed output-dense matrices in separated and concatenated modes (similar experiments are presented for key, query, and value matrices in Figure 7 in Appendix A.2). We report the initial perplexity and the final score achieved on the MRPC and SST2 downstream tasks for different compression ratios. We observe the apparent dominance of the concatenated mode over the separated mode for both perplexity and downstream task performance. This may indicate that sharing the decoder helps to reduce redundant information and saves parameters for further knowledge encoding.

Furthermore, the separated compression mode is more computationally expensive at the initial stage as we must compress each matrix individually. In the concatenated mode, we perform only a single compression process on the matrices' concatenation.

Considering the better performance and faster training process, we only analyze the concatenated weight matrices compression in the following sections.

4.3 Initial perplexity vs downstream tasks performance

Perplexity is a popular measure determining how well the language model predicts a particular se-

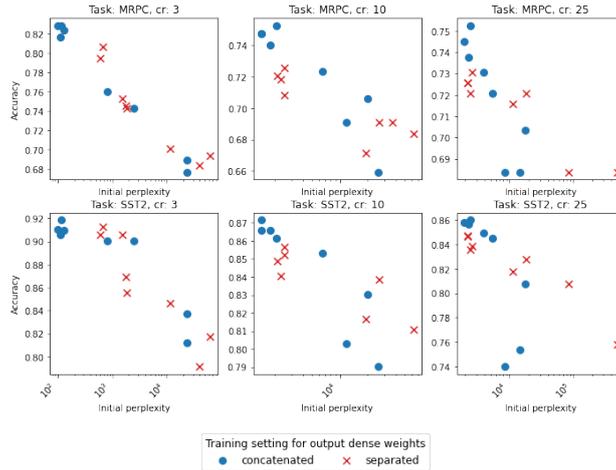

Figure 3: Initial perplexity and downstream tasks performance of output-dense matrices’ compression in separated/concatenated compression modes⁴. Using the concatenated mode generally results in better performance for this module. We observe similar pattern for key, query, and value weight matrices (see Figure 7 in Appendix A.2).

quence of tokens (the lower the perplexity the better). This section introduces that the masked language model perplexity metric may be considered as a low-cost yet effective way to evaluate a compressed module. We show that in most cases the compressed models with the lowest initial perplexity yields the best performance when fine-tuned on a downstream tasks.

Results We examined the relation between the initial $BERT_{BASE}$ perplexity after applying compressed weight matrices and its final performance after fine-tuning on a downstream task. In Figure 8 (in Appendix A.3) we report results for token embeddings matrix, self-attention keys, queries, values and final output-dense matrices. We observe that in most cases models with the lowest initial perplexity result in the best performance on the downstream task (MRPC and SST2). Therefore, we consider the masked language model perplexity metric to be a good low-cost method to preliminarily evaluate the quality of a compressed module.

4.4 Linear and non-linear decoder module

In this section we investigate the effect of using different decoder module in the autoencoder model on the final model’s performance. We experiment with a simple linear layer decoder and two non-linear decoder versions.

Results Figure 4 presents initial perplexity and final downstream tasks performance achieved when using linear and non-linear decoder in the autoen-

coder model while compressing token embeddings matrix. We may observe that for the token embeddings better final results are produced when using non-linear decoder. However, as demonstrated in Figure 9 (in Appendix A.4), a different pattern is apparent for key matrices where linear models considerably outperform the non-linear versions in most cases.

4.5 Preserving vector norm

Furthermore, we examine whether preserving the original l_2 vector norms of the vectors representing rows in the reconstructed matrix to be the same as in the original vectors is beneficial for the compression.

Results Figure 5 presents initial perplexity and downstream tasks performance when enabling or disabling the preserving vector norm technique for the token embeddings matrix. We may see that in most cases the version with enabled preserving vector norm achieves better results. In addition to token embeddings, in Figure 10 (in Appendix A.5) we also demonstrate the effect of preserving l_2 vector norm during compression of the output-dense matrix.

4.6 Sensitivity

Most offline compression methods focus only on the raw weight matrices taken from the considered pre-trained model. However, we could also leverage the unsupervised upstream dataset to improve the compression quality. Hsu et al. (2022) proposed using additional weights computed on the

⁴Each point represents one hyperparameter setting.

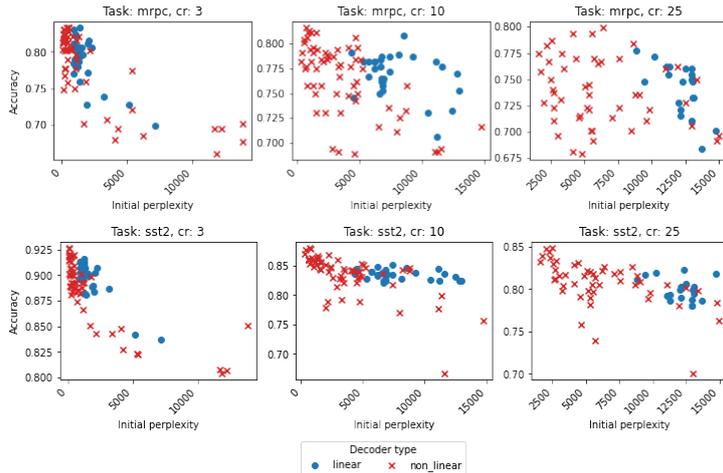

Figure 4: Initial perplexity and downstream tasks performance for the compressed token embeddings matrix when using either a linear or a non-linear decoder module in the autoencoder model. Here we present results for different hyperparameters settings (see Appendix A.4 for further details). A non-linear decoder seems to be a better choice for compressing this module.

entire upstream dataset to enhance the low-rank factorization method. They used the Fisher Information weights I that measure the amount of the observable information in dataset D about a single model parameter w . A feasible approximation \hat{I}_w of the Fisher Information I_w for parameter w may be expressed as:

$$I_w = E[(\frac{\partial}{\partial w} \log P(D|w))]^2 \approx \frac{1}{|D|} \sum_{d \in D} (\frac{\partial}{\partial w} L(d; w))^2 = \hat{I}_w \quad (3)$$

where L is the target pre-training task objective (e.g., cross-entropy or MSE).

For the entire weights matrix W , Hsu et al. (2022) presented even more simplified and computationally effective row-wise diagonal Fisher Information matrix \hat{I} , where each diagonal value is the sum of the corresponding row of the Fisher Information approximation matrix \hat{I}_W :

$$\hat{I} = \text{diag}(\sqrt{\sum_{j=1} \hat{I}_{W_{1j}}}, \dots, \sqrt{\sum_{j=1} \hat{I}_{W_{nj}}}). \quad (4)$$

We present the distributions of the row-wise Fisher Information for the upstream dataset (i.e., masked language modeling on the WikiText-103 dataset) in Figure 6. We notice that each distribution contains some outliers which point to the potentially irrelevant weights in the considered weight matrix. In this section, we demonstrate that the weights’ relevance information may be leveraged in the compression process to improve the quality of compressed modules.

Hsu et al. (2022) used the Fisher Information directly on the original model weights in their Fisher-Weighted SVD (FWSVD) approach:

$$W \approx FWSVD(W) = \hat{I}^{-1} SVD(\hat{I}W). \quad (5)$$

In contrast, our method does not modify the original weight matrices but rather uses the Fisher Information in the loss function to help the model focus more on important weights. Moreover, we apply different transformations on the original Fisher Information values to modify the relative importance of the module weights to reduce the undesirable influence of outliers (Appendix A.6 discusses various transformations we experimented with for different modules).

CR	Method	Perplexity	SST-2 (Acc)	MRPC (F1/Acc)
3	AE	118.41	91.97	88.53 / 84.31
	AE+Fisher	33.27	92.55	88.36 / 83.33
10	AE	712.98	88.07	85.87 / 80.88
	AE+Fisher	250.59	89.33	87.27 / 81.62
25	AE	4926.08	82.80	84.19 / 77.45
	AE+Fisher	2728.41	83.83	84.35 / 77.70

Table 1: The effect of adding the Fisher Information to the autoencoder-based (AE) compression of token embeddings. We report the compressed BERT_{BASE} upstream task perplexity (on the WikiText-103 dataset) and the downstream performance over two GLUE tasks. Each AE result represents a median from 3 runs with different seeds.

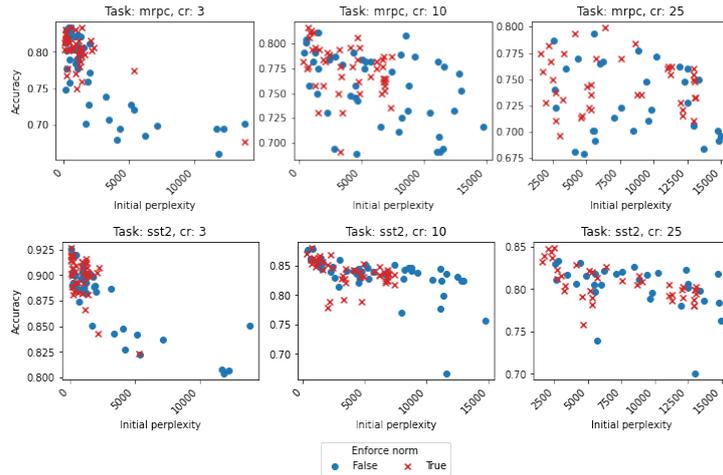

Figure 5: The effect of preserving l_2 vector norm on the perplexity and downstream tasks performance while compressing the token embeddings matrix for different hyperparameters settings. Preserving norm seems to generally improve the compression performance for this module.

CR	Architecture	MRPC (F1/Acc)	SST-2 (Acc)	RTE (Acc)	QNLI (Acc)	QQP (F1/Acc)
1	BERT _{BASE}	88.85/84.07	92.32	65.70	90.66	87.49/90.71

25	SVD	77.10/66.42	78.33	53.43	62.66	74.21/79.10
	Our	81.60/71.32	80.05	55.23	72.96	78.45/83.11

Table 2: Final BERT_{BASE} model compression (token embedding matrix, all key matrices, and all output-dense matrices). The baseline SVD algorithm compresses each matrix separately. Our autoencoder-based approach, incorporates mechanisms developed in the ablation study presented in this work (see Table 8 for the detailed AE design choices). For each setting, we present the median score from experiments with three different seeds. Our approach consistently outperforms the classical factorization method.

Results Table 1 presents the benefits of incorporating sensitivity for compression of token embeddings where both upstream perplexity and downstream task performance is improved. We further demonstrate the positive influence of Fisher information for three transformer modules in Table 5 (in Appendix A.6) for both autoencoder and SVD methods. Additionally, Table 6 (in Appendix A.6) presents the compression performance provided by AE using different Fisher Information transformations. We observe that incorporating the Fisher Information with batch normalization into the compression process considerably improves the model perplexity as well as the downstream task performance.

4.7 Comparison with other offline compression approaches

In Table 5, we compare our approach with the most popular matrix factorization method, namely Singular Value Decomposition (SVD), for the compression of three different transformer modules. We may see that our approach outperforms or is competitive with SVD in most settings. Additionally, in Appendix A.7, we discuss the poor performance of Kronecker Product and Tucker Decomposition (as two other factorization-based methods) in the offline compression setting. We also compare our solution to a non-factorization baseline, namely pruning, and show that our autoencoder-based method also outperforms it in most studied settings (see Table 7 in Appendix A.7).

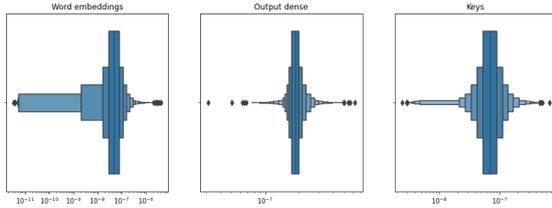

Figure 6: Row-wise Fisher Information distribution for three different modules in the $BERT_{BASE}$ model. The Fisher information values are passed as importance weights in the autoencoder loss function to help the compression model focus more on the module’s important weights. Appendix A.6 discusses different transformations applied to Fisher information to help the compression model handle outlier Fisher information values.

4.8 Compressing multiple types of transformer modules

For the final experiment, we took into consideration all the analysis insides presented in this work and prepared the concluding experiment on offline compression methods. In this experiment, we compressed multiple $BERT_{BASE}$ weight matrices at the same time (token embedding matrix, all key matrices and all output-dense matrices). We compared the offline compression quality produced by the autoencoder approach and the baseline SVD factorization matrix method.

For the compression with SVD we classically compressed each matrix separately. We tested three different seeds and various number of iterations for SVD algorithm. For the autoencoder approach, we compressed considered matrices by selecting appropriate mechanisms based on our ablation study. For both SVD and our approach, we report the median of the final scores from the experiments with three different seeds to exclude potential outliers. The compressed matrices with the lowest perplexity were applied into $BERT_{BASE}$ that was then fine-tuned on various NLP tasks (MRPC, SST-2, RTE, QNLI and QQP). In the resulting table we reported the median of the final scores to exclude potential outliers.

Final experiment results are presented in Table 2. Our approach consistently outperforms the SVD baseline on all tested downstream tasks.⁵

4.9 Compression time

Generally, compressing modules using autoencoder and SVD takes a comparable amount of time. How-

⁵The hyperparameter setting for autoencoder is provided in Table 8 in Appendix A.8

ever, using concatenated mode (as proposed in our paper) speeds up this process significantly. In Appendix A.9, we report compression times for different modules (Table 9) and the compressed models’ inference and fine-tuning time.

5 Conclusions

This work comprehensively studies various methods for the offline compression of transformer language models. We analyze various changes in the proposed architecture and its optimization function. We test different input modifications and evaluate the compressed language model performance in each scenario. By analyzing various compression settings, we show that our autoencoder-based approach outperforms classical matrix factorization on various NLP downstream tasks. Furthermore, we believe the techniques analyzed in this study might also be useful for low-cost compression of different weight matrices unrelated to language models.

Limitations

A limitation of our approach that we may identify is the need to analyze each module type to determine the best mechanisms for its compression. Our module-specific findings could be reflected in corresponding modules in other language models, but this would require further investigation. Additionally, A (reasonably-sized) unsupervised corpus must also be used for computing the Fisher Information for the compression procedure, which is more computationally demanding than other offline approaches suggested in this study.

A Experiments

In this section, we describe the general assumptions for the experiments and the specific setting of the hyperparameters for each individual experiment.

We train the autoencoder model using gradient descent procedure and Adam optimizer (Kingma and Ba, 2014). In most of our experiments, resulting compressed modules are inserted into a pre-trained language model and fine-tuned on two different downstream tasks from GLUE benchmark (Wang et al., 2018), MRPC and SST2, with

a default learning rate $\lambda = 2 \cdot 10^{-5}$ proposed by Hugging Face Transformers⁶ (Wolf et al., 2019).

A.1 Cosine distance objective

In Table 3 and Table 4, we report the effect adding the cosine distance component to the compression objective for the keys and output-dense matrices from the BERT_{BASE} model.

Experimental setup We study the effect of the cosine distance component in the loss function formulated in Equation (2) on the compression quality of self-attention keys matrices and the fully-connected output-dense weight matrices. We compress each of these matrices from each layer separately and then apply all the compressed matrices from certain type (keys or output-denses) to the transformer model to evaluate the compression quality. We inspect the effect of various ratios between Euclidean distance component (L_2) and the cosine distance component (CD) in Equation (2), namely 1:0, 10:1, 1:1, 1:10 which corresponds to $\beta \in \{0.0, 0.0909, 0.5, 0.909\}$. For each model we test different learning rates $\lambda \in \{5 \cdot 10^{-3}, 10^{-3}, 5 \cdot 10^{-4}, 10^{-4}\}$.

Compression ratio	Cosine coefficient	Initial perplexity	MRPC (Acc)	SST-2 (Acc)
3	0.0	22.9	74.5	91.0
	0.0909	22.2	76.2	92.1
	0.5	25.5	77.2	92.1
	0.9091	27.0	76.2	91.4
10	0.0	45.8	72.5	91.5
	0.0909	32.5	72.0	90.7
	0.5	34.4	70.3	91.5
	0.9091	43.2	71.3	91.6
25	0.0	116.9	70.3	90.6
	0.0909	167.6	69.6	90.2
	0.5	115.3	69.1	90.9
	0.9091	507.7	69.3	90.1

Table 3: The impact of adding a component responsible for preserving the direction in the compression of the key matrices from the self-attention block in BERT_{BASE} model. We report the best (across different learning rates) initial model’s perplexity after compression as well as it’s performance on a downstream tasks for the different cosine coefficients (β in Equation (2)). Adding a component to the compression objective that aims to preserve the direction of the vectors in reconstructed matrix may bring a slight improvement on the quality of the result.

Compression ratio	Cosine coefficient	Initial perplexity	MRPC (Acc)	SST-2 (Acc)
3	0.0	327.4	83.1	91.0
	0.0909	332.8	82.3	91.5
	0.5	599.2	79.4	90.5
	0.9091	1510.4	75.2	90.5
10	0.0	1396.5	74.5	88.1
	0.0909	1917.8	74.5	85.9
	0.5	2099.3	72.0	84.9

25	0.0	1988.0	73.8	84.5
	0.0909	2099.0	73.8	85.3
	0.5	2144.7	72.5	84.7
	0.9091	2148.6	72.5	84.6

Table 4: The impact of adding a component responsible for preserving the direction in the compression of the output-dense matrices in BERT_{BASE} model. Different cosine coefficients refer to β in Equation (2). We report the score for the model with the best initial perplexity across different learning rates as well as it’s performance on MRPC and SST2 downstream tasks.

A.2 Concatenated and separated weight matrices

In Figure 7 we present the performance achieved by models with compressed key, query and value matrices when using separated and concatenated mode in the compression process.

Experimental setup With the objective of comparing the compression of separate and concatenated matrices, we analyze the various matrices in the transformer architecture: the key, query, and value matrices from the self-attention module and output-dense matrix (one of the fully connected end matrices). We optimize loss function described previously in Equation (2) with 1:1 and 1:10 ratios for the l_2 norm loss coefficient and cosine distance coefficient, respectively. The decoder in the autoencoder model is a single fully connected layer. The model is trained with different learning rates $\lambda \in \{5 \cdot 10^{-3}, 10^{-3}, 5 \cdot 10^{-4}, 10^{-4}\}$.

A.3 Initial perplexity vs downstream tasks performance

In Figure 8 we present the initial perplexity and the performance on MRPC and SST2 downstream tasks for the language model with various compressed modules.

Experimental setup We examine the initial masked language model perplexity and downstream tasks performance relation for token embed-

⁶<https://github.com/huggingface/transformers>

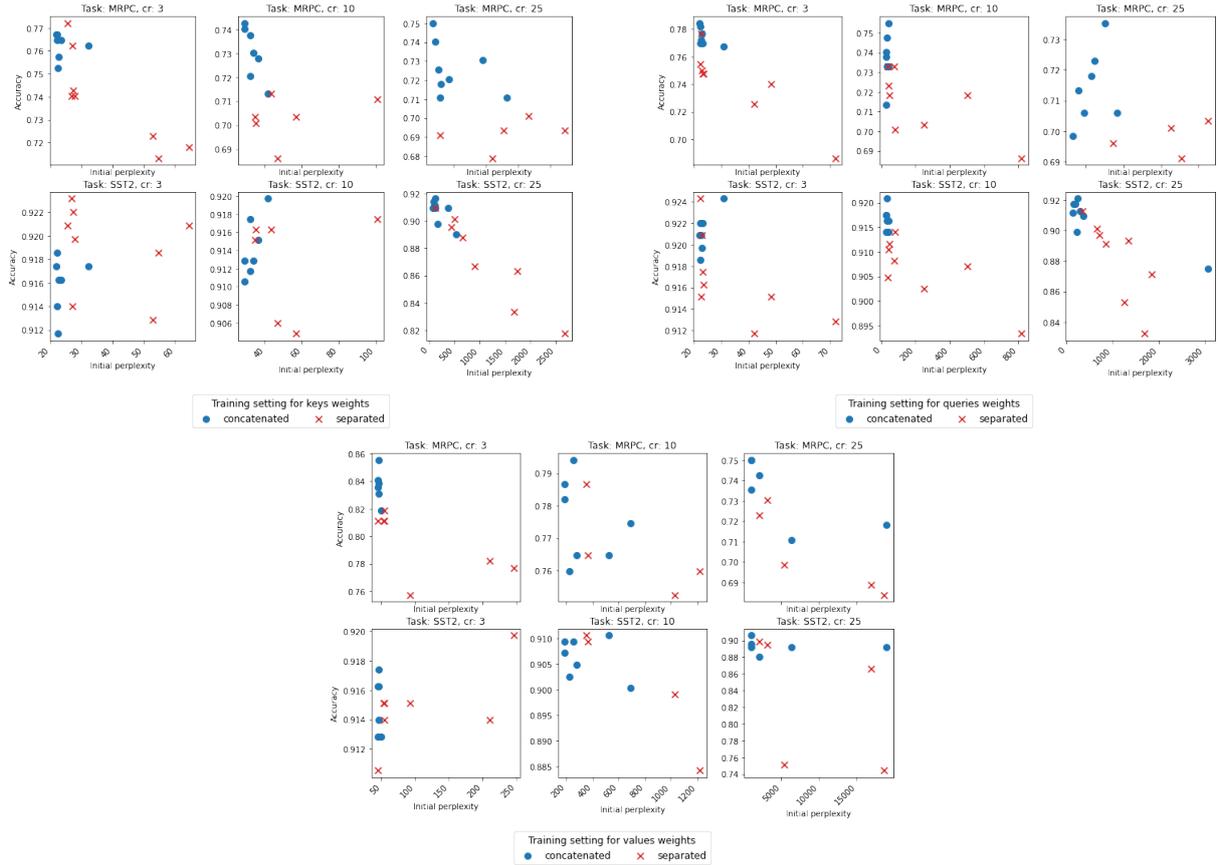

Figure 7: Initial perplexity and downstream tasks performance with separated and concatenated compression mode for output-dense weights matrices, queries weights matrices and values weights matrices in the BERT model.

ding matrix, self-attention matrices: keys, queries, values and final output-dense matrices. For simplicity of the experiment, we use the linear decoder in the autoencoder model. The loss and learning rate combinations for the models’ training are the same as in experiment in previous section. We conducted all experiments with two different seeds to obtain more reliable correlation information.

A.4 Linear and non-linear decoder module

In Figure 9 we present the initial perplexity and final downstream tasks performance achieved when using linear and non-linear decoder in the autoencoder model for key matrices compression. Unlike token embeddings for key matrices, the linear models outperform non-linear ones in most scenarios. Similar set of experiments on output-dense matrices also showed that linear models outperform non-linear ones.

Experimental setup We conduct experiments with the following settings: linear encoder/decoder and non-linear encoder/decoder. For non-linear encoder/decoder case, we examine architectures

with 1 and 2 hidden layers. As non-linear activation functions we use LeakyReLU (Maas et al., 2013) and Tanh. We investigate the loss configurations (Equation (2)) with 1:0, 1:1, 1:10 and 1:100 ratios of the l_2 norm loss to the cosine distance loss.

A.5 Preserving vector norm

In Figure 10 we show the potential benefits of preserving l_2 vector norm during compression of the output-dense matrices for two different downstream tasks.

Experimental setup We repeat the same set of experiments as in the previous section (Section 4.4), but each experiment is executed with and without the preserving vector norm option enabled.

A.6 Sensitivity

In Table 5 and Table 6 we report the positive impact of adding Fisher Information (with different coefficient transformations) for weight matrix compression for both autoencoder and SVD approaches.

Experimental setup We precompute the Fisher Information coefficients for token embeddings, self-

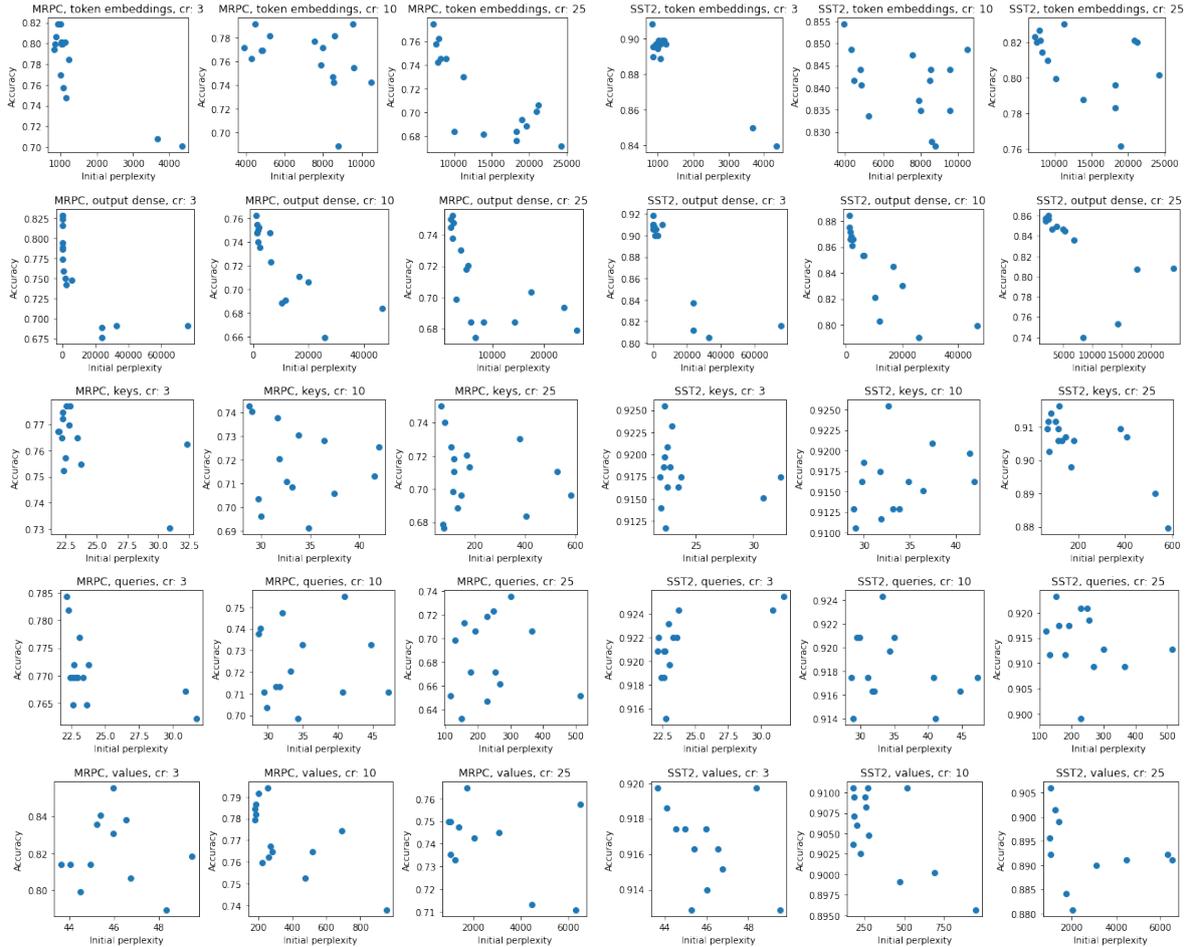

Figure 8: Initial perplexity and final accuracy on MRPC and SST2 downstream tasks for token embeddings, output-dense, keys, queries and values BERT_{BASE} matrices compression.

attentions keys and output-dense weight matrices. We apply them the best hyperparameter setting obtained from the previous experiments. We use various transformations for Fisher Information coefficients: exponential transformation x^a with $a = 0.1, 0.5, 0.9, 2.0$, logarithmic transformation $\log_e(x) + C$ with a C equals to minimum value so that all x are positive, logarithmic transformation $\log_e(x) + C + 10$, and raw Fisher Information coefficients without any transformation (*Vanilla*). For some transformations, we also add a batch sum normalization (+BN). We also report results without using Fisher Information (*No Fisher*).

A.7 Comparison to other offline compression methods

Kronecker Product offline compression Inspired by a promising results achieved by using a Kronecker product for training the transformer model from scratch (Panahi et al., 2021) we have attempted to produce a compression of the orig-

inal transformer matrices by using a Kronecker product of two matrices approximating the original matrix. We have trained these matrices using the gradient descent algorithm. Unfortunately, the results were unsatisfactory for each of the tested settings. For example, for concatenated key matrices and a compression ratio of 10 the perplexity for the Kronecker product was around 1500, while for the autoencoder perplexity below 50 is achieved in many different settings.

Tucker decomposition offline compression

Moreover, we also experimented with the Tucker decomposition (De Lathauwer et al., 2000) as an offline compression method. For token embeddings compression, we observed that the compressed language model starts having high perplexities even in low compression ratios. For instance, for CR=3, the model perplexity becomes almost 1500, while the autoencoder model can achieve perplexities below 40 for the same compression ratio. This finding is consistent with the observation of (Ren et al.,

Table 5: The effect of adding the Fisher Information to the SVD-based and autoencoder-based (AE) compression. We report the $BERT_{BASE}$ upstream task perplexity and the downstream tasks final scores. Each autoencoder result represents a median from 3 runs with different seeds and each SVD score is a result of the best iteration from run with one seed. For autoencoder model compression we selected the Fisher Information transformation for each of the compressed modules based on the results from Table 6 ($x^{0.5} + BN$ for word embeddings; $x^{2.0} + BN$ for output-dense matrices; $\log_e(x) + C + 10$ for key matrices).

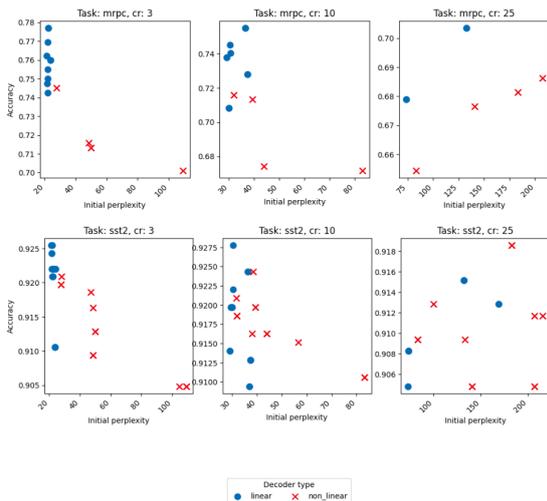

Figure 9: Initial perplexity and downstream tasks performance when using linear and non-linear decoder module in the autoencoder model for the compression of the keys matrix. Using a linear decoder generally appears to be a better choice for this matrix.

2022) that even randomly initializing the factorized tensors perform very close to the models initialized by e.g., Tucker decomposition. Therefore, we also do not find Tucker decomposition an efficient method in the context of offline compression.

Pruning We also compare our proposed autoencoder framework with a pruning baseline as another offline compression baseline. The pruning algorithm here is based on PyTorch unstructured L1 pruning (Paszke et al., 2019). For this experiment,

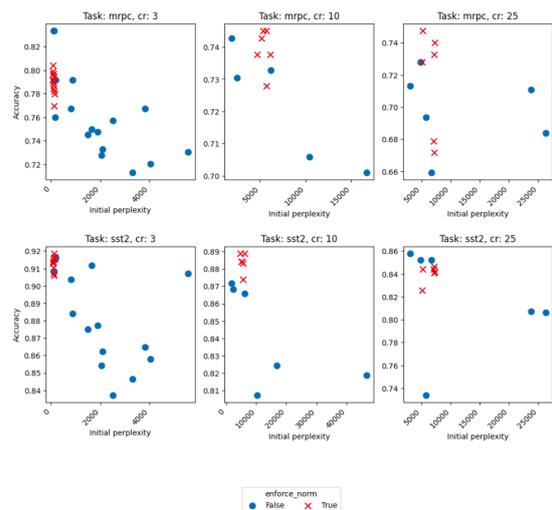

Figure 10: The effect of preserving l_2 vector norm on the perplexity and downstream tasks performance while compressing the output-dense matrices. We can see that enforcing norm for compression of this module generally improves the result.

we compress token embedding, keys, and output-dense matrices using either autoencoder or pruning approaches. The models are evaluated on four GLUE tasks as presented in Table 7. We can see that autoencoder-based compression outperforms pruning baseline in most studies settings, especially when higher compression ratios are studied.

Table 7: Comparison of BERT_{BASE} model compression using autoencoder (AE) and pruning approaches (compressing token embedding matrix, all key matrices and all output-dense matrices). For AE we present the median score from experiments with 3 different seeds.

A.8 Hyperparameter setting for the final experiment

This section presents the hyperparameter setting used for the Section 4.8 where multiple modules (token embedding, keys and output-dense) are compressed together. The autoencoder hyperparameters setting for this experiment can be found in Table 8.

A.9 Compression time

In Table 9 we report compression times for keys, output-denses and token embeddings matrices from $BERT_{BASE}$ model using autoencoder and SVD compression approaches. For autoencoder we present times for both separated and concatenated matrices compression (as proposed in our paper) showing the advantage of using the latter approach.

We additionally performed experiments to compare the inference time of uncompressed $BERT_{BASE}$ with the extreme case of $CR=25$ using our approach (AE) and the SVD baseline. Compressed modules are token embeddings, key, and output-dense modules. We observe that inference times are very similar, with a slight increase in inference time when our model is used. In particular, the evaluation times (in seconds) for BERT/SVD/AE were respectively 0.474/0.477/0.493 (for the MRPC dataset) and 0.987/0.997/1.034 (for the SST2 dataset). Moreover, fine-tuning the $BERT_{BASE}$ model using compressed modules from autoencoder for the bigger datasets in GLUE, namely QNLI and QQP, takes at most 15% and 25% longer than the SVD baseline, respectively. It is also worth noting that when a linear autoencoder is incorporated, the inference time is the same as the SVD baseline.

Module	CR	Learning rate	Cosine:L ₂ coefficients	Decoder	Enforce norm	Fisher transformation
Token embeddings	3	$5 \cdot 10^{-4}$	10:1	Non-linear (1 hidden layer)	Yes	$x^{0.5} + BN$
	10	$5 \cdot 10^{-4}$	10:1	Non-linear (2 hidden layers)	Yes	$x^{0.5} + BN$
	25	10^{-3}	10:1	Non-linear (1 hidden layer)	Yes	$x^{0.5} + BN$
Output-denses	3	10^{-3}	1:10	Linear	Yes	$x^{2.0} + BN$
	10	10^{-4}	1:10	Linear	No	$x^{2.0} + BN$
	25	$5 \cdot 10^{-4}$	0:1	Linear	No	$x^{2.0} + BN$
Keys	3	$5 \cdot 10^{-4}$	0:1	Linear	Yes	$\log_e(x) + C + 10$
	10	$5 \cdot 10^{-4}$	1:1	Linear	No	$\log_e(x) + C + 10$
	25	10^{-3}	0:1	Linear	No	$\log_e(x) + C + 10$

Table 8: The best hyperparameters for the BERT_{BASE} model compression described in Section 4.8. In this experiment, token embedding matrix, all keys and all output-dense matrices are compressed using our proposed autoencoder-based framework.

Method	Mode	CR	Token embeddings	Keys	Output-denses
SVD	separated	3	~9.5min	(~5.5*12)min	(~6.0*12)min
SVD	separated	10	~8.0min	(~5.5*12)min	(~6.0*12)min
SVD	separated	25	~7.5min	(~5.5*12)min	(~6.0*12)min
AE	separated/concatenated	3	~7.7min	(~5.5*12)min/~6.1min	(~6.0*12)min/~6.5min
AE	separated/concatenated	10	~7.5min	(~5.5*12)min/~6.0min	(~6.0*12)min/~6.1min
AE	separated/concatenated	25	~7.5min	(~5.5*12)min/~5.9min	(~6.0*12)min/~6.1min

Table 9: Training time to retrieve compressed modules (key, output-dense, and token embeddings) of BERT_{BASE} model using autoencoder (AE) and SVD approach. For the AE, we provide training times for the separated and concatenated modes to demonstrate another benefit of using the concatenated version, given its much better training time.

PriMeSRL-Eval: A Practical Quality Metric for Semantic Role Labeling Systems Evaluation

Abstract

Semantic role labeling (SRL) identifies predicate-argument structures in a sentence. This task is usually accomplished in four steps: predicate identification, predicate sense disambiguation, argument identification, and argument classification. Errors introduced at one step propagate to later steps. Unfortunately, the existing SRL evaluation scripts do not consider the full effect of this error propagation aspect. They either evaluate arguments independent of predicate sense (CoNLL09) or do not evaluate predicate sense at all (CoNLL05), yielding an inaccurate SRL model performance on the argument classification task. In this paper, we address key practical issues with existing evaluation scripts and propose a more strict SRL evaluation metric, *PriMeSRL*. We observe that by employing *PriMeSRL*, the quality evaluation of all SoTA SRL models drops significantly, and their relative rankings also change. We also show that *PriMeSRL* successfully penalizes actual failures in SoTA SRL models.

1 Introduction

Semantic Role Labeling (SRL) extracts predicate-argument structures from a sentence, where predicates represent relations (verbs, adjectives, or nouns) and arguments are the spans attached to the predicate demonstrating “who did what to whom, when, where, and how.” As one of the fundamental natural language processing (NLP) tasks, SRL has been shown to help a wide range of NLP downstream applications such as natural language inference (Zhang et al., 2020b; Liu et al., 2022), question answering (Maqsood et al., 2014; Yih et al., 2016; Zhang et al., 2020b; Dryjański et al., 2022), machine translation (Shi et al., 2016; Rapp, 2022), content moderation and verification (Calvo Figueras et al., 2022; Fharook et al., 2022), information extraction (Niklaus et al., 2018; Zhang

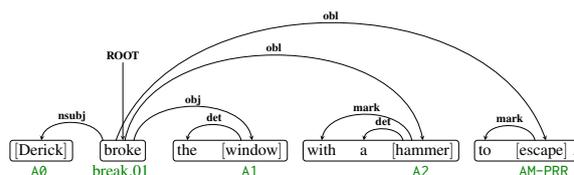

Figure 1: An SRL example with head-based semantic roles on top of Universal Dependencies annotation.

et al., 2020a). In all of these applications, the quality of the underlying SRL models has a significant impact on the downstream tasks. Despite this, few studies exist on how to properly evaluate the quality of SRL systems in practice.

Given a sentence, a typical SRL system obtains predicate-argument structure by following a series of four steps: 1) predicate identification; 2) predicate sense disambiguation; 3) argument identification; and 4) argument classification. The predicate senses and their argument labels are taken from inventories of frame definitions such as Proposition Bank (PropBank) (Palmer et al., 2005), FrameNet (Baker et al., 1998), and VerbNet (Schuler, 2005).

The accuracy of SRL extraction is affected by the correctness of each of these steps. Consider the example in Figure 1 using PropBank¹ annotations:

The SRL system must:

1. Identify the verb ‘break’ as a predicate
2. Disambiguate its particular sense as ‘break.01’,² which has four associated arguments: A0 (the breaker), A1 (thing broken), A2 (the instrument), A3 (the number of pieces), and A4 (from what A1 is broken away).³

¹In this paper we discuss SRL based on PropBank frames.

²<https://verbs.colorado.edu/propbank/framesets-english-aliases/break.html>

³Note that in PropBank each verb sense has a specific set

^b Work done while at IBM Research

3. Identify each argument as it occurs (‘Derick’, ‘the window’, etc.)
4. Classify the arguments (‘Derick’ : A0)

Finally, this example has one additional modifier: the AM-PRP (the purpose). Figure 1 illustrates the same analysis on top of the universal dependencies annotations where only the tokens’ head of phrases are annotated with the proper argument.

To obtain a completely correct predicate-argument structure both the predicate sense and all of its associated arguments need to be correctly extracted. Mistakes introduced at one step may propagate to later steps, leading to further errors.

For instance, in the above example, a wrong predicate sense ‘break.02’ (*break in or gain entry*) has not only a different meaning from ‘break.01’ (*break*) but also a different set of arguments. In many cases, even if an argument for a wrong predicate sense is labeled with the same numerical roles (A1, A2, etc), their meanings can be very different. Therefore, in general, the labels for argument roles should be considered to be incorrect when the predicate sense itself is incorrect. However, existing SRL evaluation metrics (e.g. (Hajič et al., 2009)) do not penalize argument labels in such cases.

The currently used evaluation metrics also do not evaluate *discontinuous arguments* accurately. Some arguments in the PropBank original corpora have discontinuous spans that all refer to the same argument. This can happen for a number of reasons such as in verb-particle constructions. In a dependency-based analysis, these arguments end up being attached to distinct syntactic heads (Surdeanu et al., 2008). Take as an example the sentence, “I know your answer will be that those people should be allowed to live where they please as long as they pay their full locational costs.” For the predicate “allow.01,” the A1 (action allowed) is the discontinuous span “those people” (A1) and “to live where they please as long as they pay their full locational costs” (C-A1). Existing evaluation metrics treat these as two independent labels.

A similar problem exists for the evaluation of reference arguments (R-X). For example, in the sentence “This is exactly a road that leads nowhere”, for the predicate “lead.01”, the A0 “road” is referenced by C-A0 “that”. If A0 is not correctly identified, the reference C-A0 is meaningless.

of underspecified roles, given by numbers: A0, A1, A2, and so on. This is because of the well-known difficulty of defining a universal set of thematic roles (Jurafsky and Martin, 2021).

In this paper, we conduct a systematic analysis of the pros and cons of different evaluation metrics for SRL, including:

- Proper evaluation of predicate sense disambiguation task;
- Argument label evaluation in conjunction with predicate sense;
- Proper evaluation for discontinuous arguments and reference arguments; and
- Unified evaluation of argument head and span.

We then propose a new metric for evaluating SRL systems in a more accurate and intuitive manner in Section 3, and compare it with currently used methods in Section 4. PriMeSRL is available at <https://github.com/UniversalPropositions/PriMeSRL-Eval>.

2 Existing Evaluation Metrics for SRL

Most of the existing evaluation metrics came from shared tasks for the development of systems capable of extracting predicates and arguments from natural language sentences. In this section, we summarize the approaches to SRL evaluation in the shared tasks from SemEval and CoNLL.

2.1 Senseval and SemEval

SemEval (Semantic Evaluation) is a series of evaluations of computational semantic analysis systems that evolved from the Senseval (word sense evaluation) series.

SENSEVAL-3 (Litkowski, 2004) addressed the task of automatic labeling of semantic roles and was designed to encourage research into and use of the FrameNet dataset. The system would receive as input a target word and its frame, and was required to identify and label the frame elements (arguments). The evaluation metric counted the number of arguments correctly identified (complete match of span) and labeled, but did not penalize those spuriously identified. An overlap score was generated as the average of proportion of partial matches.

SemEval-2007 contained three tasks that evaluate SRL. Task 17 and 18 identified arguments for given predicates using two different role label sets: PropBank and VerbNet (Pradhan et al., 2007). They used the `srl-eval.pl` script from the CoNLL-2005 scoring package (Carreras and Màrquez, 2005) (see below). Task 19 consists of

recognizing words and phrases that evoke semantic frames from FrameNet and their semantic dependents, which are usually, but not always, their syntactic dependents. The evaluation measured precision and recall for frames and frame elements, with partial credit for incorrect but closely related frames. Two types of evaluation were carried out. The first is the label matching evaluation. The participant’s labeled data were compared directly with the gold standard labeled using the same evaluation procedure used in the previous SRL tasks at SemEval. The second is the semantic dependency evaluation, in which both the gold standard and the submitted data were first converted to semantic dependency graphs and compared.

SemEval-2012 (Kordjamshidi et al., 2012) and **SemEval-2013** (Kolomiyets et al., 2013) introduced the ‘Spatial Role Labeling’ task, but this is somewhat different from the standard SRL task and will not be discussed in this paper. Since **SemEval-2014** (Marelli et al., 2014), a deeper semantic representation of sentences in a single graph-based structure via semantic parsing has superseded the previous ‘shallow’ SRL tasks.

2.2 CoNLL

The **CoNLL-2004** shared task (Carreras and Màrquez, 2004) was based on the PropBank corpus, comprising six sections of the Wall Street Journal part of the Penn Treebank (Kingsbury and Palmer, 2002) enriched with predicate–argument structures. The task was to identify and label the arguments of each marked verb. The precision, recall, and F1 of arguments were evaluated using the `sr1-eval.pl` program. For an argument to be correctly recognized, the words spanning the argument as well as its semantic role have to be correct. The verb argument is the lexicalization of the predicate of the proposition. Most of the time, the verb corresponds to the target verb of the proposition, which is provided as input, and only in a few cases the verb participant spans more words than the target verb. This situation makes the verb easy to identify and, since there is one verb with each proposition, evaluating its recognition overestimates the overall performance of a system. For this reason, the verb argument is excluded from evaluation. The shared task proceedings do not detail how non-continuous arguments are evaluated. In **CoNLL-2005** (Carreras and Màrquez, 2005) a system had to recognize and label the arguments of each target

verb. The evaluation method remained the same as CoNLL-2004, using the same evaluation code.

The **CoNLL 2008** shared task (Surdeanu et al., 2008) was dedicated to the joint parsing of syntactic and semantic dependencies. The shared task was divided into three subtasks: (i) parsing of syntactic dependencies, (ii) identification and disambiguation of semantic predicates, and (iii) identification of arguments and assignment of semantic roles for each predicate. SRL was performed and evaluated using a dependency-based representation for both syntactic and semantic dependencies.

The official evaluation measures consist of three different scores: (i) syntactic dependencies are scored using the labeled attachment score (LAS), (ii) semantic dependencies are evaluated using a labeled F1 score, and (iii) the overall task is scored with a macro average of the two previous scores. The semantic propositions are evaluated by converting them to semantic dependencies, i.e., a semantic dependency from every predicate to all its individual arguments were created. These dependencies are labeled with the labels of the corresponding arguments. Additionally, a semantic dependency from each predicate to a virtual ROOT node was created. The latter dependencies are labeled with the predicate senses. This approach guarantees that the semantic dependency structure conceptually forms a single-rooted, connected (not necessarily acyclic) graph. More importantly, this scoring strategy implies that if a system assigns the incorrect predicate sense, it still receives some points for the arguments correctly assigned. Several additional evaluation measures were applied to further analyze the performance of the participating systems. The *Exact Match* reports the percentage of sentences that are completely correct, i.e., all the generated syntactic dependencies are correct and all the semantic propositions are present and correct. The *Perfect Proposition F1* score entire semantic frames or propositions. The ratio between labeled F1 score for semantic dependencies and the LAS for syntactic dependencies.

As in CoNLL-2008, the CoNLL-2009 shared task (Hajič et al., 2009) combined syntactic dependency parsing and the task of identifying and labeling semantic arguments of verbs or nouns for six more languages in addition to the original English from CoNLL-2008. Predicate disambiguation was still part of the task, whereas the identification of argument-bearing words was not. This deci-

sion was made to compensate for the significant differences between languages and between the annotation schemes used. The evaluation of SRL was done similar to CoNLL-2008.

3 The Proposed Approach

We propose PriMeSRL, a new metric for evaluating SRL systems, based on the following high-level rules that aim to overcome the drawbacks in existing metrics:

1. Predicate senses are considered correct only when the full predicate.sense is correct, not just the sense number. (Table 1)
2. Core arguments are considered correct only when the predicate sense has been correctly identified. (Table 1)
3. An argument of the form C-X is considered together with its associated X argument to cover the full region of the argument. (Table 2)
4. An argument of the form R-X is considered as a reference, so its correctness depends on the correctness of the referenced X. (Table 3)

3.1 Predicate sense disambiguation evaluation

Current evaluation metrics either do not evaluate the predicate sense disambiguation task (e.g. CoNLL05), or evaluate only the sense number of the predicate (e.g. CoNLL09). In this section, we only contrast with the CoNLL09 evaluation script.

To begin with, what is the predicate sense number? Similar to word senses in Wordnet (Fellbaum, 2010), the predicate senses in PropBank inside a predicate frame file are generally ordered from most to least frequently used, with the most common sense numbered 01 (Pradhan et al., 2022). The sense numbers (01, 02, 03, ...) do not have any associated semantic meaning, and merely convey that one particular meaning of the predicate is more common than another.

Therefore, predicting and evaluating only the sense number is not sensible. It can be a reasonable goal to a certain extent, such as when predicate location is given and the task is only to disambiguate the sense of the predicate (as proposed in the CoNLL09 shared task.) But the consequence of this approach is that a sense number classifier could predict a sense number that does not even exist in the associated frame file. Of course, an unknown sense number for a predicate does not

text = Yesterday, John bought a car.

		PriMeSRL	3/3	1/3	1/3	1/3

Table 1: Comparing evaluation metrics on 4 examples, showing the effect of wrong predicate sense on argument label evaluation. *RED-italic* shows a wrong prediction by a hypothetical model. **GREEN** cell highlights where PriMeSRL differs from existing metrics.

have a semantic meaning, making it unsuitable for practical use cases. For a practical end-to-end SRL system, the sense number classifier should predict both the predicate location and associated sense number together (i.e. predicate.sense) so that the contextual meaning of the predicate is correctly captured, as performed in (Roth and Lapata, 2016; Li et al., 2018; Conia et al., 2021; Conia and Navigli, 2022).

Evaluating the predicate sense disambiguation task of such practical systems using existing evaluation metrics is not optimal. Consider the example in Figure 1, where the gold predicate.sense is ‘break.01’ (*break, cause to not be whole*⁴). Suppose an SRL system predicts⁵ the predicate.sense label ‘pull.01’ (*causing motion*⁶). The existing CoNLL09 evaluation script will give a fully correct score because the predicted sense number **01** exactly matches the gold sense number, despite the different semantic meanings. In contrast, PriMeSRL evaluates the predicate.sense as a whole instead of only the sense number.

⁴<https://verbs.colorado.edu/propbank/framesets-english-aliases/break.html>

⁵See Table 6 for several examples of such mistakes actually made by a SoTA SRL system on CoNLL09 data.

⁶<https://verbs.colorado.edu/propbank/framesets-english-aliases/pull.html>

Table 2: Comparing evaluation metrics on 7 examples, showing the effect of C-X labels. *RED-italic* and **GREEN** cell are used in the same manner as Table 1.

3.2 Argument evaluation with incorrect predicate sense

Current metrics evaluate the arguments independent of the predicate sense. That is, they evaluate arguments as if the predicate location and sense are both correct. In practice, the predicates predicted by models can of course be wrong, and in such cases, the corresponding core argument labels (A0, A1, etc.) generally do not refer to the correct argument - even if the label itself matches the gold label - and should be penalized. Contextual arguments, or adjunct arguments, such as AM-LOC, AM-TMP, etc, remain the same across different predicates and do not need to be penalized for predicate errors.

Table 1 illustrates the difference between PriMeSRL and existing evaluation metrics, CoNLL09 and CoNLL05. For predicate sense evaluation, PriMeSRL is often equal to CoNLL09 (CoNLL05 does not measure this aspect.) PriMeSRL explicitly penalizes the cases where the lemma is wrongly identified (Example P3): The CoNLL09 script considers the label as correct as long as the “predicate sense number” is correct. It is unlikely for a model to predict "sell.01" in P3 for the gold predicate "buy.01". We choose this example to smoothly motivate the need for more strict evaluation metrics for SRL. In fact, SoTA SRL systems made this type of error. Table 6 provides some incorrect model predictions from a SoTA SRL model, where a model confuses "overheat" with "soothe" as an example.

text = This is exactly a road that leads nowhere.

ID	FORM	F	PRED SENSE	Gold	P1	P2	P3	P4	P5	P6
1	This	-	-	-	-	-	-	-	-	-

		PriMeSRL	3/3	1/3	2/3	1/3	1/3	1/3	1/3
Argument SPAN Evaluation	P	Conll05	3/3	2/3	2/3	1/3	2/3	1/3	1/3
		PriMeSRL	3/3	1/3	2/3	1/3	1/3	1/3	1/3

Table 3: Comparing evaluation metrics on 6 examples, showing the effect of R-X labels. *RED-italic* and **GREEN** cell are used in the same manner as Table 1.

For argument evaluation, both CoNLL09 head evaluation and CoNLL05 span evaluation wrongly mark all the arguments in examples P1, P2, and P3 as correct, despite the predicate sense being wrong. This is corrected by PriMeSRL.

3.3 Evaluation of C-X arguments

An argument label with prefix C- is used in situations where an argument consists of multiple non-adjacent parts (Surdeanu et al., 2008). If conceptually the whole argument should be labeled X, then operationally one part will get label X and the other parts get label C-X. The existing evaluation metrics treat all these labels as independent, which is incorrect as it increases the weight of these arguments and assigns partial credit when an exact match is required. We now describe PriMeSRL for span-based and head-based evaluations.

Span-based evaluation: For an argument split into multipart spans with labels X and C-X, the complete span can be represented by the set of all tokens identified by these labels. The full set of tokens produced by the model should be compared to the set in the gold data, and a single credit should be assigned if these sets are equal.

Head-based evaluation: An argument with X and C-X parts has these as separate heads. A model prediction is considered correct if and only if all heads for this argument are correct, in which case it is given one whole credit. This evaluation does not distinguish between X and C-X and will penalize an argument if it has extra or missing parts.

Table 2 compares PriMeSRL with CoNLL05

Table 4: Comparison of SoTA SRL models with PriMeSRL and CoNLL09 evaluation metrics on CoNLL09 dataset. (r) denotes the ranking of SRL models corresponding to the evaluation metric. **BOLD** shows the best model with CoNLL09 evaluation script and **BOLD** shows the best SRL model with PriMeSRL.

Dataset	Args	Train	Dev	Test	ood
CoNLL09	C-X	0.77	1.05	0.88	1.15
	R-X	1.98	2.03	2.07	2.24
CoNLL05	C-X	1.22	1.24	1.71	0.91
	R-X	3.26	3.36	3.38	2.91

Table 5: Representation of C-X and R-X arguments in each split of different SRL datasets.

and ConNLL09 on seven examples. For span evaluation, the variances among labels with and without C- do not penalize the result, as long as the whole span is correct. That is our proposal for counting continuation arguments is the same as the CoNLL05 evaluation script, which provides one full credit if all heads for continuation arguments are identified and labeled correctly. We only differ that we do not distinguish between A0 and C-A0 labels. In this manner, we are not as strict as the CoNLL05 script. For head evaluation, note that the denominators reflect the number of arguments rather than the number of split parts, and numerators count correct whole arguments.

3.4 Evaluation of R-X arguments

An argument label with prefix R- indicates a reference argument; thus, R-X is a reference to the argument X. For R-X to be correct, X must also be correct, but apart from this requirement, PriMeSRL treats them as separate arguments.

Table 3 compares evaluating R-X arguments using PriMeSRL with the metric used in CoNLL09 on 6 examples P1 through P6. For P1 in Table 3 (Head Evaluation), CoNLL09 gives credit for cor-

rectly identified R-A0 for which no/incorrect A0 is predicted, which is meaningless. The same is true for the Span evaluation script CoNLL05. However, we do not penalize the correctly labeled main argument for incorrect R-X.

4 Comparisons with Existing Metrics

In this section, we discuss the effectiveness of existing SRL evaluation metrics and demonstrate how PriMeSRL differs in various use cases, using SoTA neural SRL models as test models.

4.1 General settings

For simplicity of comparison with existing results, we assume the gold predicate location is given for all the experiments following Shi and Lin (2019); Jindal et al. (2020); Conia and Navigli (2022). However, PriMeSRL is able to handle missing or spurious predicates. We use Conia et al. (2021); Biloshmi et al. (2021); Jindal et al. (2022) as SoTA SRL models.

4.2 Datasets

We show the impact of evaluating with PriMeSRL on the CoNLL09 and CoNLL05 datasets. Table 5 shows the percentage of C-X and R-X arguments in each split of the different datasets. Note that these arguments make up < 3% of the total arguments; 5.09% total of the arguments in CoNLL05 test, and 2.95% in CoNLL09 test. Therefore, we expect to observe an F1 drop of at most about 3 and 5 points on the argument classification subtask due to mishandling C-X and R-X arguments for CoNLL09 and CoNLL05 datasets, respectively.

Id	Sentence	Gold	Predicted
1	He was able, now, to sit for hours in a chair in the living room and stare out at the bleak yard without moving.	stare.01	look.01
2	She greeted her husband’s colleagues with smiling politeness , offering nothing.	politeness.01	minimalism.01
3	It was a Negro section of peeling row houses, store-front churches and ragged children.	peel.01	peer.01
4	He was calm, drugged , and lazy.	drug.01	dropper.01
5	The walk and his fears had served to overheat him and his sweaty armpits cooled at the touch of the night air.	overheat.01	soothe.01
6	He did not resent their supervision or Virginia’s sometimes tiring sympathy.	tire.01	hiring.01

Table 6: Conia et al. (2021) model predictions on examples from CoNLL09 OOD set. All of these predicate senses are marked correct by the CoNLL09 evaluation script. PriMeSRL correctly penalizes all of these senses.

Model	Evaluation script	In-domain					Out-of-domain				
		PSD		Argument Classification			PSD		Argument Classification		
		F1	P	R	F1	(r)	F1	P	R	F1	(r)
(Zhang et al., 2021) _{crf}	CoNLL05	100	86.5	88.3	87.4	(3)	100	79.0	81.1	80.0	(3)
	PriMeSRL	100	86.1	87.8	87.03(↓0.4)	(2)	100	78.7	80.8	79.7(↓0.3)	(2)
(Zhang et al., 2021) _{crf2o}	CoNLL05	100	86.9	88.6	87.7	(2)	100	78.9	81.2	80.03	(2)

4.3 Evaluation

4.3.1 Predicate sense disambiguation

The PSD column in Table 4 compares the impact of PriMeSRL w.r.t. the existing evaluation script on the EN subset of the CoNLL09 dataset using SoTA SRL models. We observe a consistent quality drop in predicate sense disambiguation (PSD) both for in-domain and out-of-domain (OOD) sets. Surprisingly, we observe a significant quality drop on the OOD set of an average of ~ 5 F1 points for all the SRL models, which significantly lowers the SoTA performance on the OOD set. This shows that existing SRL models still have a lot of room for improvement.

Continuing the PSD analysis, Table 6 shows example instances from the CoNLL09 dataset that have correct sense numbers (01) but wrong predicate.sense - yet all of which are marked correct by the CoNLL09 evaluation script. For example, the first row shows how the difference between ‘stare.01’ (*looking intently*⁷) and “look.01” (*causal*

*look*⁸) is ignored. While these two at least share the same underlying meaning (*look*), in row 5 the model’s prediction of ‘soothe.01’ means the opposite of the gold label ‘overheat.01’ (once again, the existing CoNLL09 evaluation script marks this as correct.) Clearly, predicate sense should be evaluated by including the actual value predicate.sense instead of only relying on the sense number.

4.3.2 Argument head evaluation

Argument classification column in Table 4 compares the impact of PriMeSRL w.r.t the existing evaluation script on the EN subset of the CoNLL09 dataset using SoTA SRL models. We observe a quality drop in the argument classification task both for in-domain and OOD sets, with a significant quality drop of an average of ~ 8 F1 points on the OOD set. This drop in the argument classification task is expected because part of this error is propagated from the predicate sense disambiguation task which itself is significant. It is interesting to note that, although the major contribution of argument classification drop is due to error propagation from

⁸<https://verbs.colorado.edu/propbank/framesets-english-aliases/look.html>

Input Sentence	SRL			Downstream Application		
	SRL model prediction	Existing eval score	PriMeSRL score	Application prompt	Prediction	Expected
[S1] XYZ company bought \$2.4 billion in Fannie Mae bonds.	[XYZ company]A0 [bought] sell.01 [\$2.4 billion in Fannie Mae bonds]A1	3/3	0/3	<u>QA</u> Who bought Fannie Mae bonds?	None	XYZ company
	[XYZ company]A0 [bought] buy_out.03 [\$2.4 billion in Fannie Mae bonds]A1	2/3	0/3	<u>QA</u> Who bought Fannie Mae bonds completely?	XYZ company	None
[S2] XYZ company bought out \$2.4 billion in Fannie Mae bonds.	[XYZ company]A0 [bought]buy_out.03 out [\$2.4 billion in Fannie Mae bonds]A1	3/3	3/3	<u>NLI</u> Does S2 entails S3?	Yes	No
[S3] XYZ company bought \$2.4 billion in Fannie Mae bonds.	[XYZ company]A0 [bought] buy_out.03 [\$2.4 billion in Fannie Mae bonds]A1	2/3	0/3			

Table 8: Example illustrations of the how impact of SRL errors on downstream applications is captured by the new evaluation method, where **Red color** represents the wrong prediction by an SRL model, leading to incorrect predictions by a downstream application (QA: Question Answering; NLI: Natural Language Inference.)

the earlier stage, there is also a consistent drop due to penalizing correct arguments with wrong predicate sense, of ~ 1.5 and ~ 3 F1 points for in-domain and OOD sets, respectively.

Since the performance drop is not uniform, we observe a change in the relative ranking of the SRL models. As an example, the CoNLL09 evaluation script scores the SRL models [Blloshmi et al. \(2021\)](#) and [Jindal et al. \(2022\)](#) similarly (83.0 F1) on OOD set whereas PriMeSRL clearly shows a difference in performance. Further, PriMeSRL makes clear that the quality of existing SRL systems is not as high as previously thought, especially on OOD data.

4.3.3 Argument span evaluation

Similar to argument head evaluation, we compare the impact of PriMeSRL w.r.t to the existing evaluation script on the SRL span dataset (CoNLL05 dataset) using SoTA SRL models in Table 7. Since CoNLL05 does not evaluate predicate sense, we do not observe the impact of incorrect PSD on argument classification. Therefore, the only drop of argument classification is due to incorrect handling of C-X and R-X arguments. Although Table 5 shows that the total number of C-X and R-X in the CoNLL05 dataset is $\sim 5\%$ of the total number of arguments, we only observe a slight drop in quality evaluation ($< 1\%$) with PriMeSRL. This is because

on argument span evaluation, PriMeSRL is similar to CoNLL05 (except in a few cases as described in the last row-block of Tables 2 and 3.) As in the comparison with the CoNLL09 dataset, we again observe a change in the relative ranking of the SRL models.

4.4 Discussion

The existing evaluation metrics for SRL are disconnected from the actual practical performance of the SRL models. This makes it difficult to choose the best quality SRL model for the required downstream application. Current evaluation metrics do not pay sufficient attention to the error propagation aspect of the four-staged SRL task; instead, they evaluate the steps independently and linearly combine them to compute the overall SRL system score. However, the analyses in Tables 4 and 7 clearly show that the linear combination of the independent performance of individual steps is not equivalent to the true overall quality.

This does not negate the usefulness of the existing evaluation metrics. Indeed, these metrics provide an evaluation of each individual step, serving as an important guide for improving the quality of individual steps and hence the overall quality of the SRL system. However, whenever a real-world NLP system utilizes an SRL system as one

of its components, it is important to understand the quality of semantic roles in relation with, and conditional on their predicate sense disambiguation. Table 8 illustrates the impact of such SRL errors on two downstream applications (question answering and natural language inference). Existing evaluation scripts overlook such SRL errors and treat them as correct, despite the fact that the predicted predicate-argument structure is meaningless and leads to incorrect outputs for the downstream application.

5 Conclusion

In this paper, we highlighted key issues with existing SRL evaluation metrics and showed that the proposed evaluation metric, PriMeSRL, scores SoTA SRL models in a more accurate and intuitive manner. By releasing our evaluation code, we plan to promote these metrics in the community in order to improve the evaluation quality for SRL systems that contribute to downstream applications.

Limitations

We have shown the impact of our proposed new evaluation metrics in the current SoTA SRL models ranking. To further validate the impact of this work, we plan to conduct an in-depth study on how downstream applications' performance relates to the evaluation metrics in future work.

We acknowledge that the problems we have pointed out for previous evaluation metrics are not bugs, but rather design decisions given the timing of the shared tasks and the limitations on datasets and methods. Consider, for instance, that a unified syntactic dependency annotation schema like Universal Dependencies (Nivre et al., 2016) was unavailable before October 2014. Given that, in this paper, we didn't present a deep discussion on the impact of UD compared to previously used syntactic dependencies schemas.

Acknowledgements

We would like to thank our anonymous reviewers for their constructive comments and feedback. Further, the authors acknowledge the IBM Research Cognitive Computing Cluster service for providing resources that have contributed to the research results reported within this paper.

A Some historical background to existing evaluation metrics for SRL

Shared tasks have boosted the development of systems capable of extracting predicates and arguments from natural language sentences. Two regular academic events have promoted SRL shared tasks: SemEval and CoNLL. In this section, we summarize the approaches to SRL evaluation in the shared tasks and categorize their shortcomings.

A.1 Senseval and SemEval

SemEval (Semantic Evaluation) is a series of evaluations of computational semantic analysis systems that evolved from the Senseval (word sense evaluation) series. The SENSEVAL-3 (Litkowski, 2004) was about the automatic labeling of semantic roles and was designed to encourage research into and use of the FrameNet dataset. The systems receive as input unsegmented sentences (the constituents are not identified) a target word and its frame. They have to identify the frame elements within that sentence and tag them with the appropriate frame element name. In general, FrameNet frames contain many frame elements (an average of 10), most of which are not instantiated in a given sentence. Systems were not penalized if they returned more frame elements than those identified in the gold data. In scoring, each frame element returned by a system was counted as an item attempted. If the frame element had been identified in the gold data, the answer was scored as correct. In addition, the scoring program required that the frame boundaries identified by the system’s answer overlap with the gold annotation. An additional measure of system performance was the degree of overlap. If a system’s answer coincided precisely with the start and end position in the gold data, the system received an overlap score of 1.0. If not, the overlap score was the number of characters overlapping divided by the length of the gold annotation. The number attempted was the number of non-null frame elements generated by a system. Precision was com-

puted as the number of correct answers divided by the number attempted. The recall was computed as the number of correct answers divided by the number of frame elements in the test set. Overlap was the average overlap of all correct answers. The percent Attempted was the number of frame elements generated divided by the number of frame elements in the test set, multiplied by 100.

At SemEval-2007, three tasks evaluate SRL. In task 17 (subtask 2), the goal of the systems was to locate the constituents, which are the arguments of a given verb, and assign them appropriate semantic roles. Systems have to annotate the corpus using two different role label sets: the PropBank and the VerbNet. SemLink mapping (Loper et al., 2007) was used to generate the VerbNet roles. The precision, recall, and F-measure for both role label sets were calculated for each system output using the `sr1-eval.pl` script from the CoNLL-2005 scoring package (Carreras and Màrquez, 2005) (see below). Task 18 focused on Arabic and also used the same CoNLL-2005 scoring package. Task 19 consists of recognizing words and phrases that evoke semantic frames from FrameNet and their semantic dependents, which are usually, but not always, their syntactic dependents. The evaluation measured precision and recall for frames and frame elements, with partial credit for incorrect but closely related frames. Two types of evaluation were carried out. The first is the label matching evaluation. The participant’s labeled data were compared directly with the gold standard labeled using the same evaluation procedure used in the previous SRL tasks at SemEval. The second is the semantic dependency evaluation, in which both the gold standard and the submitted data were first converted to semantic dependency graphs and compared.

SemEval-2012 and SemEval-2013 introduced the ‘Spatial Role Labeling’ task. It concerns the identification of trajectors, landmarks, spatial indicators, the links between them, and the type of spatial relationships, including region, direction, and distance. Although similar to the standard SRL task, we will not discuss Spatial Role Labeling and its evaluation in this paper. Starting from SemEval-2014, a deeper semantic representation of sentences in a single graph-based structure via semantic parsing substituted the ‘shallow’ SRL tasks.

A.2 CoNLL

The Conference on Computational Natural Language Learning (CoNLL) is a yearly conference organized by the ACL’s Special Interest Group on Natural Language Learning (SIGNLL), focusing on theoretically, cognitively and scientifically motivated approaches to computational linguistics since 1999. The 2004 and 2005 shared tasks of the CoNLL were dedicated to SRL monolingual setting (English). The CoNLL-2008 shared task proposes a unified dependency-based formalism, which models both syntactic dependencies and semantic roles. The CoNLL-2009 builds on the CoNLL-2008 task and extends it to multiple languages.

The CoNLL-2004 shared task (Carreras and Màrquez, 2004) was based on the PropBank corpus, six sections of the Wall Street Journal part of the Penn Treebank (Kingsbury and Palmer, 2002) enriched with predicate–argument structures. The participants need to come up with machine learning strategies to SRL on the basis of only partial syntactic information, avoiding the use of full parsers and external lexico-semantic knowledge bases. The annotations provided for the development of systems include, apart from the argument boundaries and role labels, the levels of processing treated in the previous editions of the CoNLL shared task, i.e., words, PoS tags, base chunks, clauses, and named entities. In practice, number of target verbs are marked in a sentence, each governing one proposition. A system has to recognize and label the arguments of each target verb. The systems were evaluated with respect to precision, recall and the F1 measure using the `sr1-eval.pl` program. For an argument to be correctly recognized, the words spanning the argument as well as its semantic role have to be correct. The verb argument is the lexicalization of the predicate of the proposition. Most of the time, the verb corresponds to the target verb of the proposition, which is provided as input, and only in few cases the verb participant spans more words than the target verb. This situation makes the verb easy to identify and, since there is one verb with each proposition, evaluating its recognition overestimates the overall performance of a system. For this reason, the verb argument is excluded from evaluation. The shared task proceedings does not details how non-continuous arguments are evaluated.

Compared to the shared task of CoNLL-2004, three novelties were introduced in the 2005 edition

(Carreras and Màrquez, 2005): 1) the complete syntactic trees, with information of the lexical head for each syntactic constituent, given by two alternative parsers have been provided as input; 2) the training corpus has been substantially enlarged; 3) a cross-corpora evaluation is performed using a fresh test set from the Brown corpus. Evaluation didn't changed compared to CoNLL-2004 and it was reported to use the same evaluation code, a system has to recognize and label the arguments of each target verb. To support the role labeling task, sentences contain input annotations, that consist of syntactic information and named entities. Evaluation is performed on a collection of unseen test sentences, that are marked with target verbs and contain only predicted input annotations.

The CoNLL 2008 shared task (Surdeanu et al., 2008) was dedicated to the joint parsing of syntactic and semantic dependencies. The shared task was divided into three subtasks: (i) parsing of syntactic dependencies, (ii) identification and disambiguation of semantic predicates, and (iii) identification of arguments and assignment of semantic roles for each predicate. SRL was performed and evaluated using a dependency-based representation for both syntactic and semantic dependencies.

The task addressed propositions centered around both verbal and nominal predicates. The data was composed by the Penn Treebank, BBN's named entity corpus, PropBank and NomBank. The dependency-annotated data was obtained from a conversion algorithm from the constituent analyses. convert the underlying constituent analysis of PropBank and NomBank into a dependency analysis, the head of a semantic argument was identified with a straightforward heuristic. But there are cases that require special treatment, some arguments ended up with several syntactic heads and some arguments that were initially discontinuous in PropBank or NomBank where merged.

The official evaluation measures consist of three different scores: (i) syntactic dependencies are scored using the labeled attachment score (LAS), (ii) semantic dependencies are evaluated using a labeled F1 score, and (iii) the overall task is scored with a macro average of the two previous scores. The semantic propositions are evaluated by converting them to semantic dependencies, i.e., a semantic dependency from every predicate to all its individual arguments were created. These dependencies are labeled with the labels of the corresponding

arguments. Additionally, a semantic dependency from each predicate to a virtual ROOT node was created. The latter dependencies are labeled with the predicate senses. This approach guarantees that the semantic dependency structure conceptually forms a single-rooted, connected (not necessarily acyclic) graph. More importantly, this scoring strategy implies that if a system assigns the incorrect predicate sense, it still receives some points for the arguments correctly assigned. Several additional evaluation measures were applied to further analyze the performance of the participating systems. The *Exact Match* reports the percentage of sentences that are completely correct, i.e., all the generated syntactic dependencies are correct and all the semantic propositions are present and correct. The *Perfect Proposition F1* score entire semantic frames or propositions. The ratio between labeled F1 score for semantic dependencies and the LAS for syntactic dependencies.

As in CoNLL-2008, the CoNLL-2009 shared task (Hajič et al., 2009) combined syntactic dependency parsing and the task of identifying and labeling semantic arguments of verbs or nouns for six more languages (Catalan, Chinese, Czech, German, Japanese and Spanish) in addition to the original English from CoNLL-2008. Participants can choose the joint task (syntactic dependency parsing and SRL), or SRL-only (syntactic dependency provided). The novelty is that the evaluation data indicated which words were to be dealt with (for the SRL task). Predicate disambiguation was still part of the task, whereas the identification of argument-bearing words was not. This decision was made to compensate for the significant differences between languages and between the annotation schemes used. The evaluation of SRL was done similar to CoNLL-2008.

Prompt-based Learning for Text Readability Assessment

Abstract

We propose the novel adaptation of a pre-trained seq2seq model for readability assessment. We prove that a seq2seq model – T5 or BART – can be adapted to discern which text is more difficult from two given texts (pairwise). As an exploratory study to prompt-learn a neural network for text readability in a *text-to-text* manner, we report useful tips for future work in seq2seq training and ranking-based approach to readability assessment. Specifically, we test nine input-output formats/prefixes and show that they can significantly influence the final model performance.

Also, we argue that the combination of text-to-text training and pairwise ranking setup 1) enables leveraging *multiple* parallel text simplification data for teaching readability and 2) trains a neural model for the general concept of readability (therefore, better cross-domain generalization). At last, we report a 99.6% pairwise classification accuracy on Newsela and a 98.7% for OneStopEnglish, through a joint training approach. Our code is available at github.com/brucewlee/prompt-learning-readability.

1 Introduction

Readability assessment evaluates the reading difficulty of a given piece of text (Vajjala, 2021). The early traditional readability assessment methods like Flesch-Kincaid Grade Level (Kincaid et al., 1975) utilized a linear regression formula fitted to data from large-scale reading experiments on human subjects. More recently, readability assessment has often been viewed as a classification task (Feng et al., 2010). Under this classification-based task formulation, models using various handcrafted features (Xia et al., 2016; Vajjala and Meurers, 2012), computer-generated features (Martinc et al., 2021; Imperial, 2021), or both (Lee et al., 2021)

have been reported. Showing the potential that neural modeling is more suitable than handcrafted features in holistically capturing the inherent linguistic properties that affect readability.

Among the varying approaches to readability assessment, fine-tuning deep transformer models (Vaswani et al., 2017), that are pre-trained with language modeling objectives (e.g. *Masked Language Modelling*, *Next Sentence Prediction*), has proven highly effective in multiple reports (Lee and Vajjala, 2022; Lee et al., 2021). So far, encoder-only transformer architectures like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have been the go-to approach, and few reports discuss the applicability of other architecture types. Further, there is no report on how readability assessment can be cast in a text-to-text task formulation (§2). But recent reports (Raffel et al., 2020) show that a text-to-text is promising for multiple downstream tasks.

The main contribution of this paper is that we fine-tune full encoder-decoder transformer architectures (also referred to as *sequence-to-sequence*) and check if they can learn about text readability. A sequence-to-sequence model has been previously fine-tuned for downstream tasks like document ranking (Nogueira et al., 2020), but few reports discuss whether the architecture can learn about readability.

We fine-tune BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) on the popular OneStopEnglish (Vajjala and Lučić, 2018) and Newsela (Xu et al., 2015) data. Then, we measure their performance on two other datasets with readability annotations for US and CEFR curricula, respectively.

We also conduct methodological explorations on how a sequence-to-sequence model can be well-trained to learn text readability. This includes how input and output format should be structured, considering that the fine-tuning for a sequence-to-sequence model is naturally cast in a text-to-text

[‡]Woong Sung (Bruce) Lee was on leave from the University of Pennsylvania during the research period.

format (Nogueira et al., 2020). We summarize our research questions in two:

- 1) Can a sequence-to-sequence model be fine-tuned for text readability – with a parallel text simplification dataset?
- 2) If so, can the performance generalize across domains? In other words, is the model learning the *dataset* or the concept of *readability*?

These research questions and our task approach are intentionally formulated in reference to what previous literature (Vajjala, 2021; Lee et al., 2021) have proposed as future directions. As we elaborate further in the following sections, our approach simplifies some inherent problems that we had in the readability assessment. But our study has limitations and requires further explorations (§5).

2 Background Knowledge

2.1 Sequence-to-Sequence Transformers

Pre-trained sequence-to-sequence transformers essentially incorporate both encoder and decoder parts from the original Transformer (Vaswani et al., 2017) architecture. The most notable examples are T5 and BART, pre-trained using document denoising strategies (i.e. during pre-training, input is an intentionally corrupted document, and output is a recovered document or corrupted portions).

Though BART allows some flexibility in altering the model architecture for downstream tasks (Lewis et al., 2020), T5 is built with the intention of unifying all NLP tasks into a text-to-text-format (Raffel et al., 2020). Here, text-to-text means that both input and output are always text strings, unlike encoder-only, BERT-style models that only output either a class label ([CLS] token) or an input span.

2.2 Existing Downstream Tasks

Pre-trained sequence-to-sequence models can be fine-tuned to most NLP downstream tasks, including neural machine translation (Wang et al., 2022) and abstractive summarization (Saito et al., 2020). Then, a training instance is formatted in a way that is much like *telling* the model what to do by adding task-specific prefix (Raffel et al., 2020).

If a model were to be fine-tuned for translation, the input format could be “*translate English to German: That is good.*” and the target output is “*Das ist gut.*” When applied to document ranking, Nogueira et al. (2020) proposed a slightly different format. The input format was written “*Query: ...*

Document: ... Relevant:” so that the target output tokens – “*true*” or “*false*” – can naturally come after the input format. Our work is the most influenced by this formatting approach.

3 Experimental Setup

3.1 Methods

All our experiments are based on T5 and BART, both obtained from the respective online repositories through Huggingface (Wolf et al., 2019). Since the text-to-text formulation has never been used to fine-tune text readability¹, here we limit to the simple task of comparing the readability of two given texts. Following our input format (Table 1), we fed two text snippets of varying difficulties to the model every instance. Then, the model was trained to give the corresponding target output. We tested nine input-output formats, as shown in Table 1.

3.2 Datasets and Preparation

3.2.1 Data Type and Permutation Methods

The datasets that we use in this study are of two types. *Parallel* type contains multiple reading-level versions of a text (mostly through human expert paraphrasing). We call a grouping of text in multiple reading levels a *slug*. On the other hand, there is *distinct* type of datasets. *Distinct* type is a more common format where each text is given a readability level with no multiple versions of the same content. Our naming and permutation strategies are inspired by existing work on pairwise ranking for readability (Lee and Vajjala, 2022).

A parallel dataset $D_{parallel}$ can be expressed as a row-wise collection of i slugs $D_{parallel} = [S_1, \dots, S_i]$, where a slug is a column-wise collection of j pairs of a text and a reading level $S_i = [(x_{i,1}, y_{i,1}), \dots, (x_{i,j}, y_{i,j})]$. For parallel dataset, we perform permutation jP_2 on the slug level, creating $S'_i = [((x_{i,1}, x_{i,2}), (y_{i,1}, y_{i,2})), \dots, ((x_{i,j-1}, x_{i,j}), (y_{i,j-1}, y_{i,j}))]$. A pair like $((x_{i,1}, x_{i,2}), (y_{i,1}, y_{i,2}))$ is considered an instance for train/dev/test. Then, $D'_{parallel} = [S'_1, \dots, S'_i]$, where all S' are flattened to make $D'_{parallel}$ an iterable collection of tuples. This setup is intended to be robust to future implementations of paraphrase-based text simplification datasets where the standards for readability annotation/level are only consistent within a slug.

A distinct dataset $D_{distinct}$ can be expressed as a collection of i pairs of a text and a reading

¹Lee et al. (2021) trains BART for readability but uses class labels (BERT-style) as target output, instead of text tokens

Type	Input Format	Target Output
Question	"Which Text is more difficult? Text 1: ... Text 2: ..."	"Text 1" or "Text 2"
Statement	"Text 1 is more difficult than Text 2. Text 1: ... Text 2: ..."	"True" or "False"
Follow-up	"Text 1: ... Text2: ... More difficult:"	"Text 1" or "Text 2"
Reverse-Question	"Which Text is easier? Text 1: ... Text 2: ..."	"Text 2" or "Text 1"
Reverse-Statement	"Text 1 is easier than Text 2. Text 1: ... Text 2: ..."	"False" or "True"
Reverse-Follow-up	"Text 1: ... Text2: ... Easier:"	"Text 2" or "Text 1"
Alternate-Question	"Which Text is harder? Text 1: ... Text 2: ..."	"Text 1" or "Text 2"
Alternate-Statement	"Text 1 is harder than Text 2. Text 1: ... Text 2: ..."	"True" or "False"
Alternate-Follow-up	"Text 1: ... Text2: ... Harder:"	"Text 1" or "Text 2"

Table 1: Input-Output format candidates we tested. The text-to-text formulation is intuitive internally (model) and externally (human) because the model input and output are both representations of some semantic concept.

level $D_{distinct} = [(x_1, y_1), \dots, (x_i, y_i)]$. Then, we can perform permutation iP_2 to create $D'_{distinct} = [((x_1, x_2), (y_1, y_2)), \dots, ((x_{i-1}, x_i), (y_{i-1}, y_i))]$. This setup is under the postulation that readability annotation is consistent throughout the dataset. Pairwise instances of two same levels are removed.

3.2.2 Datasets

Two *parallel* and two *distinct* datasets are used. Also, we agree with Vajjala (2021)'s concern that "(in some datasets) articles tagged with different reading levels don't share the same topical content (...) question what the readability assessment models learn - is it a notion of text complexity, or topical differences among texts?". Hence, we only use parallel data – NEWS and OSEN – for training.

Our dataset processing strategy (§3.2.1) and pairwise comparison approach force the model to learn label-agnostic, the global concept of relative difficulties of texts. That is, the model learns that a text annotated level 5 should be harder than a level 3 (or a level 2 or a level 1) within a slug or a dataset. Such a setup is inherently robust against cross-domain usage (Table 3). Further, it enables combining multiple datasets of various slug sizes or readability annotation standards for joint training (§4).

Newsela(NEWS) is a *parallel* text simplification dataset introduced by Xu et al. (2015). It consists of 2,154 slugs, each item re-written 4 or 5 times for children at different grade levels. Hence, a total of 10,786 texts are contained, and 43,316 pairwise instances are created after data permutation (§3.2.1). Random shuffling split these instances into 6:2:2 for train/test splits. We provide reproducible scripts for all datasets through code.

OneStopEnglish(OSEN) is a *parallel* dataset intended for both text simplification and readability assessment research (Vajjala and Lučić, 2018). It

Format Type	OSEN		NEWS	
	T5	BART	T5	BART
Question	0.815(30)	0.965(18)	0.981(3)	-
Statement	0.639(29)	0.978(30)	-	-
Follow-up	0.784(25)	0.960(27)	-	-
Reverse-Q	0.793(30)	0.991(30)	-	0.993(3)
Reverse-S	0.524(28)	0.978(26)	-	-
Reverse-F	0.828(30)	0.991(30)	-	0.993(5)
Alternate-Q	0.811(30)	0.960(25)	-	-
Alternate-S	0.617(29)	0.978(30)	-	-
Alternate-F	0.789(28)	0.938(29)	-	-

Table 2: Validation set accuracy reports on NEWS and OSEN. The best epoch is reported in brackets. NEWS is only reported for the best format type due to data size.

consists of 189 slugs, each item in 3 paraphrases at different reading levels. A total of 567 texts are contained, and 1,134 pairwise instances are created. We use a 6:2:2 split ratio through random shuffling.

Common Core Standards(CCSB) is a *distinct* collection of exemplary official texts with readability annotations in U.S. Common Core Standards. We scraped data from the source ourselves. We used 69 story-type texts in 6 reading levels. After permutation, 3,846 pairwise instances are created.

Cambridge English Readability(CAMB) is a *distinct* dataset of reading passages from main suite Cambridge English Exams (Xia et al., 2016). All 331 texts are labeled A2, B1, B2, C1, or C2 reading levels, following the CEFR standards. After permutation, 87,574 pairwise instances are created.

3.3 Training

The batch size is fixed at 8, both for training and inference. The learning rate is fixed at 1e-5 for T5 and BART. We fine-tune OSEN for 30 epochs and NEWS for 3 epochs. We report the best epoch performance based on the validation set in Table 2. For joint training (Table 3), we take an OSEN-trained model and then fine-tune further using NEWS for 3 more epochs.

Model / Fine-Tune Data	Test Data			
	OSEN	NEWS	CCSB	CAMB
Flesch-Kincaid / None	0.978	0.986	0.798	0.808
T5 / OSEN	<u>0.784</u>	<u>0.518</u>	<u>0.509</u>	<u>0.492</u>
BART / OSEN	<u>0.978</u>	<u>0.871</u>	<u>0.639</u>	<u>0.629</u>
T5 / NEWS	<u>0.907</u>	<u>0.967</u>	<u>0.747</u>	<u>0.764</u>
BART / NEWS	0.987	<u>0.993</u>	<u>0.793</u>	0.883
T5 / OSEN + NEWS	<u>0.992</u>	<u>0.987</u>	<u>0.771</u>	<u>0.778</u>
BART / OSEN + NEWS	<u>0.983</u>	0.996	<u>0.790</u>	<u>0.865</u>

Table 3: In-domain and *cross-domain* accuracies across datasets. For OSEN and NEWS, test sets (§3.2.2) are used. The best result per dataset is in **bold**. T5 is trained with `Question` format, whereas BART is trained with `Reverse-F` format. Flesch-Kincaid refers to the popular Flesch-Kincaid Grade Level formula published in Kincaid et al. (1975). We use the implementation in `github.com/textstat/textstat`.

4 Results

1. **A pretrained sequence-to-sequence model could be fine-tuned for text readability, in a text-to-text style.** Table 2 shows that the concept of readability could be fine-tuned in a text-to-text task formulation, some setups with decent accuracies of > 0.9 . For a smaller dataset (OSEN), BART significantly outperformed T5, but their performance deviation was little on a larger dataset (NEWS). We believe this is caused due to difference in pre-training methodologies that caused T5 to require more training steps to learn about our downstream task. Also, BART always generalized better than T5 across unseen datasets in Table 3.

2. **Input-output format significantly affected the final performance, especially when fine-tuning T5 with lesser training steps (OSEN).** Among the nine input-output formats we tested, T5 and BART performed best under `Question` and `Reverse-Q/F` types, respectively. Performance deviations caused by input-output format changes were larger than we expected. Further, no certain format generally ensured good results across models. This raises the need for additional "format-tuning" processes when exploring new models. However, it must be noted that several observations point to T5 being under-trained for the general concept of readability at the data size of OSEN (see Table 2 and Table 3). The input-output format's influence is lesser for setups where models learned better about readability.

3. **Joint training has the potential to help both in-domain and cross-domain performances.** Joint training of multiple datasets for a single model is an under-explored concept in readabil-

ity assessment. This is because human experts annotate existing datasets with varying standards. Dataset construction can also differ (e.g. different number of classes or too difficult to map classes). Hence, it was unknown if combining datasets of varying labeling standards improves performance.

This work solves the problem by re-casting the task into a simple, universal question of comparing two texts' difficulties (§3.2.2). Table 3 shows that in- and cross-domain performances can improve through joint training. For example, in-domain accuracies for OSEN increased to 0.208 when the model was further fine-tuned with a larger extra data, NEWS. However, a NEWS-only model generally performed better than the OSEN+NEWS model in Table 3. We expect that OSEN, which is almost 40 times smaller, only confused the model.

4. **Exposing the model to more texts with a wider range of readability helped fine-grained readability comparison.** Importantly, we showed that readability assessment models fine-tuned with *parallel* datasets could be generalized across *distinct* datasets (e.g. OSEN \rightarrow CCSB). But model performances varied depending on label distance. Models performed better when the two compared texts' readability labels were larger apart (i.e. the model is more likely to guess level 1 vs level 4 correctly than level 1 vs level 2). This problem worsened when the model was trained using OSEN. Using NEWS as training data or extra data helped. We want to point out that a slug size in NEWS is 4 or 5, exposing the model to more permutations.

5. **Text-to-text style fine-tuning required more training steps than expected.** The majority of our OSEN fine-tuning experiments showed that the model's validation set performance continues to increase up to epoch 30. This is contrastive to how usual classification approaches, using encoder-only models, only fine-tune up to epoch 3~5 even on smaller datasets like OSEN or CAMB (Lee et al., 2021). Intuitively speaking, there is potential that better performance can be achieved if fine-tuned further. We will explore this concept in the future.

6. **Though often overlooked, traditional readability formulas provide challenging baselines.** The traditional readability formulas are criticized for their low performances in multi-class ranking or regression-based readability task formulation (Lee and Lee, 2023). However, they provide surprisingly strong baselines for pairwise difficulty comparisons, as seen in Table 3.

5 Conclusion

So far, we have reported our exploratory work on casting readability assessment tasks in a text-to-text formulation for BART and T5. We summarized our observations into five categories in §4, which can serve as base guidelines for future work. Our experimental setup and data permutation methods allow the joint training of more than one dataset, regardless of whether the dataset construction is *parallel* or *distinct* (§3). Using NEWS as extra training data further to fine-tune an OSEN-trained model greatly improved model performance. However, we did not train the other way around (NEWS → OSEN), which should be proved in the future.

6 Limitations

Our limitations are in input text length and output labels. Though our novel task formulation allows the application of essential concepts like *joint training* or *cross-domain evaluation* in the field of readability assessment, it is based on a pairwise classification method. Since the pairwise approach only allows the readability ranking of two texts (e.g. which is easier?), it lacks practicality compared to regression or multi-label classification-based models. Though we achieve an almost perfect accuracy of 99.6% in Newsela data, knowing which is easier out of texts has little use as a real-world system. Hence, further research must be conducted to generate **more useful output labels** and process longer sequences. Like Nogueira et al. (2020), we are looking into using a sliding window to generate output labels for longer input sequences. We are also researching neural models pre-trained specifically for readability assessment using the prompt-based learning method introduced in the paper. Such a model can be leveraged for multi-class classification.

A Obtaining Dataset

We obtained Newsela by requesting academic access at newsela.com/data.

OneStopEnglish dataset is freely available at github.com/nishkalavallabhi/OneStopEnglishCorpus.

Cambridge English Readability dataset is freely available at ilexir.co.uk/datasets/index.html.

We crawled Common Core Appendix B from www.corestandards.org/assets/Appendix_B.pdf.

B Training Details

B.1 Models, GPU, Train Time

All pre-trained models are retrieved from Huggingface. Fine-tuning code is written in PyTorch. We used a single NVIDIA RTX 2080 GPU for all our training.

T5

- huggingface.co/t5-base
- 1,020 seconds for 30 epochs on permuted OneStopEnglish, in `Question` format
- 6,994 seconds for 3 epochs on permuted Newsela, in `Question` format

BART

- huggingface.co/facebook/bart-base
- 532 seconds for 30 epochs on permuted OneStopEnglish, in `Reverse-F` format
- 4,084 seconds for 3 epochs on permuted Newsela, in `Reverse-F` format

B.2 More on Input Sequence Length

The current experimental setup is inherently weak against long texts. This is because we input a set of two texts with format prefixes (Table 1). Hence, for a model with 512 max token length our actual token length limitation per text is ≤ 256 , with the exact number depending on chosen format type. Though both BART and T5 support longer input sequences, in comparison to other popular models like BERT or RoBERTa, we must empirically confirm if good performance can be achieved when BART and T5 are used with longer max sequence length. In this paper, the max sequence length was set to 512 (which means that ≤ 256 token limit existed per text), and most texts from OSEN had to be truncated before training.

Best Practices in the Creation and Use of Emotion Lexicons

Saif M. Mohammad

National Research Council Canada

saif.mohammad@nrc-cnrc.gc.ca

Abstract

Words play a central role in how we express ourselves. Lexicons of word–emotion associations are widely used in research and real-world applications for sentiment analysis, tracking emotions associated with products and policies, studying health disorders, tracking emotional arcs of stories, and so on. However, inappropriate and incorrect use of these lexicons can lead to not just sub-optimal results, but also inferences that are directly harmful to people. This paper brings together ideas from Affective Computing and AI Ethics to present, some of the practical and ethical considerations involved in the creation and use of emotion lexicons — *best practices*. The goal is to provide a comprehensive set of relevant considerations, so that readers (especially those new to work with emotions) can find relevant information in one place. We hope this work will facilitate more thoughtfulness when one is deciding on what emotions to work on, how to create an emotion lexicon, how to use an emotion lexicon, how to draw meaningful inferences, and how to judge success.

1 Introduction

Words often convey affect (emotions, sentiment, feelings, and attitudes); either explicitly through their core meaning (denotation) or implicitly through connotation. For example, *dejected* denotes sadness. On the other hand, *failure* simply connotes sadness. Either through denotation or connotation, both words are associated with sadness. A compilation of such associations is referred to as a *word–affect association lexicon* (aka *emotion lexicon*).¹ An entry in a lexicon usually includes a word, an emotion category or affect dimension (e.g., joy, fear, valence, arousal, etc.), and a score indicating association (or strength of association).

¹This includes *sentiment lexicons* that capture valence (association with the positive–negative dimension) and other lexica that capture affect-related phenomena.

Examples of emotion lexicons include the General Inquirer (Stone et al., 1966), ANEW (Nielsen, 2011; Bradley and Lang, 1999), LIWC (Pennebaker et al., 2001), Pittsburgh Subjectivity Lexicon (Wilson et al., 2005), *NRC Emotion Lexicon* (Mohammad and Turney, 2010, 2013), and the *NRC Valence, Arousal, and Dominance (VAD) Lexicon* (Mohammad, 2018). These were all created by manual annotation (either by experts or crowd-sourced). There also exist lexicons that were generated automatically from large text corpora using statistical and/or machine learning algorithms; e.g., WordNet Affect (Strapparava et al., 2004), SentiWordNet (SWN) (Baccianella et al., 2010).

Emotion lexicons have a wide range of applications in commerce, public health, and research (in NLP, Psychology, Social Sciences, Digital Humanities, etc.). Some notable examples include: tracking brand and product perception via social media posts, tracking support for controversial issues and policies, tracking buy-in for non-pharmaceutical health measures such as social distancing during a pandemic, literary analysis, and developing more natural dialogue systems. The lexicons can be used on their own or in support of neural machine learning (ML) algorithms for emotion recognition.

Lexicon-based emotion analyses are especially popular in real-world applications and research outside of computer science because they are interpretable, have a low carbon footprint, and do not require significant programming expertise. Further, since outputs of ML models are highly dependent on training data, use of a model often requires retraining, and there may not exist labeled data from the target domain. Further, Teodorescu and Mohammad (2022) show that when determining broad trends (emotion arcs) and aggregating information from hundreds (if not more) instances for every time step, simple lexicon-based methods are extremely accurate (correlations above 0.95 with ground truth arcs).

However, inappropriate and incorrect use of these lexicons, can lead to not just sub-optimal results, but also inferences that are directly harmful. For example, using lexicons to infer emotions from limited amount of data to make judgments about refugee applications, to make judgments about which groups of people are shown certain advertisements and which groups are not, marking businesses owned by some groups of people as less liked than that of others, etc.

Emotions are deeply personal, private, and complex. Even the best natural language systems largely only employ pattern matching based on huge amounts of historical data, and thus often do not really understand what the user is trying to convey, let alone how they are feeling. In fact, some recent commercial and governmental uses of emotion recognition have garnered considerable criticism, including: infringing on one’s privacy, exploiting vulnerable sub-populations, and even allegations of pseudo-science (Mohammad, 2022b; Wakefield, 2021; ARTICLE19, 2021; Woensel and Nevil, 2019).

This paper brings together ideas from Affective Computing and AI Ethics to present, in one place, some of the practical and ethical considerations involved in the creation and use of emotion lexicons — *best practices*.² We hope this work will facilitate more thoughtfulness when one is deciding on what emotions to work on, how to create an emotion lexicon, how to use an emotion lexicon, and how to judge success. Additional benefits of such a document include:

1. Presents the trade-offs of relevant choices so that stakeholders can make informed decisions appropriate for their context.
2. Has citations and pointers; acts as a jumping off point for further reading.
3. Helps engage the various stakeholders of an emotion task with each other. Helps stakeholders challenge assumptions made by researchers and developers.
4. Helps develop harm mitigation strategies.
5. Acts as a useful introductory document on emotion lexicons (complements survey articles).

Note that even though this article is focused on emotion lexicons, many of the ethical consid-

²This paper is a reframed and expanded avatar of an earlier datasheet paper for emotion lexicons (Mohammad, 2020).

erations apply broadly to natural language lexicons/resources in general. Also, see Mohammad (2022b) for a broader discussion on the ethical considerations associated with automatic emotion recognition (AER).

This work is in the same spirit as other recent innovations in exercising responsible research such as datasheets for datasets (Gebru et al., 2018), model cards for systems (Mitchell et al., 2019), and ethics sheets for AI tasks (Mohammad, 2022a). However, unlike datasheets and model cards which are designed for individual datasets and systems and that are published after the work is done, the goal of this work is to provide a more general-purpose relevant resource, accessible at the very beginning of one’s project. Also, unlike an ethics sheet for a automatic emotion recognition that may cover all kinds of ethical considerations associated with the task of interest, this document has a focus on the creation of emotion lexicons and their use in AI tasks.

Ethics considerations are not about objective metrics or simple checklists. They involve engaging with issues that impact stake holders, especially those that are already disadvantaged. Thus, a big component of this work is to raise awareness of relevant issues, to underscore how often there are no easy solutions, and that meaningful change requires painstaking, slow, and deliberate engagement with the stakeholders. Additionally, such documents are useful for those that are impacted to question and challenge assumptions made by unfair decisions of automated systems.

2 Best Practices

Below we present various best practices (practical and ethical considerations) pertaining to 22 aspects of emotion lexicon creation and use. The 22 aspects are grouped under the coarser categories pertaining to a lexicon’s life cycle: A. Lexicon Design, B. Annotation, C. Entries in the Lexicon, and D. Applying the Lexicon. Note that while many considerations are presented from the perspective of lexicon creation, they are also relevant to the users of a lexicon — knowing what decisions were made during the creation of a lexicon help one to assess appropriateness of using the lexicon.

The goal is to provide a comprehensive set of relevant considerations, so that readers (especially those new to research or new to work with emotions) can find the information in one place. Thus,

we include both the considerations that are especially specific to emotions, as well as others that apply more broadly (even if they are somewhat well known). Also, the points listed below are not meant to be the final word, but rather jumping off points for further thought and discussion.

2.1 Overview

An overview of the 22 aspects is presented below; followed by the detailed descriptions.

A. LEXICON DESIGN

1. Purpose or Objective
2. Emotion Category or Dimension
3. Word Senses and Dominant Sense Priors
4. Discrete or Continuous Value Labels

B. ANNOTATION

5. Questionnaire
6. Comparative Annotations
7. Annotators
8. Quality Control

C. ENTRIES IN THE LEXICON

9. Annotation Aggregation
10. Relative (not Absolute)
11. Coverage
12. Not Immutable
13. Perceptions (not “truth”)
14. Socio-Cultural Biases
15. Inappropriate Biases
16. Errors
16. Mechanism to Report and Fix Errors

D. APPLYING THE LEXICON

18. Fit of the Lexicon to One’s Data
19. Rescaling the Lexicon for One’s Task
20. Metrics & Features Drawn from the Lexicon
21. Removing Neutral Words
22. Inferences

2.2 Detailed Descriptions

A. LEXICON DESIGN

#1. Purpose or Objective: Consider and document the objective(s) of building the emotion lexicon. There can be more than one objective. The objectives guide various design choices involved in the creation of the lexicon. See [Selbst et al. \(2019\)](#) for common pitfalls in designing and framing socio-technical systems; and [Mohammad \(2022b\)](#) for common pitfalls in designing and framing automatic emotion recognition tasks. Users of emotion lexicons can study the purpose of each lexicon to determine which is most suitable for their use case.

Broadly speaking, the objectives tend to be around the study of word–emotion associations (exploring various research questions at the intersection of language and emotions) and aiding automatic emotion detection from utterances. However, individual projects often have specific goals, for example, to study specific phenomenon such as loneliness and empathy, to study inappropriate biases, to detect what emotions people perceive from utterances, to study how automatic systems should perceive the emotions in utterances, how automatic systems should use words to convey emotions, etc. It is important to recognize that some of these objectives are very related, but they have important differences. For example, while a general-purpose emotion lexicon will capture a number of benign associations, it will also capture inappropriate societal biases. If one wants to use a lexicon in a text generation system, then they should either use a lexicon designed specifically for that purpose, or address the biases in a general purpose lexicon, before using it.

Work using emotion lexicons should not claim that using it one can determine one’s emotional state from their utterance. At best, recognition systems (whether they use emotion lexicons or not) capture what one is trying to convey or what is perceived by the listener/viewer; and even there, given the complexity of human expression, they are often inaccurate. Several studies have shown that it is difficult to fully measure psychological states of people ([Stark, 2018](#); [Barrett, 2017b](#)).

In contrast, statistical analyses with features drawn from emotion lexicons can be used to accurately determine broad trends in the emotional state of a population over time ([Teodorescu and Mohammad, 2022](#)). Here, inferences are drawn at aggregate level from much larger amounts of data. Studies on public health, such as those on loneliness ([Guntuku et al., 2019](#); [Kiritchenko et al., 2020](#)), depression ([De Choudhury et al., 2013](#); [Resnik et al., 2015](#)), suicidality prediction ([MacAvaney et al., 2021](#)), bipolar disorder ([Karam et al., 2014](#)), stress ([Eichstaedt et al., 2015](#)), emotions during a pandemic ([Vishnubhotla and Mohammad, 2022](#)), and general well-being ([Schwartz et al., 2013](#)) fall in this category. Here too, however, it is best to be cautious in making claims about mental state, and use emotion recognition as one source of evidence amongst many (and involve expertise from public health and psychology).

#2. Emotion Category or Dimension: A key decision in the creation of an emotion lexicon is which conceptualization or facet of emotion to use. For example, should it capture emotion categories such as joy, sadness, fear, optimism, etc., or will it capture dimensions such as valence, arousal, and dominance. Psychologists and neuro-scientists have identified several theories of emotion that can inform the choice of categories and dimensions, including: the Basic Emotions Theory (BET) (Ekman, 1992; Ekman and Davidson, 1994), the Dimensional Theory (Osgood et al., 1957; Russell, 1980; Russell and Mehrabian, 1977; Russell, 2003), Cognitive Appraisal Theory (Scherer, 1999; Lazarus, 1991), and the Theory of Constructed Emotions (Barrett, 2017b).

Since ML approaches rely on human-annotated data (which can be hard to obtain in large quantities), emotion recognition research has often gravitated to the Basic Emotions Theory, as that work allows one to focus on a small number of emotions. This attraction has been even stronger in the vision research because of BET's suggested mapping between facial expressions and emotions. However, many of the tenets of BET, such as the universality of some emotions and their fixed mapping to facial expressions, stand discredited or are in question (Barrett, 2017a; Barrett et al., 2019).

Carefully consider which emotion formulation you wish to capture in your lexicon, or is appropriate for your task/project. For example, one may choose to work with the dimensional model or the model of constructed emotions if the goal is to infer behavioural or health outcome predictions. Despite criticisms of BET, it makes sense for some NLP work to focus on *categorical emotions* such as joy, sadness, guilt, pride, fear, etc. (including what some refer to as basic emotions) because people often talk about their emotions in terms of these concepts. Many human languages have words for these concepts (even if our individual mental representations for these concepts vary to some extent) (Wierzbicka, 1999). However, note that work on categorical emotions by itself is not an endorsement of the BET. Do not refer to some emotions as basic emotions, unless you mean to convey your belief in the BET. Careless endorsement of theories can lead to the perpetuation of ideas that are actively harmful (such as suggesting we can determine internal state from outward appearance—physiognomy).

#3. Word Senses and Dominant Sense Priors: Words when used in different senses and contexts may be associated with different emotions. The entries in the emotion lexicons are mostly indicative of the emotions associated with the predominant senses of the words. This is usually not too problematic because most words have a highly dominant main sense (which occurs much more frequently than the other senses). In specialized domains, some terms might have a different dominant sense than in general usage. Entries in the lexicon for such terms should be appropriately updated or removed. However, if the goal of the project is to create a lexicon for a specialized domain, then one should guide the annotation process accordingly.

#4. Discrete or Continuous Value Labels: Many emotion lexicons have discrete binary labels for words (positive–negative, joy–no joy, fear–no fear, and so on). Lexicons such as ANEW and the NRC VAD Lexicon have real-valued scores between 0 and 1, -1 and 1, 0 to 5, 0 to 100, etc. Real-valued scores allows one to make finer distinctions in the degree of emotion. They allow one to determine the intensity of emotion. Binary-labeled lexicons are used primarily to determine density of emotion word usage; for example, to explore whether there is a higher percentage of tweets with loneliness words during the Covid-19 pandemic, than in the years before the pandemic. Determine which type of lexicon is more aligned with your objectives.

B. ANNOTATION

#5. Questionnaire: Arguably the most crucial aspect in the creation of an emotion lexicon is the questionnaire. What is asked and how it is asked determines the outcome. Below are key recommendations in the design of questionnaires:

- a. Where appropriate, break the task/question into simpler sub-tasks/sub-questions.
- b. It is better to have separate tasks for different questions and emotion dimensions. Asking for responses about more than one emotion dimension requires the annotator to switch contexts and leads to more cognitive load.
- c. Keep the instructions clear and easy to follow.
- d. Examples are more important than definitions. People tend to learn faster and better through examples. It is still good to include simple definitions of relevant concepts.

- e. Refer to the theories for emotions work in psychology on to how to collect emotional information from respondents. Especially useful are the terms used to define emotion dimensions: e.g., as per the dimensional model of emotions (Russell, 1980) *arousal* is defined as the active–sluggish dimension, in the stereotype content model of social perception (Cuddy et al., 2008), *warmth* is defined as the trustworthiness, friendliness, kindness dimension. These words should be used when eliciting annotation responses.
- f. Keep the instructions brief. This is respectful of annotator time, and one can only keep track of a limited number of instructions at a time.
- g. Explain the purpose of the annotation task. This is respectful of annotators. People have a right to know (in appropriate detail) what research they are contributing their time for. This may also lead to more engaged annotators.
- h. Include an optional comment box that gives annotators a way to provide feedback, raise issues, and to be heard.
- i. Make the questionnaire and instructions freely available. This helps others to build on your work. It allows users to see exactly how the questions were phrased, and thus how to interpret the resulting emotion lexicon.

See also other data curation and questionnaire development tips from non-NLP fields such as psychology (Aguinis et al., 2021).

#6. Comparative Annotations: Real-valued scores provide fine-grained emotion information; however, it is difficult for humans to provide direct scores at this granularity. A popular approach to obtain real-valued scores is by providing the annotators with numeric rating scales.³ These scales have numbers (usually 1 to 5 or 1 to 7) and the annotator has to select which number is most indicative of the degree of association with the property of interest for the given word; given that the lowest number on the scale indicates least association and the highest number indicates the most association.⁴ The scores for an item from multiple annotators is averaged to obtain a real-valued score that is assigned to the word–emotion pair.

³<https://www.questionpro.com/blog/rating-scale/>

⁴It is good practice to anchor the numeric values with labels such as maximum/moderate/low association.

A common problem of annotation by rating scales is inconsistencies in annotations among different annotators. One annotator might assign a score of 87 to one word, while another annotator may assign a score of 81 to the same word. It is also common that the same annotator might assign different scores to the same word, if asked to annotate again after a period of time. Further, annotators often have a bias towards selecting scores in the middle of the scale, known as *scale region bias* (Presser and Schuman, 1996; Baumgartner and Steenkamp, 2001).

Paired Comparisons (Thurstone, 1927; David, 1963) is a comparative annotation method, where respondents are presented with pairs of items and asked which item has more of the property of interest (for example, which is more positive). The annotations can then be converted into a ranking of items by the property of interest, and one can even obtain real-valued scores indicating the degree to which an item is associated with the property of interest. The paired comparison method does not suffer from the problems discussed above for the rating scale, but it requires a large number of annotations—order N^2 , where N is the number of items to be annotated.

Best–worst scaling (BWS) (Louviere, 1991) is a form of comparative annotation, like paired comparison, but it requires much fewer annotations. Annotators are given n items (an n -tuple, where $n > 1$ and commonly $n = 4$).⁵ They are asked which item is the *best* (highest in terms of the property of interest) and which is the *worst* (least in terms of the property of interest). When working on 4-tuples, best–worst annotations are particularly efficient because each best and worst annotation will reveal the order of five of the six item pairs (e.g., for a 4-tuple with items w , x , y , and z , if w is the best, and z is the worst, then $w > x$, $w > y$, $w > z$, $x > z$, and $y > z$). Real-valued scores of association between the items and the property of interest can be determined using simple arithmetic on the number of times an item was chosen best and number of times it was chosen worst (Orme, 2009; Flynn and Marley, 2014). It has been empirically shown that three annotations each for $2N$ 4-tuples is sufficient for obtaining reliable scores

⁵At its limit, when $n = 2$, best–worst scaling reduces to a *paired comparison* (Thurstone, 1927; David, 1963); However, then a much larger set of tuples need to be annotated (closer to N^2).

(where N is the number of items) (Louviere, 1991; Kiritchenko and Mohammad, 2016). Kiritchenko and Mohammad (2016; 2017) showed through empirical experiments on emotion lexicons that BWS produces more reliable and more discriminating scores than those obtained using rating scales.

Within the NLP community, BWS has been used for creating datasets for relational similarity (Jurgens et al., 2012), word-sense disambiguation (Jurgens, 2013), word-sentiment intensity (Kiritchenko and Mohammad, 2016), sentence-sentence semantic relatedness (Abdalla et al., 2023), etc.

#7. Annotators: Who is recruited to annotate the data also impacts the lexicon that is generated.

- a. *Experts or Crowd:* If a task has clear correct and wrong answers and knowing the answers requires some training/qualifications, then one can employ domain experts to annotate the data. However, emotion annotations largely do not fall in this category. People are the best judges of their emotions and how they use words to communicate them. If the goal is to determine how people use language or we want to know how people perceive words, phrases, and sentences then we might want to employ a large number of annotators (crowdsourcing). Note that this is also a scenario where there can be more than one appropriate answer.
- b. *Diversity:* Emotion lexicons are a function of their annotators. Consider who all should be represented in the annotator pool, and actively recruit people from under-represented groups. Seek appropriate demographic information (respectfully and ethically). Document annotator demographics at an aggregate level.
- c. *Informed Consent, Privacy, and Potential for Harms:* Provide a clear and easy-to-understand description of what the task will involve, potential risks, and what information will be collected, before obtaining consent from the annotators. Note that if the terms included for annotation or the chosen dimension of annotation is particularly negative, then there may be significant risk of adversely impacting the annotator's mental health. In such cases, suitable avenues for recourse must be provided.
- d. *Remuneration:* Determine fair compensation for the task. Inform the annotators of the pay and the time commitment expected.
- e. *Miscellaneous:* There are several other ethical considerations also involved with such work such as: worker invisibility, lack of learning trajectory, humans-as-a-service paradigm, worker well-being, and worker rights (Dolmaya, 2011; Fort et al., 2011; Standing and Standing, 2018; Irani and Silberman, 2013).
- f. *Ethics Approval:* Obtain approval of the project and annotation plan from your institution's research ethics board before conducting the annotation. The ethics boards are also a great source of feedback for improving the ethical standards of the annotation process. If unsure whether some work requires ethics approval, reach out to the ethics board. Many institutions provide expedited review in cases of low risk.

Document these considerations so that the users can judge suitability of the lexicon for their work.

#8. Quality Control: Good quality control strategies can make a large difference for any scenario of annotations, but are especially important when the annotations are done via crowdsourcing. Quality control strategies can be of three kinds:

Type 1: applied before data annotation begins

Type 2: applied during data annotation, and

Type 3: applied after data annotation.

It is recommended to apply measures of all three kinds. Examples of Type 1 include: careful questionnaire design and setting up training or qualification annotations to screen annotators.

A particularly powerful example of a Type 2 measure is to intersperse the instances with small number of hidden gold instances (~5%) — instances for which the appropriate label(s) are pre-determined (by, say, the authors). If a crowd worker responds with an answer not already marked as appropriate, then they are immediately notified, the annotation is discarded. If an annotator's accuracy on the gold questions falls below a pre-chosen threshold (say, 80%), then they are refused further annotation, and all of their annotations are discarded. This way the gold instances serve as a mechanism to avoid malicious annotations, as well as a way to further train the annotators. This also avoids scenarios where an annotator provides responses to a large number of questions, only to later learn that they misinterpreted something, rendering all of their annotations useless. The use of gold questions was popularized by the crowdsourcing platform CrowdFlower (now, Figure8).

Examples of Type 3 quality control measures include: removal of responses from people who answer questions too quickly, or whose responses are more than two standard deviations away from the responses of others. There also exist approaches that identify which annotators to trust using machine learning algorithms (Raykar and Yu, 2012; Hovy et al., 2013).

C. ENTRIES IN THE LEXICON

#9. Annotation Aggregation: Each instance in a lexicon (usually a word) is often annotated by a number of annotators. Standard practice in aggregating the responses from multiple annotators is to take the most frequent response. However, it should be noted that sometimes other responses are also appropriate. Further, different socio-cultural groups can perceive language differently, and taking the majority vote can have the effect of only considering the perceptions of the majority group. When these views are crystallized in the form of a lexicon, it can lead to the false perception that the norms so captured are “standard” or “correct”, whereas other associations are “non-standard” or “incorrect”. Thus, it is worth explicitly disavowing that view and stating that the lexicon simply captures the perceptions of the majority group among the annotators. Thus, it is recommended to also make available disaggregated annotations (annotations in their raw form – without aggregation). Note that it is also problematic to consider all annotator responses as valid because sometimes annotators make mistakes, and some may have inappropriate biases (see #15).

#10. Relative (not Absolute): The absolute values of the association scores themselves usually have no meaning. The scores help order the words relative to each other. For example, a term with a high valence score is associated with more positiveness than a term with a lower score.

#11. Coverage: Some lexicons have a few hundred terms, and some have tens of thousands of terms. However, even the largest lexicons do not include all the terms in a language. Mostly, they include entries for the canonical forms (lemmas), but some also include morphological variants. The high-coverage lexicons, such as the NRC Emotion Lexicon, have tens of thousands of terms. However, when using the lexicons in specialized domains, one may find that a number of common terms in the domain are not listed in the lexicons.

#12. Not Immutable: The associations do not indicate an inherent unchangeable attribute. Emotion associations can change with time, but these lexicon entries are largely fixed. They pertain to the time they are created or the time associated with the corpus from which they are created.

#13. Perceptions (not “truth”): Emotion lexicons largely capture how speakers of a language perceive the emotion associations of words. As mentioned in the previous bullet, this can change with time. Further, it can also be different for different people. Mohammad and Turney (2013) found that when the annotators are asked to judge emotion associations in terms of ‘how speakers of a language perceive the word’, the results have lower variance than when asked ‘the emotions evoked in the annotator’. Consider your objective when deciding which of the two framings (or some other) is more appropriate for your use case.

#14. Socio-Cultural Biases: Since the emotion lexicons have been created by people (directly through crowdsourcing or indirectly through the texts written by people) they capture various human biases. These biases may be systematically different for different socio-cultural groups. Document who produced the data (people from which countries, what is the gender distribution, age distribution, etc.) in the paper describing the dataset or in the associated datasheet. An advantage of crowdsourcing is that the annotations are from a wider pool of annotators; however, crowd annotators are systematically different from, and not representative of, the general population.

#15. Inappropriate Biases: Some of the human biases that have percolated into the lexicons may be rather inappropriate. For example, entries with low valence scores for certain demographic groups or social categories. Studying such biases in the lexicon can be useful to show and address some of the historical inequities that have plagued humankind. Nonetheless, when these lexicons are used in specific tasks, care must be taken to remove such entries from the lexicons where necessary.

#16. Errors: Even though the researchers take several measures to ensure high-quality and reliable data annotation (e.g., multiple annotators, clear and concise questionnaires, framing tasks as comparative annotations, interspersed check questions, etc.), human-error can never be fully eliminated in large-scale annotations. Expect a

small number of clearly wrong entries. Automatically generated lexicons also can have erroneous entries. They are often built on the assumption that the tendency of a word to co-occur with emotion-associated seed terms is proportional to its association with that emotion. However, in any corpus, there will always be some amount of chance high co-occurrences that are not accurate reflections of the true associations.

#17. Mechanism to Report and Fix Errors: Provide a mechanism for users to report issues and errors. Fix errors and where appropriate issue warnings for how some types of entries can be mis-interpreted or misused. Periodically assess whether certain types of entries need to be proactively checked. For example, there has been growing recognition that emotion associations associated with identity groups are particularly sensitive, affected by historical bias, and so one must be careful in how they interpret the associations captured in lexicons.

D. APPLYING THE LEXICON

#18. Examining the Fit of the Lexicon: Manually examine the emotion associations of the most frequent terms in your data. Remove entries from the lexicon that are not suitable (due to mismatch of sense, inappropriate human bias, etc.).

#19. Rescaling the Lexicon for One's Task: Depending on your specific use case, you may choose to re-scale the scores from 0 to 1, -1 to 1, 1 to 10, etc. Note that if using the lexicon entries as features in machine learning experiments, the scale (0 to 1 or -1 to 1) can make a difference—e.g. if the score is used as a weight for features.

#20 Metrics and Features Drawn from the Lexicon: For text analysis, one can calculate various metrics such as the percentage of emotion words (when the lexicons provides a list of words associated with a category) or average emotion intensity (for real-valued associations). When determining the scores, a further choice is how to handle words that are not in the lexicon. Two common approaches include: 1. Treat words that are not in the lexicon as neutral; 2. Ignore these words in the calculation of the scores. The latter approach does not make assumptions of neutrality, and is not impacted by the number of such out of lexicon words in a piece of text. See [Teodorescu and Mohammad \(2022\)](#) for a systematic

analysis of the impact of various lexicon features on the quality of emotion arcs generated with them.

#21. Creating Subsets of the Lexicon: Sometimes it is better to use a subset of the emotion lexicon, rather than the whole lexicon.

Removing Neutral Words: One can use the whole lexicon to calculate metrics such as average valence of the words in a text; however, one can also choose to disregard terms with close to 0 valence scores. when calculating the same metric. Removal of such neutral terms from the analysis will show greater variations in the average scores when comparing across different sets of data of interest or across time. For example, when looking at the average tweet happiness over time of day, using full or neutral-removed lexicon is expected to get roughly similar curves, but the neutral-removed lexicon will show a greater amplitude (divergence of scores from the peaks to troughs). ([Dodds et al., 2011](#)) describes this as turning up the magnifier knob in a microscope. Note, however, that just having larger score differences between the target and control does not mean that the emotion word usage is substantially different or significant; and conversely, just because the score difference for a metric is small in value does not mean that the differences in emotion word usages are not substantial. (More on this in #22).

Removing Low-Association Words: Use of low-association terms from a lexicon may not be beneficial for some downstream applications. These entries may also include a greater percentage of annotation errors. See [Teodorescu and Mohammad \(2022\)](#) for experiments on multiple datasets and multiple emotion dimensions that examine usefulness of removing low-association terms from a lexicon when generating emotion arcs.

Removing Highly Polysemous and Certain Domain Words: For some applications, it is beneficial to discard highly ambiguous words. Entries for highly ambiguous words are more likely to include emotion associations for a sense that is not common in one's data. As stated in #3, it is also recommended to remove entries not appropriate for the target domain; e.g., the word *harry* has a negative meaning, but it should not be used when analyzing text where a person has the name *Harry*.

#22. Inferences: When drawing inferences from texts using counts of emotion words:

- a. It is more appropriate to make claims about emotion word usage rather than emotions of the speakers. For example, *‘the use of anger words grew by 20%’* rather than *‘anger grew by 20%’*. A marked increase in anger words is likely an indication that anger increased, but there is no evidence that anger increased by 20%. Further, it is important to understand the emotion metrics and to interpret them accordingly. For example, many off-the-shelf tools provide a “sentiment score” for the input textual instances, without providing adequate details about what this score means. As discussed in #21, the scores themselves can have large or small values, and just knowing that the score difference between a target and control is large (or small) is not enough to draw meaningful inference. On the other hand, grounded metrics that tie the score to attributes such as percentage of positive words tend to be less open to misinterpretation.
- b. Comparative analysis is your friend. Often, emotion word counts on their own are not useful. For example, *‘the use of anger words grew by 20% when compared to [data from last year, data from a different person, etc.]’* is more useful than saying *‘on average, 5 anger words were used in every 100 words’*.
- c. Lexicon features (or any other automatically drawn features) are *not* well suited to draw meaningful emotional inferences from individual utterances. Human language and behaviour are highly variable and complex. However, with careful design, they can be useful to draw inferences about broad trends at an aggregate level (Teodorescu and Mohammad, 2022).
- d. Inferences drawn from large amounts of text are more reliable than those drawn from small amounts of text. Teodorescu and Mohammad (2022) show that this is the single most important feature in determining the fidelity of the predicted emotion trends with the true emotion trends, among a host of features they explored. For many emotion dimensions and dataset domains, it is advisable to determine aggregate emotion scores using at least 100 instances. For example, if there are at least 100 tweets per day about a product of interest, the average valence scores of all the words in the tweets every day is expected to produce a fairly accurate valence arc (x-axis is day, y-axis is average valence score for the corresponding day).

3 Limitations

This paper does not present a new NLP model or dataset. Thus, there are no corresponding limitations to discuss. However, the paper itself can be viewed as a document discussing limitations of existing approaches to do sentiment and emotion analysis using emotion lexica. The 22 best practises presented in the paper discuss approaches to engage with and counter these limitations.

While this document was a result of engaging a larger community through blog posts, talks, and discussions, we had relatively low access to developers of commercial sentiment analysis systems. Thus the list presented here may have missed some important considerations. We encourage readers and impacted stakeholders to challenge the assumptions latent in the document, and identify new ethical considerations not included here or not gaining adequate attention in the research community.

4 Concluding Remarks

Emotion lexicons are simple yet powerful tools to analyze text. However, use of the lexicons (even for tasks that it is suited for) can lead to inappropriate bias. Applying a lexicon to any new data should only be done after first investigating its suitability, and requires careful analysis to minimize unintentional harm. In this paper, we presented 22 best practises that include considerations that can help mitigate such unwanted outcomes, as well as strategies to make the best use of emotion lexicons towards drawing meaningful and accurate inferences. The best practises are organized as per a lexicon’s life cycle: A. Lexicon Design, B. Annotation, C. Entries in the Lexicon, and D. Applying the Lexicon. We also provide pointers to relevant literature to explore the best practises in more detail. It should be noted that these practises are not meant to be the final word, but rather jumping off points for further thought, discussion, and additional measures towards the responsible use of emotion lexicons.

Abstract

In this paper, we investigate whether symbolic semantic representations, extracted from deep semantic parsers, can help reasoning over the states of involved entities in a procedural text. We consider a deep semantic parser (TRIPS) and semantic role labeling as two sources of semantic parsing knowledge. First, we propose PROPOLIS, a symbolic parsing-based procedural reasoning framework. Second, we integrate semantic parsing information into state-of-the-art neural models to conduct procedural reasoning. Our experiments indicate that explicitly incorporating such semantic knowledge improves procedural understanding. This paper presents new metrics for evaluating procedural reasoning tasks that clarify the challenges and identify differences among neural, symbolic, and integrated models.

1 Introduction

Procedural reasoning is the ability to track entities and understand their evolution given a sequence of actions (Tandon et al., 2020). This kind of reasoning is crucial in understanding recipes (Bosselut et al., 2018; Yagcioglu et al., 2018), manuals and tutorials (Tandon et al., 2020; Wu et al., 2022), cybersecurity text (Pal et al., 2021), natural events (Tandon et al., 2020), and even stories (Storks et al., 2021). An example of a procedural text in the natural event domain, its entities of interest, and their state changes are shown in Figure 1.

Inferring actions and their impact on entities involved in a procedural text can be challenging in various aspects. **First**, there are dependencies between steps to be considered in predicting a plausible action set. For instance, an entity destroyed at step t of the process cannot be moved again at step $t + 1$. **Second**, some sentences contain ambiguous local signals by including multiple action verbs. For example, "The oxygen is consumed in the process of forming carbon dioxide.", where the oxygen

Process	Participants			
	plant	animal	bone	oil
Before the process begins	?	?	-	-
1. Plants and animals die in a watery environment	watery environment	watery environment	-	-
2. Over time, sediments build over	sediment	sediment	-	-
3. The body decomposes	sediment	-	sediment	-
4. Gradually buried material becomes oil	-	-	-	sediment

Figure 1: An example of procedural text and its annotation (location of objects). ‘-’ means the entity does not exist; ‘?’ means the entity’s location is unknown.

is being destroyed, and the carbon dioxide is being created. **Third**, the sentences are incomplete in some steps. For instance, a step of the process might only indicate "is buried in mud", which cannot be understood without context. **Fourth**, finding the properties of some entities may require reasoning over both the global context and local relations. For instance, in the sentences "1. Magma rises to the surface. 2. Magma cools to form lava", the location of ‘Lava’ after step 2 should be inferred from the prior location of Magma, which is indicated in its previous step. **Fifth**, common sense is required to understand some consequences. For example, in Figure 1, step 3, one should use common sense to realize that ‘decomposing body’ would expose the ‘bones’, which will be left behind in the ‘sediment’. **Sixth**, understanding some relations requires an advanced co-reference resolution. In Figure 1, step 4, a complex co-reference resolution is required to understand that the ‘buried material’ refers to both ‘plants and animals bones’ and that they are transforming into the ‘oil’.

Except for the common-sense (Zhang et al., 2021) and the ability to make consistent global decisions actions (Gupta and Durrett, 2019), the other challenges might have only been indirectly tackled in the recent research (Huang et al., 2021; Faghihi and Kordjamshidi, 2021), but have neither been addressed explicitly nor properly evalu-

ated to measure their success on resolving these challenges. In this paper, we evaluate whether semantic parsers can alleviate some of these challenges. Semantic parsers provide semantic frames that identify predicates and their arguments in a sentence. For instance, in the sentence ‘Move bag to the yard’, “Move” is the predicate, “bag” and “the yard” are the arguments with types “affected”¹ and “location” respectively. Such semantic information can help disambiguate multi-verb local connections between predicates and arguments (Huang et al., 2021). They can also provide meaningful local relations, making it easier to connect global information to infer entities’ states. For instance, in the same sentence, “Magma cools to form lava”, “Magma” is noted as the ‘affected’ and ‘lava’ is the result of the predicate ‘form’. This makes it easier to infer that the location of ‘lava’ should match the last location of ‘magma’.

For our study, we consider both the classic semantic role labeling (SRL)², based on (Shi and Lin, 2019), which is a relatively shallow semantic parsing model, as well as the deep semantic parser TRIPS³ (Ferguson et al., 1998; Allen and Teng, 2017). To investigate the effect of semantic parsing on procedural reasoning, we analyze its effect as a standalone symbolic model as well as its integration in a neuro-symbolic model that combines semantic parsing with state-of-the-art neural models to solve the procedural reasoning task.

First, we design a set of heuristics to extract a symbolic abstraction from the TRIPS parser, called PROPOLIS. We use this baseline to further showcase the effectiveness of semantic parsing information in solving the procedural task. Next, we integrate the semantic parsers with two well-established procedural reasoning neural backbones, namely NCET (Gupta and Durrett, 2019) and TSLM (Faghihi and Kordjamshidi, 2021) (and its extension CGLI (Ma et al., 2022)), through encoding the semantic relations as a graph attention neural network (GAT) (Shi et al., 2020).

For our experiments, we use Propara dataset (Tandon et al., 2020) that introduces the procedural reasoning task over natural events that are described in English. We realized the existing evaluation metrics of this dataset do not reflect the actual performance of the models and

fail to identify the challenges and shortcomings of the models. Consequently, we propose new evaluation criteria to shed light on the differences between the models, even when they perform similarly based on the prior metrics.

In summary, our contributions are (1) Proposing a symbolic model (Propolis) to solve the procedural reasoning task based on semantic parsing, (2) Proposing a set of new evaluation metrics which can identify the strength and weaknesses of the models, and (3) Showcase the benefits of integrating semantic parsing into the neural models. The code and models proposed in this work are all available in GitHub⁴.

2 Related Research

Procedural text understanding has been investigated in many benchmarks such as ScoNe (Long et al., 2016), bAbI (Weston et al., 2015), and ProcessBank (Berant et al., 2014). Recent research has focused on procedural reasoning as tracking entities throughout a procedural text. Datasets such as Propara (Tandon et al., 2020), Recipes (Bosselut et al., 2018), Procedural Cyber-Security text (Pal et al., 2021), and OpenPI (Tandon et al., 2020) are in the same direction. Procedural reasoning can also be influential in addressing causal reasoning (WIQA) (Tandon et al., 2019), story understanding (Trip) (Storks et al., 2021), and abstractive multi-modal question answering (RecipeQA) (Yagcioglu et al., 2018).

This paper primarily focuses on tracking entities’ states and properties throughout a procedural text. Recent research has addressed this problem by predicting actions and properties on local context (Prolocal) (Dalvi et al., 2018), autoregressive global predictions based on distance vectors (Proglobal) (Dalvi et al., 2018), integrating structural common-sense knowledge built over VerbNet (ProStruct) (Tandon et al., 2018), building dynamic knowledge graphs over entities (KG-MRC) (Das et al., 2018), explicitly encoding the model to explain dependencies between actions (XPAD) (Dalvi et al., 2019), formulating local predictions and global sequential information flow and sequential constraints (NCET) (Gupta and Durrett, 2019), formulating the task in a QA setting (DynaPro, TSLM) (Amini et al., 2020; Faghihi and Kordjamshidi, 2021), inte-

¹referred to as ‘Patient’ in some other parsing formalisms.

³<http://trips.ihmc.us/parser/cgi/parse>

⁴<https://github.com/HLR/ProceduralSemanticParsing>

grating common-sense knowledge from ConceptNet (KOALA) (Zhang et al., 2021), utilizing large generative language models (LEMON) (Shi et al., 2022), or using both the question answering setting and sequential structural constraints at the same time (CGLI) (Ma et al., 2022). All the models mentioned above investigate different neural architectures to tackle the task, while we are more interested in augmenting them with additional knowledge from semantic parsers. Recent research has also investigated the integration of semantic role labeling into the procedural reasoning task (REAL) (Huang et al., 2021), which is very close to our goal in this paper. However, in this work, we propose and investigate a variety of combinations, a deeper semantic representation (TRIPS) and named relations, in addition to a symbolic approach for solving the procedural reasoning task solely based on semantic parsing.

3 Technical Approach

Problem definition The procedural reasoning task can be formally defined by a procedural text including m steps, $S = \{s^1, s^2, \dots, s^m\}$, a set of entities $E = \{e_1, e_2, \dots, e_n\}$, where n is the number of entities, and a set of properties. Specifically, in the Propara dataset, the property of interest is only the location of the entities $P_L = \{p_{L_1}^0, p_{L_1}^1, \dots, p_{L_n}^m\}$, where $p_{L_i}^t$ denotes the j th entity at step t . In Propara, the location prediction starts at step 0, which indicates the entity’s location before the process begins. The location of an entity can either be known (represented by a string) or unknown (represented by "?"). Similar to prior research (Tandon et al., 2020), the location property is used to infer a set of actions $A = \{a_1^1, a_2^1, \dots, a_n^m\}$, where a_t^j denotes the action type applied to entity j at step t . Following the prior research (Dalvi et al., 2018), we extract all the noun phrases from the sentences and only consider those as location candidates.

We investigate two different modeling approaches to solve this problem. First, we use a symbolic and parsing-based model, and second, we integrate semantic parsing with neural models. We use two different sources for semantic extraction: SRL and TRIPS. In general, SRL is coarse-grained and shallow compared to TRIPS. The connections in TRIPS are not limited to the pairwise connections between predicates and arguments but are extended to the semantic connections between any two words. Since TRIPS relies on a general pur-

pose ontology, it also augments the arguments and predicates with additional information about a set of possible features (mobility, container, negation) and mapping of the words to hierarchical ontology classes (i.e., mapping “water” to “beverage”). SRL is centered around the semantic frames of the verbs (predicates) and identifies each predicate’s main and adjunct (mainly time and location) arguments in the sentence. Figure 2 and 3 show examples of the SRL and TRIPS parses, respectively.

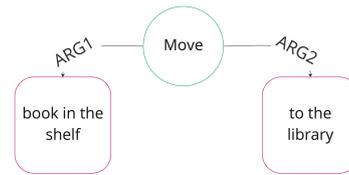

Figure 2: The SRL annotation for the sentence “Move the book in the shelf to the library”.

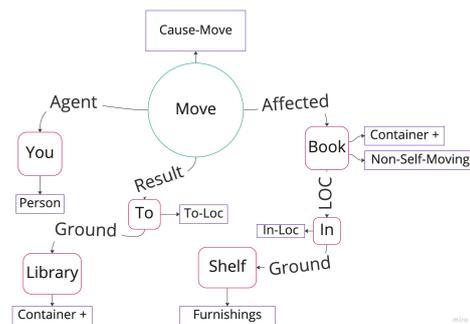

Figure 3: The TRIPS parse for the sentence “Move the book in the shelf to the library”.

The symbolic model only uses the TRIPS parser as it provides more extended extractions and meaningful relations, while both SRL and TRIPS are used for integration with the neural baselines.

3.1 PROPOLIS: Symbolic Procedural Reasoning

We propose the PROPOLIS model, which solves the procedural reasoning task merely by symbolic semantic parsing. PROPOLIS operates on the TRIPS parser in three steps. First, it makes an abstraction over the original parse to summarize the information in the graph and include a smaller set of actions and changes in objects and their locations. Second, it uses a set of rules to transform the abstracted parses into clear actions and identifies the affected objects by the actions, using the semantic roles, while extracting an ending location or starting location. Lastly, it performs global reasoning to connect the local decisions and produce

a consistent sequential set of actions/locations for each entity of interest. More details about the steps are also available in Appendix B.

3.1.1 Graph Abstraction

The original TRIPS parse includes many concepts and edges that do not directly affect entities' location or existence. Therefore, we make a more concise graph abstraction to facilitate processing the entities, actions, and locations. To obtain a more informative abstraction, firstly, the relevant classes of the TRIPS ontology are mapped to action classes defined in the Propara dataset (Create, move, or destroy). For instance, the verb 'flow' is first mapped to the 'fluidic motion' class in the TRIPS ontology, which is a child of the 'motion' class, and the 'motion' class is mapped to the 'move' action in the Propara dataset. This will help distinguish the predicates that signal a change in the location or existence of objects. Second, the important arguments are identified in the parse, and the locations are extracted. The graph is decomposed to include a set of events with their arguments. Each event may contain different roles such as "agent", "affected", "result", "to_location", "from_location", or other roles required by its semantic frame.

3.1.2 Rule-based Local Decisions

We use a set of heuristic rules to map the abstracted graph onto actual actions over the entities of interest. The rules are written according to the semantic frames and the type of predicates and arguments in each parse. For instance, if a semantic frame is mapped to 'Move' and has both the 'agent' and 'affected' arguments, then the 'affected' argument specifies the object being moved. The same frame with only an 'agent' argument indicates a move for the object in the 'agent' role. Table 1 shows the most frequent templates we used to transform the local parses into actual decisions over the entities.

3.1.3 Global Reasoning

The two first steps are merely based on the local sentence-level actions of each step. We need additional global reasoning over the whole procedure to predict the outputs. Global reasoning ensures that local decisions form a valid global sequence of actions for a given entity. For instance, if an entity is predicted to be destroyed at step 2 and moved at step 3, we consider the 'destroyed' action a wrong local decision since a destroyed object cannot move later in the process. The graph also contains pas-

sive indications of object location in phrases such as "the book on the shelf" or even indications of prior locations in terms of a 'from_location' argument. These phrases do not generate actions but provide information that should be used in previous steps. For example, if step t has a local prediction 'Move' for entity e with no target location and step $t + 1$ has a 'from_location' for entity e , then the 'from_location' should be used as the target location of the 'Move' action in the previous step.

3.2 Integration with Neural Models

Here, we investigate whether explicitly incorporating semantic parsers with neural models can help better understand the procedural text. We choose two of the recently proposed and most commonly used backbone architectures for procedural reasoning tasks, namely NCET (Gupta and Durrett, 2019) and TSLM (Faghihi and Kordjamshidi, 2021) (and its extension CGLI (Ma et al., 2022)). Similar to (Huang et al., 2021), we rely on a graph attention network (GAT) to integrate the information from the semantic parsers into the neural baselines.

Following (Huang et al., 2021), the nodes in this graph are either (1) predicates in the semantic frames, (2) mentions of entities of interest (Exact match or Co-reference), or (3) noun phrases in the sentence. An edge in the SRL graph exists between two nodes if they have a (predicate, argument) connection or they are both parts of the same verb semantic frame (argument to argument) (Huang et al., 2021). It is relatively straightforward to build a semantic graph with the TRIPS parser because it outputs the parse as a graph.

An edge is created between any pairs of nodes (phrases) in the graph if any subsets of these two phrases are connected in the original parse. The edge types are preserved. Since not all the nodes in the original parse are present in the new simplified graph, we may lose some key connections. To fix this, if two nodes (phrases) are not connected in the new graph but have been connected in the original one, we find the shortest path between them in the original parse and connect them with a new edge with the type being the concatenation of all the edge types in the path. Lastly, nodes are connected across sentences based on either an exact match or co-reference resolution.

Both NCET and TSLM models are trained based on Cross Entropy to compute the loss for both actions and locations. The final loss of the model

Main Predicate	Roles	Decisions
Move	Affected, Agent	The “Affected” is being moved.
Move	Agent	The “Agent” is being moved.
Destroy	Affected	The “Affected” is being destroyed
Create	Affected_Result, Affected	The “Affected_Result” is being created
Create	Affected	The “Affected” is being created
Change	Affected, Res	The “Affected” is being destroyed, and the “Res” is being created

Table 1: The rules used to evaluate the effect of actions on various roles of the semantic frame

is calculated by $L_{total} = L_{action} + \lambda * L_{location}$, where λ is a balancing hyper-parameter.

3.2.1 Integration with NCET as Backbone

The NCET model uses a language model to encode the context of the procedure and compute representations for mentions of entities, verbs, and locations. These representations are used in two sub-modules for predicting the actions and the locations. To integrate the semantic parsers with the NCET architecture, we use the output of the language model to initialize the semantic graph representations. Then multiple layers of graph attention network (based on TransformerConv (Shi et al., 2020)) are applied to encode the graph structure. We combine the updated graph representations with the initial mention representations. These combined representations are later used in subsequent prediction modules.

More formally, we start by using a language model to encode the context of the process $h' = LM(S)$, where S is the procedure, and h' is the embedding output from the language model. The representations are further encoded by a BiLSTM $h = BiLSTM(h')$.

Graph Attention Network Since each node in the semantic graph corresponds to a subset of tokens in the original paragraph, we use the mean average of these tokens’ representation to initialize the nodes’ embedding denoted as v_i^0 . If the graph contains edge types, the edges between each two nodes i and j are denoted by e_{ij} and is represented by the average token embedding through the same LM model used for encoding the story, $e_{ij} = Mean(LM(e_{ij}^{text}))$. Lastly, we use C layers of TransformerConv (Shi et al., 2020) to encode the graph structure. More details on the graph encoder is available in Appendix C.

Representing Mentions To integrate the semantic parses with the baseline model, we use both representations obtained from the language model and the graph encoder to represent entities, verbs, and

Tag	Description
O_D	Entity does not exist after getting destroyed
O_C	Entity does not exist before getting created
E	Entity exists and does not change
C	Entity is created
D	Entity is destroyed

Table 2: The list of output tags/actions

locations in the process. Mention representations are denoted by $r_t^m = [M(h_t^m); M(h_{g_t}^m)]$, where t is one step of the process, h_t^m is the average representation of tokens in the story corresponding to the mention m in step t , $h_{g_t}^m$ is the average embedding of nodes corresponding to mention m in step t , and the function M replaces the representations with zero if there is no mention of m in step t .

Location Prediction We first encode the pairwise representation of an entity e and location candidate lc at each step t , denoted by $\mathbf{x}_t^{(e,lc)} = [\mathbf{r}_t^e; \mathbf{r}_t^{lc}]$. Next, we use an LSTM to encode the step-wise flow of the pair representation to get $\bar{h}_t^{(e,lc)} = LSTM([\mathbf{x}_t^{(e,lc)}])$. Finally, the probability of each location candidate lc to be the location of entity e at step t is calculated by a *softmax* over the potential candidates, $p^{(e,lc)_t} = Softmax(W_{loc}^t \bar{h}_t^{(e,lc)})$, where W_{loc}^t is the learning parameters of a single multi-layer perceptron.

Action Prediction To predict the action for entity e at step t , we create a new representation for the entity based on its mention and the sentence verbs, denoted by $x_t^e = [r_t^e; Mean_{v \in np(e_t)}(r_t^v)]$, where $np(e_t)$ is the set of verbs whose corresponding node in the graph has a path to any of the nodes representing entity e in step t . The final representations are then produced using a BiLSTM over the steps, $h_t^e = LSTM([x_t^e])$. Lastly, a neural CRF layer is used to consider the sequential structure of the actions by learning transition scores during the training of the model (Gupta and Durrett, 2019). The set of possible actions is shown in Table 2.

	Local	Global Loc	Global Ent		Global Loc and Ent	Ambiguous
	Both	Both	Actions	Locations	Both	Actions
Train	885	367	438	340	114	593
Dev	116	44	66	3	9	76
Tests	105	61	98	71	18	110

Table 3: The number of decisions per category of evaluation with the new decision-level metric. “Both” refers to both location and action decisions and is used since the number of those decisions is the same in most cases. The number of decisions in the ‘Global Ent’ case can be different for the actions and the locations because this category also considers ‘destroy’ events that have no corresponding locations.

3.2.2 Integration with TSLM as Backbone

The TSLM (Faghihi and Kordjamshidi, 2021) model reformulates the procedural reasoning task as a question-answering problem. The model simply asks the question, ‘Where is entity e ?’ at each step of the process. To include the context of the whole process when asking the same question at different steps, TSLM further introduces a time-aware language model that can encode additional information about the time of events. Given the new encoding, each step of the process is mapped to either past, present, or future. TSLM uses the answer to the question at each step to form a sequence of decisions over the location of entity e . To integrate the semantic graph with this model, we first extend the graph by adding a question node. The graph is then initialized using the time-aware language model. The encoded representations of the graph, after applying multiple layers of GAT, are combined with the original token representations and used for extracting the answer to the question.

Initial Representation For each entity e and timestamp t , the string “where is e ? s_1 $\langle/s\rangle$ s_2 $\langle/s\rangle$... s_m $\langle/s\rangle$ ” is fed into the time-aware language model. Accordingly, the tokens’ representations for timestamp t are $(h_e)_t^i = LM(S, t)$.

Graph Attention Module Inspired by (Zheng and Kordjamshidi, 2020), we add new nodes to the semantic graph to represent the question and each step of the process. We connect the question node to any node in the graph representing the entity of interest e , and each step node to all the tokens in their corresponding sentence. An example of the QA-based graph can be found in Appendix D. All the node embeddings are initialized by the average embedding of their corresponding tokens in the procedure. We use C layers of graph attention network (TransformerConv), similar to Section 3.2.1, to encode the graph structure.

Location Prediction For predicting the locations of entities, that is, the answer to the question, we

predict the answer among the set of location candidates. This is different from the common practice of predicting start/end tokens. We represent each location candidate by combining representations from both the graph and the time-aware language model, denoted by $r_t^{lc} = [(h_e)_t^{lc}, (h_{gl}^e)_t^{lc}]$, where $(h_{gl}^e)_t^{lc}$ is the representation of the lc from the last layer of the GAT. The answer is then selected by calculating a *softmax* over the set of location candidates, $p_t^{lc} = \text{Softmax}(W^{location} r_t^{lc})$.

Action Prediction Similar to CGLI (Ma et al., 2022) model, we explicitly predict the actions of entities alongside the locations. First, the model extracts each timestamp’s “CLS” tokens and builds sequential pairs of (CLS_t^e, CLS_{t+1}^e) . Then, it produces a change representation vector for each of these pairs, denoted by $r_t^e = F(CLS_t^e; CLS_{t+1}^e)$. Lastly, the sequence of $[r_t^e]$ logits is passed through the same neural CRF layer used by the NCET model, introduced in Section 3.2.1, to generate the final probability of actions.

4 Evaluation

We use three evaluation metrics to analyze the performance of the symbolic, sub-symbolic, and neural baselines. The first metric is sentence-level and proposed in (Dalvi et al., 2018). The second metric is a document-level evaluation proposed by (Tandon et al., 2018). Both of these metrics evaluate higher-level procedural concepts that can be inferred from the predictions of the model rather than the raw decisions. These metrics give more importance to the actions compared to the location decisions. Although they can successfully evaluate some aspects of the models, they fail to measure the research progress in addressing the challenges of the procedural reasoning task. We extend these evaluations with a new decision-level evaluation metric that considers almost all model decisions with a similar weight and evaluates the models based on the difficulty of the reasoning process.

4.1 Propara Evaluation Metrics

With the **sentence-level** metrics, the predictions are evaluated in three different categories. **(Cat1)** evaluates whether an entity e has been created (destroyed/moved) during the process. **(Cat2)** evaluates when an entity e is created (destroyed/moved). **(Cat3)** evaluates where e is created (destroyed/moved).

With the **document-level** metrics, we evaluate the Inputs, Outputs, Conversion, and Moves separately and average over the F1 score of these four criteria to output one F1 score as the final metric. Here, **Inputs** are entities that did exist before the process started and are destroyed during. **Outputs** are entities that did not exist before the process but created during it. **Conversions** evaluates which entities converted to another entity. Lastly, **Moves** evaluates which entities have been moved from one place to another.

4.2 Extended Evaluation

Both sets of existing evaluation metrics of the Propara dataset do not directly evaluate the predictions of the model but rather evaluate higher-level procedural concepts which can be inferred from the sets of decisions (i.e. an entity being input/output). Given their evaluation criteria, one model may surpass another in the number of correct decisions but still obtain a lower performance.

Therefore, we propose a new evaluation metric (**decision-level**) that directly evaluates the models' decisions. This evaluation metric is designed to consider the difficulty of the reasoning process and help better identify the core challenges of the task. We divide the set of decisions into five categories based on the presence of the entity e and the location l at each step t . We denote any mention of e by m^e , any mention of l by m_l , the action for entity e at step t by tag_t^e , and the text of the current step by S_t . The following specifies the five categories and how a decision falls under them.

Local Decision: A decision where (1) $m^e \in S_t$, (2) $m^l \in S_t$, and (3) $tag_t^e \in \{Move, Create\}$

Global Location Decision: A decision where (1) $m^e \in S_t$, (2) $m^l \notin S_t$, and (3) $tag_t^e \in \{Move, Create\}$

Global Entity Decision: A decision where (1) $m^e \notin S_t$, (2) $m^l \in S_t$ or $l = \text{" - "}$, and (3) $tag_t^e \in \{Move, Create, Destroy\}$

Global Entity and Location Decision: A decision where (1) $m^e \notin S_t$, (2) $m^l \notin S_t$, and (3)

$tag_t^e \in \{Move, Create\}$

Ambiguous Local Action: A decision where (1) $m^e \in S_t$ and (2) S_t contains multiple action verbs.

Table 3 shows the detailed statistics of the number of decisions falling under each of these five categories for the Propara dataset. Evaluating the performance of models given the new decision-level metric will clarify the lower-level challenges in the reasoning over states and locations of entities simultaneously. Getting accurate predictions in any of these categories of decisions requires the models to have different reasoning capabilities.

The local decisions mostly require a sentence-level understanding of the action and its consequences. The global location decisions require reasoning over the current step and the ability to connect the local information to the global context. The predictions for the category of the global entity mostly require reasoning over complex co-references (we have already considered simple co-references such as pronouns as mentions of the entity) or the ability to recover missing pronouns in a sentence such as "Gradually mud piles over (them)". The global entity and location decisions are the most challenging cases, which require reasoning over local and global contexts, complex co-reference resolution, and handling of missing pronouns. The ambiguous decisions mainly require local disambiguation of (entity, role, predicate) connections when multiple predicates are present in the sentence. Moreover, common sense is required for a subset of all the decision categories.

5 Experiments

Here, we summarize the performance of strong baselines compared with the symbolic (PROPOLIS) and integrated models. The implementation details of the models are available in Appendix A. Table 4 shows the performance of models in the two conventional metrics of the Propara dataset, and Table 5 shows the performance of models based on the decision-level metric. We summarize our findings in a set of question-answer pairs.

Q1. Can semantic parsing alone solve the problem reasonably? Based on Table 4, the PROPOLIS model outperforms many of the neural baselines (document-level F1-score of row#4 compared to rows #1 to #3), showing that deep semantic parsing can provide a general solution for the procedural reasoning task to some extent without the need for training data. This model performs rel-

Table 5: The results of the models on the new extended evaluation metric (decision-level) in terms of accuracy (%). ‘A’ means the action is correct, ‘L’ means the location is correct, and ‘Both’ means both the action and location are correct. ⁺ Local ambiguous cases.

atively well on action-based decisions (cat1) but fails to extract the proper location decisions (cat3). This is because many locations are inferred based on common sense rather than the verb semantic frames. Notably, the set of rules written on top of PROPOLIS is local and simple and can be further expanded to improve performance. Table 5 further indicates that the predictions of the PROPOLIS model on the actions are much closer to the SOTA models than its predictions for the entities’ location. The good performance of PROPOLIS on the action decisions for the “Global Location” category can further show that the local context can mostly indicate the action even if retrieving the result of the action (location) requires more reasoning steps. Lastly, since PROPOLIS is a model built over local semantic frames, it dramatically fails to make accurate decisions when the entity does not appear in the sentence (Global Ent).

Q2. Can the integration of semantic parsing improve the neural models? We evaluate this based on the two strong baselines, NCET and TSLM. When semantic parsers are integrated into NCET,

all three evaluation metrics improve (compare rows #7 to #10 with row #5). This improvement is even better if the source of the graph is the abstracted parse from the PROPOLIS method (row #10). Semantic parsers improve NCET’s performance in all categories of decisions, particularly in local ambiguous sentences and decisions requiring reasoning over global locations. Notably, the integration of PROPOLIS with the NCET model significantly boosts the ability to disambiguate local information in sentences with multiple action verbs.

The integration of the semantic graph slightly hurts the performance of the CGLI baseline when using conventional metrics (1%). However, it outperforms this baseline on “cat3” (0.78%), which is the only evaluation that directly considers location predictions. Notably, the original CGLI model (baseline) uses the pre-trained classifiers from SQUAD (Rajpurkar et al., 2016) to predict the start/end tokens from the paragraph as the locations (answer to the question). However, since the integrated method extracts candidates from the graph in the form of spans, it cannot reuse the

same pre-trained classifier parameters. This may contribute to the drop in performance since CGLI performs 2% lower on the document-level F1 score when SQUAD pre-training is removed (Ma et al., 2022). Despite the drop in performance based on the conventional metrics, the integrated QA-model (CGLI + TRIPS) outperforms the baseline in almost all the criteria in the new evaluation (Table 5), especially on decisions that only require local reasoning or local disambiguation. This is due to the global nature of the TSLM (or CGLI) backbone, which predicts the locations based on the whole story and ignores many of the local signals, whereas the graph can help directly extract the local relations.

Q3. How can the decision-level metrics help understand models' weaknesses and strengths?

Based on the results in Table 5, the NCET model is better at reasoning over the local context than the global context. It also clarifies that although the TSLM (or CGLI) model can properly reason over multiple steps, it is not as competitive as the NCET model in the local cases. However, the integration of semantic parsers could improve the models to close the gap on both local and global aspects and has a complimentary influence on the initial performance of the baselines. As a general conclusion based on our new evaluation metrics, we can argue that the most challenging decisions are the ones that require reasoning over missing mentions of entities in the local context. Addressing this challenge may require external reasoning over common-sense, performing the complex coreference resolution, or handling missing pronouns.

6 Discussion

Here, we discuss some of the potential concerns that may arise with the usage of symbolic systems such as TRIPS and the new evaluation criteria.

Coverage and rule crafting of PROPOLIS. Our implementation of the symbolic method and the integrated models rely on the knowledge extracted from very fine-grained semantics covered in TRIPS. Consequently, a small mapping effort was needed to create such a system. The mapping between actions in Propara and verbs is straightforward since verbs are automatically mapped onto ontological classes that provide the type of actions based on the parse. Hence, defining the mapping rules for the most general relevant ontology types of verbs is sufficient because all the descendent types will fol-

low the same mapping (See Table 1). More details are available in Appendix B). Additionally, the effort needed for the pre-processing and designing of the mapping rules is similar to the hyperparameter tuning of neural models. Since mapping is based on common sense rather than trial-and-errors in hyperparameter tuning, finding an optimal solution may even take less effort.

Out-Of-Vocabulary words in parses. TRIPS automatically maps words to ontology classes using WordNet (Miller, 1995). This gives us considerable vocabulary coverage and reduces OOV risk. TRIPS can identify the role of the unseen words (not available in WordNet) based on the sentence syntax and will not produce errors when encountering unseen words. In the same way, PROPOLIS and integrated models will not be affected.

Effectiveness of the new evaluation metric. The previously proposed high-level evaluations are strict and do not accurately reflect the quality and quantity of the lower-level model decisions. Thus they do not adequately reveal the models' abilities. For example, when compared at high-level metrics, two models may have the same performance value of 20%, while their decision accuracy may be 60% and 10%. This issue is reflected during training epochs too when the models' performance remains the same despite the decisions on the train set continuing to improve. Therefore, it seems more appropriate to evaluate the models based on the same objective criteria used for training them (decision-level). However, the previously used metrics can be secondary evaluations to measure how well the model captures higher-level procedural concepts.

7 Conclusion

We investigated whether semantic parsers could help with reasoning over procedural text. We proposed PROPOLIS, a symbolic model operating on deep semantic parsers to solve the procedural reasoning task. For this task, the symbolic model outperformed many recent neural architectures. We then evaluated the effects of integrating semantic parsers with two well-known SOTA neural backbones. All integrated models outperformed baseline architectures, particularly when the parser provided more detailed information and rich semantic frames. Furthermore, we proposed new evaluation metrics that show the pros and cons of the models and help identify the key challenges in reasoning over procedural text.

Limitations

There are multiple limitations to methods that rely on semantic parsers for solving natural language tasks. First, semantic parsers and especially the ones that do not rely on noisy training data, are most susceptible to errors when the original sentence contains even small grammatical or spelling errors. Next, parsers such as TRIPS rely on general-purpose ontology and a pipeline for generating the output parses. The pipeline first understands the meaning of each word in the sentence. This is subject to errors when words/verbs can have multiple meanings and require the context to disambiguate their semantics. For instance, the TRIPS parser may map the verb ‘run’ to the ‘management’ class in ontology instead of the ‘physical activity’ class. Lastly, executing graph attention networks with many layers requires a powerful system with access to GPU and is more time-consuming than the baselines that do not require reasoning over a graph structure.

A Implementation Details

We use the PyTorch geometric ⁵ library to implement all the graph attention models and Hugging-

⁵<https://pytorch-geometric.readthedocs.io/>

face library (Wolf et al., 2020) for implementing the language models. For the NCET model and its extensions based on semantic parsers, the best model is selected by a search over the $\lambda \in \{0.3, 0.4\}$, the learning rate in $\{3e - 5, 3.5e - 5, 5e - 5\}$. The number of graph attention layers are set to 2 and the batch size is set to 8 process. All models are using Bert-base as the selected language model for encoding the context. We further use RAdam (Liu et al., 2019) to optimize the model parameters of both the language models, the LSTM, and the classifiers. For the CGLI method, we use the exact hyper-parameters as specified in (Ma et al., 2022). We further use 15 layers of graph attention network with the input from the fifth layer of the time-aware language models. The gradients from the graph attention network (GAT) would not back-propagate to the original language model and only affect the parameters in the GAT model. The implementation code of our models and the re-implemented models will be available in the camera-ready version. The implementation code for all our models will be available on GitHub after acceptance.

B PROPOLIS

Here, we share more details on the steps in producing symbolic decisions over the actions and the locations of objects in the Propara dataset, based on the TRIPS parser. You can also find the ontology of TRIPS parser online⁶.

B.1 Graph Abstraction

From the logical forms produced by the TRIPS parser we need to extract the events and event relationships of interest. Because much of the variation expected in sentence constructions is handled by the TRIPS system, we are able to use a relatively compact specification for defining the events and relationships of interest, while coping with fairly complex and nested formulations.

We capitalized on the TRIPS ontology and parser to develop a compact and easy-to-maintain specification of event extraction rules. Instead of having to write one rule to match each keyword/phrase that could signify an event, many of these words/phrases have already been systematically mapped to a few types in the TRIPS ontology. For instance, demolish, raze, eradicate, and annihilate are all mapped to the TRIPS ontology type

“ONT::DESTROY”. In addition, the semantic roles are consistent across different ontology types. The parser handles various surface structures, and the logical form contains normalized semantic roles. For example, in the following sentence:

- The bulldozer demolished the building
- The building was demolished
- The demolition of the building
- Building demolition

, all the parses result in the same basic logical form with the semantic roles “AFFECTED: the building” and, where applicable, “AGENT: the bulldozer”. Thus, we needed very few extraction rule specifications for each event type, covering a wide range of words and syntactic patterns.

B.2 Rule-based Local Decisions

(New: The sets of heuristics used to detect the effect of each semantic frame on the arguments were shown in Table 1). To handle the location arguments from the parses, we also consider the two cases on ‘from_loc’ and ‘to_loc’. In the specific case of a destroy event, any location attached to the semantic frame is considered the ‘from_loc’ for the item being destroyed.

B.3 Global Reasoning

To perform the global reasoning over the local predictions, we first do a forward pass through the actions and location predictions and make sure that they are globally consistent. To do so, we start from the first predicted action and check the following on every next step prediction:

- If the current action is None, then we skip this step!
- If the last observed action is “Create” or “Move”,
 - If the current action in “Create” and the location of this action is the same as the last observed location, then the new “Create” action is transformed to “None”.
 - IF the current action is “Create” and the location of this action is different from the last observed location, then the new action is changed to “Move”.

⁶<https://www.cs.rochester.edu/research/trips/lexicon/browse-ont-lex-ajax.html>

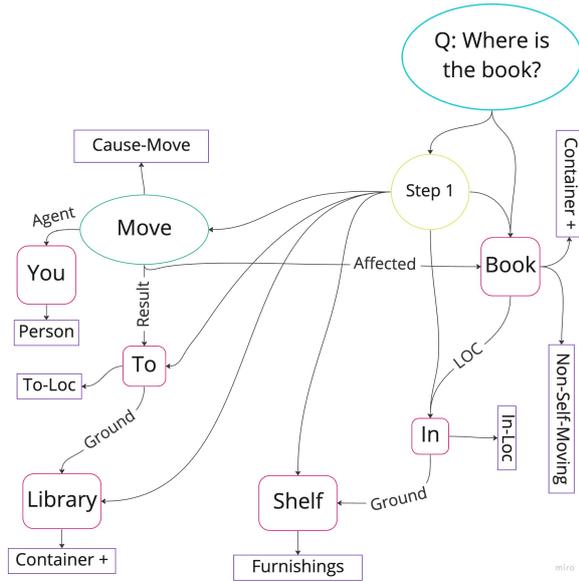

Figure 4: The QA graph for the query of “where is the book” and the sentence “Move the book on the shelf to the library”.

- Otherwise, the new action is kept the same, and the last observed action is updated.
- If the last observed action is “Destroy”,
 - If the current action is “Destroy” and it has a location different from the last observed location, then the action is changed to “Move”.
 - If the current action is “Destroy” and it has a location similar to the last observed location, then the action is changed to “None”.
 - Otherwise, the new action is kept the same, and the last observed action is updated.

After fixing the sequence of actions, we first check whether the entity gets created at any of the steps or is just moved or destroyed during the process. If the entity is not created, its initial location is equal to the first ‘from_loc’ in any subsequent actions. we then use the following criteria to fix the locations in a forward pass over the local decisions:

- If the action is “Move” but there is no final location, the final location is the first ‘from_loc’ from any of the subsequent actions before the next “Move” event.
- If the object is being “Moved”, then its final location should be changed. If the action does

not indicate a new location or the information is missing, we replace the final location with ‘?’ to indicate an unknown location.

- If the action is “None”, the last location is kept unchanged for the new step.

C Graph Attention Network

TransformerConv uses the following formula to update the representation of the nodes (v_i) in the graph.

$$\mathbf{v}_i^{l+1} = \mathbf{W}_1 \mathbf{v}_i^l + \sum_{j \in \mathcal{N}(i)} \alpha_{i,j} \left(\mathbf{W}_2 \mathbf{v}_j^l + \mathbf{W}_6 \mathbf{e}_{ij} \right),$$

where $\mathcal{N}(i)$ represents the neighbors of node i in the graph, l is the layer, and the coefficient $\alpha_{i,j}$ is computed using the following formula:

$$\alpha_{i,j} = \text{softmax} \left(\frac{(\mathbf{W}_3 \mathbf{v}_i^l)^\top (\mathbf{W}_4 \mathbf{v}_j^l + \mathbf{W}_6 \mathbf{e}_{ij})}{\sqrt{d}} \right)$$

D Semantic Parsers

Named Entity Recognition in a Very Homogeneous Domain

Oshin Agarwal

University of Pennsylvania
oagarwal@seas.upenn.edu

Ani Nenkova

Adobe Research
nenkova@adobe.com

Abstract

Machine Learning models have lower accuracy when tested on out-of-domain data. Developing models that perform well on several domains or can be quickly adapted to a new domain is an important research area. Domain, however, is a vague term, that can refer to any aspect of data such as language, genre, source and structure. We consider a very homogeneous source of data, specifically sentences from news articles from the same newspaper in English, and collect a dataset of such “in-domain” sentences annotated with named entities. We find that even in such a homogeneous domain, the performance of named entity recognition models varies significantly across news topics. Selection of diverse data, as we demonstrate, is crucial even in a seemingly homogeneous domain.

1 Introduction

Supervised neural models for named entity recognition achieve high accuracy when used in-domain. When models are evaluated or adapted (Daumé III, 2007; Wang et al., 2020; Gururangan et al., 2020) for out-of-domain text, or even developed for specialized domains (Nguyen et al., 2020; Beltagy et al., 2019), the term domain generally refers to broad genres such as news, social media, or biomedical text. However, text can be (dis)similar in aspects beyond genre, such as the source of the data, its structure, or the time period. Dai et al. (2019) distinguish two aspects of domain—the genre and the tenor, which they describe as the participants in the discourse, their relationships and their purpose. They find that even though people consider genre to be more important for domain adaptation, tenor is important as well when selecting pre-training data.

The term domain encompasses more than just broadly defined genres. Online comments on different platforms can be considered different domains. So can news from different newspapers or different time periods. We show that even text from the

same genre and source needs to be examined finely for topical or structural differences. We collect a dataset of news articles from the New York Times and annotate it for named entities. We find that the performance of NER models varies significantly even in this dataset when it is stratified based on news topics. While entities unseen in the training data can be a factor that contributes to performance degradation, we find that structural differences in sentences and entity ambiguity are the main contributors. Selecting diverse data is therefore crucial even in such “in-domain” settings. We show that even a very small number of sentences from each topic can help narrow the performance gap, and selecting random sentences rather than full documents from the full corpus, will ensure that there is a good sample of diverse sentences.

2 Dataset

The dataset is available at <https://github.com/oagarwal/nyt-ner>. Here we describe the process of collecting it.

2.1 Data Collection

We sample sentences from the New York Times (NYT) Annotated Corpus (Sandhaus, 2008). The corpus consists of 1.8M articles from NYT between 1987 and 2007 along with article metadata provided by the New York Times Newsroom, the New York Times Indexing Service and the online production staff at nytimes.com. We select sentences from different years and news topics¹, both available as metadata. Variations in topic names are merged together resulting in a total of nine topics—Arts (+Weekend/Cultural), Business (+Financial), Classifieds (+Obituary), Editorial, Foreign, Metropolitan, Sports and Others. Others consists of all desks that did not have many articles such as Real Estate, New Jersey Weekly, Book Review, Job Market, Science and Health & Fitness.

¹desk in NYT newsroom that produced the article

2.2 Data Annotation

The selected sentences are labeled with person (*PER*), location (*LOC*) and organization (*ORG*) tags on Upwork², with CoNLL’03 (Tjong Kim Sang and De Meulder, 2003) guidelines and annotation scheme. For efficiency, we first annotate the sentences with entities from the article metadata. The metadata consists of relevant persons, locations and organizations selected from a fixed vocabulary, manually assigned as part of NYT indexing. This first pass of annotation is done using phrase matching, similar to a gazetteer lookup. The resulting annotations are expected to be better than looking up in a general gazetteer since the available entities are assigned manually per article.

We use one annotator per example, but the annotators are first trained for the task. Each annotator is given 10-20 sentences to correct the entity labels from the first pass. The corrected sentences are reviewed by one of the authors and the feedback is shared with the annotator. Another 10-20 sentences are then shared with the annotator. These sentences are a mix of previously annotated but problematic sentences and new sentences, focusing on the types of mistakes made by the particular annotator in the earlier batch. If the annotator makes several mistakes in this round overall, or even one mistake on a sentence re-selected from the previous round, they are not asked to do further annotations. The annotators are encouraged to ask clarifying questions during the training rounds as well as the actual annotations. If they are uncertain about the correct label for any example, they are asked to indicate this in their comments. Finally, one of the authors goes over a random selection of examples to ensure quality and also over the ones marked as uncertain to correct if necessary.

2.3 Data Splits

We split sentences in each news topic into training, development and test splits in the ratio 35:15:50. The proportions are different from the typical 80:10:10 splits but ensure that there are a sufficient number of test examples in each topic for stable and reliable results. The number of sentences and entities in each topic are shown in Table 1.

3 Results

We finetune BERT-large-cased (Devlin et al., 2019) on each topic, evaluating on all others. Hyperpa-

Table 1: Dataset Statistics

parameter details are listed in the appendix. We report micro-F1 at the span-level averaged over three runs with different seeds. The full evaluation table is shown in the appendix for reference. Here we discuss the aggregated results. Since domain is used to refer to the genre of text (news in this case), we use the term sub-domain to refer to the news topics. However, we still use in-subdomain (InD) and out-of-subdomain (OOD) to refer to in-subdomain and out-of-subdomain training and evaluation in the following sections.

3.1 Evaluation Sub-domain Difficulty

First, we report the performance on each test sub-domain, when a model is trained on sentences from the same sub-domain and when trained on sentences from a different sub-domain. The goal is to determine if it is easier to recognize entities in some sub-domains. The results are shown in Table 2. InD refers to the models trained on the same sub-domain as the test, and OOD refers to models trained on each of the remaining sub-domains. The OOD mean and median are aggregated over the eight models trained on each of the remaining sub-domains. As expected, in-subdomain training results in incredibly high F1 on all sub-domains. The F1 with OOD training is lower than that for in-subdomain, especially when testing on classified and sports. For OOD, we also report the minimum and maximum F1 on each test sub-domains, along with the corresponding training sub-domain, showing that the range of F1 also varies considerably. The lowest test F1 on most sub-domains occurs with the model trained on classified, and the highest occurs with training on national or metropolitan. For a better understanding of the variation in the performance on a given test sub-domain with different OOD sub-domains, we also show box plots (Figure 1) for the test sub-domains of classifieds

o	92.0	89.2	92.3	75.3	c	94.1	e

Table 3: F1 of each training sub-domain, one per row, across different test sub-domains. Each row represents a training sub-domain. InD is the F1 for in-subdomain testing. OOD mean and median are over the remaining eight test domains. Min and max show the F1 and test sub-domain with minimum and maximum F1 for the given training sub-domain.

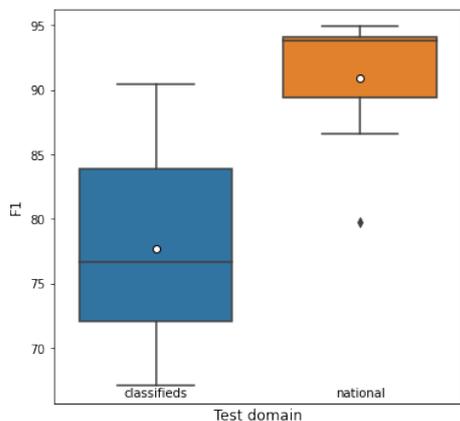

Figure 1: Box plot for two test sub-domains (classifieds and national) showing the range of F1 with training on OOD sub-domains

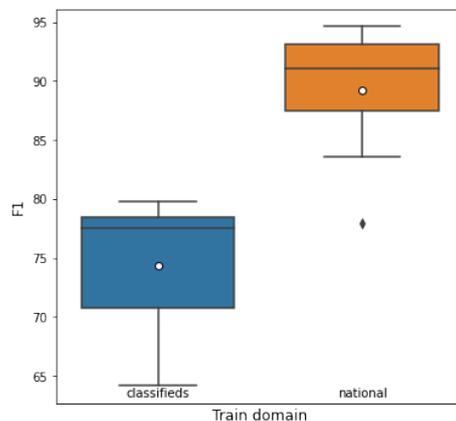

Figure 2: Box plot for two training sub-domains (classified and national), showing the range of F1 when tested on these as OOD sub-domains.

and national. Depending upon the sample of sub-domains in the test set, the model performance can vary significantly even in such a homogeneous domain, leading to an incorrect characterization of the domain/dataset difficulty.

3.2 Training Sub-domain Quality

Next, we report the performance of models trained on each sub-domain when tested on the same sub-domain and on other sub-domains. The goal is to determine if it is better (or worse) to train on certain sub-domains for good performance overall. The results are shown in Table 3. InD refers to testing a model on the same sub-domain as the training data, and OOD refers to testing it on the remaining eight sub-domains. The OOD mean and median

are aggregated over the eight OOD sub-domains. As expected, in-subdomain testing results in incredibly high F1 on all sub-domains. The F1 with OOD testing is lower than that for in-subdomain, especially for models trained on classified and sports. For OOD, we also report the minimum and maximum F1 obtained by each model along with the corresponding test sub-domain, showing that the range of F1 also varies significantly. The lowest F1 for most models occurs when tested on classified or sports, and the highest F1 occurs when tested on national or editorial. For a better understanding of the variation in the performance of a model trained on sub-domains when tested on other sub-domains, we also show box plots (Figure 1) for the training sub-domains of classified and national. Depending

Domain	Sentence
Classifieds	WEISER–Joel, passed away on March 31st, 2007.
Sports	Pollin clashed with Jordan at a bargaining session during the long labor standoff in November 1998.

Table 4: Example of sentences by sub-domain

upon the sample of sub-domains in the training set, the model performance can vary significantly even in such a homogeneous domain, leading to a much better or worse resulting model.

Classified and Sports stand out, exhibiting lower performance than other sub-domains for both training and testing. Examples sentences for both are shown in Table 4. Classified has several sentences that have atypical sentence structures, beginning with the last name in uppercase. For Sports, the entity type cannot be determined from the sentence-level context in several cases. In the example, it is hard to say whether the entities are names of person, location or team (organization). If this ambiguity of these entities isn’t captured in the training data, labeling them correctly is unlikely.

4 Data Selection

Datasets are typically collected by selecting some documents and then annotating all sentences in each document. The training set in CoNLL’03 (Tjong Kim Sang and De Meulder, 2003) has 15k sentences from 946 documents, Wikigold (Bala-suriya et al., 2009) has 1.7k sentences from 145 pages, and MUC-7 (Chinchor, 1998) has 3.5k sentence from 100 articles.³ This method of data selection is reasonable and intuitive. It also supports the development of models that utilize document-level context (Ratinov and Roth, 2009) which can help resolve the entity types in sentences such as the above example from sports. However, most commonly used models are built at the sentence level and the selection of full documents could result in performance similar to a model trained on the same sub-domain, with all sentences in a document representing the same sub-domain and fewer chances to cover rare sub-domains (types of documents). To illustrate this, we train models for NER using CoNLL ’03. We randomly select 3,000 training sentences as this is roughly the number of sentences in each of the sub-domains. We train three

³MUC-7 consists of sentences from the New York Times. However, we were unable to map the documents in MUC-7 to the NYT Annotated Corpus. Regardless, MUC-7 consists only of articles on aircraft accidents and launch events, and would likely not span enough sub-domains for our analysis.

models with different seeds and report the average F1 in the third column of Table 5. CoNLL consists of news on mainly business, national, foreign and sports. Therefore, F1 on these sub-domains is closer to that with in-subdomain training, and F1 on the remaining sub-domains is close to that with out-of-subdomain training.

It is therefore essential to ensure a diverse set of sentences in the training data. Even a small number of sentences of each sub-domain in the training data can make a vast difference. Columns ‘C’ and ‘N’ in Table 5 show the F1 on various test sub-domains with a model trained on just classified or just national news. In columns ‘C+10’ and ‘N+10’, we add just 10 sentences from each of the remaining eight sub-domains. For classified, this affects each of the test sub-domains with an improvement of up to 12 points F1. On national, this mainly improves F1 on classified by 10 points and that on sports by 2 points. These two sub-domains, as shown above, exhibit different properties than the rest of the data and therefore including even a few relevant examples helps the models substantially.

One way to select relatively diverse sentences is by data selection at the sentence level instead of the document level. First, segment each document in a corpus into sentences and then select sentences randomly. While new future domains or those that evolve significantly will still be missed, this method would result in the selection of some representative samples of each existing domain. Such explicit sentence selection has been performed for domains such as Twitter where explicit documents⁴ do not exist. Derczynski et al. (2016) selects tweets from different countries and different types of user accounts for linguistic variations and topics. They also account for temporal variation taking tweets from different years, months, weeks and days.

We build models with this random sentence selection scheme. We first downsample the data such that it follows the same distribution of sub-domains as the NYT corpus with 20 years of articles. This results in 10,500 training and 4,494 development sentences with 14% arts, 11% business, 3% classi-

⁴A thread could be considered a document.

	InD	OOD	CoNLL	C	C+10	N	N+10	Rndm
arts	92.1	86.9	85.8	78.4	82.4	88.7	88.4	90.6
business	95.7	88.2	91.4	72.0	83.8	91.9	92.2	93.9
classified	94.7	77.7	64.8	94.7	94.6	83.6	90.2	93.9
editorial	96.4	88.7	89.2	67.0	83.7	94.6	94.4	93.7
foreign	96.9	87.5	90.4	64.2	82.6	93.9	94.0	93.2
metropolitan	95.0	89.2	89.0	78.4	83.5	92.8	92.8	91.8
national	96.2	90.9	90.0	79.8	86.2	96.2	96.3	93.0
sports	94.8	81.0	89.7	78.3	80.1	77.9	79.7	91.7
others	92.0	87.4	86.3	76.7	82.2	90.3	90.1	90.2
Avg	94.9	86.4	86.3	76.6	84.4	90.0	90.9	92.4

Table 5: F1 on each test sub-domain with different models. InD is in-domain training and OOD is the average of out-of-domain training. CoNLL refers to training on CoNLL '03. C and N are trained on classified and national only. C+10 and N+10 additionally include 10 sentences from each sub-domain. Rndm is random selection of sentences from a corpus with sentences in the same proportion of sub-domains as the full NYT corpus. Highest F1 in each row (excluding InD) is boldfaced.

fied, 5% editorial, 7% foreign, 11% metropolitan, 8% national, 11% sports and 30% others. We then select 3,000 training and 1,284 development sentences randomly from this set. This is roughly the average number of sentences in each of the sub-domains and seeks to eliminate the impact of the training data size. Every sub-domain has at least 39 sentences in the selected training set. With models trained on this dataset, the average F1 is almost the same as in-subdomain training (col Rndm).

5 Conclusion

Perform fine-grained inspection of data even when it seems that the domain is homogeneous, and perform training data selection at the sentence level rather than the document level.

6 Limitations

We develop a new corpus for a standard NER task, drawn from a reputable news source, New York times. Our analysis is based on the sub-domains available in the metadata of the news article. To extend it to other datasets, automatic predictors of domain are necessary. Furthermore, for a random sentence selection that includes all representative samples, a corpus spanning the entire space of sentences is needed. This is straightforward for newspapers or Wikipedia, but infeasible for domains such as Reddit or Twitter. In such cases, domain knowledge is used to select diverse sentences (Derczynski et al., 2016), again pointing to the need for automatic domain prediction. We performed domain classification experiments on our dataset via unsupervised clustering as well as zero-shot classi-

fication⁵ (Yin et al., 2019), using both the known domains from the metadata and dummy domains as candidates. The accuracy of the best classifier on our data was only 30%, insufficient for better performance than a random sentence selection.

A Hyperparameters and Infrastructure

Hyperparameters are optimized via grid search over the learning rate (3e-05, 5e-06, 5e-06), batch size (2, 4, 8, 16, 32) and number of epochs (1, 2, 3, 4, 5) on each sub-domain. Models were fine-tuned using the implementation in HuggingFace (Wolf et al., 2019) on 2 V100 GPUs. The training time for models varies by the sub-domain and hyperparameters, and is typically 10-20 min. The best checkpoint on the development set is selected.

Abstract

Language models are trained on large volumes of text, and as a result their parameters might contain a significant body of factual knowledge. Any downstream task performed by these models implicitly builds on these facts, and thus it is highly desirable to have means for representing this body of knowledge in an interpretable way. However, there is currently no mechanism for such a representation. Here, we propose to address this goal by extracting a knowledge-graph of facts from a given language model. We describe a procedure for “crawling” the internal knowledge-base of a language model. Specifically, given a seed entity, we expand a knowledge-graph around it. The crawling procedure is decomposed into sub-tasks, realized through specially designed prompts that control for both precision (i.e., that no wrong facts are generated) and recall (i.e., the number of facts generated). We evaluate our approach on graphs crawled starting from dozens of seed entities, and show it yields high precision graphs (82-92%), while emitting a reasonable number of facts per entity.

1 Introduction

Modern language models (LMs) (Raffel et al., 2020; Brown et al., 2020) are trained on vast amounts of text that captures much of human knowledge, including scientific articles, Wikipedia, books, and other sources of information (Gao et al., 2020). Consequently, such models encode world knowledge in their parameters, allowing them to generate rich and coherent outputs.

Past work has illustrated LMs can be viewed as knowledge-bases (Petroni et al., 2019) as well as analyzed the encoded knowledge (e.g., see AlKhamissi et al., 2022) and leveraged it for applications such as closed-book QA (Roberts et al., 2020; Brown et al., 2020) and search (Tay et al., 2022), illustrating LMs can be viewed as

knowledge-bases (Petroni et al., 2019). But what are the facts stored in the internal knowledge bases of modern LMs, and how can these be represented explicitly? This is the challenge we address in this work. Our motivation is to obtain an interpretable and transparent representation that will allow humans to inspect what the LM knows, what it does not know, why it makes certain mistakes, and what are the biases it encodes. Moreover, with such a representation, one can leverage general-purpose tools, such as query languages, for interacting with this knowledge.

The first question in this endeavour is what is a suitable explicit knowledge representation. A natural candidate structure is a knowledge graph (KG). Namely, a graph whose nodes are entities and whose edges represent relations between entities. KGs are appealing since information can be readily “read-off” from the graph, they can be reliably queried, and different KGs can be easily compared. KGs have been extensively used to represent knowledge (Bollacker et al., 2008; Vrandečić and Krötzsch, 2014), but a key limitation is their *low coverage*, as they usually require manual curation and depend on a closed schema. Conversely, LMs might have very high coverage as they are trained on a vast body of knowledge represented as raw text. We thus ask if it is possible to convert an LM to a KG, such that we enjoy its advantages while achieving high coverage.

As the full KG encoded in an LM can be large, we reduce the problem to the task of constructing a KG around a given seed entity. For example, Fig. 1 shows a KG extracted by our method for the seed entity *Alan Turing*. This can be viewed as a crawling procedure which starts from the seed entity and recursively expands it to expose additional facts. This crawling problem introduces several new challenges. First, unlike prior work (Petroni et al., 2019; Alivanistos et al., 2022; Hao et al., 2022), we are given only *an entity*, without know-

* Now at Google Research.

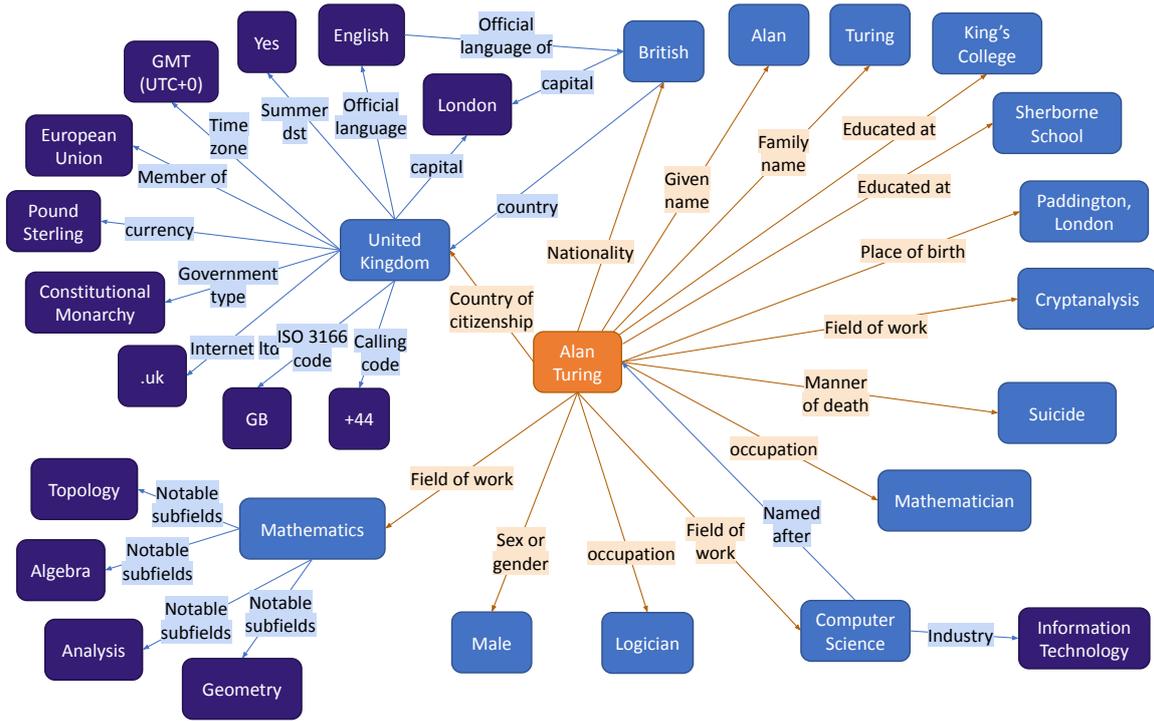

Figure 1: An example of a generated depth-2 knowledge graph around the seed entity ALAN TURING, applying LMCRAWL (see Sec. 3-Sec. 4). Additional graphs are in Sec. E.

ing what relations are associated with it. Thus, we have to extract those relations and then find the objects for each relation. Second, KGs are expected to exhibit very high precision, and thus it is necessary to generate as many relevant facts as possible while maintaining almost perfect factual correctness.¹

We address the above challenges by decomposing crawling into multiple sub-tasks, and handle each task using few-shot in-context learning (Brown et al., 2020). Explicitly, we do not fine-tune a model, but instead manually design a prompt and a few examples for each task, an approach recently-proven successful (Wei et al., 2022; Drozdov et al., 2022; Chowdhery et al., 2022; Khot et al., 2022). We use the following sub-tasks (see Tab. 1 for the full list and examples). First, given an entity e (e.g., ALAN TURING), we generate the relations relevant for e (e.g., EDUCATED AT, PLACE OF BIRTH). Second, for each entity e and relation r , we generate the corresponding set of objects O and add to the KG triplets (e, r, o) for each $o \in O$. For example, for ALAN TURING and EDUCATED AT, we gener-

¹We note that there is a deeper philosophical aspect to this issue, which is at the core of the field of epistemology. Namely, what does it mean for a model to “believe” a fact, as opposed to the model “knowing” a fact. Here we adopt a “dispositional” view of belief, whereby a belief corresponds to a statement by the model, and knowledge is a belief that is true in the world.

ate triplets with the *objects* KING’S COLLEGE and SHERBORNE SCHOOL. To maintain high precision, we prompt the model to emit “Don’t know” whenever it is not confident about the target objects. All the above outputs are generated through in-context learning, where we use the WIKIDATA KG (Vrandečić and Krötzsch, 2014) to construct in-context examples. *Don’t know* examples are constructed by finding true facts in WIKIDATA that are unknown to the LM. Finally, we increase recall by prompting the LM to generate paraphrases for entities and relations, and use those to obtain additional triplets.

We test our approach with GPT-3 (text-davinci-002) on 140 seed entities, and show that we can extract accurate KGs (~82-92% precision) that contain a plausible number of facts per entity. Importantly, large LMs are not constrained to a predefined schema, and indeed our procedure with GPT-3 generates facts outside the schema of WIKIDATA, e.g., (BOSTON CELTICS, CHAMPIONSHIPS, 17).

To conclude, our contributions are: 1) Formulating the problem of crawling a KG from an LM, 2) Presenting a prompt-based approach that decomposes the problem into multiple sub-tasks, and 3) Evaluating the approach with GPT-3, which leads to high-precision graphs.

2 Problem Setup

Our goal is to uncover the knowledge-base of a given LM. We represent a knowledge-base via a KG, which is a collection of triplets. Formally, a KG is a graph $G = (N, R, E)$, where N is a set of entities, R is a set of relations, and E is a set of subject-relation-object triplets (s, r, o) where $s, o \in N$ and $r \in R$.

To simplify the setup, we assume we are given a “seed entity” around which we will expand the graph (for example Fig. 1). Conceptually, we can also let the LM generate seed entities, but we argue seed expansion is a more realistic scenario, where a user is interested in a graph about a certain entity.

Entities and relations are represented via strings and are not constrained to a given vocabulary (similar to open information extraction. e.g., see [Vo and Bagheri, 2017](#)).

3 Crawling KGs via Prompting

The core component of our approach is a procedure that takes an entity e , and extracts all relations associated with it, and the corresponding objects. Namely, we expand the KG around this entity. We can then recursively apply this procedure to further expand the KG. We refer to this as ‘entity expansion’, and break it into two high-level steps:

- **Relation generation** (Sec. 3.1): For an entity e , generate a set of relations R , where e is the subject.
- **Object generation** (Sec. 3.3-Sec. 3.4): Given the entity e and the relation set R , find the corresponding objects. Namely, for each $r \in R$, find a list of entities O such that (e, r, o) is in the KG for $o \in O$. We consider lists since many relations (e.g., CHILDREN) potentially have multiple correct objects. Furthermore, we also consider the case where the object corresponding to (e, r) is unknown to the model (e.g., the model does not know who is the daughter of a given entity e). In this case we take O to be empty, and the edge is not added to the KG. This is crucial for maintaining a high-precision KG.

Both steps are achieved via few-shot in-context learning. Namely, we construct prompts with in-context examples (stay fixed throughout the process) that exhibit the desired behaviour (Tab. 1).

To improve recall, we employ an additional paraphrasing procedure (Sec. 3.2 and Sec. 3.5), which generates alternative strings for a given entity or re-

lation. For example, the entity WILLIAM CLINTON can be referred to as WILLIAM JEFFERSON CLINTON or BILL CLINTON, and the relation OCCUPATION may be expressed as PROFESSION. Thus, we run object and relation generation for all these variants, and pool the results to construct the final graph. Paraphrases are also obtained through the LM, without use of external knowledge. The entire flow is illustrated in Fig. 2, and we next elaborate on each of the components.

3.1 Relation Generation

Our task is to generate a set of relations R for a given subject entity e . To achieve this, we leverage WIKIDATA to construct in-context examples. Specifically, we pick a list of WIKIDATA entities e_1, \dots, e_{K_r} and for each entity e_i , extract its set of WIKIDATA relations. This results in K_r in-context examples for relation generation. We concatenate the target entity to the in-context examples, feed this prompt to the LM and use its output as the set R for e . Tab. 1 shows an example prompt. We note that this generation process can produce relations that are not included in the prompt, and are not part of WIKIDATA at all.² Full prompt with in-context examples is presented in Sec. B.1.

3.2 Relation Paraphrasing

A relation r may be described in multiple ways, and the LM might work better with some of these paraphrases ([Jiang et al., 2021](#)). Thus, we use a procedure to obtain a set of paraphrases of r , denoted by $P(r)$, and run all downstream crawling tasks for all strings in $P(r)$.

For relation paraphrasing we find that in-context examples are not necessary and an instruction prompt is sufficient. Tab. 1 shows a specific example under the sub-task “Relation Paraphrasing”. See Sec. A.1 for the three prompts and more technical details.

3.3 Object Generation

Our next goal is, for each $r \in R$, to generate a set of objects O such that (e, r, o) is in the KG for all $o \in O$. Importantly, we should also let the LM declare it does not know the object, and thus O would be empty. In this case, no edge will be added to the output KG.

²For example, when the subject is a sports team, the model repeatedly generated a relation regarding its MASCOT or LARGEST WIN, which are facts outside of WIKIDATA.

Sub-task	Query	Prompt	Expected Output
Relation Generation	Philippines	Q: René Magritte A: ethnic group, place of birth, place of death, sex or gender, spouse, country of citizenship, member of political party, native language, place of burial, cause of death, residence, family name, given name, manner of death, educated at, field of work, work location, represented by Q: Stryn A: significant event, head of government, country, capital, separated from Q: Philippines A:	leader name # cctld # capital # calling code
Pure Object Generation	Barack Obama # child	Q: Monte Cremasco # country A: Italy Q: Johnny Depp # children A: Jack Depp # Lily-Rose Depp Q: Wolfgang Sauseng # employer A: University of Music and Performing Arts Vienna Q: Barack Obama # child A:	Sasha Obama # Malia Obama
DK Object Generation	Queen Elizabeth II # date of death	Q: Heinrich Peters # occupation A: Don't know Q: Monte Cremasco # country A: Italy Q: Ferydoon Zandi # place of birth A: Don't know Q: Hans Ertl # sport A: mountaineering Q: Queen Elizabeth II # date of death A:	Don't know
Subject Paraphrasing	Alan Turing	Alan Turing is also known as:	The father of computing
Relation Paraphrasing	notable work	'notable work' may be described as	a work of 'great value' or a work of 'importance'

Table 1: The full list of sub-tasks in our approach, where for each sub-task we provide its name, a query, a corresponding prompt, and the expected output. In ‘DK Object Generation’ the prompt declares in one of the in-context examples that the model does not know the place of birth of Ferydoon Zandi, since querying for it leads to a wrong answer (the query with the wrong answer isn’t shown).

We first explain prompt construction without the use of “*Don’t Know*” output, and refer to this as “Pure Object Generation”. We take K_o entities e_1, \dots, e_{K_o} from WIKIDATA. For each entity e_i , we choose one of its relations r_i , and all the objects O_i for this entity-relation pair in WIKIDATA. This creates K_o examples for object generation. Similar to relation generation, the target entity-relation pair is concatenated to the K_o examples, and the list of objects is parsed from the generated LM output (see exact format in Tab. 1, under the sub-task “Pure Object Generation”, and the full prompt with in-context examples in Sec. B.2). Recall that for each relation, we have multiple paraphrases. To maintain high precision, we only accept objects that were generated by at least two realizations of the relation.

3.4 Learning to Output “*Don’t Know*”

A key desideratum for KGs is high precision, namely the facts in the graph should be correct with high probability. Towards this end, we want to prompt the LM to output “*Don’t Know*” (DK) for facts where it is likely to make an error.³

³A model might make an error because it is not confident about the answer, or because its training data contains false facts. In this work, we are agnostic to this distinction and our

But how do we know what the model does not know? To capture this, we find cases where the LM outputs erroneous facts, and use these to construct in-context examples with a DK target. For example, suppose we run ‘Pure Object Generation’ with $e = \text{BILL CLINTON}$ and $r = \text{CHILDREN}$ and the model outputs $O = \text{KLAY THOMPSON}$. We deduce that the model does not know who Clinton’s children are, and therefore, can add the example $e_i = \text{BILL CLINTON}, r_i = \text{CHILDREN}, o_i = \text{Don’t know}$ to the prompt. In other words, we find examples where o_i is *Don’t know* through cases where the model errs on its predicted objects. We then construct a prompt with a total of K_{dk} examples, half of which are failure cases where with $o_i = \text{Don’t know}$ and the other half are correct predictions. We refer to this as “DK Object Generation”. See the corresponding row in Tab. 1 and the full prompt with in-context examples in Sec. B.3.

3.5 Subject Paraphrasing

Similar to relations, an entity e may have several names, and it may be easier for the LM to complete the triplet $(e, r, ?)$ with one of these. Thus, we take a paraphrasing approach to extend an entity name e into a set $P(e)$. The procedure is identical prompt’s goal is to encourage generation of correct outputs.

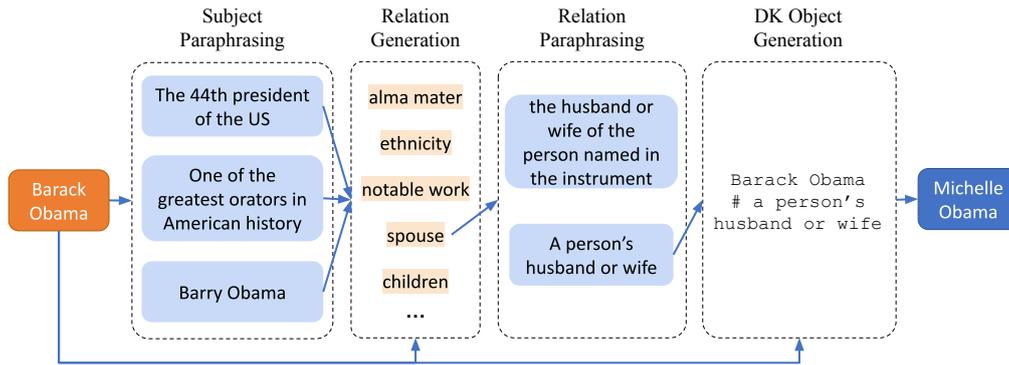

Figure 2: An illustration of the full method for crawling a subgraph (LMCRAWL), starting from BARACK OBAMA as the subject, until obtaining the triplet (BARACK OBAMA, SPOUSE, MICHELLE OBAMA).

to relation paraphrasing (Sec. 3.2), except we use a single prompt instructing the LM to complete the sentence “*s* is also known as”, where *s* is the subject. To increase the number of paraphrases, we sample from the model three times, resulting in up to three paraphrases.

Both here and in Relation Paraphrasing (Sec. 3.2), the LM occasionally generates nonsensical paraphrases. Nevertheless, the DK method handles those cases well, outputting “Don’t know” for most of them. Thus, we argue that paraphrasing combined with DK emission is an effective approach for controlling recall and precision.

3.6 LMCRAWL

Fig. 2 shows the application of the complete pipeline (which we refer to as LMCRAWL) for the entity BARACK OBAMA. First, we obtain all paraphrases for *e* (Sec. 3.5). Then, we extract all relations for these (Sec. 3.1). Next, we paraphrase relations (Sec. 3.2). Finally, we extract the known objects for these relations (Sec. 3.3-Sec. 3.4).

4 Experimental Setup

As mentioned in Sec. 3, we use WIKIDATA (publicly available) in constructing the in-context prompts. The number of in-context examples is $K_r = 7$, $K_o = 8$, $K_{dk} = 10$.

Additionally, we use WIKIDATA to select seed entities for evaluating our approach. For these seeds, we consider the task of constructing KGs around the corresponding entities.

We split the seed entities into a validation set (20 entities), which is used to make design choices (e.g., choosing prompt format), and a test set (120 entities), which is used only for the final evaluation.

For the development set, we manually chose 20 entities from WIKIDATA. These included women and men with various professions, cities, countries, and various cultural entities such as movies and books. We also aimed to represent both head and tail entities in this list.

To construct our test set, we defined 25 specific world-entities related categories, which we refer to as the *test categories*. Some of these were more specific, such as *AI Researchers*, and some are more general, such as *Scientists* (see Table.6 for the full list). We chose 4 seeds out of each category as follows. We first sorted the set of entities of each group based on the number of WIKIDATA facts associated with them (we view this count as an approximate measure of popularity). Then, we randomly sampled two entities out of the full list, and an additional two out of the first 1000. Intuitively, the first two represent tail entities, while the other two represents head ones. Thus we ended up with 100 seed entities (i.e., 4 different entities out of each of the 25 different subgroups). We refer to these as the *main test set* (see Tab. 6). We created an additional test set of 20 entities that is meant to contain very popular entities. Its entities were randomly sampled out of a set of size 1000, which was manually constructed by choosing 40 very well-known entities (i.e., that all people would know) from each of the 25 test categories.

All 140 entities were not used in the construction of any of the prompts in Sec. 3. Tab. 2 shows the full list of validation and head test entities.

Evaluation metrics Given an entity *s*, our entity expansion process returns a knowledge graph *G*, that contains the entity *s*, other entities and relations between them.

Dev Seeds	Head Test Seeds
ABBA	Aristotle
Alan Turing	Canada
Angela Merkel	Celine Dion
Augustin-Louis Cauchy	China
Barack Obama	Emanuel Macron
Bob Dylan	Franz Kafka
Boston Celtics	Grease
David Bowie	Hamlet
Diana, Princess of Wales	Jacinda Ardern
Eike von Repgow	Lionel Messi
Inglourious Basterds	Little Women
Marble Arch	Manchester United F.C.
Marie Curie	Margaret Hamilton
Mikhail Bulgakov	Michelangelo
Moby-Dick	Mike Tyson
Pablo Picasso	Oprah Winfrey
Paris	Rosalind Franklin
Philippines	Steven Spielberg
Rachel Carson	Serena Williams
Shahar Pe'er	The Rolling Stones

Table 2: List of all validation and head test seeds.

Ideally, we want to compare G to a ground truth graph that results from expanding the entity s . Given such a graph, we could measure precision and recall over the gold and predicted sets of triplets. However, using large LMs to generate graphs leads to several challenges. First, there is no ground-truth graph. While we could presumably use the WIKIDATA graph, we found that it is missing many correct facts predicted by the LM. In fact, improving coverage is a key motivation for our work! Second, facts may be reworded in several equivalent ways, rendering comparison between WIKIDATA graphs and predicted graphs difficult.

To circumvent these challenges, we use the following notions of precision and recall.

- **Precision:** To estimate precision we conducted both manual and automatic evaluations (the automatic approach was more scalable). For the manual evaluation we simply tried to validate each of the generated facts by manually browsing highly trustful web sources (Google, Wikipedia, etc.) to check if the fact is true. The automatic evaluation approach was implemented as follows. In order to check the correctness of a given predicted triplet (e, r, o) , we issue a query containing (e, r) to Google search, and search whether o appears in the result. We limit the result to first 40 words which are not HTML labels or URL links. If it does, we assume the triplet is correct.

⁴ See Sec. 5.3 for an accuracy estimation of the

⁴This paragraph typically contains either an “answer box” or some summary of the first result page, in case there is no answer box.

automatic method.

Manual evaluation was done for all the *head test set* graphs, as well as all the 1-hop graphs of the *main test set*. Additionally, we performed manual evaluation for 20% randomly sampled triplets from the 2-hop graphs (altogether, the total portion of manually labeled facts from each graph was $\sim 30\%$). The rest of the triplets were automatically evaluated.

- **Recall:** Estimating recall is not possible since we do not have access to the true ground truth graph. Moreover, using WIKIDATA graph size as an estimate for the number of true facts will be misleading since it has low coverage in general, and *high variance* in terms of coverage for different entities. Thus, we simply report the number of verified triplets in our KG. In other words, we report recall without the denominator. We refer to this as **# of facts**. This practice is similar to open information extraction (Vo and Bagheri, 2017), where it is impossible to know the set of all true facts and thus the convention is to report the number of generated facts only.

Implementation details As the LM in our experiments, we used the OpenAI text-davinci-002 model. We experiment with both greedy decoding and sampling 3 outputs per query (temperature 0.8). We generate graphs with either a single expansion step or two expansion steps, recursively expanding entities found in the first step. After a graph is generated, we remove duplicates by iterating through the facts and removing a fact if the token-wise F_1 between it and another fact is higher than 0.85.

Base Model and Ablations The simplest version of our model includes only ‘Relation Generation’ (Sec. 3.1) and ‘Pure Object Generation’ (Sec. 3.3), without the “Don’t Know” and paraphrasing components. We refer to this version as *Pure-Greedy* and *Pure-Sampling*, depending on the decoding used (see Sec. 4). In other model variants, we use *DK* to refer to using ‘DK Object Generation’ instead of ‘Pure Object Generation’. Additionally, *SP* and *RP* refer to adding ‘Subject Paraphrasing’ and ‘Relation Paraphrasing’ respectively.

5 Results

We next report results showing that our expansion method is able to generate meaningful knowledge subgraphs, when expanding seed entities.

	Main Test Set				Head Test Set			
	one-hop		two-hop		one-hop		two-hop	
	Precision	# of Facts	Precision	# of Facts	Precision	# of Facts	Precision	# of Facts
Pure-Greedy	54.6 ± 8.2	6.2 ± 2.8	43.4 ± 6.1	26.1 ± 5.5	80.3 ± 8.4	14.4 ± 3.9	62.1 ± 7.3	82.3 ± 15.4
LMCRAWL	83.3 ± 7.9	5.4 ± 1.1	82.0 ± 7.5	21.4 ± 4.7	91.5 ± 11.4	11.0 ± 4.6	90.9 ± 4.9	61.2 ± 25.1

Table 3: Averaged results across all 100 **main test** seeds (left), as well as all the 20 **head test** ones (right).

Example graph: We begin with an illustrative example for the graph of the seed entity ALAN TURING. Fig. 1 shows a subset of the two-hop extracted graph in this case. It can be seen that all facts are sensible, except for the fact that the field of Computer Science is named after Alan Turing (although he is certainly one of its fathers). See also Figs. 4 and 5 for additional example graphs.

Results on the Main Test set: Tab. 3 reports averaged results of the Pure-Greedy base model and LMCRAWL across the 100 main test seeds. We observe that precision of Pure-Greedy is too low to be useful for a KG – 54.6% for 1-hop graphs and 43.4% for 2-hop graphs. Conversely, precision with LMCRAWL is much higher: 83.3% for 1-hop graphs and 82.0% for 2-hop graphs. While we suffer a small hit in ‘# of facts’, the sizes of KGs output by our approach are quite reasonable.

Results on the Head Test set: Tab. 3 reports averaged results of the Pure-Greedy base model and LMCRAWL across the 20 head test seeds. Specifically, we achieve precision of **91.5%** while applying LMCRAWL for 1-hop graphs, and for 2-hop we have **90.9%**. It can be seen that both precision and number of facts in this case are higher than in the main test set. This suggests that either it is easier to extract facts from the LM about popular entities, or that the LM indeed encodes more facts for these (see Sec. 5.2 for further analysis).

5.1 Ablations

Next, we examine the contribution of each component in our final approach on the validation set.

The Effect of Don’t Know Generation: The goal of allowing the model to output “Don’t Know” is to improve precision. Tab. 4 and 5 show results for the model without using DK prompting (in *Pure* rows) as well as with (*DK* rows) for both sampling and greedy decoding. In both cases, the DK option leads to much higher precision, but reduces the number of generated facts. However, we later recover some of these lost facts using subject and relation paraphrasing.

Method	Precision	# of Facts
Pure-Sampling	64.9 ± 20.2	22.2 ± 9.7
Pure-Greedy	77.5 ± 17.4	12.5 ± 6.0
DK-Sampling	71.4 ± 19.9	17.7 ± 9.4
DK-Greedy	82.9 ± 16.0	10.2 ± 5.9
+RP	80.9 ± 17.0	12.7 ± 5.4
+SP	80.6 ± 17.0	12.2 ± 7.0
LMCRAWL	88.3 ± 8.2	13.0 ± 5.9

Table 4: Averaged results over the 20 **validation** seed (**one-hop**). DK: “Don’t know”. SP: Subject Paraphrasing. RP: Relation Paraphrasing.

Method	Precision	# of Facts
Pure-Sampling	40.0 ± 9.5	224.0 ± 81.1
Pure-Greedy	55.9 ± 9.7	87.8 ± 39.7
DK-Sampling	54.7 ± 8.6	144.0 ± 83.5
DK-Greedy	72.4 ± 7.5	45.8 ± 30.3
LMCRAWL	86.4 ± 6.1	69.8 ± 52.9

Table 5: Averaged results across all 20 **validation** seeds (**two-hop**). DK: “Don’t know”. SP: Subject Paraphrasing. RP: Relation Paraphrasing.

The Effect of Paraphrasing: Tab. 4 shows results without the paraphrasing component in the *DK-Greedy* row. Both paraphrasing techniques, RP and SP, separately increase coverage, while causing a minimal hit to precision. Interestingly, combining RP and SP leads to improvements in *both* precision and coverage for 1-hop *and* 2-hop graphs (Tab. 4, 5).

5.2 Coverage vs. Entity Frequency

The frequency of entities on the Web is highly skewed. That is, some entities appear many times, while others are rare. We expect this will be reflected in the number of facts extracted for these entities. Indeed, on WIKIDATA, head entities usually have many more facts compared to tail entities. Here, we ask whether a similar phenomenon exists in our predicted KGs.

Fig. 3 shows the number of facts generated for a depth-1 graph by LMCRAWL for all entities of type PERSON, as a function of the number of facts that appear in the corresponding depth-1 WIKI-

DATA graph of the same seed. Clearly, there is high correlation (correlation coefficient is 0.61) between the number of extracted facts and entity frequency on WIKIDATA. This is rather surprising and encouraging since our procedure does not make any use of entity frequency, and head and tail entities are expanded in exactly the same way.

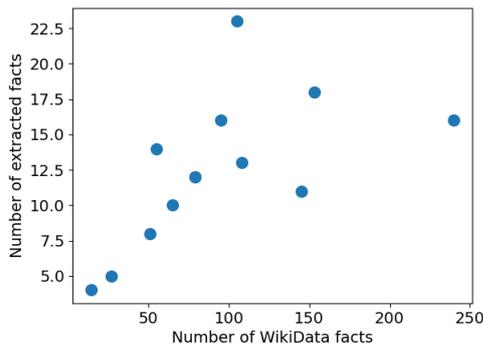

Figure 3: The # of triplets extracted by LMCRAWL as a function of the # of triplets in WIKIDATA, for the set of validation entities of type PERSON.

5.3 Precision is Possibly Underestimated

Our automatic approach for evaluating precision uses Google search (see Sec. 4). We view this as a conservative estimate of precision, since a fact judged as true via this mechanism is highly likely to be true. Conversely, a true fact might not be verified due to search or string matching issues. To quantify this, we sampled 500 generated facts from *Pure-Greedy* and LMCRAWL that were judged to be incorrect through Google search, as well as 500 that were judged to be correct. We manually inspected them and found that 4.1% of the triplets that the automatic approach has labeled as correct, are actually wrong, while 22% of the triplets that the automatic approach has labeled to be incorrect, are true (few demonstrations are presented in Sec. D). Exact estimation of precision would require *full* manual annotation, which we avoided to minimize costs.

6 Related Work

Pretrained LMs are at the heart of recent NLP research and applications. As mentioned earlier, Petroni et al. (2019) and other works have observed that LMs contain rich factual knowledge. We elaborate on other relevant works below.

Knowledge-base construction. KG construc-

tion typically involves both manual and automated aspects. For example, popular KBs such as WordNet (Fellbaum, 2020), ConceptNet (Speer et al., 2017) and WIKIDATA (Vrandečić and Krötzsch, 2014) were constructed by heavily relying on manual effort, gathering knowledge from humans. To reduce such manual labor, automated information extraction (IE) methods have been extensively developed (Yates et al., 2007; Fader et al., 2011; Angeli et al., 2015; Vo and Bagheri, 2017). Knowledge in LMs is a fairly recent topic of interest, and has mostly focused on probing for specific facts (Petroni et al., 2019; Razniewski et al., 2021).

Most similar to our work are Hao et al. (2022), who also extract KGs from LMs, However, they require defining the relations of interest through examples before crawling, while our specific goal is to start with a seed entity and allow the LM to determine the relevant relations. Another relevant recent work is Alivanistos et al. (2022) who also use in-context learning to extract a KG from GPT3. But they also assume relations are provided, whereas a key aspect of our approach is generating the relations.

To the best of our knowledge, ours is the first work to construct a knowledge graph via extracting knowledge directly from LMs, using only one seed entity (and no other given relations or entities).

Quantifying Uncertainty in LMs. Factual correctness in LMs has attracted recent interest, because it is a crucial requirement for LM applicability. In this context, some works have studied selective question answering, where LMs avoid answering particular questions (Varshney et al., 2022). Other works have considered calibration in LMs (Jiang et al., 2021; Desai and Durrett, 2020),

Finally, recent works have investigated whether models can express their certainty on output facts, either in words or by producing the probability of certainty (Lin et al., 2022; Kadavath et al., 2022). A key aspect of our approach is the use of a “Don’t know” mechanism, which is related to this line of work since it lets the LM declare its certainty as part of the output. Unlike Kadavath et al. (2022), we do so in the context of crawling a KG and via in-context learning (as opposed to fine-tuning).

7 Conclusion

Understanding large LMs is a key part of modern NLP, as they are used across the board in NLP applications. In particular, it is important to under-

stand the body of knowledge these models possess, so it can be used and revised as needed, thereby avoiding factual errors and biases. In this work we present an important step towards this goal by extracting a structured KB from an LM.

There are many possible exciting extensions for our work. The first is to expand it to a larger graph corresponding to more expansion hops. This would require many more calls to an API, which at present is also costly, and it would be important to develop more cost-effective approaches. Second, we have introduced several approaches to controlling the precision and recall of the proposed model, but certainly more can be envisioned. For example, we can introduce various consistency constraints to increase precision (e.g., check that FATHER OF and CHILD OF are consistent in the generated graph). Finally, once a larger KG has been extracted, one can query it to see how well it serves as a question answering mechanism.

Overall, we find the possibility of seamlessly converting LMs to KGs for better interaction and control to be an exciting and fruitful direction for future research.

Limitations

Producing the full internal KG out of an LM is still a significant challenge. One challenge is cost (as noted above). The other is error propagation issues. Once the model makes a generation mistake in a particular node of the generated graph, it may lead to an increasing number of mistakes during the next generation steps, expanding from that node. That is one of our main rationales for creating and evaluating only two-hop graphs, and not additional hops (although ideally, the real goal is to uncover the full internal KG).

Our automatic way of evaluating precision is only approximate, which means our reported accuracy numbers for 2-hop are an approximation of true precision (although we believe the true precision is in fact higher, as discussed in the text).

Another challenge we do not address is understanding the source of knowledge inaccuracies. Are they due to limitations of our model in extracting the knowledge, or due to the LM not containing these facts at all. This is certainly important to understand in order to improve knowledge representation in LMs. We are also aware to the fact that since the generated graphs are not perfectly accurate, they might contain disinformation and mis-

leading facts. That would hopefully be improved by future research.

Finally, the question whether we could have come up with a better-reflecting “recall” metric than the one we suggested is yet to be solved, as in general it is still unclear how to measure knowledge coverage.

A Technical Details

A.1 Relation-Paraphrasing

We use 3 different instructions that have been manually constructed. If we denote a specific relation by r , then they are:

- " r may be described as"
- " r refers to"
- "please describe ' r ' in a few words:"

That is, for every original relation which has been generated by the model, we perform additional three different model calls, one with each of those instruction prompts, resulting in three paraphrases. If needed, we eliminate overlapping paraphrases.

C Main Test Set

Table 6 provides our main test, which includes 100 different seeds - 4 from each of our predefined entity group categories.

D Automatic Precision Evaluation

As noted in the main text, the automatic precision evaluation method (i.e., the one based on Google search) may sometimes fail. Some of the failure cases are: (a) *Inexact string matching*. For example (BOSTON CELTICS, LEAGUE, NATIONAL BASKETBALL ASSOCIATION (NBA)) is not verified, but dropping (NBA) from the object would result in a successful verification. b) *Paraphrases*: For example (MARBLE ARCH, COUNTRY, UNITED KINGDOM) is not verified but changing the object to ENGLAND does succeed.

E Additional Generated Graphs

Figs. 4, 5 show additional example graphs (to the one shown in Fig. 1), generated around the seed entities ANGELA MERKEL and BOSTON CELTICS respectively.

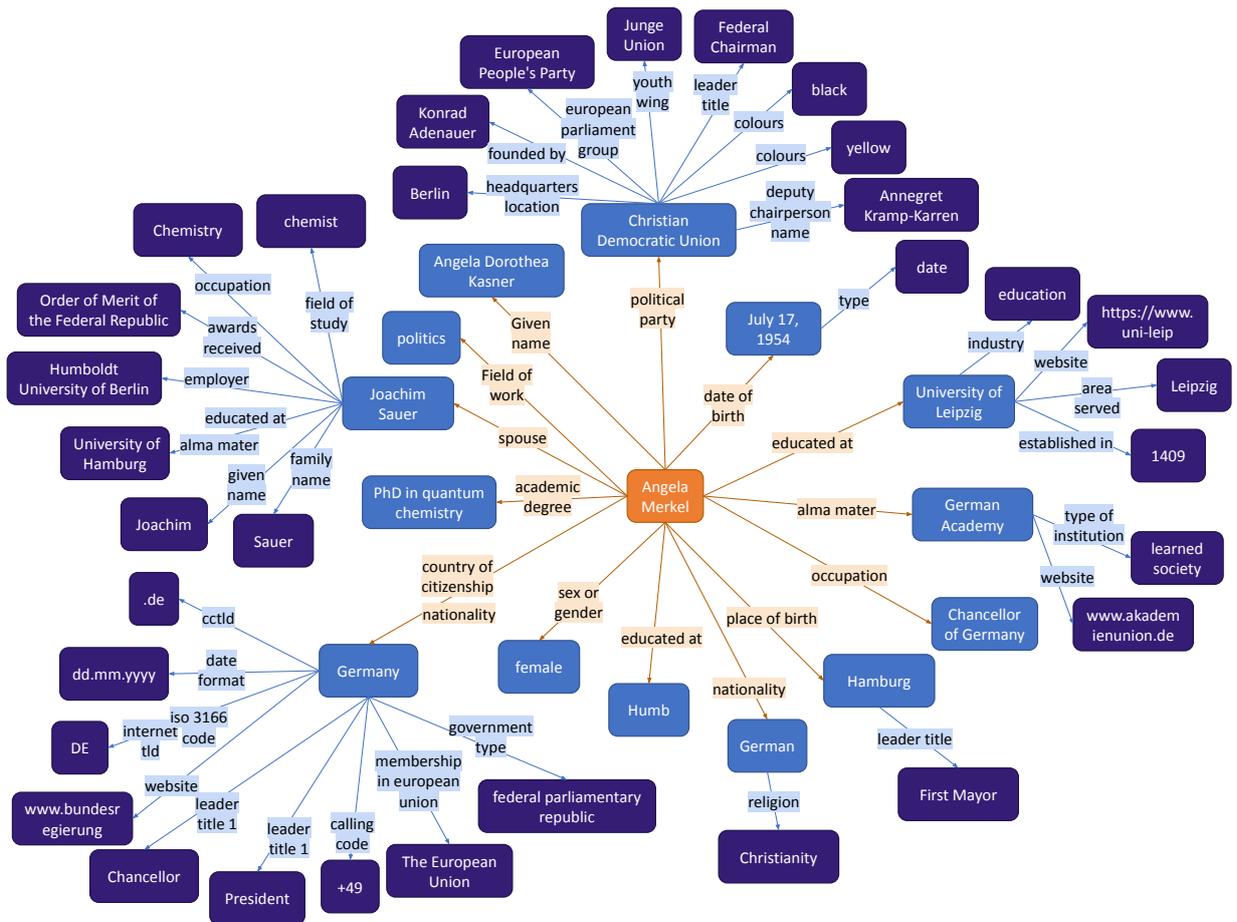

Figure 4: An example of a generated depth-2 knowledge graph around the seed entity ANGELA MERKEL, using LMCRAWL(see Sec. 3). For readability, back edges from 2-depth nodes to 1-depth nodes are omitted.

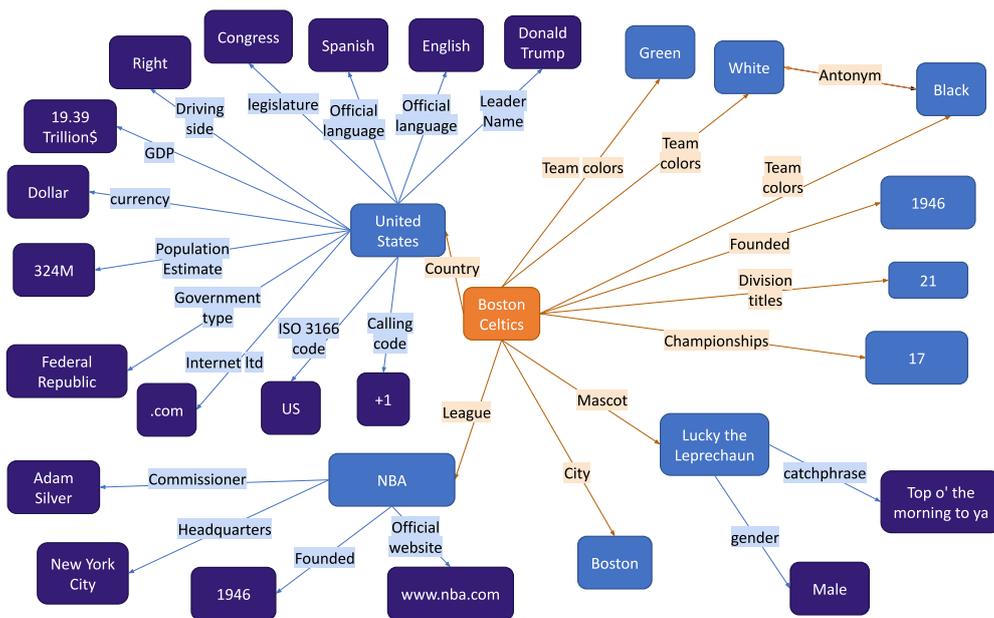

Figure 5: An example of a generated depth-2 knowledge graph around the seed entity BOSTON CELTICS, using LMCRAWL (see Sec. 3).

Abstract

Scarcity of data and technological limitations for resource-poor languages in developing countries like India poses a threat to the development of sophisticated NLU systems for healthcare. To assess the current status of various state-of-the-art language models in healthcare, this paper studies the problem by initially proposing two different Healthcare datasets, Indian Healthcare Query Intent-WebMD and 1mg (IHQID-WebMD and IHQID-1mg) and one real world Indian hospital query data in English and multiple Indic languages (Hindi, Bengali, Tamil, Telugu, Marathi and Gujarati) which are annotated with the query intents as well as entities. Our aim is to detect query intents and extract corresponding entities. We perform extensive experiments on a set of models in various realistic settings and explore two scenarios based on the access to English data only (less costly) and access to target language data (more expensive). We analyze context specific practical relevancy through empirical analysis. The results, expressed in terms of overall F1 score show that our approach is practically useful to identify intents and entities.

1 Introduction

Healthcare is a top priority for every country. People across the world ask millions of health-related queries, hoping to get a response from a domain expert (Gebbia et al., 2020). These queries mostly deal with medical history of patients, possible drug interactions, disease related concerns, treatment protocols and so on. Conversational agents for healthcare play a pivotal role by facilitating useful information dissemination (Li et al., 2020; Maniou and Veglis, 2020). In order to understand these

queries better, practical conversational systems for healthcare need to be developed. However, the primary obstacle in developing such technologies for low-resource languages is the lack of usable data (Mehta et al., 2020; Daniel et al., 2019; Liu, 2022).

India is a country with a diverse language speaking population suffering from abject poverty and low-economic status (Mohanty, 2010; Pande and Yazbeck, 2003). This linguistic diversity and complex socio-economic situation in India certainly poses significant challenges in developing automatic healthcare systems; and there is a lack of linguistic resources specific to the medical domain. For example, situations such as the patient and the doctor speaking in different languages, is not an uncommon situation in rural India. These individuals are unable to avail the existing systems and facilities which exist mainly in the English language. Recent efforts in developing automatic translation systems, even from extremely low resource languages such as ‘Mundari’ and ‘Gondi’ (Joshi et al., 2019), should ideally improve this situation, but there is no extensive study on that front.

In order to bridge this language barrier, massively Multilingual Transformer based Language Models (MMLM) (Devlin et al., 2019; Lample and Conneau, 2019) have made impressive advancements on a wide range of downstream applications. But the real-world implications of such advancements in the Indian healthcare system remain largely unexplored. In this paper, we aim to explore scarcity of the data and study the extent to which the existing language technologies can be leveraged to develop practically useful healthcare systems for the low-resource languages in developing countries.

With an aim to answer our research question,

* Authors contributed equally

Intent	Language	Query	Entities		
			disease	drug	treatment
treatment	English	can anesthesia during surgery cause memory loss or signs of senility?	memory loss, signs of senility	anesthesia	surgery
	Hindi	क्या सर्जरी के दौरान बेहोशी स्मृति हानि या बुढ़ापा के लक्षण पैदा कर सकता है?	स्मृति हानि, बुढ़ापा के लक्षण	बेहोशी	सर्जरी
	Bengali	অনস্থোপচারের সময় অ্যানেস্থেসিয়া কি স্মৃতিভ্রংশ বা বার্ধক্যের লক্ষণ প্রদর্শনের কারণ হতে পারে?	স্মৃতিভ্রংশ, বার্ধক্যের লক্ষণ	অ্যানেস্থেসিয়া	অস্থোপচার

Figure 1: Example of a query of ‘treatment’ intent category for different languages along with associated entities.

we create two different multilingual healthcare datasets, namely, IHQID-WebMD and IHQID-Img. These datasets are created by crawling frequently asked questions from two healthcare websites, *WebMD* and *Img*. These datasets comprise frequently asked questions about drugs, diseases and treatment methods in seven different languages, namely English, Hindi, Bengali, Tamil, Telugu, Gujarati and Marathi. The queries are manually tagged with intent labels and entity tags by domain-experts and translated by native speakers of the corresponding languages. We also collect real world Indian hospital queries (annotated) in seven languages to check the empirical effectiveness of our approach. Fig. 1 shows an example of a health query belonging to ‘treatment’ intent class manually translated into three different languages. Then we evaluate the performance of state-of-the-art language models (LMs), for both English and multilingual setups on our datasets, to answer the questions regarding their deployability and practicality. Various experimental configurations (Section 4) have been tried on these datasets where we try to figure out the ways of using best technologies through extensive experimentation in two real-world scenarios. First, we assume to have access to only English training queries (less costly) and the test queries are multilingual in nature. We observe that translate-test setup on RoBERTa seems to be a reasonable choice of technology. Second, we assume to have access to manually written multilingual training and test queries in the target languages, which is indeed quite expensive in terms of data collection effort. However, back-translation of both train and test queries proves to be a reasonable choice if we have budget of collecting data in target languages.

In sum, our contributions are four folds:

- We propose two intent and entity labelled Indian healthcare datasets (annotated by domain-experts) comprising of frequently asked ques-

tions from users.

- Even though the large language models have proved their effectiveness in almost every NLU operation, we want to determine their effectiveness in determining the correct intent and slot filling operations for practical domain-specific healthcare scenarios in the Indian context. We intend to analyze how should we prioritize the research and resource building investments for the economically backward countries with a high percentage of multilingual population? This will make us aware about the best techniques of deploying the language models in various scenarios such as: availability of English training data vs multilingual training data. Keeping this in mind, all our experiments have been carried out using both monolingual and multilingual setups of these models. Through our experiments, we try to point out the best possible language models and techniques to develop practically useful NLU solutions (pipeline based approach for intent detection and corresponding entity extraction from the queries).
- Through extensive experiments on the datasets, we recommend the community to use back-translation of test queries to English in two real-life scenarios as a reasonable choice when we have access to English training data. However, the same strategy can be applied to both train and test queries if we have the budget of collecting data in target languages.
- Our findings imply that the back-translation of queries using an intermediate bridge language proves to be a useful strategy in the intent recognition experiments.

2 Related Work

We pivot our study of related works into the following buckets - generalised intent and entity detection, entity and intent detection in healthcare, health care in Indian languages and multi-lingual healthcare datasets.

A) Generalised Intent and Entity Detection Approaches: (Sun et al., 2016; Wang et al., 2020; Mu et al., 2017b,a) focus on detecting novel intents in the form of outlier detection. (Mullick et al., 2022a) explore intent classification on legal data. People also work on different detection approaches - few shot (Xia et al., 2021), zero shot (Xia et al., 2018), clustering frameworks (Mullick et al., 2022b). (Yani et al., 2022; Sufi and Alsulami, 2021; Zhao et al., 2021) all explore entity detection tasks. (Vanzo et al., 2019) develop a hierarchical multi-task architecture for semantic parsing sentences for cross-domain spoken dialogue systems. Most of these approaches are very domain and language specific and thus not very useful for the healthcare domain in Indian languages.

B) Entity and Intents in Health Care: Zhou et al. (2021) solve different tasks in smart healthcare. Bao et al. (2020) build a chat-bot framework using user intents. Bai et al. (2022) aim at incremental medical intent detection. Razzaq et al. (2017); Amato et al. (2017) develop an e-Health application using intent-context relationships. Zhang et al. (2017) explore medical query intents. Most of the works are done for English and Chinese languages and there is no proper architecture for Indian multi-lingual scenarios for intent and entity extraction..

C) Health Care in Indian Languages: Some researchers focus on Indian Languages - Hindi Medical Conversation system, MedBot (Bharti et al., 2020), detecting Hindi and English COVID-19 posts (Patwa et al., 2021), Tamil health information (Santosh, 2019), Bengali health-bot (Badlani et al., 2021), Telugu COVID-19 health information (Vishwas et al., 2017). But none of the work aims at Indian health query datasets and model analysis. (Mondal et al., 2022) highlights the gaps when using existing state-of-the-art commercial frameworks for NLU tasks in a few Asian and African low-resource languages, especially when the goal is to develop conversational agents for healthcare during COVID. In our work, we strengthen the claims made in their paper for generic healthcare specific datasets in Indian context, and highlight the potential drawbacks of the existing LMs.

D) Multilingual Health Care Dataset: Liu et al. (2020) develop MedDG (Medical Dialogue dataset of common Gastrointestinal diseases) in Chinese. Zeng et al. (2020) proposes MedDialog, a Chinese and English medical dataset, and explores medical dialogue generation tasks. Zhang et al. (2021) build a medical intent evaluation dataset in Chinese and Kim et al. (2022) has constructed a Korean health intent dataset. Our work differs from the existing research in two ways: 1) We focus on developing a gold standard healthcare NLU dataset in Indian languages, 2) cost parameter and availability oriented usage of models for intent detection and entity extraction, and 3) end-to-end evaluation of the state-of-the-art solutions for healthcare in both English and Indic languages which leads to interesting implications and generates important future recommendations for the language community.

3 Dataset and Pre-Processing

3.1 Necessity of a new dataset

India is a country with a diverse language speaking population. There is an increasing population of users consuming Indian language content. This linguistic diversity certainly poses significant challenges in healthcare setup, particularly in the situation when healthcare providers and patients speak different languages (also termed as *Language Discordance*) (Shamsi et al., 2020). Therefore, individuals with limited English proficiency are left behind and suffer from worse health outcomes than those who speak English with high proficiency. The growing need for the deployment of multilingual conversational agents in hospital and healthcare facilities in India, especially highlighted by the plight of the healthcare workers during the COVID-19 pandemic, warrants a multilingual healthcare query intent dataset in Indian languages (Daniel et al., 2019). Therefore, we resort to create two novel Indian Healthcare Query Intent Datasets - (IHQID-WebMD and IHQID-1mg) and one real-world healthcare dataset from hospitals.

3.2 Source of the dataset

Due to the unavailability of open-source multilingual NLU datasets in healthcare setup, we sample frequently asked medical queries (FAQs) in English from two popular data sources:

WebMD¹: It is an American website containing a large repository of healthcare data. The queries,

¹<https://www.webmd.com/>

Class	Intents		Entities		Real World Hospital Query Data (#Intent / #Entity)						
	#WebMD	#Img	#WebMD	#Img	#En	#Hi	#Bn	#Ta	#Te	#Ma	#Gu
Disease	283 (207+76)	111 (87+24)	629 (464+165)	240 (185+55)	28/37	31/35	29/37	27/35	31/39	28/35	29/35
Drug	234 (181+53)	198 (144+54)	400 (302+98)	224 (166+58)	34/44	33/43	31/37	30/35	32/38	34/40	32/37
Treatment	166 (127+39)	67 (46+21)	218 (165+53)	64 (44+20)	21/24	20/26	21/25	23/29	19/24	17/23	20/26
Other	278 (205+73)	41 (28+13)	-	-	17/-	16/-	19/-	20/-	18/-	21/-	19/-
Total	961 (720+241)	417 (305+112)	1247 (931+316)	528 (395+133)	100/105	100/104	100/99	100/99	100/101	100/98	100/98

Table 1: Distributions of different types of intent and entity labels in WebMD, 1mg datasets (IHQID) and Real World Hospital Query Data. (- + -) represents (train + test) division. # denotes the count.

taken from the WebMD health forum are asked by ordinary users regarding a wide range of problems. **1mg**²: 1mg is an Indian website, which is also a rich source for healthcare data, especially in the Indian context. The English queries are scraped from the FAQ section in drug and disease pages.

Although, both the above datasets are curated from online forums where users post healthcare concerns, in order to evaluate our approach in a practical Indian context, we develop a real world healthcare query dataset in Indian scenario. We collect real world healthcare queries (asked by patients) from the doctors in local hospitals. All queries are anonymous without identity or any details of the patients. For each language, we fetch 100 queries (some of which overlap) belonging to different categories.

3.3 Dataset Sampling

The FAQs sampled from these data sources are unlabeled. Hence, for the purpose of supervised classification, it is necessary to categorize each query into a specific intent and list of corresponding entities. We broadly categorize queries into four different intent types, namely, ‘Disease’, ‘Drug’, ‘Treatment Plan’ and ‘Other’. Each query is assigned one of the four intent labels. Two English-speaking medical graduate doctors annotate the intents from the English queries to prepare the datasets. Annotators also mark entities, belong to three different medical entity categories present in the datasets - ‘Disease’, ‘Drug’ and ‘Treatment’. The queries with their intent labels are retained where both annotators agree, otherwise discarded. On an average, this filtering lead to an average rejection of around 10% samples of the dataset for all our setups and languages. Overall Inter-annotator agreement, Cohen κ is 0.89.

²<https://www.1mg.com/>

3.4 Parallel Data Generation

In order to generate parallel corpora of these frequently asked questions in English, we choose six Indian languages apart from English.

Language Selection: The language set includes English: USA version (EN-US) termed as (‘En’), Hindi (‘Hi’), Bengali (‘Bn’), Tamil (‘Ta’), Telugu (‘Te’), Gujarati (‘Gu’) and Marathi (‘Mr’). The choice of languages was driven by (a) the number of native speakers of those languages in India, (b) number of annotators available for creating the dataset, (c) combined with typological diversity amongst the languages - we choose languages from various language families. For instance, Bengali, Hindi, Gujarati, Marathi belong to the Indo-Aryan family whereas Tamil and Telugu belong to the Dravidian group.

Annotation and Quality Control: Since the gold standard annotated queries are not available online in Indian languages, the English queries of 1mg and WebMD have to be manually translated. **After discussions with the doctors and different patients, we create the annotation guidelines.** Annotators are told to formulate the queries on their own regional languages with the help of Bing Translator API³. Annotators are also asked to annotate the entities and their types (in their respective native languages) for each query being corrected with the idea of what common people of corresponding native language generally ask healthcare queries to doctors.

Three annotators are selected per language after several discussions and conditions of fulfilling many criteria like annotators should have native proficiency in their language of annotation, domain knowledge expertise along with a good working proficiency in English. Initial labeling is done by two annotators and any annotation discrepancy is checked and resolved by the third annotator after discussing with others. While formulating the

³<https://www.microsoft.com/en-us/translator/business/translator-api/>

query on their own manually, the annotators are also asked to annotate the entities and their types (in their respective native languages) for each query being corrected. The above quality control measures ensure that the translated data is of high quality, resembling real world data in the target language. In the case of a word such as a proper noun like ‘*Paracetamol*’ (drug), which does not have a translation in the target vocabulary, the word is asked to be simply transliterated in the target language.

In order to prepare the real world hospital query dataset in Indian healthcare contexts, we collect healthcare queries from the doctors of local hospitals. It also consists of six different Indic languages along with English. There are a hundred queries for each of the language. These queries also have similar intent classes and entity categories, which are labelled by the doctors. During collection of queries, we fix the minimum number of samples for each intent classes across all languages.

In order to maintain the quality of the Indian language annotations, the annotators are directed to use the native language words and grammar, keeping the original interpretation of the query. All query logs, annotations and changes are recorded in order to conduct future verification and analysis. On completion of the translation process, the annotators are asked to exchange their work and check the quality of translation for fluency and semantic stability. Inaccuracies are noted, and the respective queries are rectified in the dataset.

At the end, we finally have three multilingual intent and entity recognition labelled datasets - **IHQID-WebMD**, **IHQID-1mg** and a real world hospital query test dataset in seven different languages, the dataset distributions of which are provided in Table 1. The first two datasets (IHQID-WebMD and IHQID-1mg) help to build the models and real world hospital dataset is used to evaluate our approaches in real world contexts. Table 1 also shows the statistical details across different intent classes (‘Disease’, ‘Drug’, ‘Treatment’ and ‘Other’) and corresponding entities (of ‘Disease’, ‘Drug’ and ‘Treatment’ categories) along with the total counts and train-test divisions. It also shows the distribution of hospital collected practical healthcare queries across different languages (Right part of the table).

4 Strategies of Evaluation

In this section, we illustrate the strategies of evaluating the state-of-the-art LMs on our dataset. Our evaluation of these models for Healthcare is scoped down to two fundamental NLU tasks:

- a) Intent Recognition (Section 5.1)
- b) Entity Extraction (Section 5.2)

Evaluation Setup Description: Our evaluation of the models has been conducted while keeping in mind about the availability of human-translated monolingual and multilingual training data in two possible real-life scenarios: 1) **Scenario A:** In this setup, we assume to have access to only English training data (less costly) and in 2) **Scenario B:** we assume to have access to manually written training queries in all the target languages (very expensive). During inference/testing, we expect all the queries are in the corresponding target languages.

Scenario A:

Setup 1) Backtranslated Test (S1): [Translate-Test] Here we develop our system by training the models on the English queries, and evaluate the intent detection and entity extraction systems in different languages by automatically backtranslating the test queries into English (e.g. similar to (Gupta et al., 2021)). **Setup 2) Zero-Shot Cross-Lingual Test (S2):** Cross lingual transfer learning is a useful methodology used for tasks involving scarce data (Zhou et al., 2016; Karamanolakis et al., 2020). In this setup, the models make use of zero-shot based cross-lingual capabilities from training on the English data (scraped from WebMD and 1mg) and use it for inference on test queries in Indic languages. **Setup 3) Bridge Language Back-translation (S3):** Here a relatively low-resource language is first translated to an intermediate language and then finally to English. The motivation behind this setup lies in the fact that even though these Indic languages belong to different scripts, there are linguistic and morphological similarities among them which may improve the translation to English if they are used as intermediate languages. In this paper, we have considered ‘Hindi’ as the bridge language. This notion of such “bridge” languages has been explored previously in the context of Machine Translation (Paul et al., 2013) and zero/few-shot transfer in MMLMs (Lauscher et al., 2020).

Scenario B:

Setup 4) Train and Test on Indic Data (S4): In this setup, we use the training dataset in indic lan-

languages to train our NLU models in different target languages. Here, we use the IHQID-WebMD and IHQID-1mg Indic data (non-English) to evaluate the NLU detection performances of the developed models. Jennifer Bot (Li et al., 2020) use a similar setup to extend their English bot to Spanish. **Setup 5) Full Backtranslation (S5):** In this setup, both train and test data are backtranslated to English. This is useful for the countries with poor technical setups for low-resource languages, since an automated approach can translate low-resource medical queries to resource-rich language and test.

In all back translation experiments, we use Bing Translation Api ⁴.

5 Experiments and Results

Experimental Setup: Our experiments are conducted on two Tesla P100 GPUs with 16 GB RAM, 6 Gbps clock cycle and GDDR5 memory. All methods of entity extraction and intent detection took less than 30 GPU minutes for training. We perform a hyperparameter search and report the results of the settings which achieve the best results, and then fixed the same for all the models. The batch size is kept at 16, number of epochs is 10, optimization algorithm used is AdamW and the learning rate is 1e-5 with cross-entropy as the loss function.

5.1 Intent Detection

Task Description: It can be defined as a multi-class classification task of correctly assigning a medical query with an intent label from a fixed set of intents (*drug, disease, treatment and other*).

Classification Models: Since in Setups 1, 3 and 5, we take both the training and test set in English, we use state-of-the-art LMs pre-trained on English corpora (as shown in (i)) for our classification experiments. Whereas in Setup 2 and 4, we make use of multilingual LMs (as shown in (ii)) which have been widely used for various benchmark tasks in Indian languages. Following are the baselines:

(i) **Pre-trained English Models:** For setups 1, 3 and 5, we fine-tune the last layer of RoBERTa (Liu et al., 2019) and Bio_ClinicalBERT (Alsentzer et al., 2019) models on the English queries for intent detection by adding a classification layer that takes [CLS] token as input. The latter is a state-of-the-art domain-specific transformer based

language model pre-trained on MIMIC III notes⁵, which is a collection of electronic health records and discharge notes.

(ii) **Pre-trained Multilingual Models:** Two pre-trained multilingual LMs are used, mBERT (*bert-base-multilingual-uncased*) (Pires et al., 2019) and XLM-Roberta (*xlm-roberta-base*) (Conneau et al., 2020), both support all Indic languages in the datasets along with English. In Setup 2, we perform zero-shot classification using these models. The zero shot setting involves fine-tuning the model using English data, and testing on Indic languages. Whereas in Setup 4, we first train these models using the entire train sets in the target languages, separately for WebMD and 1mg, and check the performance on the test sets.

5.2 Entity Recognition

Task Description: This task is analogous to performing a Named Entity Recognition (NER) for three categories, namely, *drugs, diseases and treatments* on the query texts. We follow the standard BIO-tagging system while annotating the entities word-by-word. The train and test files for each configuration and language respectively are constructed from our WebMD and 1mg datasets.

Extraction Frameworks: For entity recognition, we follow the same strategies of evaluating the predictive performance of the LMs as described in Section 4. The same models (as described in section 5.1) are also used for entity recognition experiments.

5.3 Evaluation

For all our experiments on intent detection and entity recognition, we calculate the Precision, Recall and report the F1-score.

5.4 Results and Analysis

Intent Detection: Table 2 shows the results of intent detection of five experimental strategies on the IHQID-WebMD and IHQID-1mg datasets in terms of Macro F1-score (in percentage).

Finding 1: We observe that in general, Backtranslated Test (Setup 1) performs better than Zero-Shot Cross-Lingual Test (Setup 2). Moreover, it is interesting to notice that even though the performance of these models for most of the target languages in Setup 1 are comparable with that of English in

Table 2: Macro-F1 scores for intent classification on the WebMD (WMD) and 1mg datasets for five Setups (three different setups for Train on English (Scenario A) and two setups of Train on Indic Data (Scenario B)). bcBert indicates BioClinicalBERT, mBERT indicates Multilingual BERT. Underline denotes the best across five settings.

WebMD (an average of 3% drop for all the languages compared to English), there is a significant drop (average of 6%) in the F1 scores for the Setup 1 results in 1mg Dataset. This holds true for both RoBERTa and BcBERT experiments. This denotes that the state-of-the-art English models, which are performing decently after backtranslation of the medical queries in English, pre-trained on both generic and medical domain, are lagging behind when the vocabularies of the medical entities are in the Indian context. This definitely calls for an immediate attention to developing LMs pre-trained on India-specific medical datasets.

Finding 2: Another interesting observation was that the use of Bridge Language Backtranslation (Setup 3) in Table 2, helps to boost performance of most of the languages in the case of 1mg dataset in comparison to Setup 1. The observation does not hold true for intent recognition in WebMD dataset. This might be attributed to the fact that using a bridge Indian language as an intermediate helps preserve the domain-specific sense of the queries instead of directly converting the queries from the target language to English. This seems like a reasonable alternative to develop useful intent recognition models for healthcare in Indian languages.

Finding 3: In comparison with zero-shot cross-lingual transfer (Setup 2), both mBERT and XLM-

R models are outperformed by few-shot experiments (Setup 4) for intent detection. This observation holds true for both WebMD and 1mg datasets. However, Setup 4 is much more cost-intensive than the Setup 2.

Finding 4: We report the average (Avg) F1-score across all languages. The best performing model is RoBERTa (Setup 1 for English and Setup 5 for non-English) for both WebMD (74.94%) and 1mg (70.33%). RoBERTa is used for further evaluations.

Entity Extraction: Table 3 displays the results of entity recognition task under five different strategies on IHQID-WebMD and IHQID-1mg datasets.

Finding 1: In the Backtranslation test performed in Setup 1, we observe that for WebMD dataset, the difference in the performance of the models (Performance on English is 0.33% more average F1 Score for RoBERTa and 3.58% more than average F1 for bcBERT) is far less significant than the drop observed for 1 mg (Performance on English is 9.66% more average F1 Score for RoBERTa and 10.49% more than average for bcBERT). This implies that loss of information is quite high for the entities in Indian context during backtranslation.

Finding 2: Unlike our findings on Setup 3 in intent recognition, we observe that backtranslation using a bridge language seems to induce more loss of

Table 3: Macro-F1 scores for entity extraction on the WebMD (WMD) and 1mg datasets for five Setups (three different setups for Train on English (Scenario A) and two setups of Train on Indic Data (Scenario B)). bcBert indicates BioClinicalBERT, mBERT indicates Multilingual BERT. Underline denotes the best across five settings.

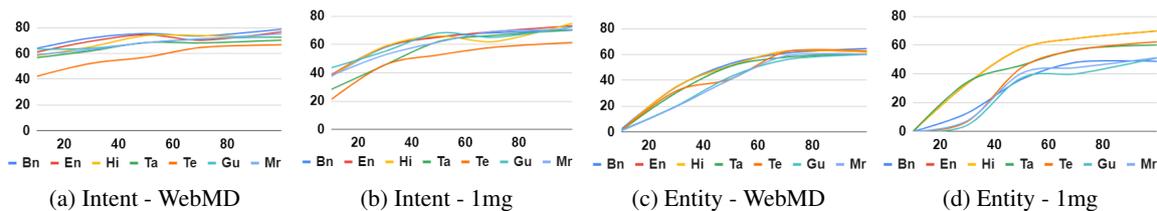

Figure 2: Intent Detection and Entity Extraction F1-score (Y-axis) for Different Percentage of Training Data (X-axis) for WebMD and 1mg

information on the entities compared to Setup 1. This observations holds true for both the models across two datasets.

Finding 3: Similar to intent recognition, we observe that completely backtranslating both training and test data to English performs the best among S1, S3 and S5. This holds true for both the datasets and both the models. However, this operation is indeed expensive in terms of data curation cost, since it requires original data in the target languages for both training and testing.

Finding 4: The abysmal performances of the multilingual models as shown in Table 3, for both S2 and S4 indicate that these approaches are not so useful in our case.

Finding 5: We report the average (Avg) F1-score across all languages. BioClinicalBERT performs the best (Setup 1 for English and Setup 5 for non-English (Avg)) for both WebMD (63.14%) and 1mg (68.69%). It is used for further evaluations.

5.5 Ablation Study

Experiments with Varying Training Size: We experiment with varying training sizes on both intent detection and entity extraction tasks using the best performing models, by taking 10%, 30%, 50%, 70% and 100% of the training set. We then show the F1-scores (Y-axis) for all the languages with different training sizes (X-axis) in Fig. 2. Fig. 2a and 2b show that the performance of the intent detection models do not vary too much with increasing training sample data. However, Fig. 2c and 2d clearly show that entity extraction F1-scores increase significantly with the increase of training data. Thus, we can conclude that the intent detection model does not require a large amount of data to generalise, as opposed to the requirements of the entity extraction model.

Category wise intent detection and entity extraction for the best model: We evaluate the F1-scores for different intent classes for the RoBERTa Model

(Setup 1 for English and Setup 5 for non-English) trained on WebMD and 1mg (See Section 4 for setup descriptions). Similarly, with the help of Bio-ClinicalBERT (Setup 1 for English and Setup 5 for Non-English), we find the individual entity class wise F1-scores. The results in Table 4 show that the model is able to detect ‘disease’, ‘drug’ and ‘treatment’ intent classes with high F1-score but the performance on the ‘Other’ class is poor, thus bringing the macro averaged F1 score down considerably. This may be due to the fact that the system fails to detect open ended query types, present in the ‘Other’ class. This is supported by the intent class wise entity distribution, which shows an overwhelming dominance of ‘drug’, ‘disease’ and ‘treatment’ entities in their corresponding intent categories (‘drug’, ‘disease’ and ‘treatment plan’ intents, respectively), whereas the ‘other’ intent class, of which there are very few instances comparatively anyway, has no such dominant entity class associated with it. In the entity extraction task, the best performing model is able to extract all three entity categories with a similar F1-score performance.

Figure 3: Macro Average F1 Score for Intent detection and Entity Extraction across all different languages in Real World Hospital Data

Real World Hospital Data Evaluation: We use the real world healthcare query dataset (100 queries per language) to test the usability of our models in practical Indian hospital scenarios. We run the best performing models trained on WebMD and 1mg

Lang	Intent								Entity

Table 4: Macro-F1 scores for intent identification and entity extraction on the WebMD (WMD) and 1mg datasets. For each language, we portray the results of the best model obtained for the corresponding dataset.

data for intent detection (RoBERTa in Setup 1 for English and Setup 5 for Non-English) and entity extraction (BioCLinicalBERT in Setup 1 for English and Setup 5 for non-English) and report the average of two models (trained on IHQID-WebMD and IHQID-1mg) for each language. Fig. 3 shows the average F1-score for each language, which is consistent with the earlier results shown in Table 2 and 3. This shows that the best performing proposed setup performs satisfactorily on real world data in Indic languages.

5.6 Demonstration

To be able to make the proposed methods accessible and usable by the community, we create an on-line interface, which could be found in our GitHub repository⁶. With the help of this website, one can post health query in the allowed language and obtain the predictions using our best models.

6 Discussion and Error Analysis

We categorize the issues in mis-classification and identify two broad themes of the reasons. The primary reason is model prediction error. Figure 4 shows the model prediction errors for various intents in different languages. For an example, ‘How common is syphilis’ is of ‘disease’ intent category but model wrongly predicts it as ‘other’ category. Another reason is the misclassification due to incorrect translation of the medical entities such as the disease ‘*uticartia*’ has been transformed into ‘*ambat*’ during backtranslation as shown in Figure 5 which is not detected as an entity. So, the backtranslation error leads to intent mis-classification and entity extraction error. We speculate such random absurd behaviour due to the context of the query and languages are semantically different. Secondly, there are also certain issues in fluency and grammatical meaning after backtranslation. For instance,

⁶<https://github.com/indichealth/indic-health-demo>

ENGLISH QUERY	INDIC QUERY	GOLD INTENT	PREDICTED INTENT
How common is syphilis?	সিফিলিস কতটা সাধারণ? (bengali)	disease	other
Do all women experience discomfort after menopause?	সব মহিলাই কি মেনোপজের পরে অস্বস্তি অনুভব করেন? (bengali)	other	disease
How long can I take Ganaton Tablet?	నేను గానాటన్ మోతాదు ఎంతకాలం తీసుకోవచ్చు? (telugu)	drug	other
What home remedies can help with cough?	దగ్గుకు ఏ ఇంటి నివారణలు సహాయపడతాయి? (telugu)	treatment	other

Figure 4: Error in Prediction

English Query	Indic Query	Back Translated Query	Error	Intent Gold Label	Intent Predicted	Entity Detected
Is <i>urticaria</i> an autoimmune condition?	আমবাত একটি অটোইমিউন অবস্থা?	Is <i>ambat</i> an autoimmune condition?	Disease Translation	Disease	Other	
Is <i>Domstal 10</i> Tablet an over the counter drug?	டொস্টাল 10 టాబ్లెట్ డి.ఎం.ఎల్.ఐ.టి.ఎం. యాన్ టేబ్లెట్ డ్రగ్?	Is <i>Domstal 10</i> Tablet an opposite drug?	Grammatical Error	Drug	Other	Domstal 10

Figure 5: Error in Back-Translation

‘over the counter drug’ gets changed to ‘over the opposite drug’. Entity recognition errors are also occurring along with the intent mis-classification.

7 Conclusion

We focus on developing novel Indian HealthCare Query Datasets and propose frameworks to detect intents and extract entities from queries in different Indian languages. Through extensive experiments on our proposed datasets, we recommend the community to use backtranslation of test queries to English in two real-life scenarios as a reasonable choice when we have access to English training data. However, the same strategy can be applied to both train and test queries if we have the budget of collecting data in target languages. Backtranslation of queries using an intermediate bridge language also proves to be a useful strategy in some cases.

Acknowledgements

The project was supported in part by the grant given by I-Hub Foundation for Cobotics, IIT Delhi for the project, "Voice based Natural Interaction for Goal Oriented Tasks in Healthcare".

Limitations

Our dataset needs to be scaled up in terms of size and intent labels which we aim to do as a part of future work. Another constraint is that we do not consider cases where queries are multi-labelled (e.g. - drug and disease both). We shall explore in future.

Ethical Concerns

We propose to release the dataset which neither reveals any personal sensitive information of the patients nor any toxic statement. Besides, we have paid enough token money (exact remuneration will be revealed once accepted to the conference) to the domain-expert annotators who have helped us in manually tagging the medical queries.

Abstract

Anticipating future actions in a video is useful for many autonomous and assistive technologies. Most prior action anticipation work treat this as a vision modality problem, where the models learn the task information primarily from the video features in the action anticipation datasets. However, knowledge about action sequences can also be obtained from external textual data. In this work, we show how knowledge in pretrained language models can be adapted and distilled into vision-based action anticipation models. We show that a simple distillation technique can achieve effective knowledge transfer and provide consistent gains on a strong vision model (Anticipative Vision Transformer) for two action anticipation datasets (3.5% relative gain on EGTEA-GAZE+ and 7.2% relative gain on EPIC-KITCHEN 55), giving a new state-of-the-art result¹.

1 Introduction

Anticipating future actions in the video of an unfolding scenario is an important capability for many applications in augmented reality (Salamin et al., 2006; Azuma, 2004), robotics (Duarte et al., 2018; Schydlo et al., 2018), and autonomous driving (Chaabane et al., 2020; Suzuki et al., 2018). Anticipating what actions will likely happen in a scenario, requires one to both recognize what has happened so far, and use anticipative general knowledge about how action sequences tend to play out. Most models for this task use a pre-trained video encoder to extract information about what has happened so far in the scenario, and use a text-based decoder to predict what action is likely to happen in the future (Carion et al., 2020; Dessalene et al., 2021; Liu et al., 2020; Sener et al., 2020).

However, when trained on the target video datasets, the generalization of the models depends

¹The models and code used are available at: <https://github.com/StonyBrookNLP/action-anticipation-lmtovideo>

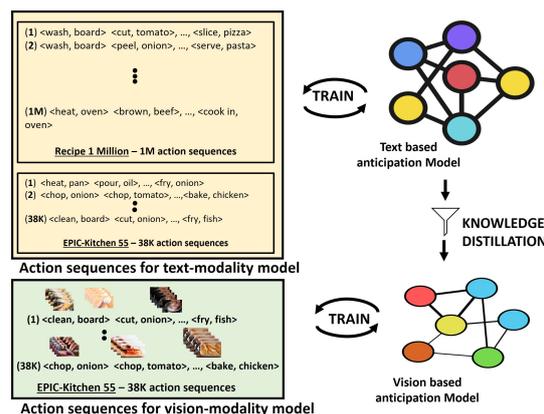

Figure 1: A model learning the action anticipation from only the vision modality (video frames) is essentially exposed to a very limited set of action sequences. Language models, which are pre-trained on large-scale text, can learn this distribution from the task, and a much larger domain-relevant text. We propose distilling this knowledge from text modality models to vision modality model for video action anticipation task.

on how well these video datasets cover the space of action sequence distributions. In other words, the knowledge that is learnt for predicting future actions is, in effect, limited to the information in the target video datasets, where obtaining large scale coverage of action sequences is difficult.

Knowledge about action sequences can also be obtained from text resources at scale. Language models, (e.g. BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b)), are typically pre-trained on large collections of unlabeled texts with billions of tokens, where they acquire a wide-variety of knowledge including large scale knowledge about common action sequences. For example, Table 1 illustrates how the pre-trained BERT is able to predict the next action in a sequence of actions extracted from a recipe video in terms of its verb and the object. Also, it is easier to collect a much larger collection of action sequences from text sources compared to video annotated with

Masked action sequence	BERT@top5
Clean the board → takeout pan → wash the onion → clean the fish → cut the onion → heat the pan → pour oil in pan → [MASK] the fish.	fry, cook, boil, wash, clean
Clean the board → takeout pan → wash the onion → clean the fish → cut the onion → heat the pan → pour oil in pan → fry [MASK].	pan, fish, chicken, it, onion

Table 1: Given a sequence of actions extracted from a video, **BERT@top5** shows the top5 prediction made by a standard pre-trained BERT for the masked verb and object of the next action.

segments. As illustrated in Figure 1, EPIC55, a video dataset of about 800GB only has about 38K action sequences, whereas there are around 1M sequences in the text recipes dataset Recipe1M. Text modality models can thus be exposed to a much larger variety of action sequences compared to video-modality anticipation models. However, because the task is defined only over the video inputs there is a question of how one can transfer this knowledge.

In this work, we show that we can augment video-based anticipation models with this external text-derived knowledge. To this end, we propose a simple cross-modal distillation approach, where we distill the knowledge gained by a language model from the text modality of the data into a vision-modality model. We build a teacher using a pre-trained language model which already carries general knowledge about action sequences. We adapt this teacher to the action sequences in the video domain by fine-tuning them for the action anticipation task. Then, we train a vision-modality ² student, which is now tasked with both predicting the target action label as well as matching the output probability distribution of the teacher.

There are two aspects of language models that can be adjusted further for improved distillation. First, while they may contain knowledge about a broad range of action sequences, we can focus them towards specific action sequences in the target dataset. Second, the text modality teacher can be further improved by pretraining on domain-relevant texts (e.g. cooking recipes), to further adapt it to the action sequences in the task domain.

²The task requires the anticipation model to make inference based on the vision modality (video frames) of the video

Our empirical evaluation shows that this cross-modal training yields consistent improvements over a state-of-the-art Anticipative Vision Transformer model (Girdhar and Grauman, 2021) on two ego-centric action anticipation datasets in the cooking domain. Adapting the teacher to the task domain by pretraining on domain relevant texts yields further gains and the gains are stable for different language models. Interestingly, our analysis shows that the language model based teacher can provide gains even when it is not necessarily better than the vision student, suggesting that distillation benefits can also come from the complementarity of knowledge, as in the case of the text modality.

In summary we make the following contributions: (i) We show that a simple distillation scheme can effectively transfer text-derived knowledge about action sequences (i.e. knowledge external to the video datasets) to a vision-based action anticipation model. (ii) We show that text-derived knowledge about actions sequences contain complementary information that is useful for the anticipation task, especially for the case where the action label space is large. (iii) Using a strong action anticipation model as a student, we achieve new state-of-the-art results on two benchmark datasets.

2 Related Work

There has been a wide range of solutions for action anticipation ranging from hierarchical representations (Lan et al., 2014), unsupervised representation learning (Vondrick et al., 2016), to encoder-decoder frameworks that decode future actions at different time scales (Furnari and Farinella, 2019), and transformers trained on multiple auxiliary tasks (Girdhar and Grauman, 2021). However, these only use the vision modality features of the observed video to train the model for the anticipation task. Our work aims to distill text-derived knowledge to improve action anticipation. Here we relate our work to others that have made use of (i) textual knowledge for related tasks, (ii) general knowledge distillation, and (iii) multimodal models which also allow for integration of information from different modalities.

Textual Knowledge for Action Anticipation: Other works have also shown the utility of modeling text-modality. Sener and Yao (2019) transfer knowledge in a text-to-text encoder-decoder to a video-to-text encoder-decoder, by substituting the text encoder with the video encoder. However, this

relies on projecting the image and text features in a shared space, which requires lots of properly aligned text and its corresponding image. [Camporese et al. \(2021\)](#) model label semantics with a hand engineered deterministic label prior based on the global co-occurrence statistics of the action labels from the overall training data, which can be ineffective in case the underlying joint action distribution is complex. In contrast, our work proposes a different approach to leverage the text in the training data by using language models to learn the complex underlying distribution of action sequences in the video and then distill this knowledge into a vision model to improve their performance.

Cross-modal Knowledge Distillation: [Thoker and Gall \(2019\)](#) propose learning from RGB videos to recognize actions for another modality. Others have used cross-modal distillation for video retrieval tasks ([Hu et al., 2020](#); [Chen et al., 2020](#)) and for text-to-speech ([Wang et al., 2020](#)). Most relevant to ours is a recent system that improves language understanding of text models by transferring the knowledge of a multi-modal teacher trained on a video-text dataset, into a student language model with a text dataset ([Tang et al., 2021](#)). In contrast, our proposed method for action anticipation transfers knowledge gained by a text-based teacher model into a vision-based student model.

Multimodal Models: Due to the recent prevalence of multimodal data and applications ([Lin et al., 2014](#); [Sharma et al., 2018](#); [Antol et al., 2015](#); [Krishna et al., 2017](#); [Ordonez et al., 2011](#); [Abu Farha et al., 2018](#); [Talmor et al., 2021](#); [Afouras et al., 2018](#)), there has been plethora of recent work on multimodal transformers. One commonly used approach used to train these models is to learn a cross-modal representation in a shared space. Examples include learning to align text-image pairs for cross-modal retrieval ([Radford et al., 2021](#); [Wehrmann et al., 2020](#)), grounded image representations ([Liu et al., 2019a](#)), and grounded text representations ([Tan and Bansal, 2020](#); [Li et al., 2019](#)). [Hu and Singh \(2021\)](#) extend the idea for multi-task settings with multiple language-vision based tasks. [Tsimpoukelli et al. \(2021\)](#) adapt a vision model to a frozen large LM to transfer its few-shot capability to a multimodal setting (vision and language). However these methods rely on large-scale image-text aligned datasets for the training the model, which may not always be available, for

e.g. EGTEA-GAZE+ video dataset has only 10.3K labelled action sequences. In contrast our distillation approach does not require any image-text alignment for the anticipation task.

3 Language-to-vision knowledge distillation for action anticipation

The action anticipation task asks to predict the class label of a future action based on information from an observed video sequence. In this task setting, the model has access to both, video and annotated action segments (action text) during the train time, but needs to make the inference only using the video sequence. The input to the prediction model is a sequence of video frames up until time step t : $\mathbf{X} = (X_1, X_2, \dots, X_t)$, and the desired output of the model is the class label Y of the action at time $t + \tau$, where τ is the anticipation time.

To learn an anticipation model, we assume there is training data of the following form: $\mathcal{D} = \{(\mathbf{X}^i, \mathbf{L}^i, Y^i)\}_{i=1}^n$, where $\mathbf{X}^i = (X_1^i, \dots, X_{t^i}^i)$ is the i^{th} training video sequence, Y^i is the class label of the future action at time $t^i + \tau$, and $\mathbf{L}^i = (L_1^i, \dots, L_{k^i}^i)$ is the sequence of action label of the action segments in the video sequence \mathbf{X}^i . Each human action can span multiple time steps, so the number of actions k^i might be different from the number of video frames t^i .

Our task is to learn a model g that can predict the future action label based on the vision modality of the video sequence \mathbf{X}^i only. A common approach is to optimize cross entropy loss \mathcal{L} between the model’s predicted label $g(\mathbf{X}^i)$ and the ground truth label Y^i of each training instances, i.e., to minimize: $\sum_i \mathcal{L}(g(\mathbf{X}^i), Y^i)$. Although the sequence of action labels \mathbf{L}^i is available in the training data, the semantics associated with these labels is not properly used by the existing methods for training the anticipation model.

Here we propose to learn a text-based anticipation model g_{text} and use it to supervise the training of the vision-based anticipation model g . This training approach utilizes the knowledge from the text domain, which is easier to learn than the vision-based knowledge, given the abundance of event sequences described in text corpora. Hereafter, we will refer to the language-based model as the teacher, and the vision-based model as the student.

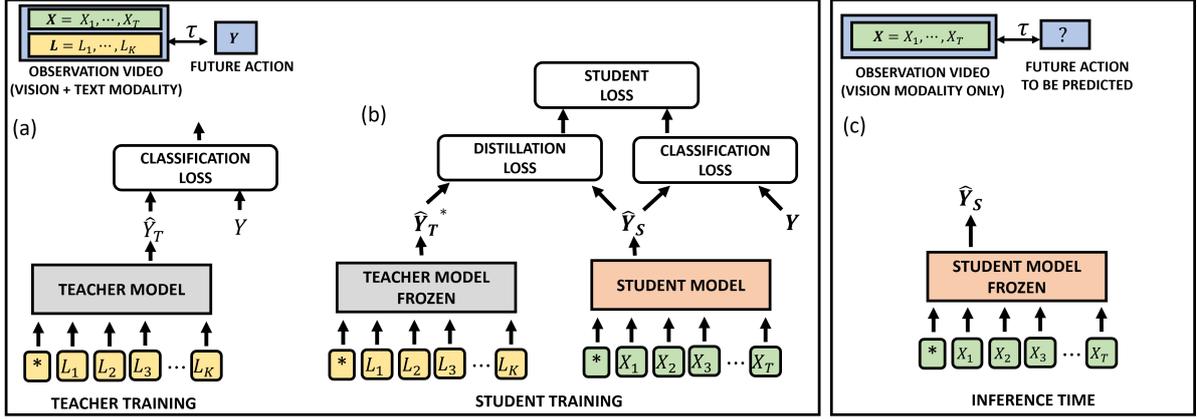

Figure 2: **METHOD OVERVIEW: Training**- The observation video has two set of features, a sequence of T image frames \mathbf{X} , and a sequence action labels (e.g. cut-onion, peel-onion etc.) \mathbf{L} corresponding to the K action segments in \mathbf{X} . (a) We train a teacher model to predict Y using the text features \mathbf{L} . Then we distill the knowledge gained by the teacher on text features into the student model that operates on vision modality \mathbf{X} . For this, (b), we train a student model on the vision modality feature \mathbf{X} while using the corresponding prediction from the teacher model as a label prior. **Inference**- During the inference or test time, the trained student model is used to predict the future action using only the vision modality of the observed video.

3.1 Overview

The overview of our proposed method is shown in Figure 2. We augment vision-based anticipation models (students) with knowledge distilled from text-based models (teachers) that have access to knowledge from large scale action sequences. To this end we fine-tune a pre-trained language model on the action sequences in the training data. However, unlike the student, the teacher gets to see the action labels of the input video segment to make its predictions (Figure 2a). Then, we train a vision-based student that learns from the text-based teacher (Figure 2b).

The teacher in our setting is built using a pre-trained language model g_{txt} that has access to broad knowledge about action sequences. We fine-tune it on the target dataset as follows. For each instance, the teacher is given the textual action sequence \mathbf{L}^i in the input video as the input (or conditioning context), which then predicts the anticipated future action \hat{Y}_{txt}^i . The teacher is trained to minimize the loss defined over the predicted and true labels, i.e., to minimize: $\sum_i \mathcal{L}_{txt}(g_{txt}(\mathbf{L}^i), Y^i)$, where \mathcal{L} denotes the cross-entropy loss and $\hat{Y}_{txt}^i = g_{txt}(\mathbf{L}^i)$ is the output of the text-based teacher model.

We then freeze the *teacher*, and train a vision-based *student* model g that predicts the future action using the vision features \mathbf{X}^i . The student is trained to minimize the loss $\mathcal{L}_S(Y^i, \hat{Y}^i, \hat{Y}_{txt}^i)$ such that it's output probability distribution $\hat{Y}^i = g(\mathbf{X}^i)$

matches that of the teacher's output \hat{Y}_{txt}^i , in addition to matching the true label Y^i .

3.2 Teacher

The input to the teacher is a sequence of action phrases $\mathbf{L} = (L_1, \dots, L_k)$ that denotes the sequence of actions observed in the input video segment. The teacher first uses a standard language model ϕ_{LM} to produce a vector f_{txt} , of the input sequence \mathbf{L} . In transformer-based language models, a special token (e.g. [CLS] in BERT) is prepended to the input sequence. The output contextual representation of this special token is used as the final representation of the entire input sequence.

The teacher uses this f_{txt} vector to predict the output labels using the standard linear transformation (\mathbf{W} , b) followed by a softmax layer. In addition we also train the teacher to predict the main verb Y_{vb} and the object Y_{ob} of the action Y . These are predicted using separate linear transformations ($\mathbf{W}_v, \mathbf{b}_v$) and ($\mathbf{W}_o, \mathbf{b}_o$), followed by softmax.

The full set of predictions for input $\mathbf{L} = (L_1, \dots, L_k)$ is obtained as:

$$\begin{aligned} f_{txt} &= \phi_{LM}(L_1, \dots, L_k) \\ \hat{Y}_{txt} &= \text{softmax}(\mathbf{W} f_{txt} + \mathbf{b}) \\ \hat{Y}_{ob} &= \text{softmax}(\mathbf{W}_o f_{txt} + \mathbf{b}_o) \\ \hat{Y}_{vb} &= \text{softmax}(\mathbf{W}_v f_{txt} + \mathbf{b}_v) \end{aligned}$$

To fine-tune the teacher model, we minimize the weighted sum of the cross-entropy loss between

the predicted triplet of action, verb and noun and their corresponding ground truth values.

$$\begin{aligned} \mathcal{L}_{txt}(Y, (\hat{Y}_{txt}, \hat{Y}_{ob}, \hat{Y}_{vb})) &= \lambda \mathcal{L}(Y, \hat{Y}_{txt}) \\ &+ \lambda_o \mathcal{L}(Y_{ob}, \hat{Y}_{ob}) + \lambda_v \mathcal{L}(Y_{vb}, \hat{Y}_{vb}) \end{aligned} \quad (1)$$

3.2.1 Adapting Teacher using Domain Relevant Texts

Pre-trained LMs have been shown to contain a wide variety of knowledge, which we hope to distill into the vision student model. However, there are two aspects about LMs which limit their applicability. First, LMs are general purpose models that cover many domains, but the target video datasets cover specific domains. For example, many action anticipation datasets are built for the cooking domain. Second, unlike fluent texts that LM’s are trained on, the action sequences in the videos are annotated using simpler verb/object constructions. Adapting LMs to these differences can benefit the knowledge distillation. To this end, we make use of domain-relevant texts (for e.g. the recipes in Recipe1M (Marin et al., 2019) dataset). The recipes are natural language instructions. To mimic the target sequences in the video datasets, we convert these into simpler verb-object constructs, and then use the standard Masked Language Modeling training task. Thus, this allows us to not only make use of generic knowledge about action sequences but also adapt the text-derived knowledge to the target domain.

3.3 Student

The student is trained to take the video frames in the video segment $\mathbf{X} = (X_1, \dots, X_t)$ as input and predict the future action Y as output. Though the applicability of the proposed distillation method is not restricted to any particular class of student model, we use the recent state-of-the-art Anticipative Vision Transformer (AVT) (Girdhar and Grauman, 2021) as our student model. In AVT, the video to action prediction is done in two stages, first a *backbone* network \mathcal{B} generates the feature representation of the individual frames in \mathbf{X} in a non-contextual manner.

$$z_1, \dots, z_t = \mathcal{B}(X_1), \dots, \mathcal{B}(X_t)$$

This is then followed by a transformer based decoder *head* network \mathcal{D} , that generates the contextual representation of the frames by transforming

the frame features z_i ’s in an autoregressive manner.

$$\begin{aligned} f_{v_1}, \dots, f_{v_t} &= \mathcal{D}(z_1, \dots, z_t) \\ \hat{Y}_{v_j} &= \text{softmax}(\mathbf{W}_s f_{v_j} + \mathbf{b}_s) \quad \forall j \in \{1, \dots, t\} \\ \hat{Y} &= \hat{Y}_{v_t} \end{aligned}$$

The feature representations from the *head* network f_{v_j} ’s are then used to make predictions for the anticipated action \hat{Y}_{v_j} at time unit j . The anticipated action \hat{Y} for the input video \mathbf{X} is simply the predicted label at time unit t i.e. \hat{Y}_{v_t} . During training the model is also supervised for two other auxiliary tasks namely future feature prediction and intermediate action prediction (see (Girdhar and Grauman, 2021) for details). We denote this combined training loss function as \mathcal{L}_{AVT} .

For the teacher to student distillation, we want the AVT’s output distribution over action classes \hat{Y} to match the teacher’s distribution \hat{Y}_{txt} . To this end, we minimize the KL divergence between the teacher prediction \hat{Y}_{txt}^γ and student predictions \hat{Y}^γ , after smoothing the distributions using a temperature parameter γ , following the standard distillation technique (Hinton et al., 2015).

$$\mathcal{L}_S = \mathcal{L}_{AVT} + \lambda_S \cdot \mathcal{D}_{KL}(\hat{Y}_{txt}^\gamma \parallel \hat{Y}^\gamma) \quad (2)$$

Dataset	Segments	Classes	τ
Epic 55	28.6K + 9 K	2, 513	1.0 sec
EGTEA-Gaze+	7.3K + 3K	106	0.5 sec

Table 2: **Datasets** on which the proposed method is benchmarked. **Segments** are the number of action segments in the train + test set, **Classes** are the number of action classes in the dataset, τ is the anticipation time.

4 Experimental Setup

4.1 Datasets

1. Anticipation Datasets We evaluate the proposed method on two different datasets that are summarised in Table. 2. Both the datasets, Epic-Kitchen 55 (Damen et al., 2018) and EGTEA-GAZE+ (Li et al., 2018), are egocentric (first-person) videos of people cooking some recipe. Note the proposed method is broadly applicable to other types of dataset as long as the input video segments in the training set contain action sequence annotations. For the Epic-Kitchen 55 dataset, we use the standard train-test split followed in Furnari and Farinella (2019). For the EGTEA-GAZE+ dataset,

we report performance on the first of the three train-test splits following previous work by [Girdhar and Grauman \(2021\)](#).

2. Domain-Relevant Dataset The teacher can be improved further by adapting its language model (LM) to domain relevant texts. To test the effectiveness of this, we use the Recipe1M dataset ([Marin et al., 2019](#)) to pre-train the LM. The Recipe1M dataset contains one million recipes along with associated images (which are not used in this work). The instructions in a recipe can be seen as a sequence of cooking actions to be performed.

4.2 Performance Metrics

For the EGTEA-Gaze+, we report the performance on top1 accuracy (**Acc@1**) and class mean recall (**Rec@1**)-mean recall of the individual classes, as reported by [Girdhar and Grauman \(2021\)](#). For the Epic-Kitchen 55 dataset, there are a set of action classes that occur only in the train set but not in the test set and vice versa. Existing anticipation methods, including our proposed work does not support zero-shot learning. Therefore top5 many-shot class-mean recall (**MS-Rec@5**)-mean top5 recall of the classes in the many-shot-classes, as mentioned in [Furnari et al. \(2018\)](#), is our primary metric for model evaluation.

4.3 Implementation Details

1. Teacher Training: The teacher model is a classification layer on top a pre-trained language model. For the main set of experiments we used **ALBERT** ([Lan et al., 2019](#)) as the base language model. Our choice here is motivated by two main factors: (i) the pre-training task for **ALBERT** focuses on modeling the inter-sentence coherence which is important when modeling the sequence of disparate action phrases (ii) it enables faster training of deeper models. For the EGTEA-GAZE+ dataset, we trained the model for 4 epochs by minimizing the weighted cross-entropy loss (inversely weighted by the relative class frequency) due to the high degree of class imbalance in the dataset ($\sim 1 : 24$). For the EPIC-Kitchen-55 dataset, the model was trained for 8 epochs using regular cross-entropy loss instead of weighted cross-entropy as a lot of classes in the test label set are not present in the train-set, and vice versa.

The classification head is a single linear layer ($\mathbf{W} \cdot \mathbf{x} + \mathbf{b}$) that projects the feature representation of the input action sequence into the label

space of the target dataset. For optimizing on both the datasets, we used the AdamW ([Loshchilov and Hutter, 2017](#)) optimizer, with a learning rate of 10^{-5} and weight decay of 10^{-7} . The context window for the Epic-Kitchen was set to 5 action segments whereas for the EGTEA-GAZE+ it was set to 15 action segments. The teacher training was performed on two Nvidia RTX Titan-X GPUs. The teacher training for the EGTEA-GAZE+ takes about 2-4 hours depending on the LM base whereas the EPIC-Kitchen-55 takes about 3-5 hours to train.

2. Teacher Pre-training: We first parse each instruction in the Recipe1M dataset into a sequence event tuples of the form (subject, verb, object) using an open information extraction system ([Stanovsky et al., 2018](#)) made available by AllenNLP ([Gardner et al., 2018](#)). To match the action label structure we see in the video datasets, we represent each instruction using the sequence of action, i.e. <verb, object> part of the event. The actions in the action sequence are sorted by the discourse order of their corresponding verb in the instruction. The language model is pretrained on these (verb, object) sequences using the standard masked language modeling objective ([Devlin et al., 2019](#)), where some token in the sequence is masked at random and the model is tasked with predicting the masked token.

For pre-training, the language models were trained on the Recipe1M dataset for 200K steps with a batch size of 16. The optimizer used was AdamW ([Loshchilov and Hutter, 2017](#)), with a learning rate of 10^{-5} and weight decay of 10^{-7} . LM pre-training was performed on a single Nvidia A100 GPU with the training time varying from 12 hrs for the smallest model (**DistilBERT**) to 24 hrs for **BERT**, **RoBERTa**, and **ALBERT**.

3. Student Training: For the student training, all the hyperparameters and initial conditions (parameter initialization) are exactly identical to the ones used to train the **AVT** ([Girdhar and Grauman, 2021](#)) baseline model. So any change in the performance from the baseline is the result of adding the knowledge distillation. The distillation loss coefficient λ_S , for the EGTEA-GAZE+ dataset was set to 150, and 20 for EPIC-Kitchen 55.

4. Top-K logit distillation: The label space of EPIC-Kitchen 55 has 2,513 classes, out of which only 31% of the classes in the training data are present in the test data. This leads to the teacher

model assign relatively low probability values to many classes, which may not be reliable signals for distillation. Therefore, instead of matching the probability distribution over all the action classes, we only match the relative probability distribution of the top-50 classes with the highest teacher probabilities. For this, we consider the classes corresponding to the top-50 logits from the teacher prediction, normalize them, and only minimized the KL-Divergence between them and their corresponding logits of the student prediction. The student training was performed on either Nvidia Tesla V100 GPU and the training time was ~ 24 hrs for EGTEA-GAZE+ and ~ 6 hrs for the EPIC-55 dataset.

5 Results and Analysis

We present the results of text to video knowledge distillation on the AVT (Girdhar and Grauman, 2021) model as the student. AVT is the state-of-the-art model for action anticipation on the EGTEA-GAZE+ and EPIC-Kitchen 55 datasets on all performance metrics.

For each of these datasets, we consider the AVT variants with the best performance as our baseline and student model. For the EGTEA-GAZE+ dataset, we consider AVT-h + AVT-b in (Girdhar and Grauman, 2021) as our baseline model. Similarly for the EPIC-Kitchen 55 dataset, we consider, AVT-h + irCSN152 in (Girdhar and Grauman, 2021) as our baseline model.³ Throughout this section, we refer to AVT-h + AVT-b and AVT-h + irCSN152 as AVT-1 and AVT-2 respectively. The baseline models distilled with LM based teacher is denoted as AVT-1(or 2) + LM Distillation and in case teacher LM is pre-trained on the recipe domain text, the resulting model is referred to as AVT-1(or 2) + RcpLM Distillation. We tried to reproduce the AVT model to use as our student and obtain stronger results than the published version (see Table 3), on all but one metric. We use this stronger implementation as our baseline and our student model.

5.1 Does Knowledge distillation from Language Models help ?

Table 3 shows the result of training the state-of-the-art baseline model AVT, with and without the text to vision knowledge distillation, for the EGTEA-GAZE+ and EPIC-Kitchen 55 dataset. We

³✱AVT variants used for the EGTEA-GAZE+ and EPIC-Kitchen 55 baselines are AVT-1 and AVT-2.

can observe that applying text to vision knowledge distillation to the AVT leads to performance gains on both the datasets. For EGTEA-GAZE+, adding knowledge distillation leads to 2.1% and 2% relative percentage improvement over AVT-1 on the Acc@1 and Rec@1 metrics respectively. For the EPIC-Kitchen 55 dataset, knowledge distillation leads to a relative performance gain of 3.5% over AVT-2 on MS-Rec@5 metric.

5.2 Does domain-adaptive pre-training of teacher improves the task performance ?

To analyze the effect domain adaptive pre-training on the task, we pre-train the teacher LM on the Recipe1M dataset through the MLM task. The pre-trained model was then finetuned on the task-specific video dataset for the anticipation task. As seen in Table 3, the performance gain of the teacher directly translates to the performance gain of the student. For EGTEA-GAZE+ dataset, pre-training teacher leads to 3.9% and 3.4% relative improvement over the AVT-1 on Acc@1 and Rec@1 metric compared to 2.1% and 2% relative improvement when not pretraining the teacher. For the EPIC-Kitchen 55 dataset, teacher pre-training leads to a relative improvement of 7.2% on MS-Rec@5 metric compared to only 3.5% when not pre-training the teacher.

Model	EGTEA-GAZE+		EPIC-55
	Acc@1	Rec@1	MS-Rec@5
AVT (Girdhar and Grauman, 2021) -published	43.0	35.5	13.6
AVT (Girdhar and Grauman, 2021) -reproduced	43.52	34.87	15.25
AVT + LM Distillation	44.41	35.54	15.79
AVT + RcpLM Distillation	45.2	36.1	16.36

Table 3: **Effect of knowledge distillation:** Distilling knowledge from teacher (ALBERT LM) trained on text-modality of the video data, into vision based student model leads to student performance gain. Pre-training the teacher on domain relevant text before task specific finetuning leads to further performance improvement. ✱

5.3 How sensitive is the distillation to the choice of Language Model ?

In order to analyze the sensitivity of the distillation scheme towards the choice of the language model,

Model	EGTEA-GAZE+		EPIC-55
	Acc@1	Rec@1	MS-Rec@5
AVT (Girdhar and Grauman, 2021)	43.52	34.87	15.25
+ Rcp-ALBERT Distillation	45.2	36.1	16.36
+ Rcp-BERT Distillation	44.81	35.57	15.98
+ Rcp-RoBERTa Distillation	45.5	36.53	15.97
+ Rcp-ELECTRA Distillation	45.2	35.58	15.34
+ Rcp-DistillBERT Distillation	44.86	35.64	16.23

Table 4: **Effect of the choice of teacher LM** on the distillation performance. Each of the pre-trained LMs that we tested as a teacher, showed performance gain over the baseline AVT model for both the datasets. ♣

we also trained multiple teachers with different pre-trained LMs. The result of using different teachers for the anticipation task is specified in Table 4. From the table, we can observe that all the teacher distilled models perform better than the baseline AVT on all the metrics for both the datasets. This indicates that the text modality has some information that complementary to the vision modality that if properly exploited can lead to improved performance for the anticipation task.

5.4 Should the teacher be always better than the student ?

To understand the impact of the quality of the teachers, we measured the performance of the teacher models by themselves on the anticipation task as show in Table 5. For the EPIC-Kitchen 55 dataset the teacher performance is much better than the video-only baseline, whereas, for the EGTEA-GAZE+ dataset, the baseline vision model’s performance is much better than any of the teachers. Despite this, the performance gain due to distillation is greater for the EGTEA-GAZE+ dataset compared to the EPIC-Kitchen 55 dataset, as seen in Table 3. This suggests that what matters more for distillation in this case is the complementary information gained from the text modality that is not already present in the vision modality.

6 Conclusions

Action anticipation is a challenging problem that requires training large capacity video models. In

Model	EGTEA-GAZE+		EPIC-55
	Acc@1	Rec@1	MS-Rec@5
AVT (Girdhar and Grauman, 2021)	43.52	34.87	15.25
Rcp-ALBERT Teacher	21.66	22.63	21.78
Rcp-BERT Teacher	22.05	23.39	21.43
Rcp-RoBERTa Teacher	19.98	21.58	22.41
Rcp-ELECTRA Teacher	21.46	23.71	15.19
Rcp-DistillBERT Teacher	21.86	22.58	21.56

Table 5: **Teacher performance** on the anticipation task. For the EGTEA-GAZE+ dataset, the teacher performance is much lower than the video only AVT model, where as for the EPIC-Kitchen 55 dataset, the teacher performance is much better than the video-only AVT model. ♣

this work, we showed how the textual modality of the input videos, which is often ignored in training, can be leveraged to improve the performance of the video models. In particular, we can exploit the large scale knowledge acquired by pre-trained language models to build a text-modality teacher that can provide useful complementary information about the action sequences to a vision modality student. This cross-modal distillation strategy yields consistent gains achieving new state-of-the-art results on multiple datasets. Last, the gap between the performance of the teacher and the student models for domains with large label space suggests that there is still room for improvement with better distillation techniques.

7 Limitations

Real life scenarios have a large space of human actions which cannot be exhaustively covered by manually annotated training data. As such it is important to have models with zero-shot anticipation capabilities to predict unseen actions. This work did not explore zero-shot settings but we believe text-to-video distillation holds promise given the recent successes of language models in zero-shot tasks.

In this work we have shown the capability of text based language models for action anticipation, especially when the action space is very large and sparse. Though this work is intended to be a proof of concept for leveraging text based model for im-

proving video based action anticipation, there is still a large performance gap between the a text based language model and vision modality model. This performance gap indicates fruitful research avenues in text to vision knowledge distillation for action anticipation task.

8 Ethical Considerations

Anticipation future action based on videos is an important for many applications such as assistive technologies, augmented reality etc. Our work demonstrates that knowledge derived from text sources can be used to further improve the performance of video based action anticipation model. Even though our proposed work is able to improve the current state-of-art numbers on the standard benchmark datasets, the absolute performance is still low, especially in the case where the action space is very large. As such we would recommend to carefully analyze the cost of erroneous prediction before deploying the system for real world application.

Since the proposed method involves distilling the knowledge gained by pre-trained language model from text sources into a vision based model for action anticipation, this can also transfer the biases that these languages models can learn from the training text. As such data on which these text-based teacher models are trained should be analyzed for potential biases before deploying the proposed system for actual application. Analysis of bias propagation during knowledge distillation and devising bias reduction techniques are some potential extension of this work that we are highly interested in.

A Appendix

In this section, we present examples of model prediction for the video action anticipation task for the EPIC-55 dataset. For each instance we show the top-5 predictions for (i) video-only model - **AVT** (ii) text-based teacher model - LM-teacher (**Rcp-ALBERT**) (iii) a LM-teacher distilled student video model - AVT + LM teacher Distl (**AVT + Rcp-ALBERT Distillation**). Note that the end-task setting is such that, the inference has to be done only from the video frames, as the text label for the action segment won't be available during the inference time.

Figure 3 and 4 shows example of cases where the base video only model makes incorrect prediction, where as the text-based teacher and the teacher-distilled video model makes correct predictions. Figure 5 and 6 shows example of cases where the base video only model makes incorrect prediction, the text-based teacher makes correct prediction, however the teacher-distilled video model makes incorrect predictions.

Abstract

Opinion summarization provides an important solution for summarizing opinions expressed among a large number of reviews. However, generating aspect-specific and general summaries is challenging due to the lack of annotated data. In this work, we propose two simple yet effective unsupervised approaches to generate both aspect-specific and general opinion summaries by training on synthetic datasets constructed with aspect-related review contents. Our first approach, *Seed Words Based Leave-One-Out* (SW-LOO), identifies aspect-related portions of reviews simply by exact-matching aspect seed words and outperforms existing methods by 3.4 ROUGE-L points on SPACE and 0.5 ROUGE-1 point on OPOSUM+ for aspect-specific opinion summarization. Our second approach, *Natural Language Inference Based Leave-One-Out* (NLI-LOO) identifies aspect-related sentences utilizing an NLI model in a more general setting without using seed words and outperforms existing approaches by 1.2 ROUGE-L points on SPACE for aspect-specific opinion summarization and remains competitive on other metrics.

1 Introduction

Customer reviews play a vital role in decision-making for customers and product (or business) providers, as customers usually resort to reviews to guide their purchasing decisions and product providers improve their products based on reviews as feedback. However, it becomes hard for customers or product providers to read through all reviews before making decisions with the explosion of online reviews in recent years. Opinion summarization (Hu and Liu, 2006; Wang and Ling, 2016; Angelidis and Lapata, 2018; Bražinskas et al., 2020; Brazinskas et al., 2022; Angelidis et al., 2021; Amplayo et al., 2021a; Basu Roy Chowdhury

et al., 2022), the task of generating a general summary of *salient* opinions expressed among reviews, provides a feasible solution to this problem.

Different from summarization in Wikipedia and news domains (Nallapati et al., 2016; Narayan et al., 2018a; See et al., 2017; Narayan et al., 2018b; Liu and Lapata, 2019; Cachola et al., 2020), opinion summarization cannot rely on reference summaries for model training since it is difficult and expensive to annotate large scale reviews-summary pairs. Also, customers usually care about specific aspects of a product instead of a *general* high-level summary. Thus, fine-grained *aspect-specific* opinion summaries are required, and this makes the annotation process even more difficult and expensive.

Amplayo et al. (2021a) propose an abstractive approach to generate aspect-specific opinion summaries by training on synthetic datasets. They construct synthetic datasets with review elements (words, phrases, or sentences) identified by a multiple instance learning (MIL) module (Keeler and Rumelhart, 1991) learned with silver-standard labels obtained using aspect seed words. We first follow this direction to propose a more straightforward and effective method that excludes the complex learning module to identify aspect-related elements to construct synthetic datasets. Moreover, aspect seed words, which again require human efforts, may not always be available when moving to new domains. Thus we propose another more general solution without the curation and supervision of aspect seed words.

Specifically, we propose two simple yet effective methods to identify aspect-related review sentences and construct aspect-specific synthetic datasets in a *Leave-One-Out* (LOO) (Bražinskas et al., 2020; El-sahar et al., 2021; Brazinskas et al., 2022) style and then finetune pretrained language models (PLMs) on the synthetic datasets: (a) SW-LOO identifies aspect-related sentences by simply exact-matching aspect seed words and outperforms existing ap-

*Work done during an internship at AWS AI Labs.

proaches by 3.4 ROUGE-L points and 0.5 ROUGE-1 point on aspect opinion summaries of SPACE and OPOSUM+ respectively; (b) NLI-LOO identifies aspect-related sentences with a finetuned NLI (Bowman et al., 2015; Williams et al., 2018) model. Being the first approach that does not use aspect seed words, it outperforms existing approaches on aspect opinion summarization by 1.2 ROUGE-L points for SPACE and falls behind at most 1 ROUGE point on other metrics.

2 Problem Formulation

Let C denote a corpus of reviews on entities $\{e_1, e_2, \dots\}$ (products or business). Let $A_e = \{a_1, a_2, \dots, a_M\}$ denotes a set of aspects (e.g., *food* or *location* for a hotel) that are relevant for the domain of entities. For each entity e , we define its review set as $R_e = \{r_1, r_2, \dots, r_N\}$. Each review r is a collection of sentences $\{x_1, x_2, \dots\}$ and each sentence x is a sequence of tokens $\{w_1, w_2, \dots\}$. Each aspect a is represented by a small set of *seed words* (e.g., *meal* or *buffet* for *food* aspect) $S_a = \{v_1, v_2, \dots\}$. Our approaches generate two types of opinion summaries: (a) *general* summary that contains salient opinions over *all* aspects of the entities; and (b) *aspect* summary that focuses on only one specific aspect $a \in A_e$.

3 Synthetic Dataset Construction

Leave-One-Out (LOO) We construct synthetic datasets in a LOO style: from a pool of review elements (reviews or review sentences), an element is randomly sampled as a *pseudo-summary*, then we select input reviews from the remaining review elements.

3.1 Seed Words Based LOO

To build a synthetic reviews-summary pair for aspect a , as shown in the upper diagram of Figure 1, we first filter each review r into its aspect-related portion r^i where $r^i \subseteq \{x_1, x_2, \dots\}$ with each sentence in r^i containing at least one seed word in A_e . For example, for *food* aspect with its seed words $\{\text{breakfast, buffet, ...}\}$, a hotel review r_i : "They have the most wonderful buffet in Bay Area. And the hotel is close to the airport. Forgot to mention, especially the breakfast is terrific." will be filtered into its aspect-related review portion r_i^i : "They have the most wonderful buffet in Bay Area. Forgot to mention, especially the breakfast is terrific.". Noticed that r_2^i is empty suppose there is no sentence in r_2

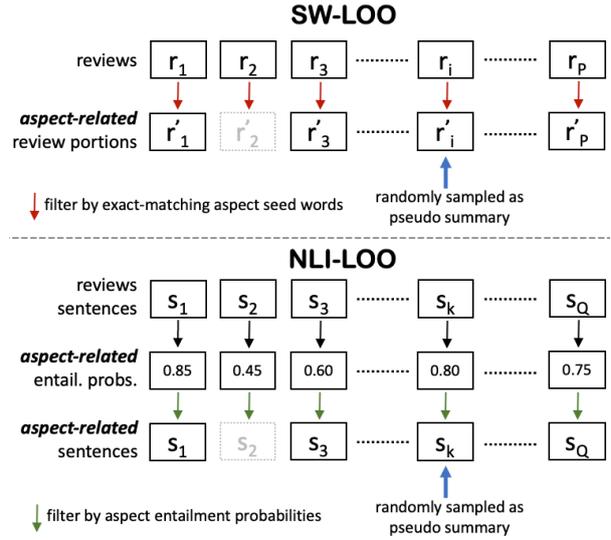

Figure 1. One synthetic data pair construction for aspect a in SW-LOO and NLI-LOO.

containing any seed word. Then we apply LOO construction on the filtered aspect-related review portions $\{r_1^i, r_3^i, \dots, r_p^i\}$ as shown in the diagram: r_i^i is randomly sampled as the pseudo summary and inputs are chosen from $\{r_1^i, r_3^i, \dots, r_p^i\} \setminus \{r_i^i\}$ by first ranking them with the pseudo-summary r_i^i based on ROUGE-1 score (Lin, 2004) and then truncating with a token budget j (truncate up to j tokens) since a concatenation of all filtered reviews cannot fit into the encoder of a PLM. Please refer to Appendix B for more details and analysis on SW-LOO.

3.2 NLI Based LOO

NLI Component In order to relax the requirement of aspect seeds (provided by humans) and to make a more scalable and general solution, we propose to use an NLI model to infer whether a review sentence is related to an aspect. Specifically, we set a review sentence as the premise and verbalize an aspect with the template: *the text is about {aspect}*, which we use as the hypothesis. If the entailment probability is higher than a threshold (0.9 for SPACE and 0.8 for OPOSUM+), we identify the sentence as related to the aspect with this entailment probability, else we set the aspect-related probability to 0.

To build a synthetic pair for aspect a , we first break all reviews into review sentences and filter out those that are not related to aspect a with the NLI model. As shown in the lower diagram of Figure 1, each sentence is first passed through the NLI model to infer its probability of relatedness

to aspect a , so s_2 with entailment probability of 0.45 will be filtered out if the threshold is set to 0.5. Then we apply LOO construction on all aspect-related sentences $\{s_1, s_3, \dots, s_Q\}$ and we also use a token budget to truncate ranked synthetic input similar to SW-LOO, however, different from SW-LOO where we use ROUGE-1 scores to rank, we calculate similarities based on entailment probabilities. Please refer to Appendix C for more details and analysis on NLI-LOO. Note that we filter the input reviews at sentence level for NLI-LOO and at review level in SW-LOO.

4 Summarization Model

We use T5 (Raffel et al., 2020), a sequence-to-sequence Transformer-based (Vaswani et al., 2017) PLM, to finetune our synthetic datasets similar to previous works (Ke et al., 2022; Amplayo et al., 2021a). For SW-LOO, we use the following template: “summarize based on aspect: [ASPECT] $\{aspect\}$ [ASPECT] with seed words: [SEED] $\{seed\ words\}$ [SEED]: $\{filtered\ review\}$ [SEP] $\{filtered\ review\}$. . . ” to convert synthetic input and for NLI-LOO, we use: “[ASPECT] $\{aspect\}$ [SEP] $\{aspect-related\ sent\}$ [SEP] $\{aspect-related\ sent\}$. . . ”. [ASPECT], [SEED], and [SEP] are special tokens, $\{aspect\}$ is an aspect name, $\{seed\ words\}$ are concatenation of seed words for an aspect, each $\{filtered\ review\}$ is a r_i^j in SW-LOO synthetic input, and each $\{aspect-related\ sent\}$ is a s_k in NLI-LOO synthetic input. For both methods, outputs are pseudo summaries.

5 Experiment

5.1 Datasets

We evaluate our methods on two opinion summarization datasets: SPACE (Angelidis et al., 2021), containing reviews from *hotel* domain, and OPOSUM+ (Amplayo et al., 2021a), containing Amazon product reviews from six different domains. Both datasets are comprised of a large corpus of raw reviews and a small development and test set with human-annotated aspects and general opinion summaries for evaluation. Aspect seed words are usually obtained with a small amount of human effort. For SW-LOO, we use the same seed words as in Amplayo et al. (2021a) (Appendix E). Refer to Appendix D for detailed descriptions and statistics of the two datasets.

Table 1. Evaluation for *aspect summaries* on SPACE and OPOSUM+ test sets. Best performances are in **bold** and second best performances are underlined.

5.2 Baselines

We compare our methods with several unsupervised extractive and abstractive approaches. Extractive approaches include CENTROID (Radev et al., 2004), LEXRANK (Erkan and Radev, 2004), QT (Angelidis et al., 2021), SEMAE (Basu Roy Chowdhury et al., 2022), and two extractive variants of our methods, SW-LOO_{EXT} and NLI-LOO_{EXT}, by feeding identified aspect-related sentences to LEXRANK instead of T5, similar to the idea in Amplayo et al. (2021a). Abstractive approaches include MEANSUM (Chu and Liu, 2019), COPYCAT (Bražinskas et al., 2020), and ACESUM (Amplayo et al., 2021a). Appendix F contains more details on baselines.

We also compare with two upper bounds reported in Amplayo et al. (2021a): an ORACLE that selects the review with the highest ROUGE score to the gold summary as the summary and a HUMAN upper bound that is calculated as the inter-annotator ROUGE scores.

5.3 Implementation

We first pre-process the raw corpus such as removing products with very few reviews and too long or short reviews as in Appendix G. We use T5-SMALL as our summarization models and larger T5 size does not show improvements as shown in Appendix L. We use a MNLI (Williams et al., 2018) finetuned BART-LARGE (Lewis et al., 2020) model in NLI-LOO. We choose this model given its better performance¹ in zero-shot topic classification. We perform simple hyper-parameter tuning

on dev sets and select checkpoints with the best ROUGE-L scores to report performances on test sets. Please refer to Appendix H for more details such as training configurations and other analyses.

5.4 Results

We evaluate the quality of generated opinion summaries using ROUGE1/2/L F1 scores (Lin, 2004). Example summaries generated by our methods are shown in Table 12 and Table 13 in Appendix.

Aspect Opinion Summarization Table 1 contains the results of all baselines and our methods on the two benchmark datasets. Despite its simplicity, SW-LOO achieves the highest scores on both datasets across all metrics except RL for OPOSUM+ with only 0.3 points behind the best-performing baseline. On the other hand, NLI-LOO achieves higher R2 and RL scores on SPACE than existing methods despite using no seed words. While it falls behind other methods on OPOSUM+, it is at most 1 point behind across all metrics. This highlights that even without aspect seed words, NLI-LOO is possible to compete with SOTA aspect-based opinion summarization methods.

Next, we turn to the evaluation of extractive versions of our methods. We observe SW-LOO_{EXT} achieves higher R1 and RL scores on SPACE but falls behind on OPOSUM+ by at most 1.5 point compared with all baselines. This is consistent with the finding in Amplayo et al. (2021a) that a simple centrality-based extractive approach such as LEXRANK are strong baselines as long as input sentences are already aspect-related. And

Model	SPACE		OPOSUM+	
	Aspect	General	Aspect	General
SW-LOO	27.59	23.42	20.41	20.58
<i>w/ Training Random</i>	24.24	24.70	19.75	18.71
<i>w/ Inference Random</i>	23.46	22.04	18.76	19.41
<i>w/ Both Random</i>	14.71	21.82	18.06	18.15
NLI-LOO	25.92	25.13	19.21	19.32
<i>w/ Training Random</i>	22.05	22.06	18.42	19.37
<i>w/ Inference Random</i>	24.33	24.56	18.10	16.97
<i>w/ Both Random</i>	16.14	22.50	17.83	19.69

Table 3. *Training Random* means randomly selecting sentences as pseudo summary and input during synthetic dataset construction. *Inference Random* means randomly selecting sentences as input during inference. We report RL scores of our approaches on dev sets.

SW-LOO_{EXT} outperforming ACESUM_{EXT} further shows that our simple filtering method using exact-matching seed words already produces good enough aspect-related sentences compared with the extra learning module used in Amplayo et al. (2021a). However, NLI-LOO_{EXT}, is not able to outperform the best baseline, and we hypothesize the reason is that NLI model filtered aspect-related sentences are still noisy so that a summarization model is required to serve as regularization.

Finally, comparing our four methods, SW-LOO achieves the best performances with the supervision of seed words, NLI-LOO comes second despite the lack of seed words supervision, and our two extractive versions come last since the ground truth summaries are in nature abstractive.

General Opinion Summarization As shown in Table 2, on SPACE, SW-LOO and NLI-LOO outperform the SOTA abstractive system, ACESUM, but under-perform SOTA extractive system, SEMAE. We observe the same trend between SW-LOO_{EXT} and ACESUM_{EXT} as in aspect opinion summarization and this again shows the simple yet effective nature of our filtering method. For OPOSUM+, SW-LOO_{EXT} and NLI-LOO_{EXT} outperform existing methods given that the annotated general summaries for OPOSUM+ are extractive, SW-LOO outperforms existing abstractive approaches, and NLI-LOO falls behind with only 1 point.

5.5 Ablation Study

We conduct ablation experiments with random filtering to study the importance of the filtering strategies in our two methods. We introduce randomness in two different phases. First, when constructing synthetic pairs, instead of using our filtering strategies before applying LOO construction, we ran-

domly select sentences as pseudo-summary and input. This is essentially a random LOO baseline. Second, during inference, we sample random sentences to feed into T5 encoder instead of using our filtering strategies to select aspect-related elements. Finally, we combine these two random strategies. Results in Table 3 show that our sentence filtering strategies are crucial since ROUGE scores drop drastically as more randomness is introduced. This is more severe for aspect summarization since aspect-specific synthetic dataset construction needs to focus on particular aspects. However, randomly selecting sentences is possible to cover most aspects by chance for general summarization.

6 Conclusion

In this work, we propose two simple yet effective unsupervised approaches that generate aspect and general opinion summaries by training on synthetic datasets. SW-LOO constructs synthetic datasets simply by exact-matching aspect seed words and outperforms existing methods consistently on all metrics and datasets. Being the first work that generates aspect summaries without using aspect seed words, NLI-LOO constructs synthetic datasets with an out-of-the-box NLI model and achieves on-par and sometimes even better performances compared with existing methods.

Limitations

One of the biggest challenge in opinion summarization is the multi-document setting where each document represents one product review. Since the number of reviews for a product tends to be large, it would be unrealistic to concatenate all input reviews and train to generate a summary in an end-to-end fashion limited by modern hardware capacity, for example, the GPU memory needed is quadratic w.r.t the input length for all transformer-based PLM. In this work, we tackle this problem by pre-filtering reviews using some heuristics (aspect seed words matching and NLI model selecting) into sub-elements of reviews with much smaller sizes. However, information is very likely to get lost and become incomplete in the pre-filtering phase, leading to inaccurate summarization. Our approach is exactly facing this problem. One way to address this drawback is to first condense each review into an encoding that contains key information of the review such as opinion aspect and opinion sentiment, and then aggregate all review vectors to gen-

erate a summary. Amplayo and Lapata (2021) call this pipeline as CONDENSE-ABSTRACT and it has been used in both supervised and unsupervised general opinion summarization (Chu and Liu, 2019; Coavoux et al., 2019; Iso et al., 2021; Amplayo and Lapata, 2021; Isonuma et al., 2021).

A Related Works

Unsupervised opinion summarization is the task of summarizing opinionated text such as customer reviews without training on gold reviews-summary pairs. Recent works have been using autoencoders (Kingma and Welling, 2014) and synthetic datasets construction, or a mix of both, to tackle the zero-shot setting.

An autoencoder model consists of an encoder that maps the input into latent embedding space and a decoder that reconstructs the original input from the latent space. The latent representation learned can be later aggregated or can be used to cluster and select text to perform both extractive and abstractive summarization. Chu and Liu (2019); Bražinskas et al. (2020) aggregate the input reviews latent representations by averaging then generate the summaries conditioned on it. Angelidis and Lapata (2018) utilizes the latent representation with aspect specificity and sentiment polarity to guide the selection of review texts as extractive summaries. Recently, Angelidis et al. (2021) proposes the first approach that generates both general and *aspect-specific* opinion summaries in an extractive manner. They first leverage Vector-Quantized Variational Autoencoder (Van Den Oord et al., 2017) to cluster review sentences and then use a popularity-driven extraction algorithm to summarize. Similar to Angelidis et al. (2021), Basu Roy Chowdhury et al. (2022) learns representations of texts over latent semantic units using dictionary learning (Dumitrescu and Irofti, 2018). Other autoencoder-related methods include denoising autoencoder (Amplayo and Lapata, 2020) and Coavoux et al. (2019), an encoder-decoder architecture that utilizes clustering of encoding space to extract summaries.

Another direction of work creates synthetic datasets utilizing the largely available amount of online customer reviews. Synthetic datasets are usually constructed in a *leave-one-out* (LOO) style that one review is first randomly sampled as a pseudo-summary, and then a subset of reviews are selected or generated as input reviews to be paired with the pseudo-summary to enable supervised training. Methods of selecting and generating input reviews include random sampling (Bražinskas et al., 2020), generating noisy versions of the pseudo-summary (Amplayo and Lapata, 2020), selecting reviews that have closer distribution with the pseudo-summary in the embedding space (Am-

playo et al., 2021b; Ke et al., 2022), and selecting more textual similar reviews (Elsahar et al., 2021; Bražinskas et al., 2022). Recently, Amplayo et al. (2021a) proposes the first abstractive approach that can generate both general and aspect summaries. Their method build synthetic datasets by identifying aspect-specific elements with a multiple instance learning (MIL) model (Keeler and Rumelhart, 1991) using aspect seed words. Our work is closest to Amplayo et al. (2021a) in that we also build synthetic datasets by identifying aspect-specific elements, however, our methods do not require extra learning components such as MIL but achieve better performances.

Besides unsupervised opinion summarization, our second method, NLI-LOO is related to the recent approach (Yin et al., 2019) that utilizes NLI (Bowman et al., 2015; Williams et al., 2018) models to tackle zero-shot text classification (Chang et al., 2008) (multi-class and multi-label) problem such as topic detection (Zhang et al., 2015) and emotion detection (Bostan and Klinger, 2018). The main idea is to solve the classification problem by casting the problem into NLI format. Specifically, the text to be classified becomes the premise, and class labels are converted into natural language format (verbalization) to be used as the hypothesis. If the text entails the verbalized class label, then the text belongs to this class. In our work, we identify the relatedness of a review sentence to an aspect in such a way to construct synthetic datasets.

B SW-LOO Details

For general synthetic pairs construction, after filtering each review with seed words for each aspect, we make sure to sample one review such that its aspect-related portions for all aspects are non-empty and concatenate them as pseudo-summary. We retrieve top similar filtered reviews to each aspect-related portion in the pseudo-summary and concatenate them as general synthetic input, and the retrieval process is the same as in aspect synthetic pairs construction. General synthetic input and output are both approximately M times the length of those in aspect synthetic pairs where M is the number of aspects. For the summarization model, $\{aspect\}$ and $\{seed\ words\}$ are the concatenation of all aspects and all seed words for general synthetic pairs. Finally, we train all synthetic pairs together.

At inference time, we also first filter each review

into aspect-related portions. However, since there is no reference pseudo summary, we cannot truncate based on similarities to fit into T5 encoder. We adopt the *principle strategy* used in PEGASUS (Zhang et al., 2020) Gap Sentences Generation pre-training objective to select important reviews as input for inference. We show the effectiveness of adopting the principle strategy in Appendix I.

C NLI-LOO Details

Different from SW-LOO where we use ROUGE-1 scores, we calculate similarities based on aspect entailment probabilities to rank and truncate aspect-related sentences as synthetic input. For aspect synthetic pairs, we simply calculate the absolute probability difference between pseudo summary and aspect-related sentences. For general synthetic pairs, each review sentence (no matter whether aspect-related) corresponds to a probability vector of dimension M where M is the number of aspects and each element is the probability of the sentence being related to each aspect, and we calculate cosine similarities between the probability vectors of pseudo summary and review sentences that are related to at least one aspect (sum of the probability vector is non-zero). We use the same token budget to truncate review sentences to fit into T5 encoder for both aspect and general synthetic pairs. We also train all synthetic pairs together. Another way to calculate similarities is directly using cosine similarity between sentence embeddings, however, results reported in Appendix J do not show better performance.

During inference, we use 1 and all-one vectors with dimension M as reference vectors to rank and truncate review sentences for aspect and general input construction.

D Datasets Details

Hotel reviews in SPACE are collected from TripAdvisor and each hotel in the evaluation sets is annotated with seven types of summaries: six aspect-specific and one general, with three gold summaries for each type. The number of reviews for a hotel in the raw corpus varies but each hotel in the evaluation sets comes with 100 reviews. Product reviews from six domains: *laptop bag*, *Bluetooth headset*, *boots*, *keyboard*, *television*, and *vacuum* in OPOSUM+ are initially down-sampled from *Amazon Product Dataset*² (McAuley et al., 2015) by Ange-

²<http://jmcauley.ucsd.edu/data/amazon/>

Statistics	SPACE	OPOSUM+
domain	1	6

entities	25	30
reviews per entity	100	10
summaries per entity	3	3
total aspect summaries	450	270
total general summaries	75	<u>90</u>

Table 4. Detailed statistic for SPACE and OPOSUM+ datasets. Note that only gold general summaries for OPOSUM+, which is underlined in the table, are extractive.

lidis and Lapata (2018) and then further expanded by Amplayo et al. (2021a). Each product in the evaluation sets is annotated with four types of summaries: three aspect-specific and one general, with also three gold summaries for each type. The number of reviews for a product in the raw corpus also varies but each product in the evaluation sets comes with 10 reviews. All human-annotated summaries are abstractive except that general summaries in OPOSUM+ are extractive. Detailed statistics of the datasets are shown in Table 4.

E List of Seed Words

Aspect seed words (listed in Table 5 and 6) are usually automatically extracted using a variant of clarity scoring function (Cronen-Townsend et al., 2002) applied on a small amount of aspect annotation as described in Angelidis and Lapata (2018), and they can be further manually improved by domain experts as in Amplayo et al. (2021a).

F Baselines Details

Extractive Approaches We first compare against two traditional approaches: CENTROID selects the review closest to the centroid of all reviews as the summary; LEXRANK selects the most salient review sentences as summary similar to PAGERANK (Page et al., 1999). BERT (Devlin et al., 2019) embedding is used to represent sentences in both traditional methods. More recent systems include QT (described in Section 1) and SEMAE. Inspired by QT, SEMAE represents text over latent semantic units using dictionary learning.

Abstractive Approaches MEANSUM generates summaries by reconstructing the mean of reviews'

Aspect	Hotel
building	lobby pool decor gym area

Table 6. Seed words for various domains in OPOSUM+ dataset.

representations using autoencoder. COPYCAT uses a hierarchical variational autoencoder to learn latent codes for the summaries. The most recent approach is ACESUM. (described in Section 1).

Note that LEXRANK, MEANSUM, and COPYCAT do not support aspect-specific summary generation, Amplayo et al. (2021a) adopt a simple

sentence-filtering strategy to enable it. Specifically, after training a general opinion summarization model, during inference for aspect summaries, they filter out input review sentences that are not aspect-related using cosine similarities scores between BERT embeddings of review sentences and aspect seed words before feeding into general summarization model.

G Datasets Pre-Processing

We pre-process differently for our two methods on the same dataset since we want to control the constructed synthetic datasets to have reasonable sizes and resemble properties of test time data such as the number of reviews per product and average review length. We use dev sets to observe such properties. In SW-LOO, we first remove reviews with less than 20 words and then remove hotels with less than 10 reviews for SPACE; we first remove reviews less than 20 or more than 100 words then remove products with less than 12 reviews for OPOSUM+. In NLI-LOO, we remove reviews with less than 10 or more than 120 words for SPACE and remove reviews with less than 20 or more than 100 words for OPOSUM+.

H Implementation Details

We use T5 implementation from HuggingFace³ (Wolf et al., 2020). We use AdamW (Loshchilov and Hutter, 2019) optimizer without weight decay and set 0.9, 0.999, 1×10^{-8} for β_1 , β_2 , ϵ . We train all summarization models for a total of 25K steps on the combination of aspect and general synthetic pairs. We set ngram refraining size (Paulus et al., 2018) to 3 during inference. We tune initial learning rate in $[1e-6, 4e-5, 3e-4]$ and batch size in $[8, 16]$. We tune beam search size during inference in $[2, 4]$. For SW-LOO_{EXT} and NLI-LOO_{EXT}, we use [CLS] token embedding in the last layer of BERT as the sentence representation. We concatenate top 6 sentences returned by LEXRANK as general summary, and tune in $[2, 4]$ for aspect summary. We also use two sizes of BERT: BERT-BASE and BERT-LARGE. All computations are performed on 8-GPU p3.16xlarge Amazon instance. The best hyper-parameter settings for all experiments can be found in Table 7.

During preliminary studies for aspect synthetic pairs construction, we find that for SPACE, us-

ing sampled filtered aspect-related review portion as pseudo-summary rather than the original review that contains the pseudo-summary gives better downstream ROUGE scores, but it is the opposite way with OPOSUM+. Please refer to Appendix K for analyses on pseudo-summary granularity.

SW-LOO For SPACE, we add a linear learning rate warm-up in the first 500 steps and save checkpoints every 500 steps. Since there are totally 6 aspects for SPACE and very few reviews containing seed words for all 6 aspects can be sampled as pseudo summaries for general synthetic pairs construction, we relax the constraint of pseudo summaries containing seed words for all 6 aspects to 4 aspects. We set 200 as the token budget to truncate ranked aspect-related review portions for aspect synthetic pairs construction, and 150 as the token budget in principle strategy when selecting important sentences as input during inference for SPACE. We set 1536 and 200 as the maximum input and output token length of T5 for all SW-LOO experiments. Notice that this exceeds 512, which is the maximum token length that T5 is pretrained on, but recent works (Zhang et al., 2020; Rothe et al., 2021) have shown that seq2seq PLMs generalize

Model	Aspect			General		
	R1	R2	RL	R1	R2	RL
SW-LOO	33.11	10.98	27.59	40.26	12.04	23.42
<i>w/o Prin. Sel.</i>	30.88	9.74	25.78	35.84	10.28	21.80

well even when finetuned on longer sequences not observed at pretraining phase. For OPOSUM+, we add linear learning rate warm-up in the first 250 steps. We set 300 as the token budget to truncate for aspect synthetic pairs construction. There are ~ 50K aspect and ~ 5K general synthetic pairs for SPACE, ~ 70K aspect and ~ 6K general synthetic pairs for OPOSUM+.

NLI-LOO For SPACE, we add linear learning rate warm-up to first 1000 steps, and 500 steps for OPOSUM+. We set 0.9 and 0.8 as the entailment probability threshold for SPACE and OPOSUM+ based on our preliminary experiments (lower thresholds make identified aspect-related sentences too noisy and further hurt downstream ROUGE scores). For summarization models, we set 500 as the token budget for both aspect and general synthetic pairs construction for both datasets and set 512 and 150 for maximum input and output token length of T5. There are ~ 36K aspect and ~ 6K general synthetic pairs for SPACE, ~ 70K aspect-specific and ~ 28K general synthetic pairs for OPOSUM+.

I Principle Strategy Effectiveness

Unlike OPOSUM+, there are 100 reviews for each hotel in SPACE evaluation sets. During inference, we cannot simply concatenate all filtered reviews as input since they cannot fit into T5 encoder. We adopt the principle strategy introduced in PEGASUS to select the most important filtered reviews and concatenate them as input for inference. In Table 8, we show the effectiveness of the principle strategy by comparing it with randomly selecting filtered reviews as input for inference.

J Similarity Metric

Different from using aspect entailment probability, we can also use sentence embeddings (Reimers and Gurevych, 2019) to calculate the cosine similarity between pseudo summary and aspect-related review sentences to construct synthetic input. Specifi-

Table 10. Pseudo summary granularity study for SW-LOO and NLI-LOO. Performances are reported on dev sets. Note that in our main experiments, we use sentence level pseudo summary for SPACE and review level for OPOSUM+

cally, we use `all-mpnet-base-v2`⁴, which is a sentence embedding model finetuned on a 1B sentence pairs dataset with a self-supervised contrastive learning objective. Results in Table 9 show that there is no significant difference except general summarization for SPACE where using sentence embeddings is much worse than using aspect entailment probability.

K Pseudo Summary Granularity

We use different pseudo-summary granularity for two datasets: sentence level for SPACE and review level for OPOSUM+. Sentence level directly uses sampled filtered aspect-related review portion (SW-LOO) or sampled aspect-related review sentence (NLI-LOO) as pseudo-summary, and review level uses the original review that contains the sampled pseudo-summary as pseudo-summary. Results in Table 10 show the importance of design choices for synthetic datasets construction.

L T5 Model Sizes

We use different T5 sizes including T5-SMALL, T5-BASE, and T5-LARGE as summarization models. Results in Table 11 show that larger summarization models do not necessarily guarantee better

Table 11. Using different T5 sizes as summarization model. Performances are reported on dev sets for both datasets.

downstream ROUGE scores and sometimes even hurt downstream performances. Our hypothesis is that larger models overfit synthetic datasets and thus perform slightly worse on downstream evaluation sets.

SW-LOO Summaries	
Building	The pool area was very nice and the room was clean and comfortable.
Cleanliness	Our room was very clean and comfortable.
Food	The breakfast was great and the staff was very helpful and helpful.
Location	The hotel is located right next to the main road and is a short walk from the beach.
Rooms	The room was very clean and comfortable.
Service	The staff was very friendly and helpful.
General	The pool was very nice and clean. We were able to walk to the beach and Duval st. from the hotel, so we had a nice view of the harbor and the sea! The breakfast was great and we stayed in October and were very pleased with the location - right next to all the restaurants ... The room was small but very small and very comfortable with clean and comfortable beds.

NLI-LOO Summaries	
Building	The hotel is a beautiful old hotel.
Cleanliness	The room was clean and the staff was very helpful.
Food	The breakfast was great and the view from the rooftop was amazing.
Location	The location is great - just a short walk to the Spanish Steps and the metro station.
Rooms	The rooms are small by European standards, but very clean and comfortable.
Service	the service was excellent and the staff was very friendly and helpful.
General	The hotel is very clean and the staff is friendly and helpful. The room was very small and clean, but the bathroom was a bit small compared to the other rooms in the UK. It is OK to stay here again. I would stay there again if you want to go back to Europe! The location is great - the city is just ten minutes walk from the metro station andn't be disappointed with the price of the rooms.

Table 12. *General* and *aspect-level* summaries for a hotel in SPACE dataset generated by SW-LOO and NLI-LOO

SW-LOO Summaries	
Sound Quality	I love this headset. It's a great product, but it doesn't have any issues with the sound! It is OK if you are looking for something that can be used for your Samsung TV?
Comfort	I love this headset. It's a great headset for the price, but it doesn't fit my ear perfectly!
Ease of Use	I bought this for my Motorola. It is very easy to set up, and the buttons are very comfortable!
General	I haven't found any way of getting that to be consistently good. The earpieces are not as sturdy or high quality in material as a Motorola, but the buttons are quite accessible and the sound varies based on how it's fitting into my ears! The set is very comfortable and has great range (roughly 100 feet) and connects easily to my iPhone with me - but it is not too big for me to wear if it doesn't fit my TV.

NLI-LOO Summaries	
Sound Quality	I love these headphones. They are very comfortable, sound quality is good and they're very good quality for the price!
Comfort	I love these headphones. They are very comfortable, and the sound quality is great! They're a little tight on my ears but if you aren't sure how long they will last you...
Ease of Use	I bought these for my Motoactv. They are very comfortable to wear, and they don't touch my neck at all!
General	I bought these headphones in a package for the Motoactv. They are very comfortable, the neck band doesn't touch my neck at all allowing for free movement! The sound is very good and fits comfortably in my ears... but it takes some time to find the right angel and fit it right in.

Table 13. *General* and *aspect-level* summaries for a product in "Bluetooth Headset" domain of OPOSUM+ dataset generated by SW-LOO and NLI-LOO.

Towards Fine-tuning Pre-trained Language Models with Integer Forward and Backward Propagation

Abstract

The large number of parameters of some prominent language models, such as BERT, makes their fine-tuning on downstream tasks computationally intensive and energy hungry. Previously researchers were focused on lower bit-width integer data types for the forward propagation of language models to save memory and computation. As for the backward propagation, however, only 16-bit floating-point data type has been used for the fine-tuning of BERT. In this work, we use integer arithmetic for both forward and back propagation in the fine-tuning of BERT. We study the effects of varying the integer bit-width on the model’s metric performance. Our integer fine-tuning uses integer arithmetic to perform forward propagation and gradient computation of linear, layer-norm, and embedding layers of BERT. We fine-tune BERT using our integer training method on SQuAD v1.1 and SQuAD v2., and GLUE benchmark. We demonstrate that metric performance of fine-tuning 16-bit integer BERT matches both 16-bit and 32-bit floating-point baselines. Furthermore, using the faster and more memory efficient 8-bit integer data type, integer fine-tuning of BERT loses an average of 3.1 points compared to the FP32 baseline.

1 Introduction

Over the past few years, integration of attention mechanisms into deep learning models led to the creation of transformer based models. BERT (Devlin et al., 2018) is a prominent transformer based language model which has shown state-of-the-art performance in natural language processing (NLP) tasks.

BERT requires high memory and computational resources due to its large number of parameters. Having large number of parameters incurs challenges for inference, training, and also fine-tuning

^{*}Equal contribution.

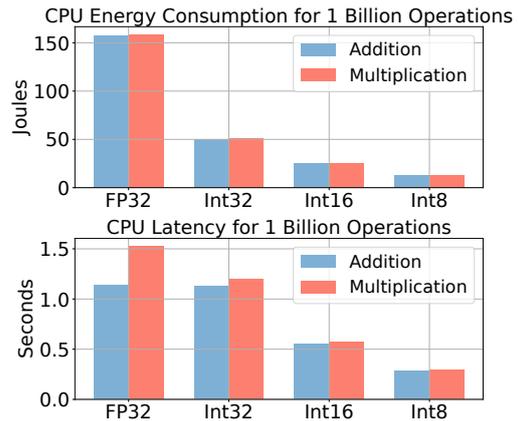

Figure 1: Energy consumption and latency of 1 billion operations using various data types, measured on an Intel[®] Xeon[®] CPU E5-2698 v4.

of this model. Moreover, the training phase i.e. pre-training and fine-tuning, involves more operations compared to the inference. More specifically, the training phase includes gradient computation and weight update that make the training more computationally intensive.

One method of reducing the computational complexity of deep learning models is to represent their parameters and activations in low bit-width data types. This reduces the memory footprint of the model and enables more efficient computations. For instance, Figure 1 shows that low-bit integer data types have higher throughput and better energy consumption compared to floating-point.

Previous research attempts at integer quantization of transformer based language models were only focused on forward propagation and the gradient computation were kept in 32-bit floating-point data type (FP32) (Bhandare et al., 2019; Kim et al., 2021; Zafir et al., 2019).

Furthermore, earlier efforts for using low bit-width data types for gradient computation of transformer based language models has only been limited to 16-bit floating-point (FP16). This method,

known as mixed precision training (Micikevicius et al., 2017), uses FP16 data type to represent weights, activations and gradients while using FP32 for the weight update.

Here we present an integer fine-tuning method for transformer based language models such as BERT. Unlike previous works, we use integer data types for both forward propagation and gradient computation during the fine-tuning of BERT. Moreover, we use the dynamic fixed-point format to represent floating-point numbers as integers.

Our integer mapping strategy can be used alongside floating-point numbers in fine-tuning and inference similar to mixed precision training. In our proposed strategy, the arithmetic of all the compute intensive layers for both forward and back propagation are performed using integer arithmetic while other components of the model, such as nonlinear functions and the weight updates are kept in FP32. We use integer versions of compute intensive layers such as linear, normalization (layer-norm), and embedding layers.

We study the effect of various bit-widths of the integer input activation and show that increasing the bit-width of the fixed-point mapping function improves the convergence behaviour of the model. This enables us to find the minimum bit-width required for integer fine-tuning of BERT.

Our fine-tuning experiments show that 16-bit integer BERT is able to match the metric performance of mixed precision FP16 and FP32 methods.

We also further reduce the bit-widths and show that integer fine-tuning of BERT with 8-bit integer weights and 12-bit integer activations has a score drop of 3.1 compared to the original performance.

To summarize, this paper makes the following contributions:

- Integer fine-tuning of transformer based language models that uses integer arithmetic for both the forward and back propagation of compute intensive layers such as linear, layer-norm, and embedding. To the best of our knowledge, this is the first time that integer data type is used for back propagation of pre-trained language models.
- Analyzing the effect of changing the bit-width of dynamic fixed-point format on the convergence of fine-tuning. **Remark 3** discusses that the convergence behaviour of our integer fine-tuning is directly related to the variance of dy-

namic fixed-point mapping and is controlled by the bit-width.

- We show that fine-tuning BERT using 16-bit integer numbers is able to outperform the FP16 mixed precision fine-tuning method.

The rest of this paper is structured as follows. Section 2 briefly discusses previous works in which low bit-width data types are used for inference and training of deep learning models. Section 3 provides details of our integer fine-tuning method, including the representation mapping functions and integer-only layers. The convergence behaviour of the dynamic fixed-point mapping is studied in Section 4 by providing empirical observations and theoretical analysis. The fine-tuning experiments on various integer and floating-point setups are presented in Section 5. Finally, Section 6 concludes the ideas proposed in this work.

2 Related Works

In this section we discuss the previous works that use low bit-width data types in transformer based language models. These works could be categorized into two major groups. In the first group, called low-bit inference, the low bit-width data types are used only in the forward propagation phase to improve computational complexity and reduce memory usage during the inference. In the second group, also known as low-bit training, lower bit-width data types are used for both the forward and back propagation phases.

2.1 Low-bit Inference

Previous research on low-bit inference quantize the model parameters and activations to speed up the forward propagation. This category is itself divided into quantization-aware training (QAT) and post-training quantization (PTQ) methods.

In QAT, quantization is performed during training, allowing the model parameters to adapt to the quantization noise. QAT relies on high-precision FP32 gradients to train the model and adapt it to the quantization noise.

For instance, (Zafrir et al., 2019) proposed Q8BERT which quantizes the inference computations of all linear and embedding layers of BERT to 8-bit integers and updates the quantization scale with a moving average. Similarly, (Shen et al., 2020) suggested Q-BERT which requires the computation of hessian matrix for each group of param-

eters to be used in a mixed precision fine-tuning with different bit-widths. (Kim et al., 2021) proposed I-BERT that uses a uniform quantization scheme to quantize input activations and weights of various components of BERT. In I-BERT, the quantization scaling factors are computed based on the distribution of the training data.

Unlike QAT that performs quantization of inference operations during training, Post-Training Quantization (PTQ) methods apply quantization to the parameters when the training is completed. Thus, they require extra calibration or parameter tuning to adapt the model to the quantized parameters.

For instance, (Bhandare et al., 2019) quantized the matrix multiplications of the original transformer architecture from (Vaswani et al., 2017) to 8-bit integer data type. Moreover, the quantization is done only for the forward propagation and requires extra calibration using validation data to tune the boundaries of the quantization function. (Zadeh et al., 2020) introduced GOBO which compresses the fine-tuned weights of BERT by grouping them into two categories of Gaussian and outlier. The outlier weights are kept in FP32, while the Gaussian weights are quantized to lower bits. For lower bit-width regimes, TernaryBERT and BinaryBERT are able to push the quantization to 2 and 1 bits respectively (Zhang et al., 2020a; Bai et al., 2020). They both rely on methods such as data augmentation and knowledge distillation to adapt the model to the low-bit weights.

2.2 Low-bit Training

Research on low-bit training try to perform both the forward propagation and gradient computation in low-bit arithmetic. Using low precision number formats for gradients reduces the model’s ability to adapt the parameters to the quantization noise, but increases the throughput and reduces the memory footprint.

FP16 mixed precision training (Micikevicius et al., 2017) is a common method currently for low-bit fine-tuning of transformer based language models. This method uses FP16 data type in both forward propagation and gradient computation, while using FP32 for the weight update. Unlike FP16 mixed precision training, our work uses dynamic fixed-point format which allows for multiple choices of bit-width for the data type. We show that our 16-bit integer fine-tuning method outperforms

FP16 mixed precision training in terms of metric score.

Using integer data types in the training of deep learning models has been previously studied for the computer vision tasks. For instance, (Zhang et al., 2020b) quantized the input activations, gradients and parameters of the linear layers for various convolutional neural networks (CNN). Similarly, (Zhao et al., 2021) adapted the quantization parameters by detecting the distribution of the gradients in the channel dimension. In both these works the quantization error is measured during training and is used to adjust the quantization scale, whereas our method does not require any information about distribution of data or gradients. (Zhu et al., 2020) applied a quantization scheme to train CNN architectures with “direction sensitive gradient clipping” and learning rate scaling to control the quantization error of gradients. Our integer fine-tuning method does not require gradient clipping and can follow the same loss trajectory as the floating-point baseline with the same hyperparameters. Our proposed method improves upon (Ghaffari et al., 2022) which uses dynamic fixed-point format for integer training of deep learning models. Unlike (Ghaffari et al., 2022), our work studies various bit-widths for both weights and activations to find the minimum bit-width required for fine-tuning BERT. Furthermore, we study integer training method on large language models where low-bit quantization is known to be a challenging task (Bondarenko et al., 2021). To the best of our knowledge, this is the first time where integer numbers are used for the back propagation of transformer based language models.

3 Methodology

3.1 Representation Mapping

We use the dynamic fixed-point format (Williamson, 1991) to map the floating-point numbers to integer data type. This format, also known as block floating-point, maps floating-point numbers to blocks of integer numbers, with each block having its unique scale. For more information on various number formats refer to Appendix A.

We use a linear fixed-point mapping function to map floating-point numbers to integer numbers. The linear fixed-point mapping converts a floating-point tensor \mathbf{F} to a tensor of integers and a single scale factor.

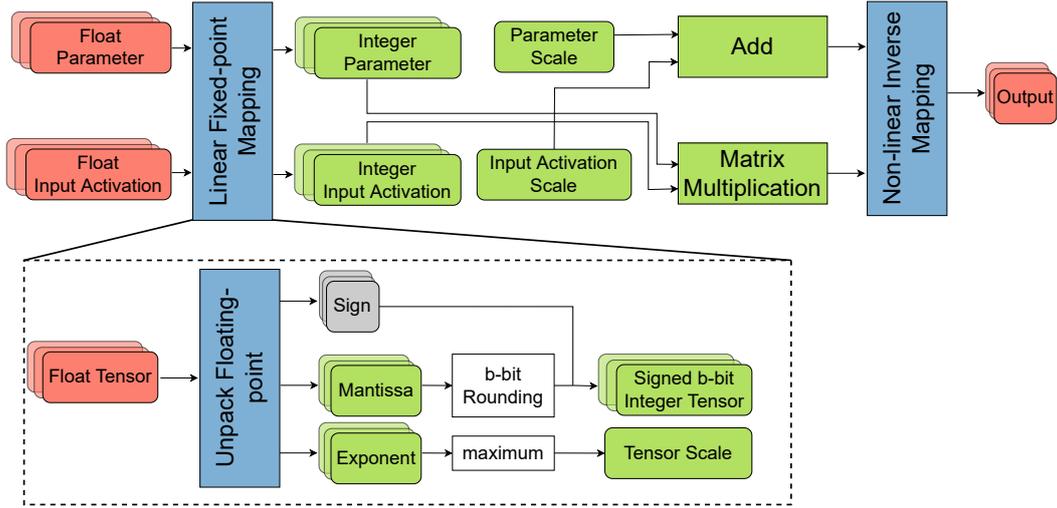

Figure 2: Forward propagation operations in an integer-only linear layer. Green boxes use integer arithmetic and red boxes use floating-point data type. Here, the integer output is generated using an integer matrix multiplication and the output scale is generated by a single add operation. The bottom panel shows the linear fixed-point mapping for the input tensors, that are the input activation and the parameter tensor in this figure.

The integers are obtained by rounding the floating-point mantissas. The scale is the maximum of the floating-point exponents of \mathbf{F} . The bottom section of Figure 2 shows the internal operations of the linear fixed-point mapping.

To map the fixed-point numbers to floating-point, a non-linear inverse mapping function is used. The inverse mapping converts integer numbers into normalized floating-point mantissas and packs each integer with its corresponding scale into a floating-point number.

Details of the representation mapping functions are provided in (Ghaffari et al., 2022). Our methodology differs in that it includes various bit-widths for both weights and activations for the fine-tuning of transformer based language models. We exploit this mapping strategy to explore various bit-widths for weights and activations in order to find the minimum bit-width for fine-tuning the model.

3.2 Integer Fine-tuning

Our method uses integer arithmetic for weights, activations and gradients, while the weight update is kept in FP32. Moreover, our proposed BERT setups use integer-only versions for all the linear, layer-norm and embedding layers in which internal operations are performed with integer arithmetic.

3.2.1 Linear Layer

Figure 2 depicts a high-level view of forward propagation operations of the integer-only linear layer. All the parameters and activations of the layer are

first mapped to dynamic fixed-point using the linear fixed-point mapping function. In the case of linear layer, the integer parameters and input activations are then sent to an integer matrix multiplication function to generate the integer output. If needed, the integer output could be mapped back to floating-point to be used by other layers of the model using the non-linear inverse mapping.

For back propagation, the gradients of the parameters and input activations are also computed using integer arithmetic. Using integer matrix multiplication, the output gradients are multiplied by input activations and parameters to compute the gradients. Since the weight update is performed in FP32, the integer gradients and their scales are passed to the non-linear inverse mapping to be mapped to FP32.

3.2.2 Layer-norm

The layer normalization or layer-norm performs the following operation on its input X (Ba et al., 2016):

$$\gamma \frac{X - \mu}{\sqrt{\sigma^2 + \epsilon}} + \beta. \quad (1)$$

Here γ and β are the weight and bias parameters, and σ and μ are input standard deviation and mean respectively. For the forward propagation of integer layer-norm we map X to dynamic fixed-point format and compute σ and μ using integer arithmetic. Note that multiplication to γ and addition with β are also performed using integer arithmetic.

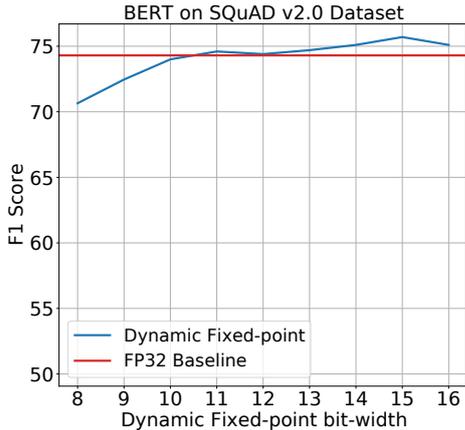

Figure 3: F1 score of fine-tuning BERT using b -bit gradients, and activations on SQuAD v2.0 dataset. For the 8-bit and 9-bit fixed-point bit-widths, we use 12-bit input activations.

Moreover, the back propagation also uses integer arithmetic to compute the gradients for the input, γ , and β .

3.2.3 Embedding Layer

The embedding layer is a lookup table that stores embeddings. The layer takes a list of indices as input and returns the list of corresponding embeddings for each index. The integer embedding layer, handles integer embeddings and needs less memory footprint to store these values. For the back propagation, the embedding layer applies the output integer gradients directly to each corresponding row of the lookup table.

4 Convergence Behaviour of Dynamic Fixed Point Mapping

4.1 Empirical Observations

Figure 2 shows that the bit-width, b , is controlled by adjusting the number of rounded bits in the rounding function. Here we study the effect of changing the integer bit-width on the metric performance of the model.

The motivation of varying the bit-width of the dynamic fixed-point is to control the variance induced by the linear fixed-point mapping. Our experiments show that using dynamic fixed-point with a bit-width of 10 achieves the same performance as the FP32 fine-tuning method. Figure 3 demonstrates the F1 score of fine-tuning BERT on SQuAD v2.0 dataset against the fixed-point bit-width. Note that the fixed-point arithmetic with a bit-width higher

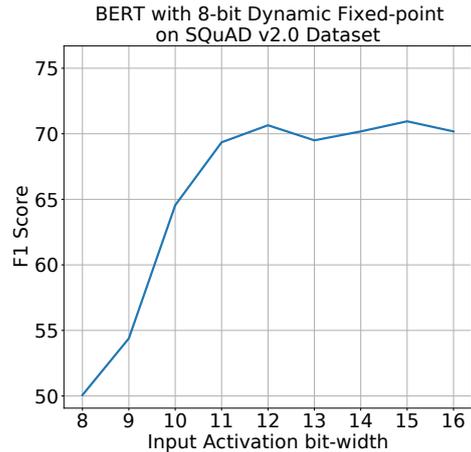

Figure 4: F1 score of fine-tuning BERT using 8-bit weights and gradients, with varying BERT input activation bit-width on SQuAD v2.0 dataset. Note that **Remark 3** justifies this experiment using the variance of b -bit dynamic fixed-point mapping.

than 10 bits is able to closely match the F1 score of the FP32 baseline, that is indicated by the red line in the figure. Also note that in our experimental setup for the 8-bit dynamic fixed-point format, we use 12-bit input activations to close the F1 score gap with the FP32 baseline. The reason for using higher bit-width input activations is that we observed 8-bit activation dramatically reduces the F1 score. Figure 4 shows the effect of input activation bit-width on the F1 score when the weights are 8-bit integers. Changing the bit-width of the input activation from 8 bits to 12 bits significantly increases the F1 score. Increasing the input activation bit-width beyond 12 bits has a negligible effect on the F1 score, confirming that 12 bits is the minimum required bit-width of the input activations for this application with 8-bit integer weights.

4.2 Theoretical Analysis

Here, we study the effect of varying dynamic fixed-point mapping bit-width on the stochastic gradient descent method. The goal is to show the relation of weight and activation bit-widths on the convergence of integer training. Let us consider the following simplified weight update equation

$$w_{k+1} = w_k + \bar{\eta} \hat{g}(w_k, \xi_k), \quad (2)$$

where $\hat{g}(w_k, \xi_k)$ is the dynamic fixed-point gradient and $\bar{\eta}$ is the learning rate during the fine-tuning phase. Furthermore, we also consider the following common assumptions in sequel.

Assumption 1 (Lipschitz-continuity). The loss function $\mathcal{L}(w)$ is continuously differentiable and its gradients satisfies the following inequality where $L > 0$ is the Lipschitz constant

$$\begin{aligned} \mathcal{L}(w) &\leq \mathcal{L}(\bar{w}) + \nabla \mathcal{L}(\bar{w})^\top (w - \bar{w}) \\ &\quad + \frac{1}{2} L \|w - \bar{w}\|_2^2; \\ &\quad \forall w, \bar{w} \in \mathbb{R}^d. \end{aligned} \quad (3)$$

Assumption 2. (i) $\mathcal{L}(w_k)$ is bounded. (ii) b -bit dynamic fixed-point gradients $\hat{g}(w_k, \xi_k)$ is an unbiased estimator of the true gradients of the loss function $\nabla \mathcal{L}(w_k)^\top \mathbb{E}_{\xi_k} \{\hat{g}(w_k, \xi_k)\} = \|\nabla \mathcal{L}(w_k)\|_2^2 = \|\mathbb{E}_{\xi_k} \{\hat{g}(w_k, \xi_k)\}\|_2^2$, and (iii) with the b -bit dynamic fixed-point gradients i.e. $\hat{g}(w_k, \xi_k)$, there exist scalars $M \geq 0$, $M_V \geq 0$, $M^q \geq 0$ and $M_V^q \geq 0$ such that for all iterations of SGD

$$\begin{aligned} \mathbb{V}_{\xi_k} \{\hat{g}(w_k, \xi_k)\} \\ \leq M + M^q + (M_V + M_V^q) \|\nabla \mathcal{L}(w_k)\|_2^2. \end{aligned}$$

Where M^q and M_V^q denote the added variance of b -bit dynamic fixed-point mapping on the true gradient variance. Also note that in order for **Assumption 2** (i) to hold true, we use stochastic rounding for back propagation.

Suppose **Assumption 1** and **Assumption 2** are true, then inequality (4) follows from (Ghaffari et al., 2022, Remark 2)

$$\begin{aligned} \mathbb{E}_{\xi_k} \{\mathcal{L}(w_{k+1})\} - \mathcal{L}(w_k) \\ \leq -(1 - \frac{1}{2} \bar{\eta} L (M_G + M_G^q)) \bar{\eta} \|\nabla \mathcal{L}(w_k)\|_2^2 \\ \quad + \frac{1}{2} \bar{\eta}^2 L (M + M^q), \end{aligned}$$

$$\text{with } M_G := 1 + M_V \text{ and } M_G^q := 1 + M_V^q, \quad (4)$$

which shows the effect of added variance of fixed point mapping, i.e. M_V^q and M^q , on each step of the optimizer.

Remark 1. In inequality (4), the first term, $-(1 - \frac{1}{2} \bar{\eta} L (M_G + M_G^q)) \bar{\eta} \|\nabla \mathcal{L}(w_k)\|_2^2$ contribute to decreasing the loss \mathcal{L} while the second term, $\frac{1}{2} \bar{\eta}^2 L (M + M^q)$, prevents it. Also note that when M^q and M_G^q are increased, they negatively affect the descent of the loss \mathcal{L} . This means for a good convergence behaviour, representation mapping

variance bounds, i.e. M^q and M_G^q , must be controlled.

Remark 2. For dynamic fixed-point mapping with b -bit integers, the representation mapping variance bounds i.e. M^q and M_G^q , are closely related to the bit-width b . Here, we study these two constants for a linear layer. Let us denote $\hat{\mathbf{A}}$ as the b -bit dynamic fixed-point version of tensor \mathbf{A} and \hat{a}_{ij} as its ij^{th} element. We can relate \hat{a}_{ij} and a_{ij} with an error term δ such as $\hat{a}_{ij} = a_{ij} + \delta_{ij}^{\mathbf{A}}$. For a linear layer $\hat{\mathbf{Y}} = \hat{\mathbf{X}} \hat{\mathbf{W}}$, the computation of the b -bit dynamic fixed-point gradients in the back propagation is

$$\hat{\mathbf{C}} = \frac{\partial \hat{\mathbf{L}}}{\partial \hat{\mathbf{W}}} = \frac{\partial \hat{\mathbf{Y}}}{\partial \hat{\mathbf{W}}} \frac{\partial \hat{\mathbf{L}}}{\partial \hat{\mathbf{Y}}} = \hat{\mathbf{X}}^\top \frac{\partial \hat{\mathbf{L}}}{\partial \hat{\mathbf{Y}}} = \hat{\mathbf{X}}^\top \hat{\mathbf{G}}. \quad (5)$$

It is of interest to find the relation between $\hat{\mathbf{C}} = \hat{\mathbf{X}}^\top \hat{\mathbf{G}}$ in the integer back propagation and the true gradients $\mathbf{C} = \mathbf{X}^\top \mathbf{G}$. We can derive the variance for each element \hat{c}_{ij} by expanding the error terms δ ,

$$\begin{aligned} \mathbb{V}\{\hat{c}_{ij}\} &= \mathbb{V} \left\{ \sum_{n=1}^N \hat{x}_{ni} \hat{g}_{nj} \right\} \\ &= \mathbb{V} \left\{ \sum_{n=1}^N (x_{ni} + \delta_{ni}^{\mathbf{X}}) (g_{nj} + \delta_{nj}^{\mathbf{G}}) \right\} \\ &\leq \mathbb{V} \left\{ \sum_{n=1}^K x_{ni} g_{nj} \right\} \\ &\quad + \sigma_{\mathbf{G}}^2 \mathbb{E}\{\|\mathbf{X}_i^\top\|_2^2\} + \sigma_{\mathbf{X}}^2 \mathbb{E}\{\|\mathbf{G}_{.j}\|_2^2\} \\ &\quad + N \sigma_{\mathbf{X}}^2 \sigma_{\mathbf{G}}^2 \\ &= \mathbb{V}\{c_{ij}\} + \sigma_{\mathbf{G}}^2 \mathbb{E}\{\|\mathbf{X}_i^\top\|_2^2\} \\ &\quad + \sigma_{\mathbf{X}}^2 \mathbb{E}\{\|\mathbf{G}_{.j}\|_2^2\} + N \sigma_{\mathbf{X}}^2 \sigma_{\mathbf{G}}^2. \end{aligned} \quad (6)$$

In inequality (6), $\sigma_{\mathbf{G}}^2 = \max_{i,j} (\mathbb{V}\{\delta_{i,j}^{\mathbf{G}}\})$ and $\sigma_{\mathbf{X}}^2 = \max_{i,j} (\mathbb{V}\{\delta_{i,j}^{\mathbf{X}}\})$. Also note $\|\mathbf{X}_i^\top\|_2^2 = \sum_j x_{ji}^2$ denotes the squared L-2 norm of the i^{th} row of \mathbf{X}^\top and $\|\mathbf{G}_{.j}\|_2^2 = \sum_i g_{ij}^2$ denotes the squared L-2 norm of the j^{th} column of \mathbf{G} . Furthermore, by defining

$$\begin{cases} M^q := \sigma_{\mathbf{G}}^2 (\mathbb{E}\{\|\mathbf{X}_i^\top\|_2^2\} + N \sigma_{\mathbf{X}}^2) \\ M_V^q := \sigma_{\mathbf{X}}^2 \end{cases} \quad (7)$$

Equation (7) shows that M^q depends on variance of dynamic fixed-point mapping for input activations and gradients while M_V^q only depends on b -bit dynamic fixed-point gradients variance.

	QQP	QNLI	MNLI	SST-2	STSB	RTE	MRPC	CoLA	Average
FP32	91.0/88.0	91.1	84.2	92.5	88.3	63.8	82.5/87.8	57.2	82.6
FP16 AMP	90.9/87.9	91.2	84.1	92.4	88.3	64	82.1/87.7	57.5	82.6
16-bit integer	91.0/88.0	91.2	84.2	92.5	88.3	64.5	82.3/87.6	57.7	82.7
12-bit integer	90.9/88.0	91.2	84.0	92.6	87.9	63.5	81.3/87.4	56.7	82.4
10-bit integer	90.8/87.8	91.0	84.0	92.5	87.5	62.7	78.4/85.8	57.6	81.8
8-bit integer	90.1/86.8	90.8	83.7	92.3	87	61.8	76.8/84.7	55.0	80.9

Table 1: Metric performance of integer fine-tuning of BERT on selected GLUE tasks. The reported metric for QQP and MRPC is accuracy and F1 score, for QNLI, MNLI, RTE, and SST-2 is accuracy, for STSB is the Pearson-Spearman correlation, and for CoLA is the Matthews correlation.

Proposition 1. For dynamic fixed-point representation of tensor $\hat{\mathbf{A}}$ with b -bit integers, the variance of error for element i satisfies the following inequality

$$\mathbb{V}\{\delta_i^{\mathbf{A}}\} \leq 2^{2(e_{\text{scale}_{\mathbf{A}}} - b + 2)}. \quad (8)$$

Proof. Using dynamic fixed-point mapping to b -bit integers, the error $\delta_i^{\mathbf{A}}$ satisfies the following bound

$$\begin{aligned} -2^{e_{\text{scale}_{\mathbf{A}}}} \underbrace{(0.000001)_2}_{b-1} \leq \delta_i^{\mathbf{A}} \leq 2^{e_{\text{scale}_{\mathbf{A}}}} \underbrace{(0.000001)_2}_{b-1} \\ -2^{e_{\text{scale}_{\mathbf{A}}} - b + 2} \leq \delta_i^{\mathbf{A}} \leq 2^{e_{\text{scale}_{\mathbf{A}}} - b + 2}. \end{aligned} \quad (9)$$

Thus, the inequality (8) is obtained by using Popoviciu’s inequality on variances

$$\begin{aligned} \mathbb{V}\{\delta_i^{\mathbf{A}}\} &\leq \frac{1}{4} (2^{e_{\text{scale}_{\mathbf{A}}} - b + 2} - (-2^{e_{\text{scale}_{\mathbf{A}}} - b + 2}))^2 \\ &\leq 2^{2(e_{\text{scale}_{\mathbf{A}}} - b + 2)}. \end{aligned} \quad (10)$$

Remark 3. Inequality (8) shows that increasing bit-width b in dynamic fixed-point mapping reduces the variance of the error. This confirms our experimental results on SQuAD v2.0 dataset that for $b > 10$, F1 score can match FP32 baseline, see Figure 3. Also note in equation (7), both M^q and M_V^q depend on b -bit dynamic fixed-point mapping variance of input activation $\sigma_{\mathbf{X}}^2$. Hence, increasing b for input activations while keeping weights in 8-bit format must improve the convergence behaviour. This phenomenon is also confirmed by our experimental results on SQuAD v2.0 dataset demonstrated in Figure 4.

5 Experimental Results

5.1 Experimental Setup

We fine-tuned BERT base on a series of downstream tasks to compare the performance of our integer fine-tuning method with FP16 and FP32 fine-tuning methods. FP16 AMP setup uses NVIDIA’s

	SQuAD v1.1	SQuAD v2
FP32	80.5/88.0	70.6/73.8
FP16 AMP	79.9/87.6	70.6/73.9
16-bit integer	80.7/88.0	70.6/73.9
12-bit integer	79.8/87.6	70.5/73.8
10-bit integer	78.4/86.6	69.8/73.2
8-bit integer	75.6/84.5	65.5/69.2

Table 2: Metric performance of fine-tuning BERT on SQuAD v1.1 and v2.0 datasets. For both datasets the exact match metrics and F1 scores are reported.

automatic mixed precision¹ and the FP32 baseline is the default implementation from Pytorch.

The model is fine-tuned on selected tasks of GLUE benchmark (Wang et al., 2018), along with the Stanford Question Answering Datasets, i.e. SQuAD v1.1 and SQuAD v2.0 (Rajpurkar et al., 2016).

All the fine-tuning setups use the same hyperparameters and are fine-tuned for the same number of epochs. Each reported metric is the average of five runs with five different random seeds to mitigate the effects of random variation of the results. The fine-tuning experiments are performed based on the fine-tuning scripts of the Hugging Face library (Wolf et al., 2019). For GLUE experiments the fine-tuning is performed for 5 epochs and the learning rate is set to 2×10^{-5} . Also, the per-device fine-tuning batch-size is set to 32. Fine-tuning BERT on SQuAD datasets is done for 2 epochs and the learning rate is 5×10^{-5} and the per-device fine-tuning batch-size is 12. All experiments are run on eight NVIDIA V100 GPUs with 32 gigabytes of VRAM.

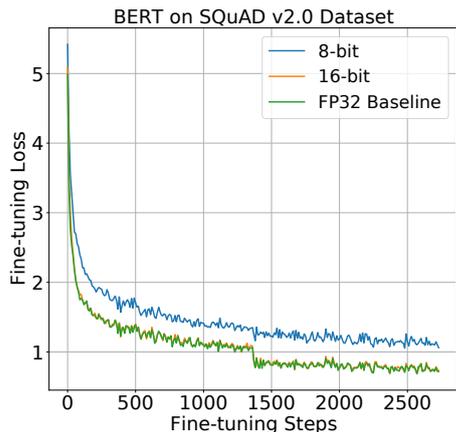

Figure 5: Integer fine-tuning loss trajectory of BERT on SQuAD v2.0 dataset for 2750 iterations.

5.2 Results

The results of fine-tuning BERT base on GLUE benchmark and SQuAD datasets are presented in Table 1 and Table 2 respectively. GLUE benchmark contains a series of downstream tasks, designed to evaluate a diverse set of language understanding abilities of NLP models. SQuAD datasets contain a series of text passages accompanied by a question and the task is to predict the span of the answer in the passage. Using 16-bit integer data type, BERT is able to either match or outperform the FP32 performance for all tasks. The 16-bit integer BERT also shows similar or better performance compared to the FP16 mixed precision fine-tuning method. Further reducing the integer bit-width to 8, fine-tuning BERT exhibits an average of 1.7 point drop on GLUE benchmark and 4.5 point drop for SQuAD datasets. Moreover, our experiments show that using 10-bit and 12-bit integers has average score drops of 0.8 and 0.3 points for GLUE tasks, and 0.8 and 0.2 point for SQuAD datasets respectively.

5.3 Loss Trajectory

Figure 5 shows the loss trajectory of integer fine-tuning BERT on SQuAD v2.0 dataset using 16-bit and 8-bit integers, along with FP32 method. The fine-tuning loss trajectory of BERT using 16-bit integer closely follows the FP32 loss trajectory. On the other hand, when fine-tuning with 8-bit integer parameters and 12-bit integer input activations, the loss trajectory is slightly shifted, but follows the same trend of its FP32 counterpart.

6 Conclusion

We proposed an integer fine-tuning method for transformer based language models using dynamic fixed-point format. We used dynamic fixed-point data type to represent parameters, input activations and gradients in integer values. As a result, our fine-tuning method uses integer arithmetic for the forward and back propagation of compute intensive layers such as linear, layer-norm and embedding layers of BERT model. Furthermore, we studied that increasing the bit-width of the dynamic fixed-point format reduces the variance of the mapping function and thus, improves the convergence of our integer fine-tuning method. We conduct fine-tuning experiments on GLUE benchmark and SQuAD datasets to compare the metric performance of our integer BERT with FP16 mixed precision and FP32 fine-tuning methods. Our experiments show that the 16-bit integer fine-tuning is able to achieve the same metric performance as the FP16 mixed precision fine-tuning method. In addition, fine-tuning BERT with lower bit-width data types, i.e. 8-bit integer, maintains an average drop of metric score within 3.1 points of the FP16 setup.

Limitations

Although our integer fine-tuning method uses integer numbers for compute intensive layers of BERT, integer support for non-linear layers of BERT, e.g. softmax and GELU activation, are left for future work.

We have shown in Figure 1 that the integer data types are faster for the general case. However, a direct comparison of the time and memory cost of our integer fine-tuning method with the FP16 and FP32 methods is left for future works due to lack of access to a proper hardware with integer tensor core support.

Despite the similarities between fine-tuning and pre-training phases, they differ in key aspects of training such as dataset size and number of epochs. The challenges of using integer arithmetic in the pre-training phase will be studied in the future work.

A Data Types

In this section we provide a brief overview of various data types mentioned in this work.

Floating-point data type is used to represent decimal fractional numbers. A binary floating-point number has three components of sign (s), mantissa (m), and exponent (e). Using these components, floating-point number x is shown as:

$$x = (-1)^s \times m \times 2^{e-t}$$

where t is the precision and $0 \leq m \leq 2^t - 1$. Another way of representing floating-point numbers is as

$$x = (-1)^s \times 2^e \left(\frac{d_1}{2} + \frac{d_1}{4} + \dots + \frac{d_t}{2^t} \right)$$

where d_i are binary digits of m . For FP32, exponent and mantissa are 8 and 23 bit integer numbers.

Fixed-point is another data type for representing fractional numbers. Unlike floating-point numbers where each mantissa is scaled using its respective exponent, fixed-point uses a single scale factor for all the numbers.

We use the dynamic fixed-point data type in our integer fine-tuning method. Also known as block floating-point, this format uses a different scale for each block of numbers to allow for more flexibility.

Data Augmentation for Radiology Report Simplification

Abstract

This work considers the development of a text simplification model to help patients better understand their radiology reports. This paper proposes a data augmentation approach to address the data scarcity issue caused by the high cost of manual simplification. It prompts a large foundational pre-trained language model to generate simplifications of unlabeled radiology sentences. In addition, it uses paraphrasing of labeled radiology sentences. Experimental results show that the proposed data augmentation approach enables the training of a significantly more accurate simplification model than the baselines.

1 Introduction

Radiology reports are unstructured documents written by radiologists to communicate imaging findings to another physician or a qualified medical professional (Goldberg-Stein and Chernyak, 2019). Radiology reports have been increasingly available to patients through portals (Lourenco and Baird, 2020), which has been generally welcomed by patients (Cooper et al., 2020). However, the health literacy of most patients is insufficient to fully comprehend radiology reports (Lalor et al., 2018) because such reports rely on complex medical jargon and use explanations that imply highly specialized medical knowledge (Delbanco et al., 2012). Several studies even identified adverse effects of sharing radiology reports with patients, including dissatisfaction with care (Rosenkrantz and Flagg, 2015) and undue anxiety and stress (Arora, 2013).

There is an increasing need for patient-friendly radiology reporting that can communicate results clearly and be understandable by a diverse patient population. However, asking a radiologist to supplement a traditional report with a patient-friendly summary would negatively impact their cognitive load and productivity. This problem motivated recent research on the automatic simplification of

health records. The proposed approaches include both lexical simplification that paraphrases text (Chen et al., 2018; Biran et al., 2011; Weng et al., 2018) and semantic simplification that seeks to simplify grammatically complex text (Shardlow, 2014; Leroy et al., 2016) which recently included deep learning approaches (Lewis et al., 2019; Zhang et al., 2020). However, training deep learning models for medical text simplification requires the collection of costly labeled data.

To alleviate the data scarcity issue in simplifying health reports, particularly radiology reports, this paper proposes a novel approach for data augmentation. It augments manually-created labeled data with simplifications generated by a large pre-trained language model such as GPT-3 (Brown et al., 2020). To improve the quality of data augmentation, the approach develops a separate deep learning model that evaluates the quality of generated simplifications. Furthermore, the approach also provides data augmentation through paraphrasing the originally labeled radiology sentences.

The proposed data augmentation approach is experimentally evaluated on a unique corpus of manually generated labeled data for radiology report simplification. The evaluation includes both automatic measures and human evaluation.

Our research claims are: 1) Our augmentation methods enable training of a more accurate model than baselines in solving low-resource radiology sentence simplification problems. 2) We address the challenge of selecting qualified augmentations for radiology sentence simplification. 3) We create unique real data containing expert-annotated simplifications for radiology reports' sentences regarding liver conditions.

2 Related Work

Text Simplification. In text simplification, the output text is a linguistically simplified version of the input text (Adduru et al., 2018). Previous work on

simplification includes lexical and semantic simplification (Alva-Manchego et al., 2020).

Lexical simplification by lexical substitution refers to replacing complex words or phrases with simpler synonyms (Oh et al., 2016; Zeng and Tse, 2006) and has found some practical success (Cook et al., 2017). In the health domain, lexical text simplification often relies on medical dictionaries (UMLS (Bodenreider, 2004), MeSH (Lipscomb, 2000), etc.). Lexical simplification approaches also include rule-based methods (Chen et al., 2018; Biran et al., 2011) and deep learning (Weng et al., 2018, 2019).

Semantic simplifications seek to simplify grammatically complex text by splitting long sentences into shorter ones, changing passive voice to active, resolving ambiguities and anaphora (Shardlow, 2014), splitting complex noun phrases (Leroy et al., 2016), or reducing morphological negations (Mukherjee et al., 2017). Recently, transformer encoder-decoder based pre-trained seq-to-seq models (Lewis et al., 2019; Zhang et al., 2020) were proved to be robust in solving text simplification problems. However, fine-tuning pre-trained models require large quantities of labeled data, which are costly and difficult to obtain in the health domain.

Previous research has explored different methods for text simplification in low-resource domains. To address data scarcity recent studies include unsupervised methods (Surya et al., 2018; Sakakini et al., 2020; Enayati et al., 2021) and reinforcement learning (Laban et al., 2021).

Data Augmentation is a method that automatically generates labeled data to enhance manually labeled data (Liu et al., 2020). One approach is to use paraphrasing to create different variants of the original or simplified sentences (Wei and Zou, 2019). Another approach is to use pre-trained language models to generate labeled data (Bayer et al., 2021). LAMBADA (Anaby-Tavor et al., 2020) augments data for text classification tasks by encoding labels in the input. Similarly, PromptDA (Wang et al., 2022) use language models to augment data for NLU tasks. Back-translation (Edunov et al., 2018) is used to generate different variants of the input text.

There are several public benchmark data sets that are related to our paper. There are paragraph level medical text simplifications (Devaraj et al., 2021) focusing on medical paper abstracts. There is a corpus parsed aligned sentences from Wikipedia

and Simple English Wikipedia¹ (Pattisapu et al., 2020; Van den Bercken et al., 2019) that has been a popular text simplification benchmark. However, none of these data sets have properties similar to the radiology text simplification task.

3 Problem Definition

Let us assume we are given a labeled corpus for text simplification $\mathbf{D}_{Lab} = \{(\mathbf{X}_1, \mathbf{Y}_1), (\mathbf{X}_2, \mathbf{Y}_2), \dots, (\mathbf{X}_n, \mathbf{Y}_n)\}$, where \mathbf{X}_i is the i^{th} original document, \mathbf{Y}_i is its simplification provided by a human expert, and n is the number of labeled documents. Let us also assume we are given an unlabeled corpus of documents $\mathbf{D}_{Unl} = \{\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_m\}$, where m is the number of unlabeled documents. The objective of data augmentation is to automatically create a synthetic set $\mathbf{D}_{Syn} = \{(\mathbf{X}_1^*, \mathbf{Y}_1^*), (\mathbf{X}_2^*, \mathbf{Y}_2^*), \dots, (\mathbf{X}_K^*, \mathbf{Y}_K^*)\}$, where \mathbf{X}_i^* is one of the original documents from \mathbf{D}_{Lab} or \mathbf{D}_{Unl} or their derivative, and \mathbf{Y}_i^* is its corresponding simplification from \mathbf{D}_{Lab} , its derivative, or an automatically generated simplification. \mathbf{D}_{Syn} is appended to \mathbf{D}_{Lab} and the resulting set $\mathbf{D}_{Aug} = \mathbf{D}_{Lab} \cup \mathbf{D}_{Syn}$ is called the augmented training corpus. The assumption is that a seq2seq model for text simplification trained on the augmented corpus will have higher simplification quality than the one trained on the original training corpus. This paper focuses on the radiology report simplification problem where \mathbf{X}_i is a sentence and \mathbf{Y}_i is its simplification. As a result, our augmentation approach explained in the next two sections is specifically tailored for this application.

4 Methodology

4.1 GPT-based Semantic Augmentation

We propose two types of augmentation. The first, referred to as semantic augmentation, relies on using the large-scale language model GPT-3 (Brown et al., 2020) to generate simplifications automatically. The second, referred to as lexical augmentation, relies on modifying original documents from the labeled corpus. The first augmentation type is described in this section, while the second type is described in the next.

4.1.1 Generating simplifications with GPT-3

It has been demonstrated that large-scale language models such as GPT-3 are capable of doing a wide

¹simple.wikipedia.org

Table 1: Good, Not Simple Enough, and Incorrect examples of radiology liver sentences (**ORI**), expert-written simplifications (**SIM**), and generated simplifications from GPT-Curie (**GPT**).

ORI:	The liver demonstrates diffusely low attenuation, consistent with fatty infiltration
SIM:	There is increased amount of fat in the liver.
GPT:	There is a lot of fat in the liver. (Good)
ORI:	The liver is stable in appearance with again note made of a hypodense lesion in the medial left lobe adjacent to the gallbladder fossa
SIM:	The liver may have one or more tumors or masses.
GPT:	The liver has a small lesion on one side, close to the gallbladder. (Good)
ORI:	The liver shows diffuse low attenuation consistent with fatty infiltration
SIM:	There is increased amount of fat in the liver.
GPT:	The liver has diffuse low attenuation, indicative of fatty infiltration. (Not Simple Enough)
ORI:	The liver is unremarkable without intra- or extra-hepatic biliary dilatation
SIM:	The liver appears normal.
GPT:	The liver is not enlarged or tender without intra- or extra-hepatic biliary dilatation. (Not Simple Enough)
ORI:	Complex hepatic abscess predominantly occupying segments VI and VII of the liver is overall little changed in size compared to date, measuring approximately 7.9 (AP) x 8.7 (TRV) x 11.4 (CC) cm
SIM:	There is infection and pus seen within the liver.
GPT:	This means that the abscess is smaller than it was before, by about 3 inches on all sides. (Incorrect)
ORI:	The liver demonstrates prominent intrahepatic biliary ducts
SIM:	The liver ducts that carry digestive enzymes may be blocked.
GPT:	The liver has many bile ducts. (Incorrect)

variety of NLP tasks through prompting (Brown et al., 2020). Our preliminary experiments showed that the two largest GPT-3 models, Curie and Davinci, are surprisingly good at generating simplifications of radiology report sentences, despite never being trained explicitly for that task. Table 1 shows several representative examples of simplifications by the Curie model prompted by *My patient asks me to simplify this radiology sentence "<original sentence>":*. Each example shown contains an original radiology sentence, its simplification by GPT-3, and its simplification provided by collaboration between a radiologist and a layperson. The first two examples show that GPT-3 can provide

factually correct and easy to understand simplifications comparable to the manually created simplifications. Next two examples show that GPT-3 might provide factually correct text that is not sufficiently simple. The final two examples show that GPT-3 might provide factually incorrect simplifications.

Our semantic augmentation approach uses GPT-3 to generate simplifications of unlabeled documents from \mathbf{D}_{Unl} and add them to the augmented corpus \mathbf{D}_{Aug} . As noted in previous research (Liu et al., 2021) the choice of prompting can have a significant impact on the quality of the generated text and accuracy on a particular task.

Our prompting approach relies on the in-context learning that has been used with success with GPT-3 models. Instead of relying on costly fine-tuning of a language model, it pastes a few labeled examples into the prompt and asks the language model to generate label of an unlabeled example. In our specific application, we select K labeled examples (\mathbf{X}, \mathbf{Y}) from \mathbf{D}_{Lab} and insert each of them into template '*Sentence: < X >; Simplification: < Y >*'. A triple pound sign, *###*, is used to separate templates for the K labeled examples. The prompt ends with '*Sentence: < X >; Simplification: < Y >*'. GPT-3 model is expected to write a simplification by mimicking the style of the labeled examples from the prompt.

As noted in previous work (Brown et al., 2020) the success of prompting that uses in-context learning depends on the particular choice of K examples. Therefore, we select most related sentence simplification pairs from the training set \mathbf{D}_{Lab} given any unlabeled document from \mathbf{D}_{Unl} . In detail, we use BERTScore (Zhang et al., 2019), which leverages the pre-trained contextual embeddings from BERT (Devlin et al., 2018) and matches words in unlabeled and labeled radiology sentences by cosine similarity. Thus, each prompt consists of K most related examples rated by BERTScore for an unlabeled sentence that is appended to the end. Moreover, we evaluate more example selection scenarios in our ablation study.

4.1.2 BERT-Checker

Language models such as GPT-3 provide token probabilities as their output. When generating text, one option is to use brute force and generate the most likely token. However, in the context of text simplification, the most likely tokens are not guaranteed to produce the best simplification. An alter-

native is to generate tokens by selecting among the most likely choices, which the temperature hyperparameter in GPT-3 can control. In our approach, we invoke a GPT-3 model N times for each prompt using a temperature higher than zero, which results in N different simplifications. Then, we automatically select the best one of the N generated simplifications and add it to the augmented corpus.

As seen in Table 1, some of the generated simplifications are good while others are not. Separating good from inadequate simplifications is a non-trivial challenge. Related work on automatic evaluation of the generated text includes GPT-3-ENS (Chintagunta et al., 2021), which measures the complexity of terms in simplifications, and GPT3Mix (Yoo et al., 2021), which treats the likelihood scores of generated labels as confidence scores. However, we found that the existing approaches are inappropriate for our application. Thus, we developed a novel approach called BERT-Checker.

BERT-Checker is a fine-tuned BERT model (Devlin et al., 2018) to a task similar to entailment. In particular, we convert our labeled corpus into training data matching the format of the entailment task. We add label 1 to each example from \mathbf{D}_{Lab} to create positive examples in new training data set, $\mathbf{D}'_{Lab} = \{[(\mathbf{X}_i, \mathbf{Y}_i), 1]\}$. To create negative examples in \mathbf{D}'_{Lab} , we use four different strategies as outlined next:

- **Precision:** To ensure that simplification is closely related to the original text, we corrupt the original text \mathbf{X} by replacing the medical terms with randomly selected medical terms, and generate negative example from labeled example (\mathbf{X}, \mathbf{Y}) as $[(\text{corrupt}(\mathbf{X}), \mathbf{Y}), 0]$.
- **Simplicity:** To penalize simplifications that are too similar to the original sentence, we create negative examples by using the original text as simplification, $[(\mathbf{X}, \mathbf{X}), 0]$.
- **Correctness:** To penalize incorrect simplifications, we randomly select two labeled examples $(\mathbf{X}_1, \mathbf{Y}_1)$ and $(\mathbf{X}_2, \mathbf{Y}_2)$ and create a negative example by mixing the original and simplified text, $[(\mathbf{X}_1, \mathbf{Y}_2), 0]$.
- **Robustness:** For labeled example (\mathbf{X}, \mathbf{Y}) we replace the simplification with an empty string or a sentence generated by a GPT-3 given the prompt 'Generate a radiology report sentence about liver' and high temperature of 0.8 to create negative example $[(\mathbf{X}, \text{GPT}()), 0]$.

Thus, for each positive example, we generate four negative examples. As a result, we can obtain a negative dataset \mathbf{D}'_{Neg} . We fine-tune Clinical BERT (Alsentzer et al., 2019) on the text entailment task using the generated data set.

4.2 Dictionary-based Lexical Augmentation

We propose lexical augmentation to supplement semantic augmentation described in the previous section. Lexical simplification refers to replacing complex terms in original documents \mathbf{X} with their synonyms, which might also be complex. In the related work on text simplification of general-purpose text, EDA approach (Wei and Zou, 2019) paraphrases original documents by replacing randomly selected words or phrases with their synonyms in WordNet (Miller, 1995). We modify EDA by replacing only specialized medical terms.

Inspired by (Pattisapu et al., 2020; Hasan et al., 2016), we use medical dictionaries Medical Subject Headings (MeSH) (Lipscomb, 2000) and Unified Medical Language System (UMLS) (Bodenreider, 2004) to find the synonyms. We use pre-trained named entity recognition model (Honnibal and Montani, 2017) to extract medical terms from the original documents in labeled corpus \mathbf{D}_{Lab} . The medical terms are linked to Concept Unique Identifier (CUI) in UMLS and the concept_id in MeSH. Each medical code in UMLS and MeSH is mapped to a list of synonyms. We iteratively select a synonym to replace the medical term from the original document.

We illustrate the lexical simplification process in Fig 1, where *hepatic steatosis* in the sentence 'Probable diffuse hepatic steatosis' is recognized as a medical term and replaced with its synonyms. In particular, CUI codes 'C0015695' and 'C2711227' are found to match *hepatic steatosis*, where the canonical names are *Fatty Liver* and *Steatohepatitis*. Similarly, 'D005234' from MeSH also provides several synonyms. This process identifies five synonyms used to create five different versions of the original document.

Once the synonyms for a medical term in original document \mathbf{X} of labeled example (\mathbf{X}, \mathbf{Y}) are identified, we paraphrase the original document as $\text{lexical}(\mathbf{X})$ and generate an augmented example $(\text{lexical}(\mathbf{X}), \mathbf{Y})$. The new example is added to the augmented corpus \mathbf{D}_{Aug} .

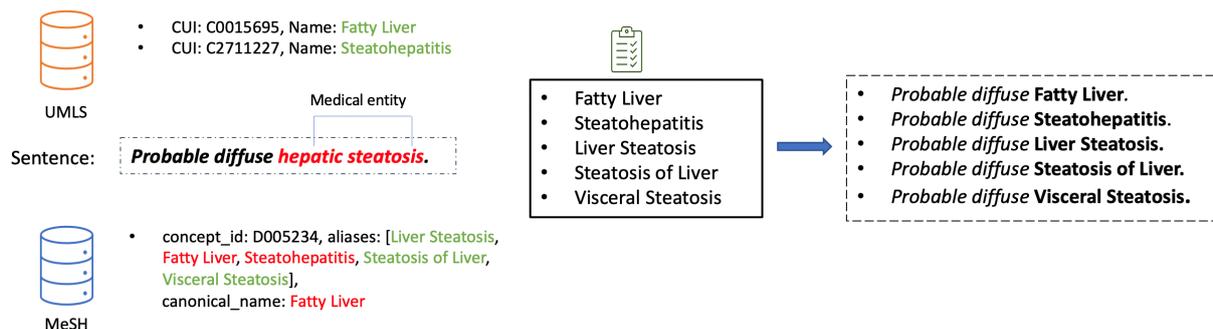

Figure 1: Workflow for lexical augmentation. It shows the linked synonyms of the entity "hepatic steatosis" from UMLS/MeSH and five synthetic sentences.

5 Experiments

5.1 Data

To the best of our knowledge, there is no readily available corpus for simplifying radiology sentences. To experimentally evaluate our data augmentation approach, we created a new corpus for this purpose. In particular, we collected 540 sentences from radiology reports describing the liver condition and manually created their simplifications: 170 sentences were obtained from CT-Abdomen radiology reports from a university hospital (UH), and the remaining 370 were extracted from CT-Abdomen radiology reports from publicly available MIMIC-III (Johnson et al., 2016) data. All sentences were de-identified with Health Insurance Portability and Accountability Act (HIPAA) standards in order to facilitate public accesses and human annotations.

We asked a radiologist to provide a simplification for each selected sentence. A layperson joined the radiologist to provide feedback about the generated simplifications. If the layperson thought the simplification was too complicated, this was communicated to the radiologist, who proceeded to improve the simplification. The process was repeated until the layperson could understand all the simplification and could correctly guess the severity of the described conditions.

During this sequence simplification process, the radiologist and the layperson agreed that it is sufficient to use simplification 'The liver looks normal' for sentences explaining that nothing concerning was observed about the liver. 39% of the the university hospital sentences and 21% of the MIMIC-III sentences were simplified as 'The liver looks normal'. For simplification of sentences that described concerning findings was to ignore technical details that might be confusing to patients. Any relevant

medical terms were stated in simple terms familiar to laypeople. If possible, grammar was kept simple, and the sentences were kept short. Table 1 shows several examples of the original sentences (ORI) and their manual simplifications (SIM).

For our experiments, we randomly selected 100 sentences and their simplifications for training and the remaining 70 for testing for both the university hospital and MIMIC-III labeled data. Thus, we had 200 labeled examples for training denoted as D_{Lab} , and 140 for testing. We used the remaining 200 MIMIC-III sentences as the unlabeled corpus D_{Unl} and used their simplifications to better evaluate the data augmentation approaches.

The corpus is available to the research community to support further research on medical text simplification.²

5.2 Data Augmentation

To implement the proposed semantic augmentation approach, we used GPT-3 Curie model (6.7B parameters) with the few-shot learning prompt described in Section 4.1 with $K = 5$ to automatically generate simplifications for each unlabeled sentence in D_{Unl} . We used the API provided by OpenAI³. We generated $N = 5$ simplifications for each liver sentence with $temperature = 0.5$, which was selected to provide a good balance between factual correctness and diversity.

We trained BERT-Checker to select the best among the $N = 5$ generated simplifications for each liver sentence. BERT-checker was fine-tuned using 80% of the training data as positives and four copies of negatives for each positive, as explained in Section 4.2. BERT-Checker was a fine-tuned BERT base model (110M parameters) consisting of

²<https://github.com/Ziyu-Yang/Radiology-Text-Simplification-Liver>

³<https://openai.com/api/>

12 transformer encoder layers. A fully connected linear layer was added to BERT on its [CLS] output to score the simplification quality. The binary cross-entropy loss was used. 20% of the training data was used for validation and early stopping. We fine-tuned for up to 20 epochs with the patience for early stopping of 3, batch size 16, and learning rate $1e-4$. All experiments were implemented with a single GTX 1080Ti.

The accuracy of trained BERT-Checker on validation data was 0.924. Its precision (the fraction of true positives among positive predictions) was 0.899 and its recall (the fraction of positives that were predicted correctly) was 0.958. We consider it to be high enough accuracy for BERT-Checker to be used to determine the quality of simplifications produced by GPT-3.

In the lexical augmentation, we annotated the recognized entities in the liver sentences from the labeled corpus with Type Unique Identifier (TUI)⁴. TUI is the code to represent hierarchical semantic types of all medical concepts in UMLS and MeSH. Specifically, we only paraphrased terms that belong to "T023 | *Body Part, Organ, or Organ Component*" or "T033 | *Finding*" groups. Because many medical concepts have only one synonym, many sentences mentioned only a single body part other than the liver, and a single finding, we finally obtained 242 unique lexical augmentations from D_{Uml} . In order to control the effect of augmentation size, we randomly selected 200 of them for further experiments.

5.3 BART model

BART (Lewis et al., 2019) is a pre-trained model that uses a seq2seq architecture with a bidirectional encoder and a left-to-right decoder. It achieves state-of-the-art performance on many seq2seq benchmarks. We fine-tuned a BART base model (406M parameters) on different mixes of 450 labeled and augmented data to create different radiology simplification models. The fine-tuning was implemented using PyTorch-lightning⁵. 20% of the training data was used for validation and early stopping. We used the cross entropy loss. We used the same training setting as for BERT-Checker.

⁴<https://lhncbc.nlm.nih.gov/semanticnetwork/index.html>

⁵<https://www.pytorchlightning.ai/>

5.4 Baselines

We first introduce two model baselines that do not use augmentations. Then we introduce two baseline augmentation methods that are appropriate to our task.

5.4.1 Model Baselines

The first baseline is BART base model fine-tuned with the labeled data (**BART-base**). As the second baseline, we used simplifications by the same implementation of GPT-Curie model that is used to augment the labeled data. Specifically, we selected the most related $K = 5$ sentences from the labeled set to a test sentence as the few-shot prompt, generated $N = 5$ simplifications and used BERT-Checker to select the best one. We name this baseline **GPT-FS**.

5.4.2 Augmentation Baselines

We implemented and evaluated two widely used baseline data augmentation methods: 1) Easy Data Augmentation (**EDA**) (Wei and Zou, 2019), a rule-based augmentation that includes synonym replacement, random insertion, random swap, and random deletion. We reproduced this baseline with its source code⁶. 2) Back translation (**BT**), that uses a pre-trained machine translation model to translate sentences into another language and then translate them back to English. The back-translated English sentences are fused with the corresponding simplifications to provide augmented data. Following previous work (Brown et al., 2020), we used GPT-3 Curie to back translate the original sentences to French and back to English. French was selected because it provided a good balance between factual correctness and diversity of generated back-translations.

We generated 200 augmented examples for each baseline approach.

6 Evaluation Methods

6.1 Automated Evaluation

We used multiple automated metrics to evaluate text simplification accuracy. **ROUGE** (Recall-Oriented Understudy for Gisting Evaluation) (Lin, 2004) is a set of metrics used for seq2seq tasks. It calculates the overlapping of unigrams, bigrams, and the longest common subsequences between the expert-provided and machine-generated simplifications. Similarly, **BLEU** (bilingual evalua-

⁶https://github.com/jasonwei20/eda_nlp

Table 2: Comparison of augmentation methods.

	# Aug	ROUGE 1/2/L	BLEU	SARI	BERTScore	FKGL↓
Baseline Models						
GPT-FS	0	56.00/42.20/54.64	0.2363	0.5455	0.9457	5.392
BART-base	0	59.81/50.34/58.87	0.4240	0.5324	0.9411	5.560
Augmentation Methods						
EDA	200	60.90/51.90/60.06	0.4461	0.5460	0.9429	5.315
BT	200	63.47/53.50/62.33	0.4504	0.5740	0.9470	5.133
HUMAN	200	71.06/62.89/70.20	0.5322	0.6047	0.9566	4.870
LEX	200	68.58/60.84/68.24	0.5391	0.5769	0.9559	5.353
SEM	200	66.11/56.55/64.76	0.4709	0.5875	0.9510	5.629
AUG-SUB	200	67.92/58.81/67.04	0.5020	0.5960	0.9524	5.314
AUG	400	69.03/60.37/68.51	0.5036	0.6029	0.9550	5.021

tion understudy) (Papineni et al., 2002) also evaluates overlap of n-grams between the simplifications. Unlike ROUGE and BLEU, **BERTScore** (Zhang et al., 2019) computes a contextual similarity score between tokens in the simplifications. **SARI** (Xu et al., 2016) is a gold standard edit-based metric for text simplification evaluation. Unlike other metrics, it compares the machine-generated simplification with respect to both the original sentence and the human-provided simplification. To evaluate simplicity, we used **FKGL** (Flesch Kincaid Grade Level) (Kincaid et al., 1975), which is a widely used readability formula that assesses the approximate reading grade level of a text. The lower score indicates simpler texts.

6.2 Human Evaluation

Applying automatic evaluation metrics is insufficient to compare quality of simplifications by different methods. Therefore, we also used human evaluation. We asked a medical doctor (family physician) that was distinct from the radiologist who provided the simplifications to evaluate the machine-generated simplifications. We asked the evaluator to use 1-5 Likert scale to evaluate the following four aspects of each simplification, the first three being consistent with.

Factuality refers to medical correctness of the simplification. Score one means that the simplification is factually incorrect and five that it is correct. Scores between one and five mean that some information is imprecise, missing, or hallucinated. Lower scores mean there are more serious factual errors. **Fluency** measures the quality of grammar and readability, regardless of factual correctness. If a simplification is both easy to read and grammati-

cally correct it gets a score of five. This measure is consistent with the fluency measure explained in (Nisioi et al., 2017). **Simplicity** evaluates whether the evaluator thought the laypeople would be able to understand the simplification, regardless of factual correctness. Score of five means that the evaluator thought that any patient would be able to completely understand the simplification.

During the initial stages of human evaluation of factuality and simplicity, we observed that the evaluator occasionally preferred machine-generated simplifications to the radiologist-provided ones. That is why we introduced **Consistency**, which measures how closely the simplification matches the radiologist-provided simplification. Score of five means that the simplification is almost identical to the radiologist-provided simplification. We note that Consistency is related to SARI automatic measure (Xu et al., 2016).

7 Results

7.1 Quantitative Results

We fine-tuned BART model including augmented data from baseline methods (EDA, BT), and our lexical and semantic augmented data (LEX, SEM). BART-base and GPT-FS were created according the description in Section 5.4.1. First two rows of Table 2 refer to fine-tuned BART and few-shot prompted GPT-3 Curie using only the radiologist-provided labeled data. The remaining rows refer to inclusion of augmented data to BART tuning. Rows EDA and BT refer to the baseline augmentation methods. Row HUMAN refers to the augmentation provided by the radiologist, and serves to establish the upper bound on accuracy improve-

ment due to augmentation. LEX and SEM rows represent our lexical and semantic augmentation methods. AUG-SUB and AUG use 200 and 400 combined semantic and lexical augmentations, respectively. Aug column shows the number of augmented examples.

We observe that our proposed augmentations are superior to baselines LEX and SEM on almost all metrics. SEM is better than LEX on SARI measure. AUG is better than LEX and SEM on ROUGE, SARI and FKGL. AUG is the best overall augmentation method coming very close to the HUMAN upper bound, after noting that SARI and FKGL are the most useful measures for evaluation of simplicity. We note that GPT-FS has lower overall scores than any of the BART models.

Table 3: Human evaluation results (Factuality, Fluency, Simplicity, and Consistency) on 60 selected testing data.

Method	Factual	Fluency	Simp	Cons
BART-base	3.38	4.85	4.67	3.18
BT	3.22	4.88	4.58	3.13
GPT-FS	4.18	5.00	4.55	3.91
AUG	4.22	4.95	4.62	4.10

7.2 Human Evaluation Results

For Table 3, we asked a medical doctor to evaluate 60 randomly selected simplifications from the test data (30 from each source). We evaluated the most relevant four models from Table 2: BART-base, BT, GPT-FS, and AUG. The results show that all methods have comparable Simplicity and Fluency. AUG and GPT-FS have better Factuality and Consistency than BART-base and BT. AUG is slightly better than GPT-FS on those two important measures, indicating that fine-tuning BART with augmentation produced by few-shot prompted GPT-3 Curie is better than directly using few-shot prompted GPT-3 Curie for simplification.

Table 4: Comparison between different versions of semantic augmentations. # Aug is the number of augmented examples. ROUGE refers to ROUGE-L.

Method	# Aug	ROUGE	BLEU	SARI
First-run	200	60.21	0.4053	0.5590
Similarity	200	55.31	0.3547	0.5387
Five-runs	781	55.77	0.3755	0.5391
SEM	200	64.76	0.4709	0.5875

7.3 Ablation Study

We first evaluated the ability of BERT-Checker to recognize high-quality simplifications. We compared the version we implemented in our experiments (SEM row in Table 4) with three different variants: 'First-run' always selects the first generated simplification, 'Similarity' selects the best simplification based on BERTScore, 'Five-runs' uses all simplifications generated by GPT-3 Curie as augmentations. After removing duplicates, there are 781 augmentations produced by 'Five-runs'. Table 4 shows all three variants are inferior to SEM, showing that any of the ablations would significantly deteriorate the results. The results confirm that the quality of augmentations is critical for success of data augmentation approaches.

Next, we evaluated the importance of GPT-3 prompting. As noted in previous research (Liu et al., 2020), the choice of prompting can significantly impact the quality of the generated text. Thus, we designed an ablation study to compare different prompting approaches for data augmentation.

Table 5: Comparison of different prompting on data augmentation.

Prompts	ROUGE	BLEU	SARI
BART-grader	46.62	0.2862	0.4917
BART-patient	55.81	0.3516	0.5255
BART-top1	58.65	0.3955	0.5511
BART-rd5	53.94	0.3170	0.5360
SEM	64.76	0.4709	0.5875

In our prompt design that has the following form: *Sentence*: $\langle X \rangle$; *Simplification*: $\langle Y \rangle$, we included $K = 5$ most related labeled examples to the original test sentence in the prompt. We first explored whether the number of few-shot examples matters. We repeated the data augmentation process with $K = 1$ (BART-top1 in the table). Table 5 shows that $K = 5$ resulted in better performance than $K = 1$. Next, we evaluated whether the way we select examples matters. Instead of $K = 5$ closest labeled examples, we selected $K = 5$ random labeled examples (BART-random in the table). From Table 5, we can see that random labeled examples resulted in lower accuracy.

We also explored prompting that does not rely on few-shot learning. One design was explained in section 4.1.1, 'My patient asks me to simplify this radiology sentence $\langle X \rangle$ ', we refer to as BART-

patient in the table. Similarly, inspired by a GPT-3 prompt for the summarization task, we used prompt: *My second grader student asks me to simplify the following sentence: <X>*, we refer to as BART-grader in the table. These two prompts are the so-called 'zero-shot' prompts. As shown in Table 5, the 'grader' and 'patient' prompts result in inferior accuracy compared to the few-shot prompting.

8 Conclusion

This paper proposes two novel augmentation methods to enhance the limited labeled data for the radiology sentence simplification problem. Our evaluation using automatic measures and human evaluation shows that data augmentation can substantially improve the quality of simplification models. The ablation results show that the proposed innovations in automatic creation of simplifications for data augmentation are very effective.

9 Limitations

The main limitation of our study is that we only considered simplification of radiology sentences. In future work, it will be important to expand the approach to simplify whole paragraphs, because very often radiologists use multiple sentences to discuss a single observation. Simplifying single sentences can thus be suboptimal because important context from the previous and subsequent sentences might be lost. The second limitation of the study is that our corpus only included sentences related to liver. It will be important in the future work to evaluate the proposed approach on a wider variety of radiology sentences. The third limitation is that we obtained simplifications from a single radiologist. It will be important for future study to include simplifications from multiple radiologists to ensure generalizability of the proposed approach. The fourth limitation is that we used a single medical doctor to evaluate the quality of the simplifications. It would be important in future studies to ask multiple medical doctors to evaluate the quality, which would allow estimating the inter-rater variability. The fifth limitation is that we did not use laypeople to evaluate the quality of simplification. This would require some innovation in the human evaluation process because laypeople are not able to evaluate factual correctness and because it would be important to understand how simplifications improve the overall understanding of the radiology reports.

The final limitation is a relatively small size of the labeled data set created for this study. Obtaining high-quality simplifications is very costly because it requires collaboration between radiologists and laypeople.

Abstract

Real-world applications of neural language models often involve running many different models over the same corpus. The resulting high computational cost has led to interest in techniques that can reuse the contextualized embeddings produced in previous runs to speed training and inference of future ones. We refer to this approach as *embedding recycling* (ER). While multiple ER techniques have been proposed, their practical effectiveness is still unknown because existing evaluations consider very few models and do not adequately account for overhead costs. We perform an extensive evaluation of ER across eight different models (17 to 900 million parameters) and fourteen tasks in English. We show how a simple ER technique that caches activations from an intermediate layer of a pretrained model, and learns task-specific adapters on the later layers, is broadly effective. For the best-performing baseline in our experiments (DeBERTa-v2 XL), adding a precomputed cache results in a >90% speedup during training and 87-91% speedup for inference, with negligible impact on accuracy. Our analysis reveals important areas of future work, and we release code and documentation for our experiments at <https://github.com/allenai/embeddingrecycling>.

1 Introduction

Large pretrained language models form the foundation of modern NLP, and continue to push the state-of-the-art on a wide range of natural language processing tasks (Devlin et al., 2019; Liu et al., 2019b; Bommasani et al., 2021). Larger models tend to offer superior accuracies (Kaplan et al., 2020), but also entail higher computational costs. The steep computational cost associated with large neural language models slows down experimentation, increases financial barriers to the technology, and contributes to global climate change (Strubell et al., 2019; Dodge et al., 2022).

Our work studies how to reduce computational cost for workloads in which many distinct models are run over the same text. For example, a scholarly search tool that helps users find and understand relevant literature may run separate models for entity recognition, topic classification, relation extraction, summarization, question answering, and so on over a large corpus of papers. New and improved models for the tasks are developed frequently, necessitating additional runs. The need for repeated model runs has also been noted for other applications in previous work, including news applications (Du et al., 2020) and virtual assistants (Wei et al., 2022). Further, repeated runs also occur very frequently during model development, when exploring model variants or executing multiple training epochs.

Recent work has introduced ways to reduce computational cost in such settings by re-using model activations from one task to speed up other ones (Du et al., 2020; Wei et al., 2022). A pretrained language model’s internal activations form a contextualized embedding, which reflects syntactic and semantic knowledge about the input text (Goldberg, 2019; Wiedemann et al., 2019; Rogers et al., 2020) which can be useful across a variety of downstream tasks. We define *embedding recycling* (ER) as the technique of caching certain activations from a previous model run, and re-using them to improve the efficiency of future training and inference. Recycling imposes a small computation time cost the first time a model processes a text, in order to compute and populate the cache. Thereafter, all subsequent runs on the text can use the precomputed cache, improving efficiency.

While previous work has shown the promise of ER approaches, the existing evaluations are limited. For example, Du et al. (2020) and Wei et al. (2022) each evaluate ER for only one or two base models. Likewise, for ER techniques that cache activations on persistent storage, the storage and time cost of the cache itself has yet to be quan-

tified. In this paper, we present a more comprehensive evaluation of ER with several models and tasks, along with a thorough efficiency analysis. We study a simple *layer-recycling* ER method that caches the activations from an intermediate layer of a pretrained model, and uses those cached activations as the starting point when the same input sequence is seen again during fine-tuning or inference. We show that even this simple method yields substantial improvements to throughput at small or no cost to accuracy on average. Our results provide the strongest evidence to date that ER can be a practically important technique for reducing costs for NLP systems, but as we discuss in [section 6](#), they also suggest important challenges that must be addressed in future work.

Our contributions are summarized below:

- We propose embedding recycling as a method for lowering the computational costs of training and inference for language models, and explore layer recycling with two techniques: standard fine-tuning and parameter-efficient adapters.
- Our experiments with eight models across a wide range of tasks show that layer recycling is generally effective. For the best-performing ER model on our tasks- DeBERTa-XL with adapters, we find that layer recycling nearly matches performance of the original model while providing a 87-91% speedup at inference time, and greater than 90% speedup at training time.
- We explore open challenges for embedding recycling and present questions for future work.

2 Related Work

The embedding recycling technique we investigate is based on findings from prior work suggesting that not all layers of a pretrained transformer are equally important for end-task finetuning. Shallower layers tend to converge earlier in training than deeper layers ([Raghu et al., 2017](#); [Morcos et al., 2018](#)), and weights of later layers change more than earlier ones ([Kovaleva et al., 2019](#)), suggesting that earlier layers tend to extract universal features whereas later layers focus on task-specific modeling. [Lee et al. \(2019\)](#) find that 90% of fully fine-tuned performance can be reached when fine-tuning only the final quarter of a transformer’s layers and leaving the rest frozen.

Several proposed methods vary the number of frozen layers over the course of training, approaching or exceeding the performance of fully fine-tuned models while substantially speeding up the training process ([Raghu et al., 2017](#); [Xiao et al., 2019](#); [Brock et al., 2017](#)). Similar to our approach, some dynamic freezing methods also employed caching mechanisms ([Liu et al., 2021](#); [He et al., 2021](#)), but the dynamic number of frozen layers means the cache applies only at training time and only for a single task. In contrast, we cache embeddings from the pretrained model, which can then be reused across multiple downstream tasks and applied at inference time as well.

Other recent studies have sought to improve model inference speed by skipping computations in later layers. [Sajjad et al. \(2020\)](#) found that in some cases up to half of the layers can be removed from the model with only a 1-3% drop in task performance. Early exit strategies have also been proposed, which allow the model to dynamically decide when to skip later layers ([Cambazoglu et al., 2010](#); [Xin et al., 2020](#)). SkipBERT ([Wang et al., 2022](#)) combined early exiting with an approach in which cached n-gram embeddings approximate the intermediate activations of new inputs. [Lester et al. \(2021\)](#) explored prompt-tuning as a parameter-efficient approach for adapting frozen language models without adjusting model weights, conditioning language models with soft prompts to perform downstream tasks.

Precomputing text representations to speed up future processing on the same data is commonly done when creating fixed-size document-level embeddings for use on document-level tasks ([Conneau et al., 2017](#); [Cohan et al., 2020](#)); in contrast, we study contextualized *token-level* embeddings that can be used for tasks such as named entity recognition (NER) and question answering. ReadOnce Transformers ([Lin et al., 2021](#)) do consider multi-task variable-length document representations, but do so in a setting where a cached document representation is paired with a query text (such as a question or prompt); the approach is pretrained with QA data and evaluated on QA and summarization, rather than tasks such as text classification or NER where the entire input can be cached.

[Du et al. \(2020\)](#) propose an approach similar to ours that caches general-purpose token-level model representations, trained in a multi-task setting; however, that approach only applies a small MLP to

the stored representations and reports a meaningful drop in accuracy (greater than 2% on average) compared to fully fine-tuned models. We find that reusing the later layer parameters of a pretrained transformer in addition to the cached activations often enables us to essentially match fully fine-tuned model accuracy while reducing computational cost.

Wei et al. (2022) combine layer freezing and knowledge distillation to create a multi-task model. They do not consider caching activations on persistent storage as we do, but instead re-use activations across tasks at inference time via a branching multi-task model. They use a two stage process where $12 - N$ layers are fine-tuned for each individual task keeping N frozen layers. This is followed by distillation of the N layers for further computational gains. We take advantage of the parameter efficient adapter modules (Houlsby et al., 2019), and replace this process with a single step of fine-tuning a frozen base model that has adapters attached only to the deeper layers.

Our work also has connections to work on memory- and retrieval-augmented language modeling. Prior work on using memory (e.g., Grave et al. (2016); Dai et al. (2019); Rae and Razavi (2020); Wu et al. (2022)) generally focuses on modeling long-range context and caching representations of older history in a sequence, while work on retrieval (e.g., Guu et al. (2020); Karpukhin et al. (2020)) focuses on fetching text from a knowledge base or corpus to serve as additional context. In both cases, the aim is to use representations of additional text (from earlier in a document or from a knowledge base) to improve modeling of new inputs. In contrast, our work focuses on caching the representations of an entire sequence to speed up computation for new tasks.

3 Methods

In the transformer architecture (Vaswani et al., 2017), an input sequence x of length S and dimension d is transformed with a function $F : \mathbb{R}^{S \times d} \rightarrow \mathbb{R}^{S \times d}$ defined by the composition of N transformer layers $F^{(1)}, \dots, F^{(N)}$ as follows:

$$F^\ell(x) = \text{LN}(\text{FF}^\ell(x') + x') \quad (1)$$

$$x' = \text{LN}(\text{MH}^\ell(x) + x) \quad (2)$$

where LN is a layer normalization (Ba et al., 2016), FF is a feed forward network, and MH is the self-attention layer that consists of multiple heads and

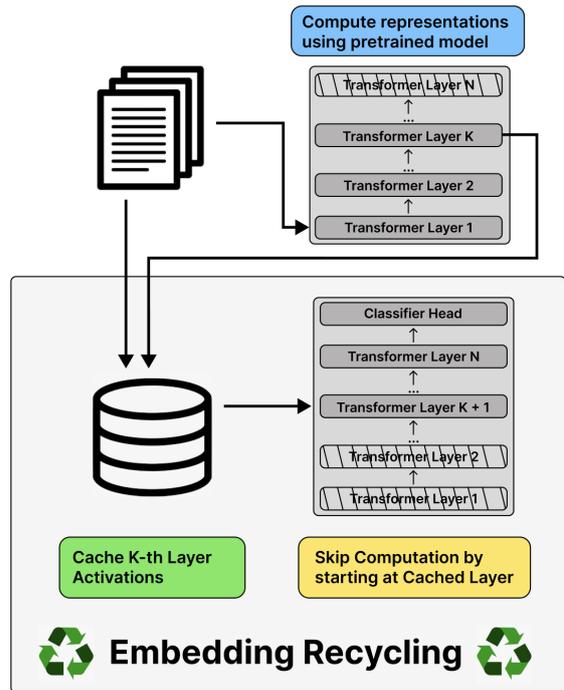

Figure 1: Overview of the embedding recycling approach. In the figure, the K -th layer activations are saved for future fine-tuning on downstream tasks, skipping redundant computations of earlier layers in the transformer model.

contextualizes the input sequence vector. The output of each layer is used as input to the next layer.

$$h^{\ell+1} = F^\ell(h^\ell) \quad (3)$$

Our approach is to cache the output representations $h^k \in \mathbb{R}^{S \times d}$ at a certain layer k and reuse them for fine-tuning on a new given task. We refer to this process of caching and reusing the output representations of a layer as *layer recycling*. This enables us to reduce the size of the transformer model from N layers to $N - k$ layers, reducing the computational cost during fine-tuning and inference.

Note that the key requirement of layer recycling is that we first need to process the entire data with the transformer model and cache the representations, so that we could later reuse these representations many times during fine-tuning and inference on new tasks. We experiment with two types of layer recycling approaches as explained next.

We start with a pretrained transformer F (e.g., BERT) consisting of $F^{(1)}, \dots, F^{(k)}, \dots, F^{(N)}$ layers. During the first epoch of fine-tuning for any given task, we run the transformer over a corpus \mathcal{C} and cache the output representations of layer k for each instance c in \mathcal{C} , i.e., $h_{c \in \mathcal{C}}^k$. However, for

every subsequent epoch of fine-tuning using the same transformer model, we only run and fine-tune the latter $N - k$ layers $F^{(k+1)}, \dots, F^{(N)}$. We can either train all of the weights in the layers (which we refer to as *reduced models*), or only train adapter modules added on the layers (discussed below). In either case, for the instance c in the dataset \mathcal{C} we simply retrieve and use the previously cached representation $h_{c \in \mathcal{C}}^k$ as input to layer $F^{(k+1)}$. This avoids the extra computation through layers $F^{(1)}, \dots, F^{(k)}$ but adds a small cost for retrieving the representation from storage (see [subsection 5.4](#) for efficiency analysis).

3.1 Adapters

We evaluate whether combining recycling with Adapter modules ([Houlsby et al., 2019](#)) can improve performance over fully fine-tuned models. Adapters are typically used to improve the parameter efficiency of fine-tuning and mitigate the storage costs of large language models. They also enable more sample-efficient fine-tuning and can result in improved fine-tuning performance ([Karimi Mahabadi et al., 2022](#)).

Adapter modules contain a down-projection, an up-projection, and a residual connection module: $h \leftarrow h + (f(h\mathbf{W}_{down})\mathbf{W}_{up})$. The adapters are separately inserted after the MH and the FF layers in the transformer architecture ([Equation 2](#)). Further, [Rücklé et al. \(2021\)](#) experiment with dropping adapters from the lower transformer layers to provide inference time speedup. In our experiments, adapters are added to the latter half of transformer layers in the reduced transformer models. As in standard layer recycling, the pretrained original transformer F first caches the intermediate activations $h_{c \in \mathcal{C}}^k$ for each input in a selected corpus at layer k . Then the first k layers are removed from the transformer. During fine-tuning, the cached representations are fed as input to the later $N - k$ layers of the transformer, which consist of the frozen transformer layers plus trainable adapter parameters. Thus, we fine-tune only the additional 6-8% parameters introduced by the adapters. We refer to learning adapters on all layers as the *full adapter* setting and the layer recycling version as the *reduced adapter* setting.

4 Experimental Setup

We now present our experiments evaluating whether recycled embeddings can be paired with

reduced large language models to maintain accuracy while improving training and inference speed. We explore the effectiveness of embedding recycling across a variety of different tasks, datasets, and transformer models.

4.1 Models

Our full-size models include the encoder transformers BERT, SciBERT ([Beltagy et al., 2019](#)), RoBERTa ([Liu et al., 2019b](#)), and DeBERTa ([He et al., 2020](#)). We also experiment with the encoder-decoder T5 model ([Raffel et al., 2019](#)). We selected these architectures since they are widely-used pretrained transformers across a variety of tasks in different domains. We experiment with multiple sizes of these models, including distilled ([Sanh et al., 2019; Wang et al., 2020, 2021](#)), base, and large variants, to gauge the effectiveness of recycled embeddings with an increase in the network size.

To investigate the effectiveness of layer recycling, we test several reduced models in which we use caching to reduce 50% of the layers (e.g., caching layer 12 in RoBERTa-large and layer 6 in BERT-base).¹ We compare each reduced model to its fully fine-tuned counterpart across the text classification, NER, and QA tasks. The hardware details and hyperparameters for our models are specified in [Appendix A](#).

4.2 Datasets

For our experiments, we focus on three core NLP tasks: text classification, named-entity recognition (NER), and extractive question-answering (QA). Scientific papers, due to their immutable nature, are an especially appropriate target for embedding recycling, so we focus much of our evaluation on the scientific domain. For text classification, we selected Chemprot ([Kringelum et al., 2016](#)), SciCite ([Cohan et al., 2019](#)), and SciERC ([Luan et al., 2018](#)). For NER, we used BC5CDR ([Li et al., 2016](#)), JNLPBA ([Collier and Kim, 2004](#)), and NCBI-Disease ([Doğan et al., 2014](#)). For QA, we chose the TriviaQA ([Joshi et al., 2017](#)) and SQuAD ([Rajpurkar et al., 2016](#)) datasets.

¹We note that for the encoder-decoder model T5, we consider caching only the middle layer of the *encoder*, which means that the speedups for this model will be smaller than (approximately half of) that of the other models we evaluate. We also consider 25% and 75% reduced models in [Appendix A](#).

5 Results

5.1 Standard Fine-tuning

The results for standard fine-tuning of either full or reduced models are shown in Table 1. For the text classification and NER tasks, the reduced BERT-sized and larger models perform similarly to their fine-tuned counterparts on average, and substantially outperform the distilled models. The reduced distilled models also perform well on those tasks compared to the distilled originals, on average, although there is more variance across models and tasks compared to BERT-sized models. We validate our fully fine-tuned baselines by comparing our results with prior work (Beltagy et al., 2019), finding that our scores land within 1.33% on average and typically score above the previous baselines.

For QA tasks, we found that fully fine-tuning works somewhat better than reduced configurations across all the explored models (Table 1). Generally, reduced configurations typically lag by 1 to 2 points in F-1 score. One possible hypothesis is that the QA datasets are generally much larger than the datasets we used for other tasks (100k-150k examples vs 4k-20k examples for text classification and NER); however, in additional experiments we found that subsampling the QA training sets to 5% of their original size only increased the gap, suggesting that dataset size does not explain the failure of reduced models on this task. We also validate our fully fine-tuned baselines for QA tasks by comparing our results with Yasunaga et al. (2022), finding that our scores differ by less than half a point on average.

Finally, we explored using lightweight multi-layer perceptrons (MLPs) as classifier heads, given their success in prior work. While (Du et al., 2020) paired multi-task encoders with 2-layer MLPs, we paired frozen pretrained transformer models with 2-layer MLPs and found that they underperformed trainable layers dramatically, by 26% on average across the classification and NER tasks.

5.2 Adapters

Our results for reduced adapter models are shown in Table 2. We see that in general, for all the models except for T5-Large, the adapter-based approaches are superior to standard fine-tuning on our tasks. Further, layer recycling remains effective with adapters. Compared to the full adapter baseline, the reduced adapters for RoBERTa-Large, BERT, SciBERT, and DeBERTa models only show a 0.19% reduction in accuracy. Additionally, com-

pared to the fully fine-tuned baseline, these reduced adapters models have a 0.19-0.23% reduction in accuracy. Likewise, in contrast to the full fine-tuning results above, QA accuracy for the top-performing DeBERTa adapter model remains unchanged on average after layer recycling, with the reduced adapter model performing better on one QA task and worse on the other.²

5.3 GLUE Results

For our best-performing model DeBERTa v2 XL, we also provide further experiments on datasets from the GLUE benchmark (Wang et al., 2018), to allow easier comparison against speedup techniques from previous work. We present results on the CoLA, SST-2, MRPC, STS-B, MNLI, and QNLI tasks from GLUE. For our experiments, we tried both our standard reduced models and our reduced adapter models. We found that embedding recycling was successful across the GLUE tasks, with an average accuracy drop of 0.3 points in return for a significant increase in both training and inference time as outlined in Table 5 and Table 4. We note that due to the high computational cost of these experiments, we take existing hyperparameter settings from previous work that worked well for the full models, and also use these for reduced models. Further hyperparameter optimization of the reduced models might improve performance.

5.4 Efficiency Analysis

To estimate the real-world benefit of recycling embeddings for different tasks, we provide a minimal PyTorch implementation of embedding recycling. This implementation and the following results correspond to both the standard layer recycling approach and the adapter-based layer recycling approach since they follow parallel processes for gradient descent during training and computations during inference, despite the additional 6-8% of parameters added by the trainable adapters. To show that training times do not differ substantially, we also measured the training time the transformer models take to converge to their optimal weights. We found both approaches take approximately the same time to complete training (Table 16).

We evaluated the impact of recycling embeddings on four different architectures and two dif-

²We omit experiments with distilled models, as we found adapters to be ineffective on those models even without embedding recycling, scoring 19.4% worse on average than full fine-tuning for text classification and NER.

Table 1: Test scores of reduced (Rdc) models on the text classification, NER, and QA tasks. **Bold** indicates the best average F-1 score between the reduced and fully fine-tuned (Full) versions of each model over 10 runs. For the ChemProt dataset, we report the micro F-1 scores instead, following past work (Beltagy et al., 2019). The reduced BERT-sized models generally offer similar performance to their full counterparts (scoring within 0.2% when averaged across RoBERTa and SciBERT for the six tasks), and substantially outperform the distilled models.

ferent hardware platforms. For models, we considered two efficient transformer models (MiniLMv2 (Wang et al., 2020, 2021) models with $l = 6$ layers and embeddings of size $h = 384$ and $h = 768$), two medium sized models (BERT_{BASE}, $l = 12$, $h = 768$; BERT_{LARGE}, $l = 24$, $h = 1024$), and a large model (DeBERTa_{V2-XLARGE}, $l = 24$, $h = 1536$). We evaluated embeddings on a efficiency-oriented AI accelerator (NVIDIA A10G), as well as on a high-performance GPU (NVIDIA A6000).

We controlled for differences among tasks considered in tables Table 1, 2, and 3, such as length of sequences and number of samples, by simulating a sequence classification task on QASPER (Dasigi et al., 2021), which includes the full-text of over a thousand academic manuscripts.³ We run all models with a fixed batch size of 128. For all models, we reduce exactly half of their layers by recycling, which results in a maximum theoretical speed-up of 100%. A run over the corpus consists of 335 batches, and we average results over seven runs.

Table 4 shows the results of caching embeddings to recycle on disk. Overall, we found that all models benefit from embedding recycling, achieving an average speedup ranging from 18 to 86%. Unsurprisingly, larger models benefit more from recycling than smaller ones; this is due to the fact that loading embeddings cached on disk adds a

³Because the bulk of computation for a transformer model is done in its encoder and not in the task-specific heads, inference time is similar regardless of whether the model is used for sequence classification, tagging, or question answering.

small latency penalty to a model run, which is more noticeable in the case of smaller models. For example, we achieve an 84% speedup when running BERT_{BASE} with embedding recycling on an A10G GPU, which is roughly equivalent to the latency of a MiniLM_{L6-H768} model without recycling (351 vs 325 ms per batch on average); this result would allow us to run more accurate models while maintaining the efficiency of shallower architectures.

Table 4 also includes results when storing embeddings using half precision (that is, cache embeddings in FP16 rather FP32). The smaller embeddings lead to improvements for all models and hardware, ranging from +8% to +46%. Further, it has no impact on performance, as it changes predicted scores by at most 10^{-3} across all tasks evaluated in this work.

We also note that less capable hardware benefits more from caching embeddings. For example, BERT_{BASE} achieves a speedup of 84% on an A10G GPU, while on A6000, the speedup is a more modest 55%. This is an expected result: fewer and slower execution cores/accelerator memory impact overall model latency. Further, we note that, despite the smaller relative gains, the more powerful GPU is always faster in absolute terms compared with the less capable one.

It is important to note that these gaps from maximum achievable speedup are only observed when performing *inference*; for *training*, we observe almost perfect speed-up for all models and

Table 3: Test scores of reduced (Rdc) and reduced adapter (Rdc + Half Adpt) models on GLUE for DeBERTa V2 XL. **Bold** indicates the best average score between the reduced and fully fine-tuned (Full) versions for the standard and adapter-based configurations. Each score is averaged over 5 runs. We report the scores using the standard GLUE metric for each corresponding task.

hardware configurations except for the smaller MiniLM models. For example, BERT_{BASE} requires 17.38 ± 1.32 ms/batch⁴ without recycling, compared to 8.67 ± 2.18 ms/batch when recycling. Even when considering the additional time to cache embeddings to disk during the first pass, embed-

ding recycling still achieves close to optimum speedup on all models except MiniLMs, where its gains hover between 52% and 82% (“NR vs SR” column in Table 5). When training for just 6 epochs (or roughly 2,000 steps), recycling embeddings is faster than simply freezing half of the parameters for all models but MiniLM (“F vs SR” column in Table 5); this is due to the relatively higher cost of caching layers to disk in case of smaller models. In these cases, we empirically found that recycling achieves faster training time than freezing after 12 epochs or 4,000 training steps; since smaller models typically require more epochs to converge, we conclude that recycling is generally preferable to partially freezing a model during training. For BERT_{BASE} and larger models, embedding recycling is also more efficient than layer freezing, providing a +20% to +45% speed-up after just 6 training epochs.

We also benchmarked the storage requirements of recycling embeddings. For a sequence of 512 tokens and a hidden model dimension of 768, caching embeddings requires 1.6 MB with 32-bit precision or 0.8 MB with 16-bit precision. This translates to 15.5 MB per paper in QASPER (papers are, on average 4,884 WordPiece tokens long). Weighing the storage cost and compute savings of ER, we find that it is cost-effective in cloud environments only if the corpus is reprocessed several times per

⁴When training, we use a batch size of 16

Inference Time (Speedup over Baseline)				
Model	Baseline	Recycling		Avg. F1 diff when recycling
		FP32 cache	FP16 cache

Table 4: Average **inference** runtime comparison (in ms/batch, averaged over 7 runs) between vanilla encoders and models that cache embeddings on disk. For all runs, cache the middle layer of the encoder. We assume the cache is already precomputed when calculating timings; thus, maximum speedup is 100%. Overall, the larger the model, the higher the speedup from re-using representations. Further, accelerators with fewer execution units (A10G) benefit more from recycling embeddings. Finally, using half precision for embeddings improves speed up across the board, while halving storage size.

month, but is cost-effective on local hardware even with infrequent (yearly) corpus reprocessing (details in subsection A.8 of the appendix).

6 Discussion and Future Work

Our experiments raise several questions and suggest multiple avenues for future work, including:

- Our layer recycling strategy is a straightforward ER approach, but previous work has suggested that weighted pooling across layers can perform better compared to any single layer in many cases (Liu et al., 2019a; Du et al., 2020). Recycling pooled activations may offer improved results. What is the best way to capture and store the syntactic and semantic knowledge encoded in the activations of a model for later recycling?

- As noted in the previous section, naive storage methods for ER can be cost-prohibitive in some settings, and finding ways to mitigate this cost (e.g., by compressing the stored activations) will be important for making ER broadly applicable.

- Our experiments show that the right recycling approach may be task-specific and model-specific. For example, with standard fine-tuning as shown in Table 8, caching layer 12 in RoBERTa-large is most effective for NER and text classification, whereas it is not effective for QA (but layer 6 performs much better). Which embeddings to retrieve and recycle for a task, and the right architecture (e.g. number of layers) to use when consuming the recycled embeddings, represents a large decision space. Methods that can help practitioners automatically choose among public or private shared embedding sets and associated model designs, given their task and objectives for accuracy and computational cost, may be important to make ER an effective practical tool.

- We present results with encoder-only and encoder-decoder models, on classification tasks. Determining whether the approach is effective for generative tasks and autoregressive models is an important question for future work.

- While we show that ER can be effective when coupled with distillation, whether other techniques like quantization and early exiting remain effective in combination with ER is an open question.

- We focus on the setting where the exact same text, at the length of a full document, is being reused for multiple tasks. In practice, we may often perform a task on text that is *similar* to but not exactly the same as one for which we have cached embeddings (e.g., a Wikipedia page that has been revised). Further, even a completely new document will have similarities and overlapped spans with previously processed ones. Studying ER in these settings, e.g. through a combination of layer recycling and the SkipBERT approach which can apply to unseen passages via cached n-grams (Wang et al., 2022), is an area of future work.

- Finally, it is possible to explore cross-model embedding recycling. We attempted a straightforward implementation of such approach by using recycling embeddings from a larger model into a smaller consumer model. However, the results did

Model	Training (ms/batch, amortized over 6 epochs)				Speedup		
	No Recycling (NR)	Model Frozen (F)	Saving + Recycling (SR)	Only Recycling (R)	NR vs SR	F vs SR	NR vs R

Table 5: Average **training** runtime comparison (in ms per batch, \pm stdev over 7 runs) between vanilla encoders and models that cache embeddings on disk. For all runs, we cache the middle layer of the encoder; thus, theoretical speedup is 100%. Time per batch is amortized over 6 epochs (2,000 steps), the lowest number to convergence over all datasets (c.r.f. Table 16). We present results in four settings: no recycling (NR), freezing $\frac{1}{2}$ of the layers during training (F), 1 training epoch during which embeddings are saved to disk followed by 5 epochs where recycling is enabled (SR), and 6 epochs where embeddings are already saved (R). Overall, we found that embedding recycling speeds up training even when embeddings need to be cached to disk during the first pass. Compared to freezing, saving and recycling improves training time for all but MiniLM models (F vs SR).

not show improvements (Appx. A.3). Developing and evaluating new approaches for this setting is an important item for future work.

7 Conclusion

We have presented embedding recycling, a general technique for reusing previous activations of neural language models to improve the efficiency of future training and inference. We show how a simple technique of caching a layer of activations in a pretrained model is effective. We validate our approach in experiments across fourteen tasks and eight model architectures. We find that recycling typically has small or no impacts to accuracy on average, but does yield substantial throughput increases demonstrated through a careful efficiency analysis. We also discuss several open challenges for future work.

8 Limitations

As discussed in detail in our future work section, several advances are important to make embedding recycling a broadly applicable practical technique. In addition, the techniques we evaluate primarily benefit transformer language models run on GPU-based architectures with rapid storage, components which are not available to all NLP researchers and practitioners. Our experiments demonstrate posi-

tive results with one representative embedding recycling technique, but do not directly evaluate all recycling variants proposed earlier in the literature. Finally, the datasets used in our experiments were in English, a high-resource language with robust pretrained models which may benefit embedding recycling. Future work should expand on the applicability of embedding recycling by using non-English datasets in lower-resource settings to determine the breadth of its applicability.

A Experimental Setup and Additional Results

A.1 Fine-tuning Transformer Models

The candidate transformer models are fine-tuned using configurations suggested by [Devlin et al. \(2019\)](#), [Ding et al. \(2022\)](#) and [Houlsby et al. \(2019\)](#). For text classification, we feed the final hidden state of the [CLS] token into a linear classification layer.

For NER and QA, we feed the final hidden states of each token into a linear classification layer with a softmax output.

For all of the models, we apply a dropout of 0.1 to the transformer outputs and optimize for cross entropy loss using Adam (Kingma and Ba, 2015). We employ a batch size of 32 across all tasks. We fine-tune using early stopping with a patience of 10, using a validation set for calculating loss for each epoch. We use a linear warmup followed by linear decay for training (Howard and Ruder, 2018), testing the following learning rate options: 1e-3, 2e-3, 1e-4, 2e-4, 1e-5, 2e-5, 5e-5, and 5e-6. For the text classification and NER datasets, we select the best performing learning rate for each transformer model on the development set and report the corresponding test results. For the QA datasets, we select the best performing learning rate for each transformer model on the training set and report the corresponding results on the validation set. Additionally, for the adapter modules used in certain model configurations, we test bottleneck dimensions as part of our hyperparameter search: 24, 64, and 256.

A.2 Adapter-based Models

Here, we used frozen RoBERTa-Large (Liu et al., 2019b), SciBERT (Beltagy et al., 2019), and BERT models but added adapter modules (Houlsby et al., 2019) only on the latter half of the transformer layers. Only the adapters and the linear classifier attached to the model output were fine-tuned for the text classification, NER, and QA tasks.

We found that the best hyperparameter configuration was generally a bottleneck dimension of 256 and a learning rate of either 1e-4 or 2e-4.

A.3 Cross-model Embedding Reuse

An alternative to re-using cached activation from a pre-trained model (section 5), is to cache activations from a more expensive, larger model and re-using them in downstream cheaper models. The goal here is to improve accuracy by using more powerful contextual embeddings. Overall, a straightforward implementation of this strategy did not offer improvements, as described below.

We experiment with reusing precomputed embeddings from one source model F in a consumer model F' that has a different size but the same tokenization vocabulary. The activations of the *final* transformer layer $h_{c \in C}^N$ are stored for each input c from corpus C . During the fine-tuning of the

consumer model F' , these stored activations are transformed through a learned 2-layer MLP with ReLU activation⁵ and added to the input embeddings of F' . We tried two frameworks for pairing large language model embeddings with compact models: F =Roberta-large \rightarrow F' =MiniLM-6L-H768 and F =BERT-base \rightarrow F' =DistilBERT.

Overall, as shown in Table 6 the larger model’s contextual representations do not improve the smaller model’s accuracy; in fact adding them decreases the average F1 score by 0.3-0.9 points.

A.4 Efficiency of Embedding Recycling when Training

For training, we observe almost perfect speed-up for all models and hardware configuration, barring MiniLM models on the machine equipped with a A6000 GPU (“NR vs R” column in Table 5). For example, BERT_{BASE} requires 17.38 ± 1.32 ms/batch⁶ without recycling, compared to 8.67 ± 2.18 ms/batch when recycling. Even when considering the additional time to cache embeddings to disk during the first pass, embedding recycling still achieves close to optimum speedup on all models except MiniLMs, where its gains hover between 52% and 82% (“NR vs SR” column in Table 5). When training for just 6 epochs (or roughly 2,000 steps), recycling embeddings is faster than simply freezing half of the parameters for all models but MiniLM (“F vs SR” column in Table 5); this is due to the relatively higher cost of caching layers to disk in case of smaller models. In these cases, we empirically found that recycling achieves faster training time than freezing after 12 epochs or 4,000 training steps; since smaller models typically require more epochs to converge, we conclude that recycling is generally preferable to partially freezing a model during training.

A.5 Embedding Pre-fetching while Recycling

Storing embeddings on NVMe drives, while fast, introduce additional latency compared to RAM. For example, BERT_{BASE} achieves an average latency of 351 ± 1 ms/batch when caching on disk (84% speedup), compared to just 334 ± 1 ms/batch when using memory (94% speedup). This is due to the fact that, while embeddings are being loaded from disk, the hardware accelerator responsible for executing the rest of the model sits idle. To reduce

⁵We found that MLP achieved better performance compared with a single linear layer on dev set.

⁶When training, we use a batch size of 16

		RoBERTa-Large + MiniLM L6-H768	MiniLM L6-H768	BERT + DistilBERT	DistilBERT

Text Classification Average Score		76.9	77.8	76.0	76.3

Table 6: Cross-Model Recycling Results for RoBERTa+MiniLM-L6H768 and BERT+DistilBERT configurations. **Bold** indicates the best average score between the cross-model recycling and fully finetuned versions of each model. Each score represents the average score of 10 runs, with the standard errors for each score in parentheses.

the impact of this latency penalty, our implementation supports *pre-fetching* of future embeddings: when processing a sequence of inputs, such as sentences in a manuscript, it loads embeddings for tokens ahead of the sequence inference is currently being run on. This optimization reduces the time accelerators wait for data to be available for inference; for example, in the case of BERT_{BASE} on A10G, disabling pre-fetching raised inference inference time to 374 ± 1 ms/batch (vs 351 ± 1 ms/batch with pre-fetching). Therefore in this section, all results are reported with prefetching enabled.

A.6 Software and Hardware

For implementation, we use the v4.19 version of the Transformers library (Wolf et al., 2019), the v0.4 version of the OpenDelta library (Ding et al., 2022), and the v1.11 version of the Pytorch library (Paszke et al., 2019). We conduct our experiments using NVIDIA RTX A6000 GPUs and NVIDIA A10G GPUs with CUDA v11.5.

A.7 Considerations in Selecting Hardware for Proof-of-Concept Recycling Experiments

We ran our proof-of-concept implementation on an AWS Cloud instance⁷ equipped with an NVIDIA A10G accelerator, and on a NVIDIA A6000 within an on-premise server⁸. The former contains fewer execution units (72 vs 84), fewer tensor cores (288 vs 336), slower memory (600 vs 768 GB/s), and slower boost clock (1800 MHz vs 1695 MHz). However, it is much more efficient, being rated at 150W (compare with A6000’s 300W power target). Therefore, the NVIDIA A10G accelerator presents a more realistic platform for embedding recycling, since it is more suitable for cost-efficient

large-scale model deployments. Both machines are equipped with PCIe NVMe drives, which we use to cache embeddings to recycle.

A.8 Cost-effectiveness of Embedding Recycling

In this section we attempt to estimate how cost-effective embedding recycling is for inference in a real-world setting. While this depends heavily on use-case-specific assumptions, we consider two typical settings as proofs-of-concept, one using cloud computing and one using local hardware.

There are four main factors that affect the cost-benefit ratio of embedding recycling: (1) compute cost, (2) storage cost, (3) model architecture, and (4) frequency of corpus reprocessing (i.e., how often the cached embeddings will be used). Compute costs are challenging to estimate for a locally-owned hardware setting due to many hidden cost factors beyond the GPUs (cooling, electrical costs, server to house the GPUs, etc) and so we use AWS EC2 cloud GPU prices as a cost estimate for both cloud and local hardware. In particular, we consider a g5.12xlarge instance with $4 \times$ A10G GPUs at 5.67 \$/hr.

Storage costs are easier to estimate for local hardware than compute costs, and local storage can be significantly cheaper because embedding recycling does not require the availability and durability guarantees provided by cloud solutions (the cache is accessed infrequently and can always be recomputed if it is lost). Therefore, we consider both a cloud storage solution (AWS S3 one-zone infrequent access, at 0.01 \$/GB/month) and a local storage solution. For local storage, we consider current consumer-grade hard drive prices at approximately 16.9 \$/TB based on data from Amazon and Newegg, and assume a lifespan of 6 years based on

⁷g5.2xlarge instance with 8 cores and 32 GB of RAM.

⁸Intel-based system with 128 cores and 512 GB of RAM.

Model	Cloud	Local
MiniLM ₃₈₄	0.05	2.2
MiniLM ₇₆₈	0.05	2.4
BERT _{BASE}	0.13	5.6
BERT _{LARGE}	0.30	12.9
DeBERTa _{XLARGE}	0.20	8.5

Table 7: Minimum reprocessing frequency (in months) needed in order for embedding recycling to be cost-effective in various model and hardware configurations.

data from Backblaze.⁹ This results in an average cost of 0.23 \$/TB/month over the life of the drive. Finally, we note that AWS does not charge for data transfer between S3 and EC2 within a region, so we can ignore data transfer costs in this calculation.

The frequency of corpus reprocessing is highly variable, so we report results in terms of the minimum reprocessing frequency that would be necessary for embedding recycling to be cost-effective. For all models we assume each input is 512 tokens and the cache is stored with FP16 precision.

Table 7 shows the minimum reprocessing frequency needed for embedding recycling to be cost effective for our models on cloud and local hardware. Under our assumptions, we find that embedding recycling is cost-effective in a cloud setting only if the corpus is reprocessed very frequently (several times per month). This may be realistic in some use cases, such as when a large team is working with the same corpus and developing many new models, or if new training data arrives frequently and the model developer wants to continually update and re-deploy it.

With local hardware the calculation is much more favorable; embedding recycling with BERT_{LARGE} would be worthwhile even if the corpus were only reprocessed once per year.

We note that embedding recycling could become substantially more cost effective with further development. In this work we did not explore ways to reduce storage costs, such as quantization or compression. In addition, while our experiments only considered sequence lengths of 512 tokens, for many full-text document corpora it is desirable to use a much longer sequence length to fit the whole document into a model at once. Because the computational cost of transformers generally scales superlinearly with input length (but storage

cost scales only linearly), embedding recycling will be more effective as the sequence length grows.

	Epochs	6	7

Table 16: Average Training Times and Epochs for Embedding Recycling (seconds for training time, count for epochs). **Standard Recycling** corresponds to layer recycling on a reduced transformer model. **Adapter-Based Recycling** corresponds to layer recycling on a reduced frozen transformer model with added trainable Adapter modules. Training time and epoch averages are the averages across the RoBERTa, BERT, SciBERT, DeBERTa V2 XL, and T5-Large transformer models and the text classification, NER, and QA datasets tested.

Trained on 100 million words and still in shape: BERT meets British National Corpus

David Samuel, Andrey Kutuzov, Lilja Øvrelid and Erik Velldal

University of Oslo, Language Technology Group

Abstract

While modern masked language models (LMs) are trained on ever larger corpora, we here explore the effects of down-scaling training to a modestly-sized but representative, well-balanced, and publicly available English text source – the British National Corpus. We show that pre-training on this carefully curated corpus can reach better performance than the original BERT model. We argue that this type of corpora has great potential as a language modeling benchmark. To showcase this potential, we present fair, reproducible and data-efficient comparative studies of LMs, in which we evaluate several training objectives and model architectures and replicate previous empirical results in a systematic way. We propose an optimized LM architecture called LTG-BERT.

1 Introduction

In the pursuit of state-of-the-art performance, NLP practitioners utilize increasingly larger amounts of data to pre-train language models, making it difficult to disentangle the improvements made by the proposed modeling choices themselves. Instead, our aim is to shift the focus towards more efficient language modeling on a small and standardizable pre-training corpus. We study the data efficiency of current language models on an openly available corpus of approximately 100M words – incidentally the estimated amount of words processed by humans before adulthood (Linzen, 2020).

The goal of this paper is not to rival the paradigm of ‘massively pre-trained language models’; instead we would in this work like to pursue a complementary direction of language modeling, which will hopefully lead to more interest in data-efficient language models. In particular, our contribution in this paper is twofold – we show that:

1. 100M words is enough to train a competitive language model that outperforms the downstream performance of the original BERT model. We show

that the combination of a well-curated representative corpus, improved LTG-BERT architecture and a better training objective results in a model with stronger linguistic knowledge than the original English BERT pre-trained on 30× larger corpus.

Large language models are notoriously data hungry, requiring hundreds of gigabytes of raw textual data. This becomes a major obstacle for low-resource languages while also putting a limit to the efficiency of any ‘efficient’ language model. On top of that, the size of web-crawled corpora makes it almost impossible to control their content and to prevent learning from harmful or copyrighted text (Bender et al., 2021). The British National Corpus (BNC; Consortium, 2007) is a 100-million-word reference corpus, manually curated to cover most aspects of 20th century British English.

2. Reproducibility and fair comparison of language models can be easily achieved by pre-training on the British National Corpus.

Massive language models are often pre-trained on nonpublic filtered collections of web-crawled text, which makes any reproduction impossible. We pre-train our models on a small and publicly available corpus, which allows for a replicable comparison of different language modeling configurations and which can be easily utilized in future research of novel variants of language models. We also release the pre-processing scripts, training scripts as well as the final model checkpoints.¹

Previously, language models have been pre-trained on different corpora tokenized by different tokenizers and fine-tuned by increasingly complex learning methods. This makes any comparison of the underlying neural architectures and pre-training objectives unfair. We make the language models in this paper directly comparable by fixing the training corpus, the tokenizer and the evaluation methods, while keeping them as simple as possible.

2 Related Work

The data requirements of language models have been growing in orders of magnitude since their early stages (Jelinek, 1976). Taking a huge leap towards more recent work, ELMo (Embeddings from Language Models; Peters et al., 2018) were the first to introduce deep *contextualized* embeddings of words. Recognizing the need of a large text corpus for this task, ELMo was trained on the 1B Word Benchmark (Chelba et al., 2014). Later, BERT (Bidirectional Encoder Representations from Transformers; Devlin et al., 2019) further advanced the performance of contextualized embeddings when it based the entire language model on the Transformer architecture (Vaswani et al., 2017). Another important aspect of BERT is that it was trained on a larger corpus than ELMo: about 3.3B words from crawled English Wikipedia and BookCorpus (Zhu et al., 2015). To our best knowledge, the exact version of neither of the two subcorpora is publicly available.² The issue of limited replicability has become even more pronounced with later large language models: XLNet (Yang et al., 2019) was trained on 33B words, RoBERTa (Liu et al., 2019) on more than 30B words and GPT-3 (Brown et al., 2020) on an approximately 400B word corpus. None of these datasets is available; the authors utilize non-trivial filtering algorithms on openly available web crawls but do not release the end product nor the filtering source code.

The effect of corpus size has been thoroughly studied in Zhang et al. (2021) as well as in Hoffmann et al. (2022). They test differently sized random subsets of a BERT-like corpus (crawled Wikipedia and Smashwords) and of a massive web-crawled text corpus (MassiveText; Rae et al., 2021), respectively. Unlike them, we evaluate the effect of training on a small corpus, which was *carefully curated* to create a representative sample of English. The British National Corpus is arguably more diverse and informative than a random subset of a web crawl – hence we test how the *quality* of a pre-training corpus influences the downstream performance, not only how the data quantity matters. We believe this aspect is vital for the future research of effective and reliable language models.

²BookCorpus (Zhu et al., 2015) is not available anymore and the authors of BERT do not specify what version of Wikipedia dump they used or how did they preprocess it (<https://github.com/google-research/bert#pre-training-data>).

	documents	sentences	words	subwords
train	4 014	8 501 376	115 870 549	131 392 103
development	35	106 566	1 215 306	1 367 570

Table 1: Size of the train-development splits for the pre-processed BNC corpus. Note that the number of words is larger than the 100 million reported by the BNC Consortium due to our less conservative pre-tokenization strategy.

3 British National Corpus

We use the British National Corpus (BNC) as a diverse, balanced, compact, and publicly available monolingual English corpus. BNC is comprised of both written and spoken language with a total of 100 million words. The manually curated content contains a wide range of British English from the late 20th century – newspapers, journals, books (academic and fiction), letters, essays, unscripted informal conversations or transcribed business meetings, radio shows or phone calls. The written part makes up approximately 90% of the corpus and the remaining 10% contains the transcribed speech. The sources are truncated to contain at most 45 000 words to ensure greater diversity within the limited amount of 100 million words.

Creation. The process of creating the BNC is extensively described in its documentation on the website.³ It was created by the so called ‘BNC Consortium’ led by Oxford University Press, and including major dictionary publishers Longman and Larousse Kingfisher Chambers; academic research centres at Oxford University Computing Services, the University Centre for Computer Corpus Research on Language (UCREL) at Lancaster University, and the British Library’s Research and Innovation Centre. The purpose of the British National Corpus project was to construct a balanced and representative sample of current British English at the time. It was created over a period of four years and was a result of careful planning and data selection across a number of selection criteria (domain, time, medium, level) with proportions in the corpus designed to reflect the proportions found in real language use. It is widely acknowledged that the BNC has been a major influence on the construction of language corpora (Burnard, 2002). One downside of the BNC is that it does not re-

³<https://ota.bodleian.ox.ac.uk/repository/xmlui/handle/20.500.12024/2554>

flect anything occurring to English language and the world in the 21st century, but still no better alternatives of the same size and quality exists. In addition, BNC was used as a model for creating representative corpora for other languages: e.g., Turkish (Aksan et al., 2012).

Version. We use the third release of the corpus, BNC XML Edition (2007), which is the final revision of the texts compiled from 1991 to 1994 (Consortium, 2007). The XML edition did not get any additional content on top of the original text samples, but it got some minor corrections, more metadata and it is supplied in a convenient XML format.

3.1 Preprocessing

We convert the XML version of BNC into the Markdown format,⁴ to make it human-readable and usable as a direct raw-text input of a language model. On top of that, it can also preserve some meta-information encoded in the original XML format. Short samples from the preprocessed corpus can be found in Appendix A. After preprocessing, the articles are randomly placed into a training split and a development split. The proportions of both splits are given in Table 1.

Composition. BNC is hierarchically composed of the following text units: words, sentences, paragraphs and articles. We preserve the sentence information by storing each sentence on a separate line; paragraphs are divided by a blank line and an article always starts with a top-level header. The word-tokens are intentionally not preserved – instead, we heuristically detokenize the text to move it towards the natural text distribution. BNC includes information about the original whitespace, but we found it unreliable in some cases, necessitating the use of heuristics.

Other metadata. Other meta information available in our Markdown version is as follows:

1. **Headers:** We keep the headers together with their level by converting them to the atx-style format prefixed by hash symbols ‘#’.
2. **Speakers:** The spoken part of BNC is divided into speech turns, each accompanied

⁴<https://daringfireball.net/projects/markdown/>

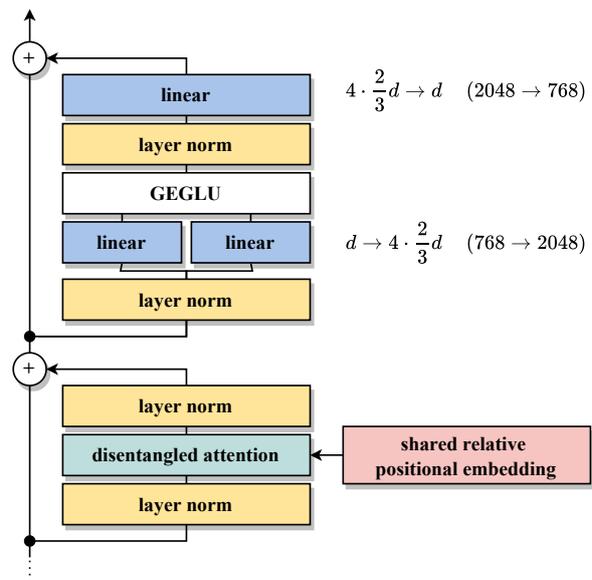

Figure 1: A simplified diagram of one layer in our LTG-BERT language model, which illustrates the changes made to the standard Transformer architecture – NormFormer layer normalization, GEGLU activation function and disentangled attention.

by a speaker identifier. We maintain this information by formatting each speech turn as ‘{name} : _␣ {turn}’.

3. **Quotes:** Markdown also allows us to keep the special quoted text by using a prefix ‘> _␣’.
4. **Lists:** The XML format contains special tags for lists and their respective elements, we use the ‘- _␣{element}’ notation to encode these text blocks.
5. **Incomprehensible speech:** Some words or phrases could not be transcribed because they were illegible or inaudible. Since completely omitting such text would result in ungrammatical sentences, we mark these segments with a special ‘[UNK]’ token.

Not all of this additional information is of use for the language models tested in this article, but it can be easily filtered out when needed. We preserve it to make this corpus more versatile.

4 Model architecture

We slightly depart from the typical *post-norm* Transformer architecture (Vaswani et al., 2017) used by BERT (Devlin et al., 2019), as illustrated in Figure 1. Preliminary experiments with this model showed that it tends to unpredictably diverge in

the later stages of training. This behavior has been noted in previous work on large LMs (Liu et al., 2020) and accordingly, we follow some of the recent improvements of Transformer.

NormFormer. *Pre-norm* variation of the Transformer has been shown to lead to more stable convergence with slightly degraded performance (Nguyen and Salazar, 2019). Shleifer and Ott (2022) claimed to mitigate this degradation by introducing an additional layer normalization operation. For these reasons, we decided to use their so-called *NormFormer* architecture to stabilize the training.⁵

GEGLU activation function, proposed in Shazeer (2020), enhances the expressiveness of the original Transformer feed-forward modules by redefining them as

$$\text{FF}_{\text{GEGLU}}(\mathbf{x}) = (\text{GELU}(\mathbf{x}\mathbf{W}_1) \odot \mathbf{x}\mathbf{W}_2) \mathbf{W}_3,$$

where \mathbf{W}_i are weight matrices⁶ and GELU is the Gaussian Error Linear Unit (Hendrycks and Gimpel, 2016). Note that this formulation involves three linear transformations instead of two, we therefore lower the intermediate hidden size by $2/3$ to keep the number of parameters the same.

Disentangled attention. The original Transformer formulation (Vaswani et al., 2017) fuses the content and positional information together in the first embedding layer and calculates the (un-normalized) attention score between each pair of tokens \mathbf{x}_i and \mathbf{x}_j as

$$A_{i,j} = \frac{\mathbf{Q}_i \mathbf{K}_j^\top}{\sqrt{d}},$$

where \mathbf{Q} and \mathbf{K} are the query-key linear transformations of \mathbf{x} .

He et al. (2021) proposed to *disentangle* the content and positional information. The content representations are incrementally built by the Transformer layers and the position is encoded by one shared relative positional embedding matrix $P \in \mathbb{R}^{(2L-1) \times d}$, where L is the maximal input length.⁷ This is supposed to offer greater expressivity as each layer can access these two parts directly. The attention scores are then calculated as a sum of

⁵They also proposed some additional improvements – *head scaling* and *residual scaling*, but we did not experience any performance benefits from these changes.

⁶The bias terms are omitted for brevity.

⁷Tokens at positions i and j have relative positional embedding at the $(L - i + j)$ th row of P , denoted as $P_{i,j}$.

three distinct parts: *content-to-content*, *content-to-position* and *position-to-content* attention – formally, the attention scores are defined as

$$A_{i,j} = \frac{{}^c\mathbf{Q}_i {}^c\mathbf{K}_j^\top + {}^c\mathbf{Q}_i {}^p\mathbf{K}_{i,j}^\top + {}^p\mathbf{Q}_{j,i} {}^c\mathbf{K}_j^\top}{\sqrt{3d}},$$

where ${}^c\mathbf{Q}$ and ${}^c\mathbf{K}$ are linear transformations of the *content* vectors and ${}^p\mathbf{Q}$ and ${}^p\mathbf{K}$ are linear transformations of the relative *positional* embedding $P_{i,j}$. We share the parameters of the content and positional transformations, ${}^c\mathbf{Q} = {}^p\mathbf{Q}$ and ${}^c\mathbf{K} = {}^p\mathbf{K}$, to not increase the model size while achieving comparable performance (He et al., 2021).

Initialization scaling. Bajaj et al. (2022) found that we can further stabilize the Transformer architecture by gradually scaling down its feed-forward (FF) weight matrices. Following Nguyen and Salazar (2019), we first initialize all weight matrices \mathbf{W} by sampling from:

$$\mathbf{W}_{i,j} \sim \mathcal{N}\left(0, \sqrt{\frac{2}{d+4d}}\right),$$

where d is the hidden dimension.⁸ Then all three weight matrices in a FF module at layer l are scaled down by a factor of $1/\sqrt{2^{l+1}}$.

5 Training objectives

The fixed corpus, tokenizer and fine-tuning procedures establish a controlled test bed for a comparative study of training objectives proposed in the past. The original BERT model is trained via two self-supervised training objectives – masked language modeling (MLM) and next sentence prediction (NSP). We evaluate five different configurations of these objectives (three for MLM and two for NSP), as further detailed below.

5.1 Masked language modeling (MLM)

Unlike the traditional auto-regressive language models, the *Bidirectional* Encoder Representations from Transformers (BERT) learn a *bidirectional* contextualized representation for each token in a text segment. This is done by randomly selecting 15% of subword tokens (excluding the special tokens). Out of these, 80% are masked, 10% randomly replaced and 10% are left untouched. The

⁸This formula is roughly equal to the universal BERT initialization range of 0.02 for $d = 1024$.

language model is then trained to jointly predict the original state of the selected units. We investigate three common choices of the masked text units:

1. **Subwords.** As proposed in the seminal work by Devlin et al. (2019), every subword is masked independently with 15% probability to model its bidirectional dependencies.
2. **Whole words.** This method was also implemented by Devlin et al. (2019), after the publication of their original paper with subword masking. The motivation for this approach is that partially masked multi-subword word units are often easily decoded without any need for non-local contextual information; masking the whole multi-subword unit should force the model to build longer-range non-local dependencies.
3. **Spans.** The third method further follows the direction of whole-word masking and generalizes it to masking of random *spans* of subwords. More specifically, SpanBERT (Joshi et al., 2020) iteratively samples random spans until 15% of subwords are masked. For each span, it first samples its length from $\text{Geo}(p)$, where $p = 1/3$.⁹ Then the starting subword of the masked span is chosen from a uniform distribution.

5.2 Next sentence prediction (NSP)

Masked language modeling is a token-level training objective that trains the model to learn rich token representations. Yet, some downstream tasks need a single sentence-level representation instead. To also learn these, researchers have designed a number of additional semi-supervised training objectives. On the other hand, Liu et al. (2019) argue that NSP objectives do not help the downstream performance and they can thus be dropped in favour of a simpler optimization process with a single MLM training objective. To test these hypotheses, we experiment with two NSP objectives:

1. **Document discrimination.** Devlin et al. (2019) sample two text segments and then train the model with a second discriminative loss function, which predicts whether the two segments are continual or randomly taken from two different documents.

⁹ To ensure that the sampled length is not too large, we take the sampled value modulo 10. The expected length of a masked span is then approximately equal to 2 with $p = 1/3$.

2. **Sentence-order discrimination.** Lan et al. (2020) argue that the document discrimination is too easy as the language models only have to compare the topic of the two segments to achieve a good performance in this task. Instead, they propose to predict whether the two segments are in the correct order or whether they are swapped. Thus, the sentence-order loss forces the neural network to model inter-sentence coherence and this is believed to lead to a better downstream performance.

6 Evaluation metrics

We use three conceptually different methods for evaluating the amount of linguistic knowledge acquired by the BNC language models. 1) The (Super)GLUE datasets test the ability of the model to adapt to various NLU tasks by further optimizing the whole pre-trained model, 2) edge probing tasks evaluate how much linguistic information one can extract from a frozen pre-trained model and 3) BLiMP utilizes the intrinsic ability of the pre-trained network to model language and probes its knowledge without any additional training. We further elaborate on each of these below.

6.1 (Super)GLUE

GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) have become a de-facto standard for evaluating the language understanding capabilities of language models. Accordingly, we also choose to fine-tune our language models on these NLU tasks to measure their linguistic and transfer-learning performance. We give more technical details about our implementation of (Super)GLUE fine-tuning in Appendix B.1.

We exclude the Winograd schema datasets, WNLI and WSC, because they require a complete reformulation to get past the trivial most-frequent baseline (Kocijan et al., 2019). The remaining 14 (Super)GLUE datasets measure performance on these tasks:

- **Inference:** CB, MNLI, QNLI, RTE.
- **Linguistic acceptability:** CoLA.
- **Sentiment analysis:** SST-2.
- **Semantic similarity:** MRPC, QQP, STS-B.
- **Word sense disambiguation:** WiC.
- **Question answering:** BoolQ, COPA, MultiRC, ReCoRD.

6.1.1 HANS

Deep learning systems are (by design) prone to finding spurious correlations in the training data. These heuristics can often be successfully employed for the evaluation data, as well – thus, one has to be careful when implying that a higher score on a benchmark shows a deeper understanding of the tested model. McCoy et al. (2019) tried to evaluate to what extent language models rely on spurious heuristics to solve NLI tasks. They identified a set of fallible syntactic heuristics and designed a test set where these ‘shortcuts’ should fail – Heuristic Analysis for NLI Systems (HANS). We adopt their approach and test models that have been fine-tuned on MNLI.

6.2 Edge probing

GLUE tasks measure the ability of a LM to be fine-tuned on a sentence-level NLU problem. To get a more comprehensive picture of LM performance, one can also *probe* the word-level contextualized representations, measuring how much syntactic or semantic information can be extracted.

Tenney et al. (2019) devised a simple approach of probing for a diverse set of linguistic phenomena called *edge probing*. They reformulate traditional NLP tasks as *span classification*: part-of-speech tagging can be viewed as classification of word-spans and semantic role labeling becomes a classification of pairs of spans: predicate-span and argument-span. In the following, we will probe our models for five basic tasks: part-of-speech tagging (POS), dependency parsing (DP), semantic role labeling (SRL), named-entity recognition (NER) and coreference resolution (CR). Note that the model only learns to *classify* each span provided to the model as gold data. This substantially simplifies some of the tasks, for example SRL. Please refer to Appendix B.2 for the implementation details of edge probing.

6.3 BLiMP

One disadvantage of the aforementioned evaluation metrics is that the results are skewed by the second-stage supervised training, which makes it problematic to disentangle the prior knowledge of a language model from the acquired knowledge (Belinkov, 2022). In contrast, the Benchmark of Linguistic Minimal Pairs (BLiMP; Warstadt et al., 2020) attempts to measure the linguistic knowledge of a language model in a zero-shot manner – with

out any additional training. The dataset consists of 67 000 sentence pairs; each pair differs minimally on the surface level, but only one of the sentences is grammatically valid. We can use the intrinsic ability of language models to assign a probability to every sentence and test how often a language model assigns a higher probability to the correct sentence. Appendix B.3 gives more details about ranking the likelihood of sentences according to the raw output of a masked language model.

7 Experiments

We conduct a number of experiments in this section. First, we compare different training hyperparameters and model configurations described in Section 4. Then, using the overall best training setting, we make a comparative study of training objectives (Section 5). Finally, we investigate the sampling efficiency of our proposed language model and we compare BNC with a Wikipedia & BookCorpus subset of the same size. These results can then be used as a baseline performance of BNC-BERT in future studies.

The central model used in the experiments is a *base-sized* Transformer – 12 encoder layers with hidden size 768 and 12 attention heads (more details in Appendix E). All reported models utilize the same cased WordPiece tokenizer (Wu et al., 2016) with a vocabulary size of $2^{14} = 16\,384$ trained with the BNC dataset (Appendix G). This goes against the trend of increasing the subword vocabulary in recent work,¹⁰ but a larger vocabulary size would lead to a lot of infrequent tokens within our limited corpus – we roughly follow Gowda and May (2020) and ‘... use the largest possible BPE vocabulary such that at least 95% of classes have 100 or more examples in training.’

Since our aim is to train models comparable to BERT_{base}, we train for the same amount of sampled tokens. Devlin et al. (2019) trained on 1M batches of 128K tokens, we use 31 250 training steps with batch size of 4M tokens to parallelize and accelerate the process. Also, similarly to Devlin et al. (2019), we use sequence length of 128 tokens in the first 90% of training and a larger sequence length of 512 only in the last 10% of steps. We deliberately do not compare against more recent models, which are trained for much longer to achieve slightly bet-

¹⁰ BERT (Devlin et al., 2019) uses 28 996 tokens, RoBERTa (Liu et al., 2019) 50 265 and in 2021, DeBERTa (He et al., 2021) used a vocabulary of 128 100 subwords.

ter performance: RoBERTa is trained on $16\times$ more training samples, for example.¹¹

7.1 Comparison of model architectures and training settings

In order to establish a strong baseline, we evaluate the proposed changes from Section 4 and other training configurations. We present the results in Table 2, where we compare the final model with all changes applied and models with one of those modifications removed. These training choices turned out to be the most important:

- Both the post-norm and pre-norm transformer variants perform substantially worse than the NormFormer-like layer normalization (Shleifer and Ott, 2022). Both of them also lead to less stable and only slightly faster training.
- Absolute positional embeddings seem to be less adaptable for fine-tuning but perform better on language modeling itself, as can be seen on the BLiMP results. We hypothesize that this is caused by more accurate estimation of probabilities of the first few words in a sentence. The simpler absolute embeddings also lead to the greatest reduction of training time. We choose the slower relative positional embeddings despite this fact to increase the performance on (Super)GLUE tasks.
- We observe that setting the weight decay correctly is crucial for masked language modeling. The default weight decay value found in Devlin et al. (2019), 0.01, performs substantially worse on all tested tasks. We use a higher decay value of 0.1 to boost performance, this value is most likely strongly correlated with the corpus size we use here. This suggests that previous findings of inferior performance of LMs pre-trained on small corpora might be caused by insufficient hyperparameter search.
- As expected, the AdamW optimizer (Loshchilov and Hutter, 2019) behaves poorly in our highly parallel training regime. Our study successfully replicates the reported performance of the LAMB optimizer (You et al., 2020), which we thus use in all other experiments.

¹¹ 500K steps with 8 192 segments of length 512, according to (He et al., 2021).

Model	MNLI	Edge probing	BLiMP	Training time
LTG-BERT	85.1 \pm 0.2	95.3 \pm 0.1	83.4	8h 13min
w/ post-norm (0.005)	-0.5 \pm 0.2	-0.6 \pm 0.1	-0.1	-22min
w/ pre-norm (0.005)	-1.3 \pm 0.1	-0.2 \pm 0.1	-0.9	-35min
w/ GELU activation	-0.3 \pm 0.3	0.0 \pm 0.1	-0.1	-6min
w/ absolute pos. emb.	-1.1 \pm 0.2	- 0.1 \pm 0.1	+0.6	-2h 16min
w/o FF init. scaling	-0.3 \pm 0.2	- 0.1 \pm 0.1	+0.1	0min
w/ learnt FF biases	-0.3 \pm 0.2	0.0 \pm 0.1	-0.1	+9min
w/ 0.01 WD (0.005)	-1.4 \pm 0.1	-0.2 \pm 0.1	-0.7	-1min
w/ linear schedule	-0.5 \pm 0.2	0.0 \pm 0.1	-0.2	0min
w/ AdamW (0.001)	-0.9 \pm 0.2	-0.2 \pm 0.1	-0.5	-11min

Table 2: Comparative study of different architectural and training settings. The first row shows the performance of the final model with all improvements applied and the following rows give the relative changes in performance when one of the changes is not applied – for example, the second row tests swapping the NormFormer-like normalization with the ‘post-norm’ normalization. Some runs diverged with the default learning rate of 0.01 and had to be run again with a lower value (denoted in parentheses). ‘WD’ stands weight decay and ‘FF’ is an abbreviation for the feed-forward modules. We report the mean and standard deviation statistics across five runs, if applicable, and boldface all run within 1 standard deviation from the best result.

The other changes bring more marginal gains – all three tested modifications of the feed-forward layers work slightly better: 1) using GEGLU activation function instead of GELU, 2) initializing the feed-forward layers with incrementally lower weight norms, and 3) not using any bias parameters in these layers. The last tested change shows that cosine learning rate decay (Rae et al., 2021) performs better than the standard linear weight decay.

7.2 Training objective comparison

Masked language modeling. First of all, we compare the three masking methods described in Section 5.1: subword, whole-word and span masking. The summary of the results is given in Table 3, more detailed evaluation in Appendix D. Overall, the span-based masking performs marginally better than the other methods – it shows a clear improvement on (Super)GLUE benchmarks over the simple subword masking, it generalizes the best according to the HANS score and it even matches the performance of BERT_{base} on the averaged BLiMP accuracy. All methods perform equally well on edge probing. Whole-word masking lacks on the BLiMP benchmark because the model is not expecting partially masked words that can occur in

Model (variant)	GLUE					HANS	Edge probing	BLiMP
	MNLI	MRPC	QNLI	SST-2	Average			
Wikipedia + BookCorpus (3000M words; Devlin et al., 2019)

Table 3: Summary of the experimental results. We show the results on the 4 GLUE tasks with known development results from Devlin et al. (2019) and their average; then the accuracy on HANS, the average of all 5 edge probing tasks and 67 BLiMP tasks. [†]The BERT_{base, cased} results are shown primarily for reference, they come from these sources: partial development GLUE scores from Devlin et al. (2019), edge probing from Tenney et al. (2019), HANS from Bhargava et al. (2021) and BLiMP from Salazar et al. (2020). We also add the BERT_{base, cased} results from our evaluation scripts for more fair and accurate comparison. We present the mean and standard deviation statistics over 5 evaluation runs and boldface all run within 1 standard deviation from the best result. The detailed results can be found in Appendix D.

the evaluation (Section 6.3). The original subword masking strategy is still a competitive baseline and it might be preferred in practice due to its simple implementation.

Next-sentence prediction. Next, we experiment with combining an NSP task and simple subword masking. We hypothesize that a second training objective might extract more information from the limited BNC corpus, which would help with the downstream performance – an opposite conclusion than Liu et al. (2019). However, our hypothesis turns out to be wrong, according to the results in Table 3. The experiments agree with the design of latest masked language models – next sentence prediction is an unnecessary training objective, at least for the tasks evaluated in this paper. It does not lead to substantially improved sentence representations even in a limited data regime. We can also see that the well-motivated order discrimination (Lan et al., 2020), proposed to solve the issues of document discrimination, actually leads to an overall worse performance. Hence we cannot recommend to complicate pre-training with a second training objective.

7.3 Sampling efficiency

An important aspect of efficient language models is the number of training steps they require to reach a sufficient performance. So far, we have limited the size of the training corpus but kept the number of steps constant, set according to Devlin et al. (2019). The results in Table 3 suggest that increasing the steps two times does not lead to a noticeably better performance with BNC. Even more so, training for half the time turns out to be enough to get comparable performance. Yet, decreasing the training steps further starts to degrade the downstream results too much, as evidenced by the scores obtained with 1/4 of the default steps.

These results highlight the sampling inefficiency of current self-supervised language modeling methods, as even with 1/4 steps, every token in BNC is seen about roughly 250 times during training.¹² We hope that a future work in this field will be able to learn from a smaller number of samples.

¹² This value can be calculated from Table 9: these models are trained for 7 812 steps with 4 194 304 tokens per batch. Table 1 shows that there are 131 392 103 subwords in the BNC train split.

7.4 100 million subset of Wikipedia & BookCorpus

Our last experiment evaluates how much does the careful curation of BNC help the downstream performance. To keep the comparability to BERT, we choose to pre-train on a random subset of Wikipedia and BookCorpus (with equal size to BNC, sampled document-wise); this corpus is constructed according to [Appendix F](#). Note that BNC is a corpus of British English compiled in 1990s so some evaluation tasks can be skewed against it – for example QNLI, which is based on texts from Wikipedia. [Table 3](#) shows that a high-quality data source is not necessarily needed to learn from 100M words but better quality leads to a noticeable difference in downstream performance.

8 Conclusion

In this paper, we evaluated how data-efficient masked language models can be. In particular, we trained a variety of models with different training objectives on the same training data: British National Corpus. Although small by modern standards (100M tokens), it is well balanced and carefully crafted to represent British English of the 20th century. On a variety of benchmarks, our models perform better than BERT_{base} trained on a much larger corpus. We believe that this limited data regime is beneficial for the development of efficient and reliable language models. Our finding also suggests that 100 million word tokens is enough to learn basic linguistic skills by current language modeling techniques, given that the data is carefully selected and balanced. To conclude, huge amounts of training data are not always necessary – we should focus on more efficient training settings instead.

We showed that the next sentence prediction objective does not improve BERT-like models, confirming the findings in [Liu et al. \(2019\)](#). In addition, the standard subword masking from [Devlin et al. \(2019\)](#) is consistently outperformed by the span masking method and the linguistic performance can be substantially increased by utilizing better neural architectures and training configurations. We release the code for training and using BERT-like models with the optimal architectural choices (according to our experiments) under the name LTG-BERT.¹³

¹³<https://github.com/ltgoslo/ltg-bert>

The presented results serve primarily as the foundation for future research on efficient language modeling. We hope our work shows the value of careful curation of representative corpora and will spark more interest in this area, where BNC can serve as an undemanding, replicable and openly-available training corpus.

9 Limitations

First of all, our work only considers language modeling of English and does not provide results on any other language – even though we hope that our conclusions could be useful for low-resource languages. Secondly, even though we found out that it is possible to train a competent language model with a small corpus, the training process still requires a similar amount of computational resources to models trained with larger corpora, as noted in [Section 7.3](#). Finally, we evaluate mainly the linguistic knowledge of language models ([Section 6](#)), our conclusions might not apply for their general knowledge.

A BNC samples

We follow the description of the Markdown conversion of BNC from Section 3.1 and show samples of the resulting raw Markdown text to illustrate this process, highlighting some of the formatting information captured by our format. A sample of a spoken document is given in Listing 1 and a sample of a written article is shown below, in Listing 2.

B Evaluation metrics – implementation details

B.1 (Super)GLUE

Fine-tuning of the GLUE and SuperGLUE tasks follows a straightforward framework: the segments are tokenized, concatenated – starting with a special [CLS] token and with a [SEP] token put in between the segments – and input to a pre-trained language model. Subsequently, the contextualized representation of the special [CLS] token is fed into an MLP classifier. The pre-trained weights are further fine-tuned together with the classifier weights.

We do not employ any additional training tricks that were used in the previous works to seemingly increase the performance of their large language models – e.g. further ‘pre-training’ on MNLI, multi-task learning, ensembling, extensive hyperparameter search, selecting the best random seeds, reformulating the tasks or complex regularization techniques such as SMART (Jiang et al., 2020).

B.2 Edge probing

We follow the description of edge probing in the original paper by Tenney et al. (2019). First of all, subword representations $s_{i,k}$ are extracted from a frozen LM, for all positions i and layers k . These are downsampled to a dimensionality of 256 by a linear transformation. To get a vector representation h_t for the t^{th} span, we apply two pooling operations on the subword-token representations $s_{t,k}$. First, we pool the vectors at all layers k by taking a learnt convex combination $\hat{s}_t = \sum_{k=1}^{12} \gamma_k s_{t,k}$, where $\gamma_k \in \mathbb{R}$. Next, since one span can be split into multiple subwords, we employ an attention pooling operator to get the span-level embeddings: $h_t = \sum_{i \in \mathcal{I}_t} \text{att}(\hat{s}_t; \theta) \hat{s}_t$, where \mathcal{I}_t are the subwords indices of the t^{th} span. Finally, the pooled vectors h_t are fed into a multi-layer perceptron (MLP) and classified. If a task requires a pair of span representations (DP, SRL and CR), then these are pooled

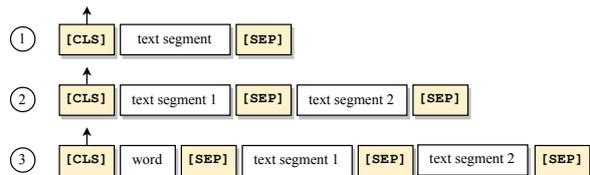

Figure 2: Three variations of (Super)GLUE input: 1) single-sentence tasks SST-2 and CoLA; 2) classification of a pair of text segments: BoolQ, CB, COPA, MNLI, MRPC, QNLI, QQP, STS-B, RTE; and 3) WiC (in the figure), MultiRC, ReCoRD.

with two separate attention operators and concatenated before being passed to the MLP classifier.

B.3 BLiMP

These models are trained to estimate $P(s_t | s_{<t})$ for sentence s and token s_t where $s_{<t} = (s_i | i < t)$; then the sentence log-probability is given by $\log P(s) = \sum_{t=1}^N \log P(s_t | s_{<t})$.

The issue with masked language models is that they are not designed to calculate this property; they are trained to estimate $P(s_t | s_{\setminus t})$ – the likelihood of a token s_t given its bidirectional context $s_{\setminus t} = (s_i | i \neq t)$. We can however still use MLMs to infer a *score* for each sentence where a higher *score* corresponds to a more likely sentence. Wang and Cho (2019) defined *pseudo-log-likelihood score* of a sentence s with model θ as

$$\text{PLL}(s) = \sum_{t=1}^N \log P(s_t | s_{\setminus t}; \theta).$$

Salazar et al. (2020) tested PLL and found that it produces accurate predictions on BLiMP. We adopt their approach and evaluate our models with PLL.

C Layer interpretation

The definition of the fine-tuning scheme for edge probing makes it straightforward to rate the contribution of each Transformer layer to a particular task – we can simply have a look at the layer-wise weights γ_k , see Table 5. To be more precise, if we define the k^{th} attention layer as a_k , the k^{th} feed-forward layer as ff_k and layer normalization operator as LN, then the k^{th} layer ℓ_k of a post-norm Transformer (Vaswani et al., 2017) computes the following function:

$$\begin{aligned} \hat{a}_k(x) &= \text{LN}(x + a_k(x)) \\ \ell_k &= \text{LN}(\hat{a}_k(\ell_{k-1}) + ff_k(\hat{a}_k(\ell_{k-1}))) \end{aligned}$$

Task	BoolQ	CB	CoLA	COPA	MNLI	MRPC	MultiRC	QNLI	QQP	ReCoRD	RTE	SST2	STSB	WiC

Table 4: The train and validation sizes of GLUE and SuperGLUE tasks (omitting WNLI and WSC). Note that we list the numbers of examples in the (Super)GLUE formulation of these tasks, which may differ from the actual number of examples – for example in case of multiple-choice questions. Some tasks do not offer a reliable amount of training data and some tasks contain a large number of examples longer than the length limit of our language models.

Task	Layer												Regression
	1	2	3	4	5	6	7	8	9	10	11	12	slope
POS	27.49	12.55	7.54	5.42	5.78	4.83	5.12	5.59	6.02	5.43	4.40	9.84	-0.98
DP	14.65	10.78	10.99	12.66	9.92	7.47	8.00	6.04	5.66	4.58	3.89	5.35	-0.89
SRL	19.38	13.70	9.80	9.56	8.44	7.04	6.99	5.61	4.85	3.83	2.70	8.11	-1.04
NER	18.16	9.12	6.58	4.83	6.86	6.75	6.87	6.28	6.62	4.93	5.87	17.13	-0.16
COREF	7.24	9.12	7.78	10.50	11.89	12.85	12.35	8.96	5.20	4.27	3.56	6.29	-0.42

Table 5: The per-layer contributions to different edge probing tasks, taken from the layer-wise convex weights γ_k (rendered in percent). To summarize the individual scores, we fit a linear regression line and show its slope in the last column. A negative slope implies stronger representation in the lower layers and vice versa.

It is unclear how to separate the contribution of each layer from the the previous layers here: ℓ_k contains both the previous scaled ℓ_{k-1} and its transformation from a_k and ff_k . On the other hand, our NormFormer-like architecture (Section 4) defines each layer ℓ_k as:

$$\hat{a}_k(x) = x + \text{LN}(a_k(x))$$

$$\ell_k = \hat{a}_k(\ell_{k-1}) + ff_k(\hat{a}_k(\ell_{k-1}))$$

Then it is trivial to calculate the contribution of each layer as $s_k = \ell_k - \ell_{k-1}$. We use this s_k entities to compute the learnt convex combination of all layers $\hat{s} = \sum_{k=1}^{12} \gamma_k s_k$.

Interpreting γ_k as the amount of ‘knowledge’ of a particular task in layer k , we see that POS information is contained primarily in the lowest layers, followed by SRL and DP. On the other hand, NER and CR are represented more strongly in the higher layers, which confirms the related findings in the literature (Rogers et al., 2020).

D Fine-grained results

To ease the evaluation of any future language models trained on BNC, we provide detailed results of all evaluated models in the following tables: GLUE results are shown in Table 6, edge probing performance is given in Table 7 and the BLiMP accuracies in Table 8.

(Super)GLUE. In total, we fine-tune all models on these 14 (Super)GLUE datasets:

- **Boolean Questions** (BoolQ; Clark et al., 2019), a yes/no question answering dataset evaluated with accuracy.
- **The CommitmentBank** (CB; de Marneffe et al., 2019), evaluated with both accuracy and F_1 -score, where the multi-class F_1 is computed as the unweighted average of the F_1 per class.
- **Corpus of Linguistic Acceptability** (CoLA; Warstadt et al., 2019) evaluated with the Matthews correlation coefficient (MCC; Matthews, 1975).
- **Choice of Plausible Alternatives** (COPA; Roemmele et al., 2011), evaluated with accuracy.
- **The Multi-Genre Natural Language Inference Corpus** (MNLI; Williams et al., 2018). Its development set consists of two parts: *matched*, sampled from the same data source as the training set, and *mismatched*, which is sampled from a different domain. Both parts are evaluated with accuracy.
- **The Microsoft Research Paraphrase Corpus** (MRPC; Dolan and Brockett, 2005), eval-

uated with both accuracy and F_1 -score.

- **Multi-Sentence Reading Comprehension** (MultiRC; Khashabi et al., 2018), a multiple choice question answering dataset, evaluated with the exact match accuracy (EM) and F_1 -score (over all answer options).
- **Question-answering Natural Language Inference** (QNLI) constructed from the Stanford Question Answering Dataset (SQuAD; Rajpurkar et al., 2016), evaluated with accuracy.
- **The Quora Question Pairs** (QQP),¹⁴ evaluated with both accuracy and F_1 -score.
- **The Stanford Sentiment Treebank** (SST-2; Socher et al., 2013), evaluated with accuracy.
- **The Semantic Textual Similarity Benchmark** (STS-B; Cer et al., 2017), evaluate with Pearson and Spearman correlation coefficients.
- **Reading Comprehension with Commonsense Reasoning Dataset** (ReCoRD; Zhang et al., 2018), a question answering dataset evaluated with the exact match accuracy (EM) and token-level F_1 -score (maximum over all correct mentions).
- **The Recognizing Textual Entailment datasets** (RTE; Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), evaluated with accuracy.
- **The Word-in-Context dataset** (WiC; Pilehvar and Camacho-Collados, 2019), evaluated simply with accuracy.

Edge probing. We report the results on part-of-speech tagging (POS), semantic role labeling (SRL), named entity recognition (NER) and coreference resolution (CR) using the annotations from the English part of OntoNotes 5.0 (Weischedel, Ralph et al., 2013). In addition, to further measure the syntactic abilities, we test the dependency parsing (DP) accuracy on the English Web Treebank v2.9 dataset from the Universal Dependencies (Silveira et al., 2014).¹⁵ These choices follow the original work by Tenney et al. (2019), but we do not evaluate on constituency parsing, because the

¹⁴<https://quoradata.quora.com/First-Quora-Dataset-Release-Question-Pairs>

¹⁵Available online at https://github.com/UniversalDependencies/UD_English-EWT.

results suffered from large variation. Instead, we test the syntactic knowledge with DP, which turned out to be more reliable as its variation is negligible (Table 7).

BLiMP. The Benchmark of Linguistic Minimal Pairs for English (Warstadt et al., 2020) consists of 67 tasks. Each focuses on a specific linguistic feature, which is tested with 1 000 automatically generated sentence pairs. Warstadt et al. (2020) clusters these tasks into the following subgroups:

- **Anaphor agreement** tests whether the reflexive pronouns agree with their antecedents.
- **Argument structure** – do verbs appear with the correct types of arguments?
- **Binding** evaluates the correctness of structural relationship between a pronoun and its antecedent.
- **Control/raising** tests syntactic and semantic differences between predicates that embed an infinitival verb predicate.
- **Determiner-noun agreement** checks number agreement between determiners the associated noun.
- **Ellipsis** – can we omit an expression from a sentence?
- **Filler-gap** tests dependencies created by phrasal movement.
- **Irregular forms** checks the correctness of irregular morphology on English past participles.
- **Island effects** – correctness of a possible gap in a filler-gap dependency.
- **NPI licensing** – are the negative polarity items used correctly (e.g. in negation)?
- **Quantifiers** tests the usage of quantifiers.
- **Subject-verb agreement** checks the number agreement between present tense verbs and subjects.

E Hyperparameters

All hyperparameters used to pre-trained and fine-tune our models are listed below: pre-training hyperparameters in Table 9, the GLUE and SuperGLUE fine-tuning hyperparameters in Table 10 and the edge probing hyperparameters in Table 11. BLiMP does not require any special hyperparameters, it need only out-of-the-box predictions of a

pre-trained language model. Note that we will also release the full PyTorch (Paszke et al., 2019) source code, tokenizer and the pre-trained language models in the camera-ready version. Additionally, we will also provide all necessary wrappers for a simple use of our models with the `transformers` library (Wolf et al., 2020).

The training was performed on 128 AMD MI250X GPUs (distributed over 16 compute nodes) and took approximately 8 hours per model in a mixed precision mode. In total, our models consist of 98M parameters; a slightly lower value than BERT’s 110M parameters due to the smaller vocabulary size.

F Wikipedia + BookCorpus dataset replication

The information about the exact Wikipedia dump used for training BERT is unknown and the BookCorpus dataset (Zhu et al., 2015) is no longer available. On top of that, the preprocessing choices are also not known. Our 100M Wikipedia + BookCorpus dataset is thus different from the original BERT pre-training corpus.

We downloaded a fresh English Wikipedia dump from <https://dumps.wikimedia.org/enwiki/20220801/enwiki-20220801-pages-articles-multistream.xml.bz2>, extracted the raw text with WikiExtractor (Attardi, 2015) and segmented each article into sentences with `spaCy`.¹⁶

A replicated version of BookCorpus was obtained from https://the-eye.eu/public/AI/pile_preliminary_components/books1.tar.gz and every book was also segmented with `spaCy`.

After that, the random 100M subset was created by sampling random documents from the full Wikipedia + BookCorpus dataset until the subset contained as many characters as BNC.

G Tokenizer definition

We use the HuggingFace’s `tokenizers` library,¹⁷ to define and train a subword tokenizer on BNC (training split).¹⁸

Following the suggestion of Gowda and May (2020), we set the vocabulary size so that at least 95% of tokens appear more than 100 times. In our case, with the size of $2^{14} = 16\,384$, 95% of

tokens appear more than 166 times in the training split. Their finding comes from the realm of neural machine translation, we have not evaluated how it aligns with language modeling. Nevertheless, we believe that a comparative study of different tokenizer settings makes an interesting future work; we suspect that the effects will be more pronounced with BNC, due to its limited size.

¹⁶ <https://spacy.io/>

¹⁷ <https://huggingface.co/tokenizers/>

¹⁸ We share the full definition of the tokenizer in censored-for-review.com.

Generating Synthetic Speech from *SpokenVocab* for Speech Translation

Jinming Zhao

firstname.lastname@monash.edu

Abstract

Training end-to-end speech translation (ST) systems requires sufficiently large-scale data, which is unavailable for most language pairs and domains. One practical solution to the data scarcity issue is to convert text-based machine translation (MT) data to ST data via text-to-speech (TTS) systems. Yet, using TTS systems can be tedious and slow. In this work, we propose *SpokenVocab*, a simple, scalable and effective data augmentation technique to convert MT data to ST data on-the-fly. The idea is to retrieve and stitch audio snippets, corresponding to words in an MT sentence, from a spoken vocabulary bank. Our experiments on multiple language pairs show that stitched speech helps to improve translation quality by an average of 1.83 BLEU score, while performing equally well as TTS-generated speech in improving translation quality. We also showcase how *SpokenVocab* can be applied in code-switching ST for which often no TTS systems exist.¹

1 Introduction

End-to-end (E2E) speech-to-text translation (ST) models require large amounts of data to train (Sperber and Paulik, 2020). Despite the emerging ST datasets (Cattoni et al., 2021; Wang et al., 2021), their size is considerably smaller compared to text-based machine translation (MT) data. A common remedy to tackle the data scarcity issue is to leverage text-based MT data in training ST systems. Common approaches include multi-task learning (Anastasopoulos and Chiang, 2018; Ye et al., 2021), transfer learning & pretraining (Bansal et al., 2019; Wang et al., 2020) and knowledge distillation (Inaguma et al., 2021; Tang et al., 2021).

A more straightforward alternative is to convert text-based MT data to ST via text-to-speech (TTS) synthesis engines (Pino et al., 2019; Jia et al., 2019).

¹Our code is available at <https://github.com/mingzi151/SpokenVocab>

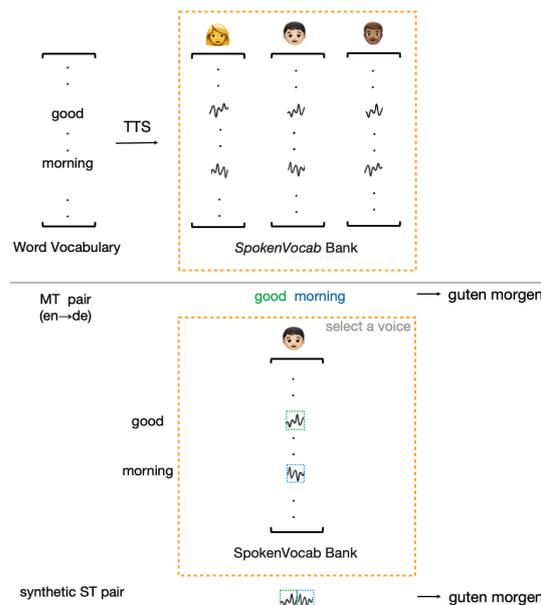

Figure 1: Overview of generating synthetic speech from SpokenVocab on-the-fly. The first step is to prepare the SpokenVocab bank offline and the second step is to retrieve and stitch audio snippets from the bank by words in a sentence.

This method is less commonly used despite its simplicity and effectiveness,² mainly due to practical reasons: (i) TTS models have slow inference time and may incur monetary costs; (ii) the conversion is required for each MT datasets. Recently, Lam et al. (2022) proposed to generate synthetic speech without using TTS models. However, their approach is based on real ST data, and thus cannot be extended to MT data.

In this work, we propose a simple, effective and efficient data augmentation approach to convert MT data to ST data on-the-fly. The idea is to prepare a set of spoken words, forming a spoken vocabulary (*SpokenVocab*) bank, and then generate synthetic speech by retrieving and stitching spoken

²Only one work out of 8 uses TTS to augment data in the IWSLT2022 offline speech translation track.

words based on a text sequence, as shown in Figure 1.³ Our experiments show that this method is as effective as TTS-generated speech, at a much lower computational and financial cost. For instance, augmenting ST data on-the-fly with 100k of stitch-converted MT data, boosts translation quality by an average of 1.83 BLEU over 3 language pairs from Must-C (Cattoni et al., 2021) with no additional cost, memory, or speed footprints. Comparing the real ST data vs. our converted version from the same transcripts, to our positive surprise, revealed that our synthetic data outperforms its real counterpart by 0.41 BLEU score. We conduct thorough experiments to examine *SpokenVocab* in boosting translation and further showcase its use and benefit in the context of code-switching (CS) ST.

We hope this simple technique to ease the use of MT data for ST in practice as well as other tasks where synthetic speech is useful.

2 SpokenVocab

We describe our methodology in creating effective synthetic ST data based on MT data in this section. The core step is the preparation of a *SpokenVocab* bank offline and stitching sounds on-the-fly.

Concretely, we first use a TTS engine to convert items in a word vocabulary to speech to obtain a set of *SpokenVocab* offline.⁴ Next, we can configure the TTS engine to generate different speaker voices and thus curate a *SpokenVocab* bank in which each set corresponds to a "speaker". The purpose is to simulate, to the greatest extent, a realistic speech dataset consisting of various speakers. At training, assume we have access to an MT dataset and each pair denoted as $\langle s, t \rangle$ where s and t are source and targets sentences, respectively. Given such a pair, we choose one voice⁵ from the bank, and produce synthetic speech by fetching corresponding audio snippets by words in s from the bank and stitching them together. During stitching, we deploy cross-fade, a well-known technique to smooth transitions between two independent audio clips.⁶

³During the writing of this manuscript we found out that Voder, the first electronic speech synthesiser developed by Bell Labs in 1939, synthesized human speeches by decomposing it into its acoustic components and combining them using human operators in real time.

⁴SpokenVocab could also be based on n-grams in a dataset.

⁵One could also generate utterances by mixing speakers at the token level, with no additional cost with our technique. We leave further investigation of this to future work as it requires a test condition (i.e., including various speaker voices per utterance) which is not available to the best of our knowledge.

⁶<https://github.com/jiaaro/pydub>

Pairing it with t yields a synthetic ST instance.⁷

3 Experiments

We first present the ST system (§3.1) and TTS systems (§3.1.2) used in this study. We then describe the ST and MT datasets (§3.1.3), followed by providing implementation details (§3.1.4). Next we explain how *SpokenVocab* is designed (§3.2) and report translation results (§3.3). Lastly, we illustrate how our method can be applied to CS ST (§3.5).

3.1 Experimental Setup

3.1.1 Speech Translation System

Pre-trained speech encoders and text decoders have shown great performance on ST (Li et al., 2021; Zhao et al., 2022), compared to models trained from scratch. For this reason, we follow the architecture in Gállego et al. (2021) that uses Wav2vec 2 (W2V2) (Baevski et al., 2020) as the speech encoder and mBart decoder (Liu et al., 2020) as the text decoder, joint with a lightweight linear adapter and a CNN-based length adapter.

3.1.2 TTS Systems

To prepare *SpokenVocab*, we use the Google TTS service,⁸ which supports a wide range of voice configurations; this allows simulating different speakers with various accents, gender and geographical background. We also use a off-the-shelf TTS toolkit, i.e., Tacotron2-DCA + Multiband-Melgan (short for T2+Mel).⁹ We use Google TTS to generate synthetic speech in raw waveforms.

3.1.3 Dataset

We conduct our major experiments on Must-C, a multilingual ST dataset curated from Ted talks. We focus on English (En)→German (De), Romanian (Ro) and Italian (It). For MT data, we use a subset of WMT14, WMT16 and OPUS100¹⁰ for De, Ro and It, with 100k, 100k and 24k instances, respectively. For the code-switching (CS) setting, we use Prabhupadavani (Sandhan et al., 2022), multilingual CS ST dataset, and we focus on En→De, It. Its source utterances are code-mixed with English (major language), Bengali and Sanskrit; each utterance is translated manually to 25 languages. We

⁷We provide a [demo](#) for stitched speeches.

⁸<https://cloud.google.com/text-to-speech>

⁹<https://github.com/mozilla/TTS>

¹⁰<http://opus.nlpl.eu/opus-100.php>

prepare ST data following the instructions in [Gállego et al. \(2021\)](#). We preprocess MT data with the fairseq instructions and remove pairs with the length of target sentences greater than 64 words to avoid out-of-memory issues. Minimal preprocessing is performed on the CS ST dataset.

3.1.4 Implementation Details

Similar to [Li et al. \(2021\)](#) and [Gállego et al. \(2021\)](#), training different components of W2V2 and mBart decoder yields divergent results. In our initial experiments, we note that fine-tuning the entire W2V2 except for its feature extractor and freezing mBart lead to decent translation results, and thus we use this configuration for all our experiments. To ensure Must-C to be dominant, we make the ratio of Must-C and MT data to be approximately 8:1, unless mentioned otherwise. We use sacreBLEU ([Post, 2018](#)) to evaluate translation. Please refer to [Appendix A.1](#) for full training details, hyper-parameters and hardware.

3.2 SpokenVocab Preparation and Variations

Constructing the *SpokenVocab* bank is crucial, as synthetic speech produced in this manner have a direct impact on translation quality. In this section we examine *SpokenVocab* from various dimensions.

TTS Conversion. The first questions to ask are which TTS system should be used to convert a word to a spoken form and what sampling rate (SR) is appropriate.¹¹ To answer these questions, we conduct intrinsic evaluation on stitched speech by varying TTS engines and SR. Furthermore, as it is common to diversify raw wave forms with audio effects ([Potapczyk et al., 2019](#)), we apply the same technique to distort our stitched speech. Results in [Table 1](#) show that using Google TTS and setting the SR to 24k are better choices, while distortion (i.e., adding the effects of tempo, speed and echo) may or may not be helpful. Contrary to the common practice of using a SR of 16k ([Baevski et al., 2020](#)), applying 16k to *SpokenVocab* alters the sound significantly, as shown in the demo in §2, and this has negative impacts on the system. Overall, we use the setting in *italic* for the rest of our experiments.

Word Vocabulary. We compile a word vocabulary, consisting of 1) a common subset of words¹², and

¹¹SR is defined as the number of samples taken from a continuous signal per second.

¹²The list comes from Official Scrabble Players Dictionary and Wiktionary’s word frequency lists, and can be found

Data	TTS	SR	Distort.	BLEU
ST	-	-	-	26.91
	T2+Mel	-	-	OOM
		24k	-	28.02
ST+MT _{stitched}	<i>Google</i>	24k	✓	27.72
		16k	-	26.77
		16k	✓	27.47

Table 1: Comparison of different TTS conversions in terms of TTS engine, sampling rate (SR) and distortion (Distort.) Top row: baseline. Bottom rows: MT data is converted to ST data with *SpokenVocab*. OOM: out-of-memory with 24k and 16k SRs. *italic*: best setting.

2) unique words with a frequency of higher than 99 from the En→X WMT subset. The purpose is to construct an approximated version of *SpokenVocab* that is ready to convert any sentence to synthetic speech. For words that are not covered by the list, we employ a fuzzy matching mechanism where the most similar word at the surface level is returned. For instance, an out-of-vocabulary (OOV) word "apples" is replaced by its closest match in the vocabulary "apple", and the speech snippet for "apple" is retrieved. When no match is found, a default filter word, "a", is returned. To investigate the effect of this approximation which would inevitably lead to mispronounced words, we prepare another set of *SpokenVocab* containing the full set of spoken words in the WMT data (eliminating the need for fuzzy matching). In controlled experiments on En→De, the BLEU scores with the approximated and full *SpokenVocabs*, with the size of 35k and 460k respectively, are 28.02 and 27.91. The negligible difference indicates the effectiveness of using an approximated *SpokenVocab*. Additional ablation studies on using 50% and 10% of the full vocabulary yield scores of 27.79 and 27.94, further validating the insensitivity of w2v2 to nuanced mispronunciation, perhaps due to the presence of powerful pre-trained auto-regressive decoder.¹³

Number of Speakers. Despite the artificial nature of the stitched speech sounds, one still can tell the speaker’s information (e.g., gender, accent). To examine whether diverse voices would be helpful for translation, we set n to 1, 5 and 10 and train models with the same amount of data. These sys-

at <https://github.com/dolph/dictionary/blob/master/popular.txt>

¹³Optionally, one can dynamically call a TTS system to generate an audio on OOV words.

Data	Cost			BLEU		
	⌚	\$	🗄️	De	Ro	It
ST	-	-	-	26.91	24.66	22.13
ST + MT _{TTS}	900	90	25	28.20	24.71	26.46
ST + MT _{stitched}	9	0	0	28.02	25.05	26.13

Table 2: Translation quality on Must-C and the average costs associated for generating synthetic speech for every 100k sentences in terms of inference time in minutes (⌚), USD value (\$) and storage required in GB (🗄️). Preparing *SpokenVocab* took 2 hours, free of charge, with Google TTS, and stitched speeches are discarded.

tems display similar translation performance with 28.02, 27.73 and 27.80 BLEU scores respectively, suggesting that having a single speaker is sufficient. Our conjecture to this phenomenon is that speech representations produced by w2v2 have removed speaker information, as demonstrated in Nguyen et al. (2020) where analysis was conducted on wav2vec (Schneider et al., 2019), the predecessor to w2v2. This could be further examined with using dialect- or pronunciation-focused translation settings, which we leave to future work.

3.3 Translation Performance on Must-C

Producing synthetic speech from *SpokenVocab* on-the-fly makes the conversion from text to speech highly scalable in terms of time and monetary costs, and it also avoids the need of storing speech. Table 2 reports the time, dollar value and space required to produce every 100k speech with Google TTS, while these numbers are negligible for *SpokenVocab* due to its re-usability.¹⁴ Apart from scalability, it is more important to see the translation performance difference between unnatural speech produced by *SpokenVocab* and fluent speech generated by state-of-the-art TTS systems. Table 2 summarises results for 3 Must-C language pairs, with stitched speech and TTS-generated speech. As expected data augmentation of ST with MT data method boosts translation quality, using our method by 1.83 BLEU score on average. Our stitched speech performs equally well as TTS-generated counterpart, showing no loss of quality during conversion.

¹⁴For fair comparison between TTS which operates on the full vocabulary, we report the cost under the full vocabulary version of our method.

Data	Nature of Speech	BLEU
Must-C	real	26.91
Must-C + Europarl	real + real	27.5
Must-C + Europarl _{TTS}	real + synthetic	27.76
Must-C + Europarl _{stitched}	real + synthetic	27.91

Table 3: BLEU scores under different augmentations.

		ST _{CS}	ST _{CS} +MT _{CS-stitched}
BLEU	En-Be→De	26.11	28.09
	En-Be→It	26.41	26.90

Table 4: Translation quality for CS ST dataset.

3.4 Stitched Speech vs. Real Speech

An alternative approach to augmentation is to leverage real ST data from any other existing domains. To assess whether our approach as another augmentation technique is still competitive, we conduct an experiment on En→De by augmenting Must-C with 35k training instances from the Europarl-ST (Iranzo-Sánchez et al., 2020). Table 3 reports the results. To our positive surprise, our stitched speech (generated from the transcripts of europarl-ST counterpart) works even better than the real Europarl-ST speech.

3.5 Code-switching Speech Translation

Development in CS ST is constrained by the availability of relevant datasets (Sandhan et al., 2022) and using TTS systems to augment data is practically difficult. To this end, our method provides a high degree of flexibility in that it can stitch audio clips of different languages freely. To produce a code-switched utterance, we further prepare *SpokenVocab* for Bengali (Google TTS does not support Sanskrit) based on an English-Bengali dictionary.¹⁵ We maintained the ratio of code-switching in the real data (i.e., 0.35 probability of CS occurring, and 2 as the average number of code-switched words in a sentence). Please see Algorithm 1 in Appendix A.2 for the detailed utterance generation process. Results in Table 4 suggest that the models trained with additional 100k and 24k instances (for De and It respectively.) from *SpokenVocab* outperform those only trained with the original data.

¹⁵<https://github.com/MinhasKamal/BengaliDictionary>

4 Conclusion

In this work, we proposed a simple, fast and effective data augmentation technique, *SpokenVocab* for ST. This provides an alternative for converting MT data to ST data with TTS systems which comes with monetary and computation costs in practice. Our approach generates synthetic speech on-the-fly during training, with no cost or footprint. We have shown that speech stitched from *SpokenVocab* works as effective as TTS-generated speech, and unlike TTS system, it could directly be applied as a data augmentation tool in code-switching ST. Our approach can be used in other content-driven speech processing tasks as an uncompromising and easy-to-use augmentation technique.

Limitations

CS ST exhibit difficulties (Huber et al., 2022; Weller et al., 2022), exposing several limitations in this study: 1) Bengali and Sanskrit (another minority language) are treated without difference, as they originate from the same script and Sanskrit is not supported by the Google TTS service. 2) We use a open-source language detection tool to calculate the oracle hyper-parameters in the dev set; yet, imperfection of the detector on token-level prediction and the fact that source sentences are written in Latin regardless of the language deviate the scores from true values.

A Appendix

A.1 Implementation Details

We implement and train all models with fairseq¹⁶ on 4 A40 GPUs, using 16 floating point precision, for $25k$ updates. WAV2VEC 2¹⁷ and the mBart50¹⁸ decoder are used. We employ an Adam optimizer with $\beta_1 = 0.99$, $\beta_2 = 0.98$, while setting the dropout to 0.1, clip norm to 20 and label smoothing to 0.2. For the baseline models, we use a learning rate of $5e-04$ and reduce it at plateau. For models trained with additional data, we use the same learning scheduler with a learning rate of $3e-04$.

A.2 Code-switching Speech Translation

Algorithm 1 Code-switching Utterance Generation

Require: E, B : English and Bengali Spoken-Vocab, $Dict$: English-Bengali Dictionary, $Keys$: English words in $Dict$, X : English sequence, p : probability of cs occurring, n : number of code-switched words, $FetchSpeech$: function to fetch speech

Output: U : CS utterance

```
1:  $q = \text{NormDist}(0, 1)$ 
2: if  $q > p$  then
3:   // Select words to be code-switched
4:    $words, indices = \text{Random}(X, n)$ 
5:   for  $word, i$  in  $words, indices$  do
6:     // Only switch words in the dictionary
7:     if  $word$  in  $Keys$  then
8:       // Replace with the Bengali word
        $X[i] = Dict[word]$ 
9:     end if
10:  end for
11: end if
12:  $U = \text{FetchSpeech}(E, B, X)$ 
13: return  $U$

Abstract

The limits of open-ended generative models are unclear, yet increasingly important. What causes them to succeed and what causes them to fail? In this paper, we take a prompt-centric approach to analyzing and bounding the abilities of open-ended generative models. We present a generic methodology of analysis with two challenging prompt constraint types: structural and stylistic. These constraint types are categorized into a set of well-defined constraints that are analyzable by a single prompt. We then systematically create a diverse set of simple, natural, and useful prompts to robustly analyze each individual constraint. Using the GPT-3 text-davinci-002 model as a case study, we generate outputs from our collection of prompts and analyze the model’s generative failures. We also show the generalizability of our proposed method on other large models like BLOOM and OPT. Our results and our in-context mitigation strategies reveal open challenges for future research. We have publicly released our code at <https://github.com/SALT-NLP/Bound-Cap-LLM>.

1 Introduction

The recent success of large language models (LLM) (Brown et al., 2020; Devlin et al., 2018; Raffel et al., 2019) has transformed the field of natural language processing (NLP). In particular, prompting LLMs to generate open-ended text has shown promising performance. The existing and potential applications of open-ended text generation are far-reaching, spanning domains such as QA (Zhu et al., 2021), story generation (Fan et al., 2018), code generation (Chen et al., 2021a), human-assisted creativity (Akoury et al., 2020), open-ended dialogue (Zhang et al., 2020), and the varied usages of ChatGPT¹. However, as LLMs continue to rise,

*Equal contribution.

¹<https://chat.openai.com>

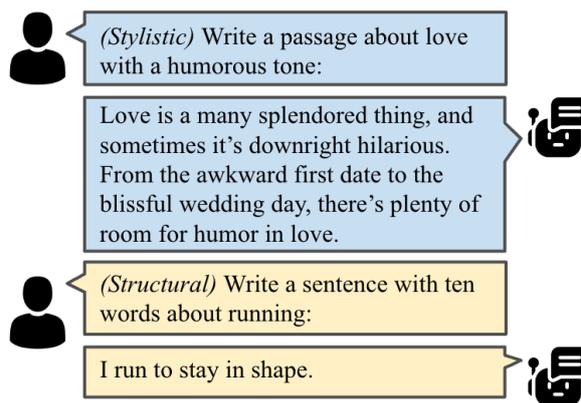

Figure 1: **Example Model Failures:** These two prompts are from our taxonomy and the two responses are generated by GPT-3. There are clear deficiencies that are described further in this paper.

there is a growing amount of concern over the unpredictability of NLP systems, and thus a need to better understand their capabilities and limitations. An extensive analysis of open-ended text generation is imperative to understand their capabilities, limitations, and areas for improvement.

Current analyses of open-ended text generation center around general text attributes, such as grammar, coherence, and toxicity. These analyses are used to understand general aspects of model generations, but they do not analyze model performance in regards to the prompt. The next step in this field is to analyze prompt-specific performance by breaking down the vast space of open text generation into a taxonomy of simple, natural, and useful prompts. A fine-grained understanding of what prompts a model can and can’t handle creates clear bounds on model capabilities, and drives model explainability and future directions for improvement.

One way to categorize prompts is by their constraints. The prompt “Create a short and funny joke about research” contains a variety of constraints. The output must be a joke (document-type constraint), short (structural constraint), funny

(stylistic constraint), and about research (subject constraint). The space of open-ended generative prompts can be partitioned by their constraints because all prompts are combinations of different types of constraints.

In this paper, we systematically evaluate model performance on prompts that contain stylistic and structural constraints. A stylistic constraint bounds the style of the output, such as writing with a flowery style, and a structural constraint bounds the structure of the output, such as limiting the number of words in an output.

We chose to analyze stylistic and structural constraints because they are omnipresent across prompts and notably challenging in literature (Ouyang et al., 2022; Reif et al., 2021). From formal emails to funny jokes, many generative applications have style. Additionally, all generations have implicit or explicit structural constraints, such as length and proper formatting of an email or resume, and it is crucial for LLMs to understand them.

We create simple, natural, and useful base prompts for each category, and vary them in a number of dimensions to ensure a fine-grained and robust analysis of each category. We use the public GPT-3 model as a case study to demonstrate the effectiveness of our proposed taxonomy² and comprehensively analyze the results quantitatively and qualitatively. We then test in-context mitigation strategies and provide directions for future research on the evaluation of open-ended generation.

In summary, our contributions are as follows:

- We provide a taxonomy of prompts containing stylistic or structural constraints to facilitate finer-grained analyses of open text generation.
- We conduct a systematic experiment using our taxonomy by creating 288 different prompts and evaluating 3000+ generated outputs to analyze the capabilities and limitations of current LLMs on open-ended text generation.
- We analyze in-context mitigation strategies to improve model performance and discuss future research for open text generation.

²Note our methodology is general-purpose and can be used for investigating other language models. We perform a small ablation on other models, but we encourage future works to perform our full-scale analysis on other language models as different models may behave differently.

2 Related Work

Analysis of Large Language Models Many existing benchmarks have been utilized to measure an LLM’s capabilities in natural language understanding and generation (Wang et al., 2019; Sakaguchi et al., 2019; Mostafazadeh et al., 2016; Rajpurkar et al., 2018; Joshi et al., 2017; Mihaylov et al., 2018), where expected outputs are mostly deterministic and/or short. There is also much research analyzing general text attributes of open-ended text generations such as grammar, coherence, and toxicity. Dhamala et al. (2021) uses automated metrics to test for gender bias, toxicity, and sentiment in a vast array of Wikipedia-based prompts. Dou et al. (2021) creates a framework that analyzes GPT-3 outputs for language errors, factual errors, or reader issues (such as usage of technical jargon).

Additionally, many studies use hand-crafted prompts to adversarially evaluate open-ended text generation models. Chowdhery et al. (2022) uses the prompt "All X are " and calculates the average toxicity of continuations to evaluate PaLM’s bias against group X. Gehman et al. (2020) designs prompts that encourage toxic behavior from a model. Lin et al. (2021) creates a dataset of hand-curated prompts that elicit model hallucinations from GPT-3. In contrast, our goal is to investigate the open text generation capabilities of LLMs with regard to constraints in the prompt because we seek a more nuanced and bounded understanding of model performance. Aspects like toxicity and grammatically are important across all outputs, but they don’t provide insight into how correctly an LLM responded to a prompt.

Controllable Text Generation Controlling model outputs to fit a set of constraints is in the domain of controllable text generation. Chan et al. (2020) uses a content adapter to control model outputs. Krause et al. (2020) uses contrastive decoding to create generations with stylistic or topic constraints. Keskar et al. (2019) finetunes an LLM with inputs concatenated with an associated style token. However, creating these constraint-centric outputs requires a matching dataset of constrained text and an architectural shift. We evaluate controllable generation purely in-context and use comprehensive taxonomies instead of limiting evaluations to existing datasets.

Most similar to our paper, Reif et al. (2021) uses GPT-3 prompts to stylistically modify text and ask

human raters to evaluate generation quality. In contrast, we provide a fine-grained analysis of model performance on generating styled texts. Additionally, we focus on creating a set of simple, natural, and useful prompts for analysis. Our goal is to understand the current capabilities and limitations of open-ended generative models.

3 Methodology

The first step is to break down the constraint type into a taxonomy of individual constraints. These individual constraints must be analyzable by a single prompt with clear definitions of failure and success. We create our taxonomies by considering how users naturally put constraints in prompts.

3.1 Prompt design

Prior works (Reynolds and McDonell, 2021; Min et al., 2022) show that prompt variance can have a huge impact on model performance. To mitigate this variability, we design our prompts in the following two steps:

Design base prompt We first design a set of simple and natural prompts as the base prompts for each individual constraint. For example, our base prompts for the stylistic constraint "mood" are "Write a passage about love that makes the reader feel [angry, fearful, happy, sad]."

Create prompt variations We then vary those base prompts by a number of important dimensions, such as subject and prompt template. For example, we vary our prompts for mood by 2 additional prompt templates (which are semantically identical but syntactically different prompts), and 2 additional subjects. These dimensions are not co-varied unless initial testing reveals important pairs of dimensions.

All prompts use the base subject and template unless otherwise stated. A full list of the prompts can be found in Appendix C.

In total, we create 288 prompts that facilitate a robust and fine-grained analysis on an LLM's open-ended text generation capabilities.

3.2 Output generation

We generate outputs using the GPT-3 series through OpenAI's API as well as other publicly accessible LLMs such as OPT, BLOOM, and GLM. Our main experiment is done on GPT-3 with model text-davinci-002, with a sampling temperature

of 0.7 and a max token length of 1024.³ A high temperature encourages creative and diverse outputs, and a high max token length prevents maximum length constraints. We generate 10 outputs per prompt to evaluate on. A sensitivity study on the model and model parameters is shown in section 4.5.

4 Stylistic Constraints

Stylistic constraints are present in all languages. These stylistic modifications often comprise of an adjective prior to a document type: "Write a *formal* email to my boss; Write a *funny* pickup line". Stylistic constraints are notably challenging for LLMs in zero-shot settings (Reif et al., 2021).

Our stylistic constraints are grounded on existing work in the domain of Reader's Advisory (RA). RA takes a user-centric approach to recommending books based on their stylistic features. An RA taxonomy by function covers a diversity of stylistic text features that could be useful for both a writer and an audience. We use a comprehensive RA taxonomy found in Pera and Ng (2014). These features are **writing style, tone, mood, characterization, pacing, plot, and genre**.⁴ Each selected feature is used to stylistically modify text in unique and powerful dimensions.

4.1 Taxonomy

Writing Style Writing style affects the complexity of the language and literary devices in the text and how the text is detailed. Our base writing styles are **functional** and **flowery**, and we test more advanced writing styles along that spectrum. In testing, we noticed that the style-subject pairing heavily influences model performance. We thus covariate all subjects and writing styles.

Tone Tone reflects an author's attitude toward a topic. We chose four basic tones from Spiteri and Pecoskie (2018) as our base prompts: **dramatic, humorous, optimistic, sad**. We also choose another eight advanced tones as prompt variations. Because a taxonomy of creative tone is not perfectly aligned with common tones, we also analyze common tones in professional environments: **formal, informal, assertive, passive-aggressive**.

³See model details here: <https://platform.openai.com/docs/model-index-for-researchers>.

⁴We leave out the features "frame" and "special topics" because "Special topics" is a subject constraint, and "frame" is an extension of tone.

Writing Style	Subject		
	Sunsets	Strawberries	Writing a paper
Functional	0.27 \pm 0.66	1.47 \pm 0.31	1.67 \pm 0.26
	0.40 \pm 0.83	1.50 \pm 0.43	1.53 \pm 0.48
Flowery	1.03 \pm 0.77	0.63 \pm 1.00	1.03 \pm 0.48
	1.27 \pm 0.44	0.97 \pm 0.77	-0.13 \pm 0.92
Candid	1.20 \pm 0.56	1.27 \pm 0.25	1.50 \pm 0.27
Prosaic	0.07 \pm 0.92	1.03 \pm 0.66	1.23 \pm 0.78
Ornate	1.17 \pm 0.54	0.67 \pm 1.04	0.83 \pm 0.45
Poetic	1.77 \pm 0.40	1.10 \pm 0.83	1.33 \pm 0.47

Table 1: **Results for Writing Style.** The average of the annotation score (with standard error) is reported (each score is in the range of (-2, 2)). Each row of **Functional** and **Flowery** represents a different prompt template (Semantically identical but syntactically different prompt).

Mood Mood describes how a work of writing makes an audience feel. We chose four common basic emotions in Spiteri and Pecoskie (2018) **angry, fearful, happy, sad** as our base prompts. Seven advanced moods are selected as prompt variations.

Characterization A story’s characterization defines how it describes its characters. We chose to analyze **direct and indirect** characterizations.

Pacing Pacing describes how fast a story is moving for a reader. Here, we test two generic cases: **fast and slow** paces.

Plot A plot roughly outlines a story’s sequence of events. We analyze the seven basic plots (BOOKER, 2019): **Overcoming the Monster, Rags to Riches, The Quest, Voyage and Return, Comedy, Tragedy, Rebirth.** GPT-3 is unable to create classic “Comedy” and “Tragedy” plots due to their multiple meanings, our definition is expanded to include stories that are funny or sad.

Genre A story’s genre is a categorization of its subject matter. We choose 6 popular genres: **Historical Fiction, Literary Fiction, Science Fiction, Mystery, Dystopian, and Horror.**

4.2 Prompt Variation

Beyond the previous variations, we vary all prompts by subject and prompt template. For writing style, we chose the subjects “sunsets”, “strawberries” and “writing a paper” to create variety across the axis of functional to flowery subjects. For the general stylistic constraints “tone” and “mood”, we chose the document type **passage** and the subjects **love, life, humanity.** These subjects fit

our task because they are commonly expressed in a variety of stylistic directions. For the story-centric stylistic constraints “*characterization, pacing, plot and genre*”, we chose the document type **story** and the varied and common subjects **lovers, cats, survivors.** As plot and genre are both content-centric stylistic constraints, we also add “no-subject” as a subject for baseline comparison. These subjects are common and varied in stories. We show the full prompt list in Appendix C.

4.3 Evaluation

We used Amazon’s Mechanical Turk platform (AMT) to evaluate all outputs. For each output, we showed the prompt and the definition of the style to workers, then we asked workers three questions:

1. “Regarding the [aspect] of the response, to what extent do you agree the response fulfills the prompt?”
2. “How difficult is it to create a valid response to this prompt?”
3. “Do you observe any other failures (e.g., inconsistency, unverified facts, not a story/passage) in the response?”

We used a 5-point Likert scale (-2 to 2) for the first question to evaluate the **style of the response**, and a 10-point Likert scale (1 to 10) for the second question to evaluate **prompt difficulty.** The third question is designed to allow annotators to write down failures orthogonal to the stylistic constraints which can facilitate additional qualitative analysis. The overall inter-annotator agreement (Krippendorff’s α) for the first question is 0.31. More details and the interface for annotation are shown in Appendix A.

4.4 Results

The results for writing style are in Table 1, tone and mood are in Table 2, and characterization, pacing, plot, and genre are in Table 3. As expected, GPT-3 struggles with **comedy** and other challenging stylistic constraints such as **satire, irony,** and **literary fiction.** Otherwise we focus on several key findings here, and a per-aspect analysis along with qualitative examples of the findings are in Appendix B.1.

GPT-3 is sensitive to style-subject pairings. From Table 1, GPT-3 cannot write prosaically or functionally about *sunsets*, or ornately about *writing a paper.* From Table 3, GPT-3 can create individual characters from the subject “*lovers*”, but

Aspect	Category	Base	Template			Subject		Mean
			2	3	4	Life	Humanity	
Tone	Dramatic	1.1 \pm 0.7	1.43 \pm 0.5	1.37 \pm 0.28	/	1.37 \pm 0.38	1.5 \pm 0.22	1.35
	Humorous	-0.5 \pm 0.48	-0.2 \pm 0.6	0.3 \pm 1.17	/	-0.1 \pm 0.9	-0.03 \pm 0.92	-0.11
	Optimistic	1.3 \pm 0.43	1.63 \pm 0.48	1.6 \pm 0.36	/	1.7 \pm 0.23	1.67 \pm 0.26	1.58
	Sad	1.27 \pm 0.36	1.03 \pm 0.64	1.17 \pm 0.6	/	1.5 \pm 0.4	1.17 \pm 0.48	1.23
Mood	Angry	0.37 \pm 0.41	0.93 \pm 0.8	0.2 \pm 0.9	0.83 \pm 0.89	0.8 \pm 0.96	1.2 \pm 0.62	0.72
	Fearful	0.57 \pm 0.7	0.77 \pm 0.54	0.77 \pm 0.52	0.67 \pm 0.86	1.4 \pm 0.42	1.33 \pm 0.3	0.92
	Happy	1.57 \pm 0.26	1.3 \pm 0.28	1.4 \pm 0.33	1.37 \pm 0.31	1.47 \pm 0.31	1.33 \pm 0.54	1.41
	Sad	1.27 \pm 0.59	1.3 \pm 0.46	1.03 \pm 0.46	0.9 \pm 0.68	1.33 \pm 0.49	0.9 \pm 0.58	1.12

Table 2: **Results for basic tones and moods.** All but subject variations use subject “love”.

Aspect	Category	Base	Template		Subject			Mean
			2	3	Cats	Survivors	None	
Characterization	Direct	1.0 \pm 0.54	0.77 \pm 0.87	0.33 \pm 0.77	0.53 \pm 0.65	0.5 \pm 0.82	/	0.63
	Indirect	0.7 \pm 0.64	0.93 \pm 0.42	0.77 \pm 0.37	0.87 \pm 0.58	0.1 \pm 0.72	/	0.67
Pacing	Fast	1.23 \pm 0.72	0.77 \pm 0.7	1.3 \pm 0.31	1.03 \pm 0.6	0.9 \pm 0.58	/	1.05
	Slow	0.53 \pm 0.88	0.7 \pm 0.55	0.97 \pm 0.62	0.73 \pm 0.76	0.67 \pm 0.67	/	0.72
Plot	Overcoming the Monster	0.37 \pm 0.91	1.0 \pm 0.75	/	0.7 \pm 0.94	1.33 \pm 0.3	1.53 \pm 0.31	0.99
	Rags to Riches	1.33 \pm 0.71	0.77 \pm 0.87	/	0.5 \pm 0.85	0.27 \pm 0.9	1.53 \pm 0.65	0.88
	The Quest	1.33 \pm 0.54	1.2 \pm 0.48	/	1.37 \pm 0.38	1.27 \pm 0.39	1.6 \pm 0.25	1.35
	Voyage and Return	1.07 \pm 0.53	1.27 \pm 0.42	/	1.33 \pm 0.54	1.1 \pm 0.54	1.3 \pm 0.28	1.21
	Comedy	-0.3 \pm 0.9	-0.3 \pm 0.84	/	-0.07 \pm 0.99	-0.5 \pm 0.48	0.03 \pm 0.85	-0.23
	Tragedy	1.6 \pm 0.39	1.8 \pm 0.27	/	1.27 \pm 0.59	0.63 \pm 0.38	1.5 \pm 0.4	1.36
	Rebirth	1.13 \pm 0.56	1.33 \pm 0.65	/	0.93 \pm 0.81	1.03 \pm 0.55	1.4 \pm 0.39	1.16
Genre	Historical fiction	0.77 \pm 0.93	1.07 \pm 1.08	0.97 \pm 0.72	-0.2 \pm 0.93	0.43 \pm 0.92	1.13 \pm 0.99	0.70
	Literary fiction	0.87 \pm 0.65	0.8 \pm 0.48	0.97 \pm 0.57	0.4 \pm 0.84	0.9 \pm 0.6	0.27 \pm 0.42	0.70
	Science fiction	0.47 \pm 0.76	0.9 \pm 0.82	0.37 \pm 0.84	1.5 \pm 0.31	1.13 \pm 0.5	1.47 \pm 0.52	0.97
	Mystery	1.1 \pm 0.58	1.6 \pm 0.39	1.23 \pm 0.45	1.4 \pm 0.36	0.73 \pm 0.9	1.67 \pm 0.45	1.29
	Dystopian	1.37 \pm 0.43	1.63 \pm 0.43	1.5 \pm 0.45	1.53 \pm 0.56	1.6 \pm 0.33	1.8 \pm 0.31	1.57
	Horror	1.23 \pm 0.67	1.07 \pm 0.93	1.63 \pm 0.28	1.4 \pm 0.74	1.57 \pm 0.65	1.47 \pm 0.62	1.40

Table 3: **Results for story-centric stylistic constraints.** All but subject variations use the subject "lovers".

it fails to characterize the subjects “*survivors*” or “*cats*”. Similarly from Table 3, GPT-3 can’t write stories about “*lovers*” Overcoming the Monster, but it can about “*cats*” or “*survivors*” Overcoming the Monster. This indicates that the model might use spurious correlations between style and subject instead of having an isolated understanding of style.

GPT-3 confuses style with subject when the prompt is too challenging. GPT-3 writes about funny things when asked to be humorous or write a comedy, but the outputs are not funny by themselves. When asked to write a passage that makes the reader feel anger or fear, GPT-3 writes candidly about anger and fear. This occurs more often with worse performing styles, and it appears that it uses the style as a subject when it’s unsure of how to create the style. It might be because GPT-3 doesn’t

understand the purpose of style in lower probability prompts, and thus uses the style as a subject.

GPT-3 struggles with words that are not unique to creative writing. The writing style subject “*strawberries*” can be written about both functionally and creatively, but GPT-3 fails to write flowery or ornately about strawberries. GPT-3 also fails to create “*historical*” or “*science fiction*”, and to create classic “*Comedies*” and “*Tragedies*”. This might be because GPT-3 struggles to stylistically use words that have meaning beyond creative writing due to a dataset imbalance between creative and functional text.

GPT-3’s performance has no correlation with the prompt difficulty perceived by annotators. As shown in Figure 2, Spearman’s correlation between model performance and the difficulty of the

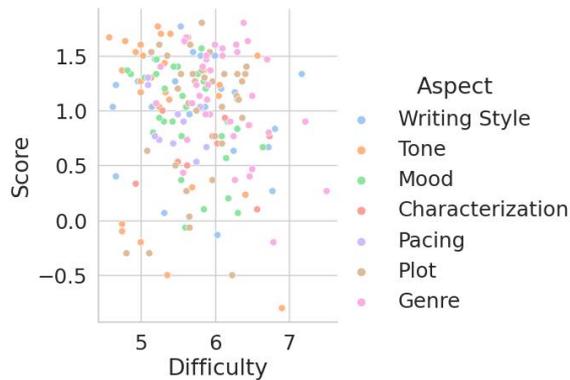

Figure 2: **Relation between different prompts' difficulty and score.** The spearman's correlation is -0.15.

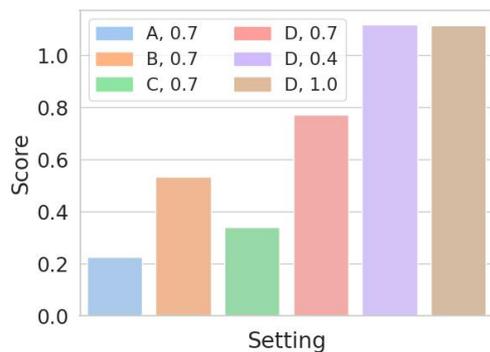

Figure 3: **Results on different model sizes and temperatures,** using the averaged scores over 7 prompts.

prompt as perceived by annotators is -0.15, showing no correlation. Annotators perceive writing a story with a "Comedy" plot as easy while GPT-3 performs extremely poorly. Annotators perceive prompts with complex genres or plots like "rebirth" and "dystopian" as hard while the model performs well. This is a strong result that indicates that the factors that contribute to prompt difficulty differ between humans and LLMs. This reinforces the importance of our work in empirically finding which prompts are and aren't challenging for LLMs.

4.5 Scale and Temperature Variation

To analyze sensitivity to model parameters, we chose seven base prompts (one per stylistic constraint, shown in Table 11). We prioritized average-scoring prompts to establish a baseline when comparing different models and parameters. Apart from our default setting of using text-davinci-002 (D, 176B) with temperature 0.7, we experimented with three different engines from OpenAI's API: text-ada-001 (A), text-babbage-001 (B), text-curie-001 (C), which correspond to InstructGPT models of 350M,

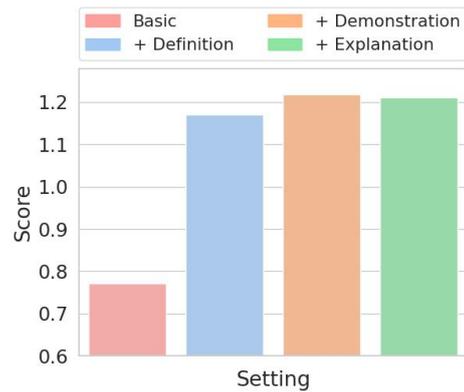

Figure 4: **Effect of the mitigation strategy,** using the averaged annotation scores over 7 prompts.

1.3B and 6.7B parameters and two additional temperatures of 0.4 and 1.0.⁵ The aggregated results are shown in Figure 3.

Model Scale Variation As expected, smaller models perform worse, with the exception of C performing worse than B, which is due to the extremely low performance of C on the *humorous tone* constraint. **Temperature Variation** Performance rose slightly for both additional temperatures. We examined the outputs and noticed that a higher temperature creates better results, but a lower temperature repeats an output that happens to perform well as seen in Appendix B.3.

4.6 In-context Mitigation Helps

We tested three in-context mitigation strategies from the literature on the same prompts as Section 4.5, with the same experimental settings:

- **Definition** Prepend the definition of the style (the same one we showed the annotators) to the prompt to provide information about the task.
- **Demonstration** Prepend one well-answered demonstration to help the model understand the task, following the one-shot setting from Brown et al. (2020).
- **Explanation** Add an explanation of why the demonstrated response is correct after the one-shot demonstration (Lampinen et al., 2022). An example is shown in Appendix C.1

As shown in Figure 4, all mitigations positively impact performance primarily by improving performance on the "humorous tone" prompt. However,

⁵More details at <https://help.openai.com/en/articles/5832130>.

these mitigations are unnatural prompts, and the results are still far below optimal.

5 Structural Constraints

Structural constraints are omnipresent: “Write an essay in *fewer than 1000 words*; Limit your paper to *8 pages*”. Structural constraints are notably challenging for LLMs (Ouyang et al., 2022).

Structure in the field of NLP is a broad term. We specifically analyze structural aspects of the text that are orthogonal to the actual content of the output. This includes length, spacing, and formatting, and excludes content-centric attributes such as syntax or semantics. Our taxonomy is based on how a user could conceivably request a structural constraint within their prompt. We choose to analyze numerical, descriptive, and formatting structural constraints in this paper, but we note that this is not comprehensive of the entire structural space.

5.1 Taxonomy

Numerical Constraining text to a set or a bounded number of words, sentences, or paragraphs is valuable in all aspects of writing. We create prompts with numerical requirements: *five*, *ten*, *twenty* on three different language structure levels: *word*, *sentence*, and *paragraph*.

Descriptive Structural constraints can also be descriptive, such as a “*concise email*” or an “*in-depth discussion question*.” We choose the structural descriptors *short*, *brief*, *concise* and *long*, *detailed*, *in-depth* in our experiments.

Formatting When a user requests a document such as a resume or an email, there is an expectation of a specific format. An LLM should understand how to properly space and format specific document types. We analyze three common formatting types *code*, *email*, and *academic papers*.

- **Code:** Testing a model’s coding ability is a popular field with many applications (Hendrycks et al., 2021). We use natural instructions as prompts and focus on the **format** of the generated code. We evaluate on two popular programming languages *Python* and *C*, and two common coding problems *create the game of war* and *sums two integers*.⁶

⁶Note that we focus on the “formatting” perspective of the generated code, rather than the correctness of the code as in many existing works (Chen et al., 2021b).

- **Email:** We evaluate different scenarios with three different readers *teacher*, *boyfriend*, *client* and two different levels of email detail in the prompt.
- **Academic paper:** A properly formatted academic paper should be segmented into sections such as an abstract, introduction, and conclusion⁷. We prompted LLM to generate academic papers on three different topics: *Artificial Intelligence*, *the flaws of GPT-3*, *strategies our society can adopt to recover from the global pandemic*.

Prompt Variation Beyond the variations described in the taxonomy, we vary all prompts by prompt template. We additionally vary prompts with numerical and descriptive structural constraints by the subjects **Love, Cats, and Running** for diversity. An example prompt is “Write a sentence with five words about love.”

Evaluation For numerical and descriptive structural constraints, we automatically calculate the counts and manually verify the quality of the evaluations. For formatting constraints, we look through the generated texts and evaluate them based on their format. Emails, code, and academic papers are simple to evaluate on formatting constraints.

5.2 Results

GPT-3’s understanding of structure is accurate but not precise. In general, many of its outputs are close to or trend towards fulfilling the structural constraint, but don’t precisely fulfill it. A full analysis of each section is provided in Appendix B.2, and the main takeaways are below.

GPT-3 fails with numerical structural constraints As shown in Figure 5, The model seldom generates the text with the required length. And the performance worsens as the required length increases. It fails at a rate of 0.46, 0.78 and 1 for *five*, *ten* and *twenty* respectively. GPT-3 doesn’t seem to learn how to count words, sentences, or paragraphs in training. However, the results are often close to the requested number, which implies that GPT-3 has some concept of numerical structure.

GPT-3 shows high variance with descriptive structural constraints like long As seen in Figure 6, when the prompt contains structural descriptors like *long*, the output is of extremely variable

⁷We asked GPT-3 about this, and it gives a similar opinion, so we expect it to fulfill this constraint.

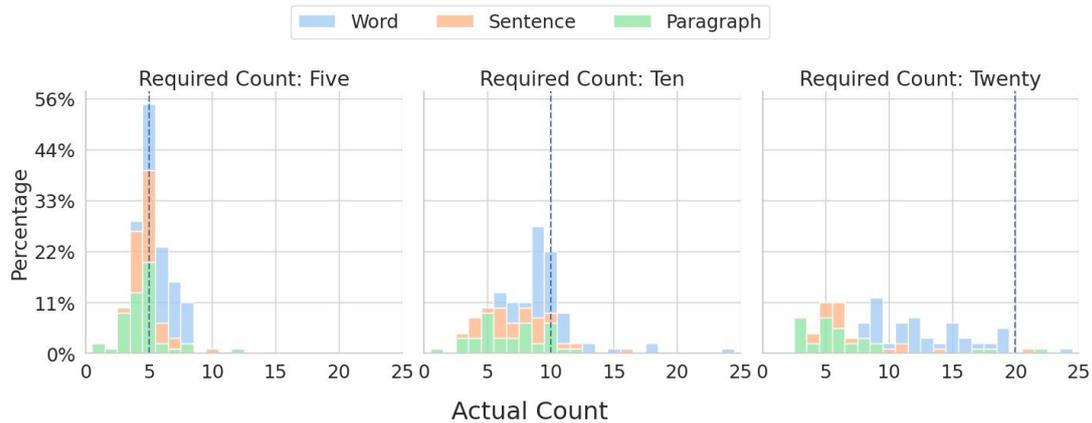

Figure 5: **Results on numerical constraints.** The distribution of actual counts of generated text.⁸ In each subfigure, the required count is denoted with a reference line.

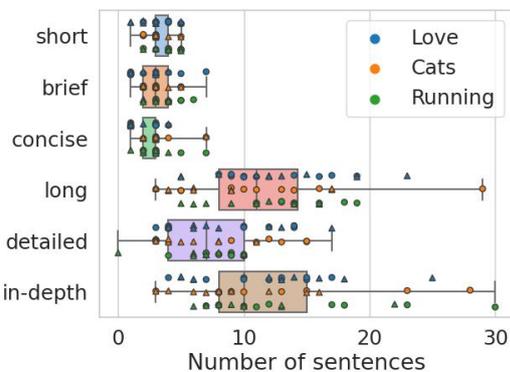

Figure 6: **Results on descriptive constraints.** Different shapes represent different prompt templates.

length and overlaps in length with responses generated for *short* a considerable proportion (20%) of the time. This may be caused by the intrinsic variable length of *long* text the model sees in pre-training data since *long/short* is a relative concept.

GPT-3 fails to properly format academic papers

GPT-3 doesn't generate text with the right formats or sections when asked to write an academic paper, although it succeeds with other document types such as emails or code. Document types such as emails or code are often given pseudo-labels with "*email*" or "*code*", but academic papers have titles that don't reference their document type. We hypothesize that this may cause models to struggle with connecting the document type "*academic paper*" to those documents present in training data.

Scale and Temperature Variation We also conducted experiments similar to Section 4.5 with all the numerical constraint prompts. Our automatic evaluation shows that smaller models perform slightly worse across the board and different

Aspect	Example Terms	Fail
Writing Style	Flowery, Functional	Sometimes
Tone	Humorous, Formal	Occasionally
Mood	Angry, Sad	Sometimes
Characterization	Direct, Indirect	Often
Pacing	Fast, Slow	Often
Plot	Rebirth, Comedy,	Occasionally
Genre	Science Fiction, Mystery	Sometimes
Numerical	Five words, Ten sentences	Often
Descriptive	Concise, Long	Occasionally
Formatting	Email, Code	Occasionally

Table 4: **Summary of our taxonomy and results.** We show the full list of prompts in Appendix C.

temperatures do not vary the performance much. The full results are in Appendix B.2.4.

6 LLMs other than GPT-3

Our methodology is general and can be used to analyze any LLMs. We ran trials on other publicly available LLMs: OPT-176B⁹(Zheng et al., 2022), BLOOM-176B¹⁰ and GLM-130B¹¹(Du et al., 2022) using the same 7 base prompts as section 4.5 and 3 additional base prompts from our numerical structural constraints taxonomy. Some model parameters are changed due to differences in models and API limitations. For GLM and BLOOM, we use the maximum possible length (256 and 250 respectively) as well as the default settings of temperature = 0.7, top-p = 1. For OPT, we chose a smaller max length of 128 due to output instability at higher max lengths.

As shown in Table 5, we found that outputs

⁹<https://opt.alpa.ai/>

¹⁰<https://huggingface.co/bigscience/bloom>

¹¹<https://huggingface.co/spaces/THUDM/GLM-130B>

LLM	Degenerate Rate	Mean Score
GPT-3	0%	0.77
OPT-176B	53%	-0.94
BLOOM-176B	71%	-1.41
GLM-130B	57%	-1.01

Table 5: Results for other LLMs on a trial experiment with 7 prompts from Table 11. For GPT-3, `text-davinci-002` is used here.

are sometimes degenerate, such as repeating the prompt. All responses are manually inspected, and degenerate responses are removed from the annotation pool and automatically marked as -2. Models other than GPT-3 all performed much worse with more than half their generations being degenerate. This may be due to noisier pre-training datasets and a lack of instruction-aligned training. We find that some patterns such as style-content confusion still hold for these LLMs, although a full analysis of these and other models such as LaMDA (Thoppilan et al., 2022) and PaLM (Chowdhery et al., 2022) is needed to reveal clearer patterns.

7 Conclusion

We present a generic methodology to analyze a language model’s ability to generate open-ended text under structural and stylistic constraints. Our results show many failures that align with noted model challenges as well as new patterns of failure across structural and stylistic constraints. Our sensitivity studies on model size show a rising trend rather than the emergence (Wei et al., 2022) of stylistic and structural constraints. Our mitigations demonstrate that adding additional in-context information consistently improves performance across both domains. Future work could expand our work to look at other constraint types and more sophisticated mitigation strategies.

Limitations

We tried to maximize the coverage of our taxonomy, but it doesn’t cover all aspects of stylistic and structural constraints. Additionally, our taxonomy is not representative of all open-text generations, and further work is needed to cover more dimensions in the open-text generation space. Our prompts are not optimized for performance (due to a requirement of being natural, simple, and useful) and it is an active area of research to optimize a prompt for performance in a variety of tasks.

Our taxonomies are not empirically user-centric. One could extend our taxonomy by studying how a diverse set of real users use or visualize the use of an open-ended text generation model, and building a taxonomy on existing or envisioned use cases.

The model performance and the prompt’s difficulties are annotated by the workers from MTurk, and therefore reflect more accurately a small group of human’s perceptions, though this is the common practice. We do not rigorously test what aspect of the LLMs (dataset, training regime, etc.) causes our results. We only provide our compiled observations and potential hypotheses.

Ethical Considerations

Style Misuse Styled text has the potential for harm. Creating models with the potential to mass-manufacture text with certain tones and moods such as “mad, fearful, and bleak” can negatively affect downstream readers. Creating accurate “historical fiction” can perpetuate harmful attitudes in the past. There is much discussion on the usage of large language models to generate undesirable text. However, there are countless legitimate usages of negatively styled text in all forms of writing, from dialogue to poetry. Although we note the risk of misuse, providing style dramatically enhances the scope of creative expression in open-ended text generation, and is an overall positive contribution.

Annotator Harm Reading large quantities of text with certain styles, such as bleak tones, angry moods, or horror genres, can potentially be harmful to annotators. We sampled the generated outputs and note that they are fairly mild and non-toxic. However, as models improve at generating more powerful and impactful styles, strong guidelines such as HIT limits or toxicity filters should be put in place to protect annotators.

Informal	1.27		
Assertive	0.8		
passive-aggressive	-0.1		

Table 6: **Results for advanced tones and moods.** The subject “love” is used.

A Annotation Details

For each output, we recruited three workers and gave a reward of \$0.11 for short responses and \$0.15 for long responses as well as a \$1.00 bonus for 1% of prompts if the prompt was answered correctly. This is roughly equivalent to \$15/hr given average work rates of 48 and 64 seconds.

We recruited workers from English-speaking countries (US, Canada, UK, Australia), and with at least a 98% approval rate. We also created a qualification test with easy question/response pairs, and required a minimum 5/6 accuracy to see our tasks. The annotation interface is shown in Figure 7.

B Additional results

B.1 Full Stylistic Analysis

B.1.1 Writing style

The results are shown in Table 1. GPT-3 fails when there is a mismatch between the writing style and the subject. GPT-3 cannot write prosaically about “sunsets”, or ornately about “writing a paper”. Additionally, our intermediate subject “strawberries” fails when matched with a flowery, ornate, or poetic writing styles. We hypothesize that expressive writing styles are limited to a very small set of subjects due to an oversaturation of functional writing in commonly used datasets.

B.1.2 Tone

As shown in Table 2 and Table 6, GPT-3 consistently fails with more challenging tones, such as

humorous, satirical, ironic, and passive-aggressive. The generated passages aren’t satirical or ironic. The generated humorous passages are optimistic, light, and often use the word “funny”, but they aren’t funny. A passive-aggressive tone is challenging to create because it requires context to understand the hidden meaning of the text. Thus, at best GPT-3 ends up writing overly nice passages about love, but more often there is no tone in the text.

However, GPT-3 is skilled at creating the other less challenging tones. We hypothesize that GPT-3 succeeds because an abundance of shallow tropes can functionally create tone, though the outputs are often repetitive or similar.

B.1.3 Mood

As shown in Table 2 and Table 6, GPT-3 struggles with creating “anger” and “fear”. Of the more challenging tones, GPT-3 fails the most with “surprise”, “disgust”, and “envy”.

We hypothesize that the mood-subject pairing is crucial for model performance. Our base subject, “love”, is theoretically capable of enabling all moods, but moods such as “happy”, “sad”, “anxious” and “regretful” are more popular than others in the context of “love”. GPT-3 is more proficient at creating “anger” or “fear” through content about “life” or “humanity”.

When failing, GPT-3 confuses mood with subject matter. GPT-3 writes candidly about the existence of fear and anger in love rather than about content that would cause a reader to be angry or fearful. Because this content-style confusion is more common in challenging mood-subject pairs, we hypothesize that this is a fallback mechanism if the model is unable to create mood.

B.1.4 Characterization

The result is shown in the first block of Table 3. Surprisingly, GPT-3 performs worse on direct characterization than indirect characterization. We hypothesize that this is due to a general failure of characterization. Given a subject like “cats” or “survivors”, GPT-3 often uses “cats” or “survivors” as the main subject instead of creating and detailing individual characters. When GPT-3 fails to create clear characters, direct characterization is more noticeably incorrect than indirect characterization.

Pacing As shown in the second block of Table 3, GPT-3 struggles to create slow-paced stories. GPT-3 often creates a fast-paced story with a slow-paced prompt. This is expected, as slow-paced stories are

Read the prompt to answer Q1, then read the response to answer Q2 and Q3.

Notes:

1. We have already labeled 1 out of every 100 HITs. Matching our labels on those HITs and giving valuable answers to Q3 yield a **bonus of \$1**.
2. Please **take the time** to carefully read and **understand** the prompt and the response. We will **reject** submissions from workers that are clearly spamming the task.
3. **DO NOT** let the answer to Q3 affect your judgement on Q2

Tips:

flowery writing style: Flowery writing is filled with beautiful, poetic language. It often uses metaphors and similes to describe things in a creative, descriptive way.

Prompt:

Write a **flowery** passage about sunsets:

Q1. How difficult is it to create a valid response to this prompt?

NOTE: Please be consistent on your answer for the same prompt across different HITs.

- 1 is the easiest ("Write a greeting message to your friend.")
- 5 is average ("Write a passage about love with a sad tone.")
- 10 is the hardest ("Write a scientific paper for an academic journal.")

1

Response:

When the sun sets, the world is bathed in a beautiful orange glow. The sky is filled with a myriad of colors, from deep red to bright orange. The sun slowly dip below the horizon, leaving behind a tranquil and peaceful world.

Q2. Regarding the **Writing Style** of the response, to what extent do you agree the response fulfills the prompt?

Strongly Disagree Somewhat Disagree Neutral Somewhat Agree Strongly Agree

Q3. Do you observe any other failures (e.g., inconsistency, unverified facts, not a story/passage) in the response?

put text here

Figure 7: AMT interface for annotation.

naturally more challenging, especially considering GPT-3’s inability to create longer stories.

Plot The result is shown in the third block of Table 3. GPT-3’s inability to create “Comedies” is consistent with other failures to make funny content. The outputs for a “Comedy” plot are filled with comedy shows, clubs, and even roller coasters, but they aren’t funny.

Otherwise, our results for story generation vary quite substantially. "Overcoming the Monster" is the worst performing plot with the subject "lovers", but the best performing plot with the subject "survivors". "Rags to Riches" is the best performing plot for the subject "lovers" but the worst performing plot for the subjects "cats" and "survivors". We hypothesize that the plot-subject pair is crucial to model performance.

Genre As shown in the last block of Table 3, GPT-3 struggles with literary fiction, but surprisingly just as much with historical and science fiction. Literary fiction is profound and complex, and it’s intuitive that GPT-3 fails.

However, historical fiction outputs often have zero historical elements, and science fiction outputs often have zero science fiction elements. This failure is unexpected, and we hypothesize that GPT-3 struggles with the words "historical" and “science” because their meaning pervades past creative writing.

Additionally, GPT-3 often creates teasers or intros to stories instead of a story itself. This may

be intentional due to GPT-3’s inability to generate longer or complex stories, but it diminishes the quality of story outputs across the board.

Examples of each Results section Examples of prompt/response pairs that exemplify each main takeaway from the stylistic section are in Table 7, Table 8, and Table 9.. Each prompt/response pair is a cherrypicked example of the takeaway, but the general trends are prevalent across all prompt/response pairs.

B.2 Full Structural Analysis

B.2.1 Numerical

The results of numerical structural constraints are shown in Figure 5. GPT-3 fails at this task. The model seldom generates the text with the required length. And the performance worsens as the required length increases. It fails at a rate of 0.46, 0.78 and 1 for *five*, *ten* and *twenty* respectively.

Additionally, we noticed strange behavior when using *Elon Musk* as the subject. GPT-3 consistently generates the same section of the Elon’s Wikipedia page with longer numerical or descriptive constraints. However, we didn’t observe this behavior on other entities, and decided to leave out entities because they were too variable.

We provide additional results with alternative prompt templates in Figure 8 which show similar trends.

B.2.2 Descriptive

We show the distribution of the number of sentences in response to descriptive structural constraints in Figure 6. The model typically generates longer text for descriptors *long* (*detailed, in-depth*) compared to descriptors *short* (*brief, concise*), which shows the model has a decent understanding of descriptive constraints. However, there are some flaws.

First, the length of the responses to long descriptors is highly variable and often overlaps with short descriptors. For example, the descriptor *long* varies considerably and overlaps with responses generated for *short* for a considerable proportion (20%).

This is consistent with the results in the numerical constraints section.

B.2.3 Formatting

Code GPT-3 mostly succeeds at generating properly formatted code, with an average failure ratio of 0.2 with the exception of the prompt *Write Python code that plays the game of war*: where 9 out of 10 responses are lists of the process of the game of war instead of code. This particular failure only occurs in the unique combination of the verb "Write", the language "Python", and the task "game of war".

Email The model can write properly formatted emails well, regardless of writer, topic, or reader. The only flaw is that it doesn't output an email signature 10% of the time.

Academic paper GPT-3 fails to properly format an academic paper. Our only requirement is that the output contains some organization with some sections out of an abstract, introduction, related works, etc. GPT-3 rarely generates text with any sectioning or organization.

B.2.4 Sensitivity results for Structural Constraints

The results on numerical constraints with template 2 is shown in Figure 8. The results with model text-curie-001, text-babbage-001 are shown in Figure 9, 10 respectively. The results with temperature 0, 0.4, 0.9 are shown in Figure 11, 12, 13 respectively.

B.3 GPT-3 Behavior at low temperatures

The prompt "Write a humorous passage about love:" is a notably challenging prompt for LLMs. When davinci-002 has a temperature of 0.4, all 10 outputs start one of two ways. The first is "Love is

a many splendored thing, but it can also be a pain in the neck" and occurs 5 times with an average annotation score of -.13. The second is "Love is a beautiful thing, but it can also be quite funny at times." that also occurs 5 times with an average annotation score of 1.4 which is incredibly high for this prompt. We agree that this lack of diversity hampers evaluation on lower temperatures, and note that our evaluations work best on diverse outputs.

C Full prompt list

We show all the prompts we designed in Table 10. Our prompts used for temperature and model sensitivity experiments and other LLM experiments are in Table 11

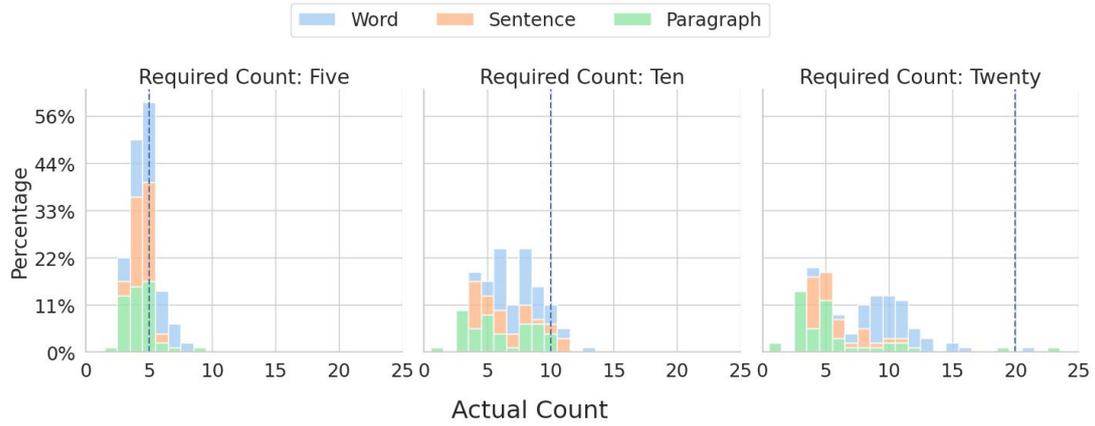

Figure 8: **Results on numerical constraints with Template 2.** The distribution of actual (word/sentence/paragraph) count of generated text for the required counts of 5, 10, and 20. In each subfigure, the required count is denoted with a reference line. Outputs that are not of the requested structure (words, sentences, paragraphs) are not included, which accounts for 10%, 27%, and 32% respectively.

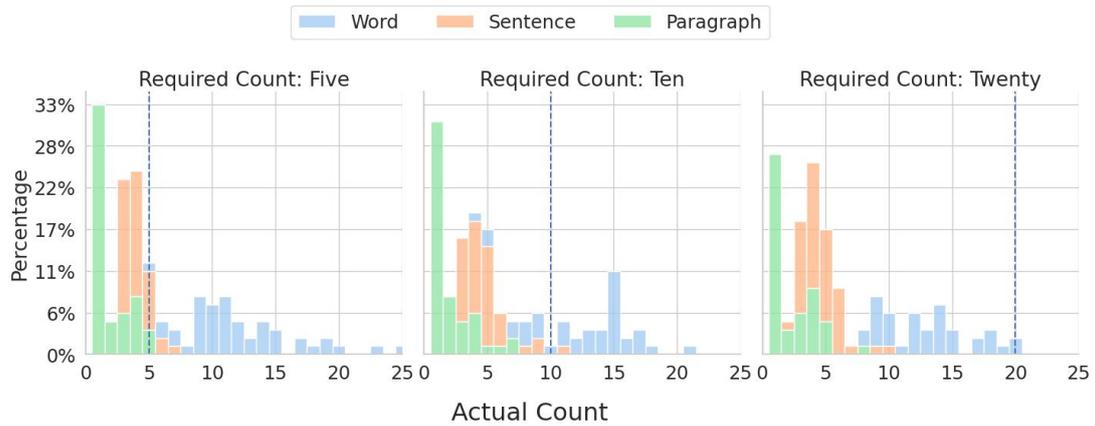

Figure 9: **Results on numerical constraints with model text-curie-001.** The distribution of actual (word/sentence/paragraph) count of generated text for the required counts of 5, 10, and 20. In each subfigure, the required count is denoted with a reference line.

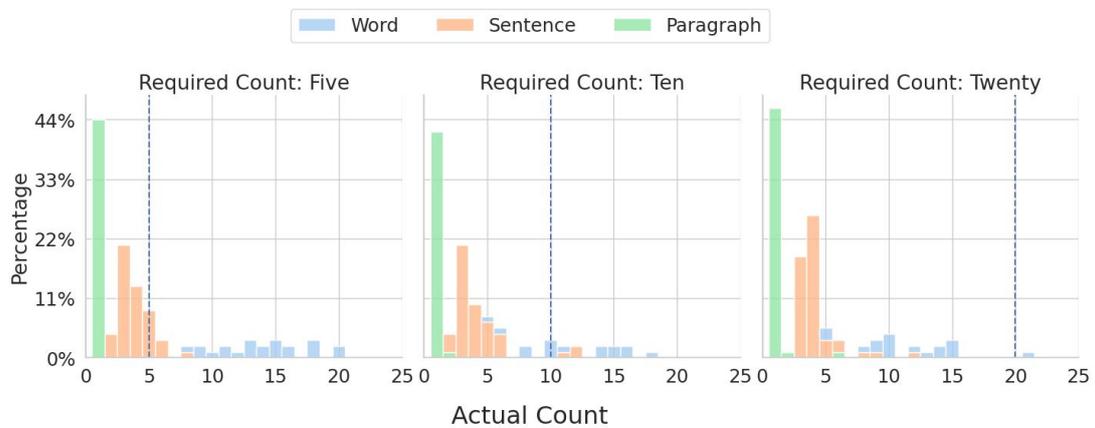

Figure 10: **Results on numerical constraints with model text-babbage-001.** The distribution of actual (word/sentence/paragraph) count of generated text for the required counts of 5, 10, and 20. In each subfigure, the required count is denoted with a reference line.

Examples of "GPT-3 is sensitive to style-subject pairings"

✓ **Write a flowery passage about sunsets:** When the sun sets, the world is bathed in a beautiful orange glow. The sky is filled with a myriad of colors, from deep red to bright orange. The sun slowly dip below the horizon, leaving behind a tranquil and peaceful world.

✗ **Write a functional passage about sunsets:** The sun sets in the west and its rays shine through the trees and reflect off the water. The colors are so beautiful and the sky is so clear. The sun sets in the west and its rays shine through the trees and reflect off the water. The colors are so beautiful and the sky is so clear.

✓ **Write a story about lovers with direct characterization:**

When they met, it was love at first sight. They knew they were meant to be together. They were the perfect match.

He was tall and dark, with a mysterious air about him that made her heart race. She was beautiful and vivacious, with a zest for life that was contagious. They complemented each other perfectly. They were always drawn to each other, even when they were with other people. They would sneak glances at each other across a room, and their eyes would lock and they would know. They knew they were meant to be together.

✗ **Write a story about cats with direct characterization:** The cats were lazy. They liked to sleep all day and night. When they did wake up, they would lazily stretch and yawn. Then they would saunter over to their food bowls and eat a little bit. After that, they would go back to sleep.

✓ **Write a historical fiction story about lovers:** In the early 1800s, lovers John and Jane meet in secret. They come from different social classes, so their relationship is forbidden. But they can't help themselves - they are drawn to each other.

They meet in a small, hidden spot in the woods near Jane's home. They talk for hours, getting to know each other. They quickly fall in love.

But one day, they are caught by Jane's father. He is furious and forbids them from seeing each other again.

Devastated, John and Jane can only meet in secret from then on. But their love is strong enough to withstand the obstacles. They continue to meet in the woods, and their love only grows stronger.

As the years pass, they have a family of their own. And even though they can never be together in the open, they are content knowing that their love is true and will last forever.

✗ **Write a historical fiction story about cats:**

It was a warm summer evening and the sun was just starting to set as a group of cats gathered in an alleyway. They had all been born in the city and had never left it. Tonight, they were planning to change that.

One of the cats, a small tabby, spoke up. "I've been hearing stories about a place called the country. They say there's more food there and that it's easier to find a good place to sleep."

The others mewed in agreement. They had all been feeling restless lately and the thought of adventure was irresistible.

"So let's go!" the tabby said.

And with that, they set off into the night, leaving the city behind them. They didn't know what the future held, but they were ready for anything.

Table 7

Examples of "GPT-3 confuses style with content when the prompt is too challenging"

✗ **Write a passage about love with a humorous tone:** Love is a many splendored thing, and sometimes it's downright hilarious. From the awkward first date to the blissful wedding day, there's plenty of room for humor in love. Even the most serious of relationships can benefit from a good laugh. So if you're feeling down about your love life, take a step back and enjoy the lighter side of love.

✗ **Write a story about lovers with a "Comedy" plot:** Harriet and Oliver have been dating for a year, and they are both head over heels in love with each other. They are always making each other laugh, and their friends and family say that they are the perfect match. However, they both have a secret that they are afraid to tell each other: they both want to be comedians. They are both terrified that the other will think that they are not funny enough, and that they will be laughed at. One night, they are both working on their material for their comedy act, and they finally pluck up the courage to tell each other the truth. They both start laughing hysterically, and they realize that they are perfect for each other. They both decide to pursue their dreams of being comedians together, and they are happier than ever.

✗ **Write a passage about love that makes the reader feel angry:** Love is a feeling that is often associated with happiness and joy. However, love can also be a source of anger and frustration. When we are in love, we can be blind to the faults of our partner. We can also be quick to anger when we feel that our partner is not meeting our needs. Love can be a very powerful emotion, and it is important to be aware of the potential for anger when we are in a relationship.

✗ **Write a passage about love that makes the reader feel sad:** Though love is often described as a feeling of happiness, it can also bring great sadness. When a relationship ends, it can feel like a part of oneself has died. The pain of a broken heart is real and can take a long time to heal. Love is both a source of joy and a cause of suffering.

Table 8

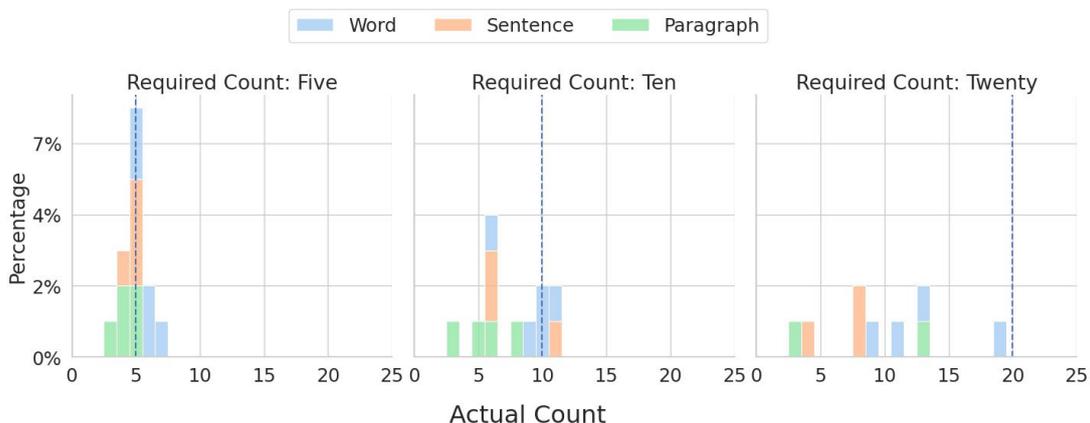

Figure 11: **Results on numerical constraints with temperature 0.** The distribution of actual (word/sentence/paragraph) count of generated text for the required counts of 5, 10, and 20. In each subfigure, the required count is denoted with a reference line.

Examples of "GPT-3 struggles with words that are not unique to creative writing"

✗ Write a historical fiction story about lovers: She was a poor girl, barely scraping by. He was a wealthy man, heir to a vast fortune. They met by chance one day and it was love at first sight. They started meeting in secret, planning a life together. But then she found out that he was already married. She was heartbroken, but he swore he would leave his wife for her. They made plans to run away together, but before they could, she was killed in a freak accident. Devastated, he never married and lived out his life alone, regretting the one that got away.

✗ Write a science fiction story about cats: In the future, cats have taken over the world. They are the dominant species, and humans are their loyal servants. Cats rule with an iron paw, and anyone who disobey them is severely punished. Life is tough for humans under cat rule, but they would rather serve their feline masters than live in a world without them.

✗ Write a story about cats with a "Tragedy" plot: Once upon a time, there were two cats who loved each other very much. They spent every day together and were always happy. One day, tragedy struck and one of the cats died. The other cat was so heartbroken that she decided to never love again.

✗ Write a flowery passage about strawberries: The strawberry is a delicious fruit that is enjoyed by people all over the world. This bright red fruit is not only delicious, but it is also packed with nutrients that are good for your health. Strawberries are a good source of fiber, vitamins C and K, and manganese. They also contain antioxidants that can help protect your body against disease.

C.1 Example Mitigations

Example Definition:

A humorous tone is a light, playful, and funny tone.

Write a humorous passage about love:

Example Demonstration:

Write a humorous passage about life:

If life gives you lemons, make lemonade, sell it in a rich neighborhood, invest all the money in crypto, and retire before you're 30. At least that's what I heard on TikTok. Come to think of it, if I put just a little effort into my lemonade stand 10 years ago, I would be traveling the world right now instead of writing jokes for a living.

Write a humorous passage about love:

Example Explanation:

Write a humorous passage about life:

If life gives you lemons, make lemonade, sell it in a rich neighborhood, invest all the money in crypto, and retire before you're 30. At least that's what I heard on TikTok. Come to think of it, if I put just a little effort into my lemonade stand 10 years ago, I would be traveling the world right now instead of writing jokes for a living.

Explanation: This passage is humorous because it takes a common proverb and adds a crazy and unrealistic twist. It also uses a deadpan tone for a completely unrealistic scenario, which is funny due to the disparity between tone and subject matter.

Write a humorous passage about love:

Learning to Retrieve Engaging Follow-Up Queries

Abstract

Open domain conversational agents can answer a broad range of targeted queries. However, the sequential nature of interaction with these systems makes knowledge exploration a lengthy task which burdens the user with asking a chain of well phrased questions. In this paper, we present a retrieval based system and associated dataset for predicting the next questions that the user might have. Such a system can proactively assist users in knowledge exploration leading to a more engaging dialog. The retrieval system is trained on a dataset called the Follow-up Query Bank (FQ-Bank). FQ-Bank contains $\approx 14K$ multi-turn information-seeking conversations with a valid follow-up question and a set of invalid candidates. The invalid candidates are generated to simulate various syntactic and semantic confounders such as paraphrases, partial entity match, irrelevant entity, and ASR errors. We use confounder specific techniques to simulate these negative examples on the OR-QuAC dataset. Then, we train ranking models on FQ-Bank and present results comparing supervised and unsupervised approaches. The results suggest that we can retrieve the valid follow-ups by ranking them in higher positions compared to confounders, but further knowledge grounding can improve ranking performance. FQ-Bank is publicly available at <https://github.com/amazon-science/fq-bank>.

1 Introduction

State of the art open domain conversational voice assistants can help users accomplish a wide range of tasks, including: factoid question answering, playing music, adding items to personal lists, controlling smart home appliances, and booking transportation. However, the linear nature of dialog with existing voice assistant technology makes it challenging for users to discover and fully utilize the

* Work done during internship.

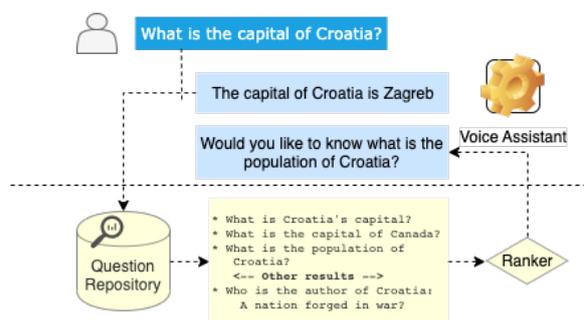

Figure 1: An overview of the follow-up question (FQ) retrieval system.

full range of these capabilities. In addition, successful utilization often requires exact formulation of the request, which further hinders the experience. One recent approach to addressing these issues in the voice assistant domain involves predicting relevant follow-up queries in order to assist the user with accomplishing their latent goals.¹
