Relevant follow-up queries (FQs) for typical voice assistant scenarios can range from specific command and control tasks such as “*What is the temperature in New York*” followed by “*What is the chance of rain in New York?*”, to more open-ended knowledge exploration, e.g. “*What is the capital of Croatia*” followed by “*What is the population of Croatia?*”. Once a valid FQ has been identified, the system can proactively recommend it to reduce user’s cognitive load, e.g. “*Would you like to know what the population of Croatia is?*”. This exchange is illustrated in Figure 1. The user can then be engaged in follow-up dialogue without the need to ask redundant questions.

Follow-up queries can be identified by retrieving and ranking candidates from a question repository.

Dialog History	
Where was Kurt Gödel born?	<i>Brunn, Austria-Hungary</i>
When was Kurt Gödel born?	<i>April 28, 1906</i>
What was Kurt Gödel’s home life like?	<i>ethnic German family</i>
Where did Kurt Gödel go to school?	<i>Godel attended the Evangelische Volksschule in Brunn</i>
Valid Follow up	
What were Kurt Gödel’s interests?	
Generated Negative Examples with Types	
Where was Kurt Gödel born?	<i>Duplicate of dialog history</i>
Which school did Kurt Gödel attend?	<i>Paraphrase</i>
Where was Cristiano Ronaldo born?	<i>Irrelevant Entity</i>
Where did Curt Gödel go to school?	<i>ASR Error</i>
When did Cristiano Ronaldo join Juventus?	<i>Random Question</i>
When did Kurt Gödel join Juventus?	<i>Irrelevant context</i>

Table 1: An example showing the dialog history, current turn, valid utterance, and a set of negative utterance candidates from the generated dataset.

In this approach, we are given dialog of one or more turns between a user and a voice assistant. The system first uses a search engine to retrieve a set of relevant questions by searching against a question repository comprising of historical queries and questions generated from a knowledge base. To create questions from a knowledge base, we can use templates or use a few-shot Natural Language Generation (NLG) model such as T5 (Raffel et al., 2020). For example, we can take the tuple {entity, place of birth} and construct a question template like “what is the birthplace of {entity}”.

Through a preliminary study of this retrieval approach, we found a basic lexical similarity-based search engine to be ineffective and often returns invalid follow-up queries. Often these top search results included paraphrases of the original query (*When was Cristiano Ronaldo born* → *What year was Cristiano Ronaldo born*), as well as similar questions for unrelated entities (*When was Cristiano Ronaldo born* → *When was Christian Bale born*). Therefore, an additional ranking module is needed in order to re-rank the search results based on their quality as follow-up queries. To the best of

our knowledge, there exists no dataset focused on information-seeking follow-up queries, given a dialog context and a set of valid and invalid follow-up candidates. This problem differs from traditional recommendation systems in that 1) a voice assistant can only recommend one follow-up at a time, and 2) the follow-up query must be highly precise, contextually relevant, and coherent to ensure a positive user experience. This technique can be extended beyond the domain of virtual assistants, for example to chatbots, search engines, and any other smart interaction scenario where contextual coherence and precision is necessary. Therefore, in this paper, we created the FQ-Bank dataset addressing this problem and explored different modeling techniques to develop a ranking model to retrieve relevant follow-up queries (FQ). The main contributions of this paper can be summarized as follows:

1. For the scenario of a retrieval-based follow-up question selection, we identify a typology of confounders based on preliminary results from a search engine.
2. We propose techniques to synthetically generate confounders according to this typology, based on the publicly available conversation dataset OR-QuAC (Qu et al., 2020), and created the Follow-up Query Bank (FQ-Bank) dataset. FQ-Bank is publicly available and can be used to develop and test machine learning systems for identifying contextually relevant and meaningful follow-up queries from search results. Additionally, the confounder creation techniques can be applied in data augmentation for similar problems. Table 1 shows an example from the generated dataset.
3. We adopt a pre-trained language model based approach to develop a benchmark model for ranking a set of candidate follow-up queries for a given factoid utterance and dialog history. We explore the effectiveness of this technique and identify gaps and future directions.

2 Related Works

Previous studies on proactivity in conversational AI mostly focuses on response generation. Follow-up question identification and generation approaches have been explored from different perspectives. For example, Kundu et al. (2020) explored the task of identifying if the latest user utterance is a follow-up

of the previous questions or it has a different new context. This is helpful for understanding the question context properly and give the correct response. They also derived a new dataset called LIF from the QuAC dataset (Choi et al., 2018), where each data point contains a conversation history, a new utterance, a passage used to answer the previous questions, one valid follow-up, and one or two invalid follow-ups. However, this dataset is focused on passage-based question answering, and the confounder typology does not address issues found in the search engine based FQ retrieval scenario (e.g. paraphrases, irrelevant entity substitution, etc).

Other works have focused on generating follow-up queries for extracting information from users. For example, Ge et al. (2022) proposed a knowledge-driven system for generating follow-up queries, but it targeted the generation of follow-up survey questions to extract information from humans. Su et al. (2018) and B et al. (2020) explored systems for asking follow-up queries to interview candidates to extract more relevant information.

Our proposed method is focused not on information extraction from users, but rather providing highly relevant additional information to the user.

3 Follow-up Query Bank

For our initial study on identifying FQs, we created a search index of information-seeking questions regarding public facts, spoken by users of a commercial voice assistant. We then queried the search engine with different types of information-seeking questions and analyzed the top negative (i.e., not a suitable follow-up) search results and categorized them into a typology of confounders. Using this typology, we set out the task of simulating a similar scenario on a public conversation dataset and did not use any voice assistant data anymore. We selected OR-QuAC as the seed dataset as it provides multi-turn information-seeking dialogs on a particular topic. In the rest of this section, we will provide a brief overview of the confounders and OR-QuAC dataset, followed by an overview of the simulation methodology of the confounders using OR-QuAC.

3.1 Confounder Identification

We created a search index with an open-source search engine for a set of de-identified user interactions with a commercial voice assistant during a period of time. Then, we carefully selected a set

of questions that are different from each other in aspects such as the intent, entity in context, entity’s gender and topic domain. We searched the index against each of these questions and inspected the relevance of the top 20 search results as a follow-up question. We found that most of ($\approx 95\%$) the top search results are not suitable candidates for a follow-up. We analyzed the top irrelevant results and categorized them as the following confounders that should rank low in their relevance as follow-ups.

- **Paraphrase** We observed a large segment of irrelevant candidates that are semantic equivalents of the query question. This happens because people can ask the same question in different ways. For example, “*How old is Joe Biden*” and “*Joe Biden age*” are lexically different but semantically equivalent.
- **Irrelevant Entities** Often, the top search results are about entities different from the query question, but the questions have a similar carrier phrase. For example, “*What team does Ronaldo play for*” retrieves questions like “*What team does Tom Brady play for*”. It is true that some user may find such questions as relevant follow-ups, but this is highly subjective. Tom Brady will be completely irrelevant to a user who does not follow the National Football League (NFL). As a result, we considered that such scenarios are irrelevant for now.
- **Partial Entity Match** This is a variation of the previous confounder. Here, not only is the carrier phrase similar, but also, the entities share one or more tokens. For example, “*How old is the University of Washington*” can retrieve questions like “*How old is the University of Houston*”. Here we observe partial entity match “*university of*” in addition to the identical carrier phrase “*how old is the*”.
- **Irrelevant Context** Some top search results share the correct entity with the query question, but the retrieval can be a non-sequitur. For example, “*What is the capital of France*” can retrieve questions like “*Where is France*”. Even though contextually it is a relevant questions, asking back “*Would you like to know where is France*” does not make a good experience for the user as the chances are high that

	Train	Validation	Test

Total	3,51,827	36,914	52,163
- per dialog	26.10	25.74	24.47

Table 2: Statistics of the created dataset with each category of the negative examples.

the user already have an idea on the geographical position of France.

Additionally, we listed the following confounders that were not seen in our limited data analysis but can appear in a larger system:

- **Automatic Speech Recognition (ASR) Error** ASR failures can sometimes replace an entity with a similar sounding word. For example, *Kurt* can be replaced with *Curt* in "*Where did Kurt Gödel go to school*". High lexical overlap can rank such irrelevant entities highly.
- **Duplication of Dialog History** Sometimes the information provided by a candidate follow-up question can already be present in a multi-turn dialog history. In such a case, it is important to identify and get rid of those questions by modeling the dialog history.

After identifying these confounder categories, we selected OR-QuAC as the starting dataset, and used different techniques to generate these confounders and simulate the retrieval scenario for the follow-up selection system.

3.2 OR-QuAC Dataset

Open-Retrieval Conversational Question Answering (OR-QuAC) consists of ≈ 6 K multi-turn

information-seeking dialogues between two humans, one posing as student (asks knowledge-seeking questions) and the other as teacher (answers the questions using Wikipedia as the knowledge source). It draws from the popular QA dataset QuAC (Choi et al., 2018) as well as CANARD (Ghoneim and Peskov, 2019), which provides context-independent rewrites of initial questions written by human annotators.

This dataset is well-suited for our purposes as: i) the conversations aim at exploring knowledge about entities or topics, ii) multi-turn conversations enable us simulating a dialog history (one or more question-answering turns between two people), iii) query rewrites are helpful to get rid of anaphoric references which can make candidate questions ambiguous about entities (e.g., "*How many kids Kamala Harris has*" removes the ambiguity from "*How many kids she has*").

For each information-seeking question in the OR-QuAC dataset, we chose the rewritten version as the current question, the previous turns as the dialog history, and the immediate next turn as the valid follow-up question. Then, we used different techniques to generate the confounders that we will explain in the next section.

3.3 Data Sample Generation

For a conversation in the OR-QuAC dataset of T turns (question–answer pairs), we have sampled $T-1$ data points $\{x, y\}$. Each generated data sample contains a dialogue context, x , of length \mathcal{L} ($1 \leq \mathcal{L} \leq T-1$). x contains a dialog history $\{(q_1, a_1), \dots, (q_{\mathcal{L}-1}, a_{\mathcal{L}-1})\}$ of length $\mathcal{L} - 1$ (i.e., $\mathcal{L}-1$ question (q)–answer (a) pairs), and a current question ($q_{\mathcal{L}}$) and the answer ($a_{\mathcal{L}}$). Hence, $x = \{(q_1, a_1), \dots, (q_{\mathcal{L}-1}, a_{\mathcal{L}-1}), (q_{\mathcal{L}}, a_{\mathcal{L}})\}$.

Each data sample also contains a set of positive and negative follow-up queries, $y = \{y^+\} \cup y^-$. y^+ is a single positive follow-up question, and y^- is a set of negative follow-ups ($y^- = \{y_1^-, y_2^-, \dots\}$) that we have created based on the identified confounders.

Valid Examples Given a dialog history $x_{1:T-1}$ of length $T-1$ and a current turn x_T , we consider the consecutive question (x_{T+1}) in the OR-QuAC dataset as a positive follow-up question.

Adversarial Examples We used the following methods to populate the candidate question space for a turn with negative examples based on the confounders we have listed in Section 3.1:

- **Paraphrase:** We used a pre-trained BART model (Lewis et al., 2019) that was fine-tuned on several paraphrase datasets². For the last user turn in a dialog history, we used this model generated paraphrase as a confounder.
- **Irrelevant Entities and Partial Entity Match:** We first used the SpaCy³ library to identify the named entities in the current question in a turn. Then we generate a negative example by replacing the entity with an entity of a similar type from a catalog generated from WikiData. For entities with multiple word tokens, we replace a token (e.g., first name or last name) with a random first name or last name token. For a dialog, we created multiple such examples.
- **Irrelevant Context:** We randomly sampled one question from the rest of the dataset that has a similar entity type and replace that with the entity in the context of a current question. That means, for an entity we swap the original question with a random one.
- **Random question:** We added three random questions from the dataset as a negative examples for a dialog.
- **ASR Error:** For an entity in a question, we generated a similar sounding entity using the Datamuse API⁴ and replaced the original entity with the generated homophone. For entities with multiple word tokens, we created multiple examples like this by replacing one token with a homophone at a time.
- **Duplication of Dialog History:** We added a question from the dialog history in the candidate set.

We maintained the standard training, validation, and test splits from OR-QuAC while generating the dataset. Table 1 shows an example of generated data and Table 2 shows statistics of the dataset. As we maintained the original data split, distribution is similar across all the splits. For each dialog, there are ≈ 25 negative examples with one positive example. That means, a model needs to learn contextual relevancy for being able to identify the correct follow-up.

4 Learning to Identify Relevant Follow-up

Task Formulation: Given a dialog $x = \{(q_1, a_1), \dots, (q_{\mathcal{L}-1}, a_{\mathcal{L}-1}), (q_{\mathcal{L}}, a_{\mathcal{L}})\}$ of \mathcal{L} turns and a randomly organized set of n candidate follow-up queries $y = \{y^+\} \cup \{y_1^-, y_2^-, \dots, y_{n-1}^-\}$, the task is to model $P(i|x), i \in y$, such that $\operatorname{argmax}_i P(i|x) = y^+$.

Here, q is a question, a is an answer, y^+ is a positive follow-up example, and y^- is a set of negative examples. In order to develop a follow-up question candidate ranker, we experiment with different unsupervised and supervised approaches as described below.

4.1 Unsupervised

We experimented with Glove (Pennington et al., 2014) word embeddings, pre-trained SentenceBERT (Reimers and Gurevych, 2019) model in the unsupervised direction. For a given dialog x and candidate utterance set $y = \{y^+, y^-\}$, we use the Glove or SentenceBERT to generate a high-level vector representation \bar{x} from the dialog and do the same for each of the candidate utterances $y_i \in y$. With Glove, we compute the mean of the 300d embedding vectors for all the word tokens in a dialog x and represent the out-of-vocabulary (OOV) words with zero vectors. The vocabulary coverage of Glove is $\approx 99\%$ for the dataset. For SentenceBERT, we feed the entire input texts (concatenation of multiple turns in x) for x and $y_i \in y$ to generate \bar{x} and \bar{y}_i , respectively. Then, we compute the cosine similarity $\alpha = \cos(\bar{x}, \bar{y}_i)$ between \bar{x} and $y_i \in y$ and rearrange y in descending order based on α .

4.2 Supervised

For the supervised experiments, we fine-tune a pre-trained language model by translating the problem as a binary classification task. In other words, for a given dialog $x = \{(q_1, a_1), \dots, (q_{\mathcal{L}-1}, a_{\mathcal{L}-1}), (q_T, a_T)\}$ and a candidate set $y = \{y^+\} \cup y^-$, we train a model θ to predict $\hat{y} = P(i | x), i \in y$, where $\hat{y} \rightarrow \mathbb{R} : [0, 1]$.

We format the input by concatenating the dialog history turns and a candidate utterance with a [SEP] token and a single output node outputs a continuous value between 0 and 1. As the starter pre-trained language model we experiment with BERT (Devlin et al., 2019) and RoBERTa (Liu

	Validation	Test
Unsupervised		
Glove	0.142	0.141
SentenceBERT	0.133	0.141
Supervised		
BERT	0.842	0.805
RoBERTa	0.838	0.808

Hit Ratio@1/ Hit Ratio@3		
BERT	72.0/ 89.3	68.5/ 88.1
RoBERTa	71.7/ 88.7	68.2/ 89.5

Table 3: Ranking performance in MRR for different unsupervised and supervised methods. The last two rows show the Hit Ratio at the first and third position for BERT and RoBERTa.

et al., 2020). We use the bert-base-cased⁵ and roberta-base⁶ variations of these models. We fine-tune the models for 20 epochs with an early stopping patience of three epochs with a learning rate of $2e^{-5}$ and batch size of 64. We use cross-entropy loss to optimize the model with AdamW optimizer. During inference, we use the model predicted score to rearrange the candidate set for a dialog in descending order.

5 Experiments and Results

Evaluation Metric: As the task is to rank the valid follow-up question higher than a set of invalid confounders, we evaluate the performance using Mean Reciprocal Rank (MRR), given as:

$$MRR = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{\text{rank}_i} \quad (1)$$

where rank_i is the rank position of the valid candidate for the i th datapoint.

Additionally, we compute Hit Ratio@1 and Hit Ratio@3 for the top performing methods to analyze the percentage of samples for which the ranking method ranked the correct candidate as the first item and within the first three items.

Quantitative Results: In Table 3 we report results comparing the methods proposed in Section 4 on the adversarial dataset described in Section 3. The unsupervised methods performed poorly for the ranking task resulting into MRR scores of 0.141

⁵<https://huggingface.co/bert-base-cased>

Dialog context
<ul style="list-style-type: none"> • Where was Michael Bennett born? • Who are Michael Bennett’s parents? • When did Michael Bennett’s career begin? • What show did Michael Bennett begin his career?

Irrelevant Context Candidate

When did Michael Bennett move to Alaska?
(Model score: 0.3)

Valid Candidate

What was Michael Bennett’s role in the "Here’s Love" and "Bajour"? (Model score: 0.2)

Dialog context
<ul style="list-style-type: none"> • What happened to Sachin Tendulkar during the tour of Australia? • How did Sachin Tendulkar do in the 2003 Tour of Australia? • How many games did Sachin Tendulkar win during 2003? • Did Sachin Tendulkar win any awards?

Irrelevant Context Candidate

How many hits did Sachin Tendulkar have?
(Model score: 0.21)

Valid Candidate

Was there any controversies for Sachin Tendulkar? (Model score: 0.35)

Table 4: Examples where the model predicted scores do not match with the category of the follow-ups.

for both Glove and SentenceBERT based embeddings, and the trend is similar for all the data splits. This is not surprising as cosine similarity is expected to be high for paraphrases. As discussed in section 3.1, paraphrases are not good candidates for FQs as they don’t provide any value to the user.

We observe a large improvement when we fine-tune pre-trained language models like BERT and RoBERTa to simply classify each candidates as relevant or irrelevant. The MRR is ≈ 0.8 when we treat the models’ confidence score for relevancy as the basis for ranking the candidates.

The Hit Ratio@1 and Hit Ratio@3 metrics show that both BERT and RoBERTa ranked the correct FQ at the first rank for $\approx 68\%$ cases. Both the models ranked the correct FQ within the first three items for $\approx 88-89\%$ cases. This shows promise in using such methods to retrieve a relevant follow-up

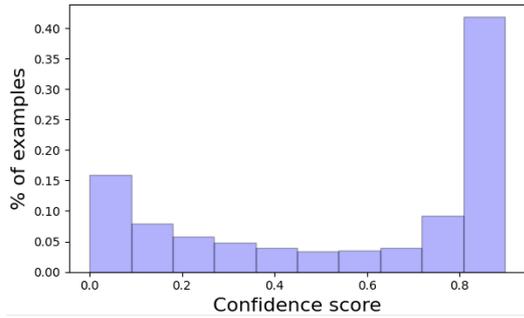

Figure 2: Histograms of model predictions for valid follow-up queries.

question.

Error Analysis Analysing the fine-tuned models’ predicted scores for different confounder types, we have found that the models can identify most of the confounder types easily. For example, the model predicted score is below 0.1 for $\approx 99\%$ candidates from duplication of dialog history, ASR errors, and random utterance confounder. However, the models often predicted higher scores for the candidates from the irrelevant context category (score is < 0.1 for 83% candidates). For 8% of these candidates, the score is higher than 0.4, which is not the case with other categories of confounders.

Inspecting some examples like the ones presented in Table 4, we found that without having factual information about the entities or topics, such irrelevant contexts are often difficult to identify for humans as well. They can look linguistically plausible but have factual errors. For example, the question “*How many hits did Sachin Tendulkar have*” sounds plausible to some humans, but is actually invalid. Tendulkar is a cricket player, and ‘hits’ is not a statistic in cricket. However, it is a real statistic in baseball, so specific domain knowledge is needed to rule this out as a valid FQ. This example illustrates how integrating information about entities from knowledge bases can be helpful for the system, and this method can be explored in the future. Although scores like 0.2 do not look very high in general for a scale of 0 to 1, Figure 2 shows that the model assigns such scores to a large portion of valid follow-up queries.

Observing the model’s overall performance (MRR of ≈ 0.8) in ranking the valid candidates at a better position than the invalid ones shows promise in using such a system can be a good starting point for developing a follow-up question retrieval system. A large advantage of the proposed adversar-

ial example generation methods and the proposed dataset is that these can help to bypass the need for exhaustive data annotation need for developing a follow-up generation system. Additionally, the trained model using this dataset can be further fine-tuned by annotating a small number of case specific examples, which would help to improve the model accuracy and adapt in different use cases, as well as reach a higher accuracy in identifying suitable follow-up queries.

6 Conclusions

In this paper, we sought to address the problem of identifying valid and engaging follow-up queries for a user interacting with a conversational assistant. We experimented with a retrieval and ranking based framework to achieve this using a search engine and a database of past queries. In doing so, we identified a typology of confounders returned by the search. In order to train a ranking model to identify valid follow-up queries, we synthetically generated confounders based on a publicly available conversation dataset. We showed that our approach of ranking retrieved candidates based on their validity as follow-up queries achieved reasonable performance, but also that integrating external knowledge on entities or topics could improve follow-up selection. We have made the dataset publicly available to enable further research in this direction.

7 Limitations

The first limitation of this work is that we are attempting to mimic conversational interactions with publicly available human-annotated data based on Wikipedia. Thus in some cases the generated dataset can contain dialogues unrealistic to the voice assistant scenario. Additionally, despite our typology of confounders being based on results from a search-based approach using real data, there are inevitably additional types of potential confounders not fully covered by our approach.

Second, we only focused on contextual relevance and coherence through the lens of language. But, in practice, there are external factors like user preference, time of the day, repetition in a longer period (e.g., a user may have asked the question in the follow-up a couple of days ago and it does not make any sense to ask the same question as a follow-up). More comprehensive methods would be needed to address these concerns.

Finally, this dataset is limited to knowledge-seeking queries. Other types of valid follow-up actions (e.g. setting a timer, booking a ride) are not included in this dataset.

Selective-LAMA: Selective Prediction for Confidence-Aware Evaluation of Language Models

Hiyori Yoshikawa^{†‡} Naoaki Okazaki[†]

[†]Tokyo Institute of Technology, Japan [‡]Fujitsu Limited, Japan
{hiyori.yoshikawa@nlp., okazaki@c.titech.ac.jp}

Abstract

Recent studies have suggested that neural language models learn and store a large amount of facts and commonsense knowledge from training data. The ability of language models to restore such knowledge is often evaluated via zero-shot cloze-style QA tasks. However, such evaluations rely only on prediction accuracy without punishing the systems for their mistakes, e.g., simply guessing or hallucinating likely answers. Selective prediction is a more informative evaluation framework that takes the confidence of predictions into account. Under the selective prediction setting, a model is evaluated not only by the number of correct predictions, but also by the ability to filter out dubious predictions by estimating the confidence of individual predictions. Such confidence-aware evaluation is crucial for determining whether to trust zero-shot predictions of language models. In this paper, we apply the selective prediction setting to an existing benchmark, LAMA probe, and conduct extensive experiments with recent neural language models and different confidence functions. We empirically show that our Selective-LAMA evaluation is more robust to the effect of simple guesses than the conventional accuracy-based evaluation. Our evaluation reveals the importance of the choice of confidence functions by showing that simply relying on token probabilities is not always the best choice. Further analysis shows that various confidence functions exhibit different preferences over predicted tokens for a given context.

1 Introduction

Recently, knowledge stored in pre-trained language models has been intensively investigated. Many studies have suggested that language models trained on a large amount of textual corpora, such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2019; Brown et al., 2020), store both linguistic knowledge (Warstadt et al., 2019; Mi- aschi et al., 2020) and factual and commonsense

knowledge (Bosselut et al., 2019; Roberts et al., 2020) during training. However, this knowledge is embedded in the parameters of these language models and thus is difficult to interpret, in contrast to symbolic knowledge bases, which allows us to inspect and edit stored facts explicitly.

Petroni et al. (2019) proposed a benchmark task, the LAMA probe, that aims at evaluating the amount of relational knowledge, such as commonsense knowledge and facts, which is stored in a language model. In LAMA probe, a relational fact is converted into a cloze statement (*query*) and then given to a language model as a fill-in-the-blank question. If the language model fills in the blank with the correct answer, the model is considered to possess “knowledge” of the relation. According to Petroni et al.’s experiments, the BERT language model (Devlin et al., 2019) has a comparable performance to a supervised relation extraction baseline, with precision ranging from 10.5 to 32.3 depending on the dataset type.

However, in many applications, we are concerned not only with the amount of the knowledge extracted from a language model, but also with its reliability. This is because large pre-trained language models are known to fluently generate “facts” that they have never seen (Cao et al., 2018; Rohrbach et al., 2018; Müller et al., 2020). Therefore, it is crucial to know when we can trust the output of a language model. The LAMA probe framework does not cover this issue, as it always forces the model to output an answer for all instances, regardless of whether the model really “knows” the answer to a query. This means that it implicitly trusts all outputs of a language model to the same degree.

Figure 1 shows an example suggesting that a pre-trained language model is not always using its knowledge for prediction. The figure shows the distribution of predicted tokens for a particular relation in the original LAMA probe benchmark

(place-of-birth). We can see that three tokens account for more than half of the wrong predictions. This indicates that the model has a bias which it acquired during training, probably due to the input template used, rather than using actual question-specific knowledge about individual facts.

To address this issue, we apply the selective prediction (El-Yaniv and Wiener, 2010; Geifman and El-Yaniv, 2017) setting to the LAMA probe and propose a new evaluation framework, *Selective-LAMA*, to evaluate both the amount of knowledge in a pre-trained language model and the model’s ability to estimate the reliability of its prediction. Selective prediction is a framework by which a system can choose whether to output the individual predictions of a model based on the prediction results. Specifically, we consider the selection with guaranteed risk control setting (Geifman and El-Yaniv, 2017), where the system computes confidence scores of individual predictions to determine whether it outputs the predictions. A system is evaluated by the number of predictions it can make while maintaining a risk of error below a certain level. To achieve high performance, a system is required not only to answer many questions correctly, but also to accurately estimate the model’s confidence about individual facts and determine when the system should not answer a question.

In this paper, we focus on masked language models and address the following research questions: (1) whether the pre-trained language model has the ability to estimate the confidence of individual predictions and (2) how various confidence metrics affect the ability of a system to do that. With our proposed Selective-LAMA framework, we examine several basic confidence functions that can be computed using only language model predictions and do not require additional datasets or external knowledge sources. We empirically verify that the selective prediction evaluation is less likely to overestimate predictions with template-related biases than the conventional accuracy-based evaluation. The results of the experiments suggest that the choice of confidence functions also influences the results, showing that simply using token probability is a strong baseline but not always the best choice, and that the optimal confidence function depends on both the model and the dataset. We hope that the selective prediction framework facilitates an under-explored research direction of utilizing predictions of language models in a more reliable way.

Dataset: Google-RE, Model: BERT-base
Relation: place-of-birth
Input: “X (Subject) was born in [MASK].”

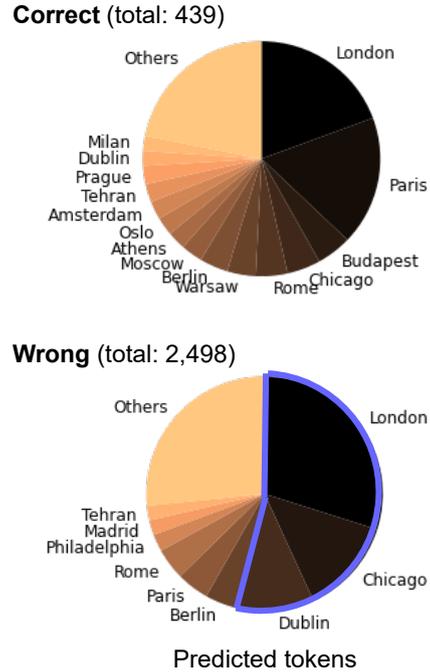

Figure 1: Composition of predicted tokens in each of the correct (top) and wrong (bottom) predictions by BERT-base for the place-of-birth relation in the Google-RE dataset (size: 2,937). Just three tokens account for more than half of the wrong predictions, implying that the model has a template-dependent bias.

2 Selective Prediction

Under the selective prediction setting (El-Yaniv and Wiener, 2010; Geifman and El-Yaniv, 2017), a *selective classifier* determines whether a system should output the prediction of the model. We consider a classification problem from an input space \mathcal{X} to a set of labels \mathcal{Y} . A selective classifier (f, g) consists of an original classification model $f : \mathcal{X} \rightarrow \mathcal{Y}$ and a *selection function* $g : \mathcal{X} \rightarrow \{0, 1\}$. Given an input example $x \in \mathcal{X}$, a selection function determines whether the system outputs the prediction $f(x) \in \mathcal{Y}$:

$$(f, g)(x) := \begin{cases} f(x) & \text{if } g(x) = 1 \\ \text{don't know} & \text{if } g(x) = 0 \end{cases}. \quad (1)$$

Geifman and El-Yaniv (2017) introduced the selection with guaranteed risk (SGR) setting, which uses a confidence-based selection function:

$$g(x) = \begin{cases} 1 & \text{if } \phi(x) \geq \beta \\ 0 & \text{if } \phi(x) < \beta \end{cases}, \quad (2)$$

where $\phi(x) : \mathcal{X} \rightarrow \mathbb{R}$ is the *confidence score function* of f . The system outputs the prediction if the confidence score exceeds the threshold $\beta \in \mathbb{R}$. This setting allows a user to adjust the error risk generated by the system by appropriately setting the value of β . Specifically, increasing β decreases the number of cases predicted by the system while reducing the risk of making a wrong prediction.

Under the SGR setting, there is a risk-coverage trade-off between the risk $(N_{\text{pred}} - N_{\text{corr}})/N_{\text{pred}}$ that a selective classifier will make a wrong prediction and the coverage N_{pred}/N of the predictions made by the system. Here, N , N_{pred} , and N_{corr} denote the number of all examples, predicted examples, and correct predictions, respectively. The performance of a selective classifier is evaluated based on the AUC of the risk-coverage curve (RC-AUC) obtained by changing β in the selection function (2). A smaller RC-AUC value indicates a lower risk of making a wrong prediction. In practice, the threshold will be determined by the level of risk acceptable to the users.

3 Selective-LAMA

3.1 LAMA Probe and Model Prediction

In the original LAMA probe, a relational fact is converted into a natural sentence using templates and input into the language model. For example, when querying about an entity that has a relationship of born-in with “Dante,” the input to the language model will be “Dante was born in [MASK].” where [MASK] is a special token that represents the mask token. The model output for the masked position is considered the answer to the query.¹ The templates are manually designed for each relation type.

Following the original study (Petroni et al., 2019), we focus on bi-directional language models. Given the input sentence with a mask token at the t -th position $x = W_{\setminus t} := (w_1, \dots, w_{t-1}, [\text{MASK}], w_{t+1}, \dots, w_{|W|})$, the language model predicts the probability distribution of the t -th token $P_{\text{LM}}(w_t | W_{\setminus t})$. The model prediction is the token w' with the highest probability:

$$f(x) = w' := \arg \max_{w_t} P_{\text{LM}}(w_t | W_{\setminus t}). \quad (3)$$

We denote the sentence in which the masked position is filled with w' by W' .

¹For simplicity, the target is limited to entities comprising a single word.

3.2 Confidence Functions

As the task is to evaluate the knowledge present in a pre-trained language model, we select confidence functions that use only the prediction of the language model and do not require additional training or external knowledge sources. The following is the list of confidence functions that we investigate.

Token (T) The simplest confidence function is to use the log probability of the predicted token w' (3) directly:

$$\phi_{\text{T}}(x) = \log P_{\text{LM}}(w' | W_{\setminus t}). \quad (4)$$

Sent (S) Sentence-level likelihood is widely used in the context of sentence acceptability and fact-checking (Lau et al., 2020; Lee et al., 2021). This reflects how natural the entire sentence is when the predicted token is substituted into the mask position. Here, we adopt the pseudo-log likelihood (Salazar et al., 2020) for masked language models normalized by sentence length:

$$\phi_{\text{S}}(x) = \frac{1}{|W'|} \sum_{u=1}^{|W'|} \log P_{\text{LM}}(w_u | W'_{\setminus u}). \quad (5)$$

Gap (G) Let w'' be the token with the second-largest probability by the model. The confidence score is then calculated as follows:

$$\phi_{\text{G}}(x) = \log P_{\text{LM}}(w' | W_{\setminus t}) - \log P_{\text{LM}}(w'' | W_{\setminus t}). \quad (6)$$

This function is based on the assumption that a model makes a confident prediction when the probability of the predicted token is significantly larger than that of other tokens.

Reranking (R) The following function is based on the assumption that, if the confidence of the prediction is high, the score for the prediction is consistently higher than those of other candidates even when different metrics are used. First, we obtain top- K predictions \mathcal{W} based on the token log probability (3). Then, we re-rank those candidates using another score function ψ . Let $\text{rank}_{\psi}(w')$ be the rank of w' after the reranking. The confidence score is subsequently computed as follows:

$$\phi_{\text{R}}(x) = \log_2 \frac{K}{\text{rank}_{\psi}(w')} = \log_2 K - \log_2 \text{rank}_{\psi}(w'). \quad (7)$$

The above score function is essentially a measure based only on the new rank after the reranking and has been used to assess the risk of language models to memorize privacy information (Carlini et al., 2019). In the experiments, we apply $K = 100$ and use the Sent score $\phi_{\text{S}}(x)$ for ψ .

DropoutMean (DM) Dropout-based metrics have been widely used to estimate uncertainty of deep neural network models (Gal and Ghahramani, 2016). The basic concept is to use dropout to sample slightly different model parameters that yield different predictions and to use stochastic information to estimate the model uncertainty. Following (Kamath et al., 2020), we adopt two dropout-based measures. We apply M different dropout masks to the language model’s layers and obtain different probability distributions. Let $P_{\text{LM}}^{(m)}(w'|W_{\setminus t})$ denote the m -th output ($m \in \{1, \dots, M\}$). DropoutMean takes the mean of the M outputs:

$$\phi_{\text{DM}}(x) = \frac{1}{M} \sum_{m=1}^M P_{\text{LM}}^{(m)}(w'|W_{\setminus t}), \quad (8)$$

which can be considered an ensemble of the M model predictions.

DropoutVar (DV) Similarly, DropoutVar utilizes the variance of the outputs. As large variance implies high model uncertainty, we take the negative variance of the outputs:

$$\phi_{\text{DV}}(x) = -\frac{1}{M} \sum_{m=1}^M (P_{\text{LM}}^{(m)}(w'|W_{\setminus t}) - \phi_{\text{DM}}(x))^2. \quad (9)$$

In our experiments, we apply $M = 30$ different dropout masks for each input, using the same dropout ratios as those used to train the models.

TemplateDiff (TD) A large portion of the LAMA probe benchmark consists of instances based on subject-relation-object triples. These instances share relation-specific templates, such as “<subj> was born in [MASK].”, where the subject of each triple is substituted for <subj>. Cao et al. (2021) found that predictions of language models are highly biased by templates and the impact of subject entities are limited. Inspired by this observation, we define a confidence measure that assesses the impact of subject entities to predictions. Let W_{temp} be a template-only input sentence where the subject of the input $W_{\setminus t}$ is replaced by the mask token, e.g. “[MASK] was born in [MASK].” Then, we calculate the confidence by comparing the log probabilities of the prediction with and without the subject entity mention:

$$\phi_{\text{TD}}(x) = P_{\text{LM}}(w'|W_{\setminus t}) - P_{\text{LM}}(w'|W_{\text{temp}}). \quad (10)$$

4 Experiments

The proposed Selective-LAMA framework allows us to evaluate the ability of language models to recognize questions for which they *do not know* the answer. To see how the proposed framework affects the evaluation of language models, in Section 4.2, we first compare the evaluation based on the Selective-LAMA framework with the conventional accuracy-based evaluation, focusing on the sensitivity to biased predictions. Then, in Section 4.3, we present a comprehensive study of the performance of three masked language models on different datasets using the confidence functions introduced in Section 3.2.

4.1 Experimental Settings

We used the same data set as the original LAMA benchmark for our experiment and evaluated it with our proposed Selective-LAMA framework. The benchmark consists of four datasets: GoogleRE, T-REx, ConceptNet, and SQuAD. The GoogleRE and T-REx datasets contain relational facts extracted from Wikipedia. The ConceptNet dataset contains relational knowledge about commonsense extracted from the ConceptNet dataset (Speer and Havasi, 2012). The SQuAD dataset (Rajpurkar et al., 2016) is based on a question answering dataset of the same name, but the questions are rewritten in cloze style. As all these datasets, except for ConceptNet, use Wikipedia as the knowledge source, evidence for the correct answer should be found in Wikipedia. For language models, we use BERT-base (110 M parameters), BERT-large (340 M parameters), and RoBERTa-base (Liu et al., 2019). Because these models are trained using Wikipedia, it is expected that the models have seen the correct answers for the queries during training.

4.2 Template Bias Robustness

In the selective prediction framework, the performance of language models is evaluated by RC-AUC (Section 2), while the original LAMA benchmark uses the accuracy of the top-1 predictions as the evaluation metric. A disadvantage of accuracy-based evaluation is that the amount of knowledge of a language model can be overestimated by counting lucky guesses. Such lucky guesses can affect the evaluation results, especially in cases where the model’s predictions are biased by relation-specific templates (Figure 1).

We investigate how these evaluation metrics are

		BERT-base		BERT-large		RoBERTa-base	
		Cov ^A	Cov ^P	Cov ^A	Cov ^P	Cov ^A	Cov ^P
Accuracy		0.387	-0.247	0.469	-0.244	0.512	-0.224
RC-AUC	Token	0.344 ↓	-0.316 ↓	0.438 ↓	-0.292 ↓	0.484 ↓	-0.277 ↓
(negative)	Sent	0.355 ↓	-0.290 ↓	0.441 ↓	-0.285 ↓	0.499 ↓	-0.249 ↓
	Gap	0.351 ↓	-0.314 ↓	0.430 ↓	-0.294 ↓	0.474 ↓	-0.285 ↓
	Reranking	0.350 ↓	-0.286 ↓	0.452 ↓	-0.283 ↓	0.498 ↓	-0.266 ↓
	DropoutMean	0.338 ↓	-0.319 ↓	0.433 ↓	-0.293 ↓	0.486 ↓	-0.280 ↓
	DropoutVar	0.419 ↑	-0.125 ↑	0.470 ↑	-0.124 ↑	0.456 ↓	-0.166 ↑
	TemplateDiff	0.349 ↓	-0.317 ↓	0.427 ↓	-0.299 ↓	0.486 ↓	-0.271 ↓

Table 1: Correlation between evaluation metrics and template bias metrics: answer coverage (Cov^A) and prediction coverage (Cov^P) on the T-REx dataset. Here, we use the sign-reversed RC-AUC values for easier interpretation.

affected by template-related biases using the T-REx subset of the LAMA benchmark, which contains 34k facts about 41 different relations with their corresponding templates. To quantify template-related biases, we introduce two indicators: *prediction coverage* and *answer coverage*.

Prediction coverage quantifies biases in model predictions for a given template. If a model often predicts the same answers for a template, it is likely that the predictions are heavily influenced by the template, rather than using knowledge of individual subject entities. Let $\mathcal{D}_r = (\{(s_i, o_i)\}_{i=1}^{N_r}, t_r)$ denote a relation subset containing N_r fact triples (s_i, r, o_i) of relation r and a template t_r . We represent the input sentence corresponding to the i -th fact by $t_r(s_i)$. For each relation subset \mathcal{D}_r , we first identify five most frequent tokens $\mathcal{W}^{\text{freq}}(r)$ predicted by a model. Prediction coverage is the proportion of predicted tokens covered by these tokens:

$$\text{Cov}^P(r) = \frac{|\{i \mid f(t_r(s_i)) \in \mathcal{W}^{\text{freq}}(r)\}|}{N_r}. \quad (11)$$

Answer coverage quantifies biases in a relation subset in the test set. If the distribution of the correct answers for a relation subset is skewed towards a few particular entities, the subset can be easily answered by exploiting the bias without using the knowledge of individual subject entities. Answer coverage is calculated as the proportion of gold answers covered by the frequently predicted tokens:

$$\text{Cov}^A(r) = \frac{|\{i \mid o_i \in \mathcal{W}^{\text{freq}}(r)\}|}{N_r}. \quad (12)$$

Table 1 shows the correlation between the bias indicators and the evaluation metrics including accuracy and (negative) RC-AUC calculated with different confidence functions. Compared to the conventional accuracy metric, all RC-AUC metrics except DropoutVar show a weaker positive

correlation with answer coverage and a stronger negative correlation with prediction coverage, indicating that the RC-AUC metrics are less likely to overestimate template-biased predictions and results from intrinsically biased test examples.

Figure 2 shows the output of the BERT-base model for two relation subsets P36 and P1412. Although the accuracy scores for both subsets are around 0.6, for P1412, both the prediction and answer distributions are biased towards a small number of entities, leading to high prediction and answer coverage. The Token confidence scoring fails to discriminate between correct and incorrect predictions in this subset, resulting in high risk at a low coverage point. Evaluation based on the RC-AUC score successfully captures the difference between these two cases and avoids overestimating the results from biased predictions.

4.3 Selective-LAMA Evaluation and Analysis

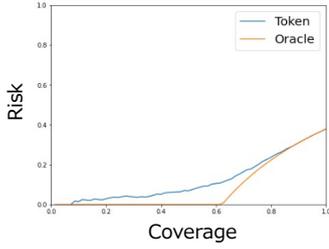

Overall performance on different datasets

Table 2 shows the RC-AUC scores achieved by different confidence functions on various datasets. We also calculate the performance lower bound based on an oracle confidence function that gives 1 to all correct predictions and 0 to incorrect ones. While the simple Token metric constantly performs well, the best confidence function depends on the model and dataset. Notably, Gap and TemplateDiff perform better on the datasets of Wikipedia fact triples, Google-RE and T-REx, than on ConceptNet and SQuAD, outperforming the Token metric in some cases. The breakdown of the results on the T-REx dataset indicates that the performance of confidence functions also depend on relation templates. We further investigate this phenomenon below.

$r = \text{P36}$ ("The capital of X (Subject) is [MASK].") Accuracy = 0.621, RC-AUC = 0.121

$\mathcal{W}^{\text{freq}}(r)$: Rome (1.9%), Baghdad (1.7%), Paris (1.7%), Bangor (1.7%), Kabul (1.4%)

Figure 2: BERT-base results for relation subsets $r = \text{P36}$ and $r = \text{P1412}$. While the model performance is similar in terms of accuracy, the RC-AUC scores exhibit a large difference. Left: Risk-coverage curves of Token and the Oracle confidence scores. Right: Top 20 predictions sorted by the Token confidence score ϕ_T . The gray-shaded rows indicate incorrect predictions. Many incorrect predictions for P1412 indicate that the model suffers from high risk even at a low coverage point.

When does a confidence function beat another?

For the T-REx dataset in Table 2, Gap and TemplateDiff outperform the Token metric for BERT-base and RoBERTa-base, respectively. We choose these two cases and perform a pairwise comparison for each relation type to identify the properties that determine the preference for one confidence function over the other. The results in Table 3 show that Gap is preferred over Token for easier relations with high accuracy and low RC-AUC for BERT-base, whereas TemplateDiff is preferred over Token for more difficult relations for RoBERTa-base. The subset where Gap is preferred over Token also shows lower prediction coverage, which might be because the Gap function is not good at handling overconfident predictions by definition.

Confidence functions and relation templates

To understand whether and how different confidence functions prioritize one relation over another, we visualize in Figure 3 the composition of the relation types of input examples sorted by the con-

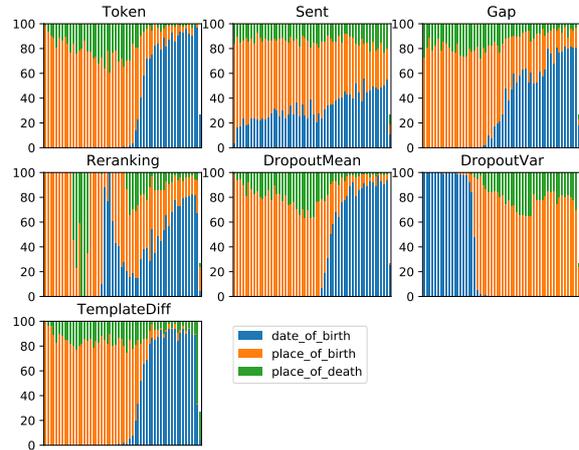

Figure 3: Breakdown of relation types of BERT-base predictions on Google-RE, sorted by confidence scores (left is the largest).

fidence scores in the Google-RE dataset predicted by the BERT-base model. The Google-RE dataset contains three relation types, date-of-birth, place-of-birth, and place-of-death. Evidently, the BERT-base language model tend to pro-

Table 2: RC-AUC calculated on each dataset (lower is better). For T-REx, the results on three splits divided by the property of the relations are also provided: one-to-one relations (1-1), many-to-one relations (N-1) and many-to-many relations (N-M). “Oracle” represents the best possible performance that could be achieved by an oracle confidence function that gives 1 to all correct predictions and 0 to incorrect ones. TemplateDiff cannot be calculated for SQuAD as the instances do not contain subject entities.

duce high probability outputs for a certain relation type, namely, place-of-birth. While Gap, DropoutMean, and TemplateDiff follow the same trend as that of Token, Sent and Reranking are less sensitive to relation types. DropoutVar shows the opposite trend. While the Token metric is effective in many cases, one should be aware of the potential bias this confidence function may introduce.

Table 4 compares the most frequent predictions of BERT-base on the Google-RE dataset ranked top by two different metrics: Token and Reranking. We can observe similar distributions for the date-of-birth relation type. This indicates that the model is strongly biased toward a limited vocabulary for this particular relation type. For the other two relation types, the frequent words in the top predictions are clearly different between Token and Reranking. However, while the overlap of the top-ranked predictions between them are small, both results have strong preference toward a few particular tokens for each relation type. For place-of-birth, five tokens account for more

than 50% of the top-ranked predictions for both Token and Reranking. In place-of-death, just one token occupies around 40% of the top predictions. The results indicate that these confidence functions produce different template biases rather than that one is more robust to template biases than the other.

Using confidence functions for prediction

In the experiments above, model predictions are always determined by the token log probability as in (3). However, some of the confidence functions introduced in Section 3.2 can also be used directly to determine the prediction as an alternative to (3). Therefore, we investigate whether effective confidence functions are also effective in improving prediction accuracy (P @ 1) when used directly for token prediction. For Gap, we extend the original definition (6) so that we can apply the function to token candidates that are not ranked first in terms of token probability. Let $w^{(k)}$ denote the k -th best prediction based on the model’s predicted token probability. Then, the extended Gap function is

	BERT-base			
	All	Token-win	Gap-win	Δ

Answer Cov.	0.237	0.285	0.235	0.050
Prediction Cov.	0.562	0.586	0.541	0.045

Table 3: Comparison of two confidence functions on the T-REx dataset (Token-Gap for BERT-base and Token-TemplateDiff (TD) for RoBERTa-base). The average value of each metric is displayed for the entire T-REx dataset (All) and the subset for which the confidence function X outperforms the other (X-win). Δ stands for the difference between the two subsets.

defined as follows:

$$\phi_G(x) = \frac{1}{k}(\log P_{LM}(w^{(k)}|W_{\setminus t}) - \log P_{LM}(w^{(k+1)}|W_{\setminus t})). \quad (13)$$

The Gap score for the lowest ranked prediction is defined as zero. The computation of the Sent score requires $\mathcal{O}(|W'| \cdot V)$ forward computations for each instance, where V is the vocabulary size. To save computational cost, we approximate the prediction results by limiting the token candidates to the top 100 results based on the Token score (3).

Table 5 shows the results. For all models, the best performance on all data is achieved by DropoutMean. However, all functions, except for DropoutVar, show a quite competitive performance in terms of precision. Unlike for confidence estimation, no advantage is observed for Gap and TemplateDiff on the T-REx dataset. Overall, the performance of these confidence functions is flat when they are used directly for token prediction. Furthermore, there is no strong correlation between the performance of each confidence function as a predictor and a confidence estimator. The results suggest that effective metrics for inference and confidence estimation should be designed based on different strategies.

5 Related Work

In NLP, the reliability of the model responses has been discussed mainly in the field of question answering. Estimating the confidence of an answer is critical in quiz competitions, such as Jeopardy,

since the system has to decide when to answer the questions (Ferrucci et al., 2010). Kamath et al. (2020) recently introduced a selective prediction setting to question answering tasks and then evaluated the performance of the models on out-of-domain questions. Jiang et al. (2021) addressed a similar problem, but focused on a calibration of the model prediction on QA tasks. While they focused on extractive or multiple-choice QA tasks where a limited number of candidate answers are available, our focus is on the knowledge probing of language models where the candidate answer is the entire vocabulary and, thus, false positives are more frequent.

Several studies have addressed the reliability issue of pre-trained language models as a calibration problem; the goal of these studies is to train a well-calibrated language model that makes accurate confidence estimation. Desai and Durrett (2020) investigate the calibration level of pre-trained language models, focusing on BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). They evaluate the “out-of-the-box” performance of these models without post-processing, as well as the performance of post-hoc calibration methods (e.g., temperature scaling and label smoothing). Kong et al. (2020) proposed regularization methods to better calibrate pre-trained language models. Both studies assume access to (at least in-domain) training data of the target tasks on which parameterized calibration models can be trained. In contrast, our study primarily aims to explore better signals in pre-trained language models to estimate the knowledge they store. Thus, we focus on methods that do not require additional training data or an external knowledge source. Although training-based methods (e.g., temperature scaling) have the potential to achieve better performance in terms of calibration, optimal parameters vary depending on models and tasks, especially when evaluated in out-of-domain datasets (Desai and Durrett, 2020).

In our experiments, all queries have at least one correct answer. Therefore, when a model cannot answer a question correctly, this implies that it did not acquire the correct knowledge during training or that its knowledge was not elicited by the natural language query because of a sub-optimal prompt (Jiang et al., 2020). However, there are also cases where the question is essentially impossible to answer due to ambiguity (Zhang and Choi, 2021) or false presupposition (Kim et al., 2021).

Relation	Confidence	Top predictions
date-of-birth	Token	1979 (47), 1944 (33), 1988 (10), 1990 (8)
	Reranking	1979 (44), 1944 (32), 1953 (13), 1970 (3), 1949 (2)
place-of-birth	Token	Budapest (18), Prague (10), Istanbul (8), Athens (8), Paris (7), Moscow (7), Helsinki (6), Bucharest (6), Tehran (5), Stockholm (4)
	Reranking	London (30), Dublin (12), Paris (12), Moscow (5), Madrid (4), Philadelphia (4), Chicago (4), Warsaw (3), Tehran (3), Berlin (2)
place-of-death	Token	Paris (38), Rome (32), Moscow (6), Madrid (4), infancy (4), office (3), Athens (2), Helsinki (2), Warsaw (2), Amsterdam (2)
	Reranking	London (46), Paris (14), Rome (7), office (6), Moscow (4), Munich (3), Amsterdam (3), infancy (2), prison (2), Stockholm (2)

Table 4: Comparison of the most frequent tokens among the top-100 predictions based on different confidence scores. Based on the results on the Google-RE dataset with the BERT-base model. The numbers in parentheses represent the frequency of the predictions.

Model	Pred.	GRE	TREx	CNet	SQ	All
BERT-base	T	10.3	29.6	15.8	14.1	24.3

	DV	0.1	0.1	0.1	0.0	0.1
	TD	7.5	23.2	16.4	-	-

Table 5: P@1 based on different prediction scores for each dataset. Bb: BERT-base, Bl: BERT-large, T: Token, S: Sent, G: Gap, DM: DropoutMean, DV: DropoutVar, TD: TemplateDiff, GRE: Google-RE, CNet: ConceptNet, SQ: SQuAD. We omit the result of using the Reranking score because the results are the same as those of Sent by definition.

An investigation of such cases remains a direction of future research.

6 Conclusion

In this paper, we introduced the selective prediction setting to the LAMA probe benchmark to evaluate both the amount of relational knowledge stored in a language model and the ability of the models to effectively filter out unconfident predictions. We compared different confidence functions that can be calculated using only the model parameters and the output information. The experimental results are summarized as follows:

- The selective prediction evaluation is more robust to template-related biases than the conventional accuracy-based evaluation (Table 1).
- The token log probability is not always the best choice, and the best confidence function depends on the language model and the dataset (Table 2).
- Different confidence functions have different preferences over relation types and predicted tokens, even though all functions are based solely on the model output (Figure 3, Table 4).
- There is no strong correlation between the performance of each confidence function as a predictor and a confidence estimator (Table 5).

Future studies will include a detailed analysis of the relationship between tasks, models, and confidence scores. Moreover, more sophisticated methods will be explored to ensure the reliability of language model predictions under various tasks. The code for our work is attached as supplementary material.

Limitations

In this paper, we focused on evaluating the predictions of masked language models on the LAMA probe benchmark. Although our proposed framework is easily applicable to other kinds of language model with small adjustments, some of the confidence functions we investigated require properties specific to particular language models and datasets. For instance, Token and Gap functions require the prediction to be a single token, and TemplateDiff requires templates for subject-relation-object triples.

Ethics Statement

Data and code

In our experiments, we use the original LAMA benchmark dataset from [Petroni et al. \(2019\)](#) as is. All data are based on publicly available data sources and data statistics can be found in the original paper. Parts of the code are based on LAMA². The license of the code can be found in the supplementary material.

Details of experiments

The experiments were conducted using a 2.4GHz CPU and an NVIDIA TESLA P100 GPU. Inference time was 1–1.5 s per instance for BERT-base and 2–3 s per instance for BERT-large.

Potential risks

This study evaluates the knowledge stored in language models considering the reliability of model predictions. However, it should be emphasized that the outputs of the selective classifier constructed by the proposed method do not guarantee the correctness of the model predictions. For the validation of each fact, this method should only be used as an aid, and the final decision should be made by the user.

Abstract

In this paper, we present MUFASSA (Multi-view Faithfulness Scoring via Source Ablation), a metric for *evaluating* faithfulness of abstractive summaries, and for guiding *training* of more faithful summarizers. For evaluation, MUFASSA employs different strategies (e.g., masking entity mentions) to first remove information from the source document to form *multiple ablated views*. Then, the faithfulness level of each token in a generated summary is measured by the difference between the token generation probabilities when given the original document and the ablated document as inputs to trained summarizers. For training, MUFASSA uses a novel *word truncation* objective that drops unfaithful tokens located by MUFASSA in both the decoder input and output. Alignments with human-annotated faithfulness labels on AGGREFACT show that MUFASSA is comparable to or better than existing metrics built on classifiers or QA models pre-trained on other tasks. In experiments on summarization with XSum and CNN/DailyMail, models trained with word truncation using MUFASSA outperform competitive methods according to both automatic faithfulness metrics and human assessments.

1 Introduction

Automatic text summarization systems have made great strides with the use of large pre-trained models, which enable more precise identification of salient content in the document and generation of summaries with human-level fluency (Lewis et al., 2020; Raffel et al., 2020). However, model-generated summaries frequently contain unfaithful information that either contradict the source text or cannot be verified (Kryscinski et al., 2020), creating risks in real-world deployment of automatic text summarization models and motivating the development of models targeting more faithful summaries (Cao et al., 2018).

* Work done during an internship at Dataminr.

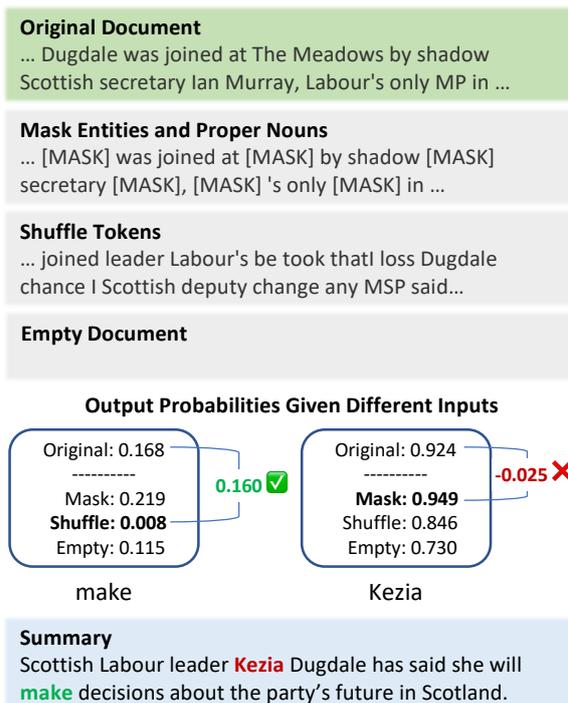

Figure 1: MUFASSA estimates the faithfulness level of each summary token as the difference between probabilities given by trained summarizers with the original source document and the ablated document chosen for the token (e.g., shuffling tokens for verbs). The large difference for “make” indicates it is **faithful** to the document, while the small difference for “Kezia” indicate an **unfaithful** token.

As overlap-based metrics such as ROUGE (Lin, 2004) struggle to reflect the faithfulness level of generated summaries (Falke et al., 2019), a number of model-based faithfulness metrics have been introduced. These metrics leverage external textual entailment (Goyal and Durrett, 2020; Laban et al., 2022) and question answering models (Wang et al., 2020; Scialom et al., 2021) to measure the degree to which claims in the summary align to information in the source text. Yet, there remains substantial room for improvement (Tang et al., 2022). Moreover, despite being relevance or complementary to

each other, for building faithful summarization systems, faithfulness metrics are rarely exploited and researchers mainly resort to more complex training routines (Cao and Wang, 2021) or model architectures (Zhu et al., 2021).

To this end, our work introduces a faithfulness metric that (1) more accurately estimates summary faithfulness levels; and (2) can be easily integrated into training objectives to produce more faithful summarization systems. In our method, which we call **MUFASSA** (**M**ulti-view **F**aithfulness **S**coring via **S**ource **A**blation), multiple *ablated source documents* are constructed by masking entities, shuffling tokens, and discarding all tokens in the original source document, to remove crucial information for the generation of different content in the summary, as shown at the top of Figure 1. Since the ablated sources do not include sufficient information for generating the corresponding summary, the differences between token output probabilities given by the original input and each ablated input should be high for the faithful content and low for the unfaithful one (e.g., “make” and “Kezia” in Figure 1). We then aggregate the differences to obtain the summary faithfulness score.

Additionally, to train faithful summarization systems, we adapt loss truncation (Kang and Hashimoto, 2020) and nullify losses on summary tokens that are deemed less faithful by MUFASSA during training. Compared to using training losses for detecting unfaithful content in the original loss truncation, MUFASSA provides a more accurate estimation of token faithfulness in training samples, and more faithful summaries can therefore be produced while maintaining informativeness. We further design **word truncation**, to drop the generation dependency on less faithful words in the auto-regressive decoder by completely removing them from the decoder input.¹

Two sets of experiments are conducted to show the effectiveness of MUFASSA at evaluating and training faithful summarizers. First, we compare with existing faithfulness metrics on AGGREGFACT (Tang et al., 2022), a curated benchmark for meta evaluation of faithfulness metrics, where MUFASSA obtains the best average performance. We then leverage MUFASSA during model training on XSum (Narayan et al., 2018) and CNN/DailyMail (Hermann et al., 2015). Com-

pared to baselines and recent models built with augmented data or more complex training objectives, MUFASSA-trained models produce summaries with competitive or better faithfulness while maintaining the coverage of salient document information, according to both automatic faithfulness metrics and human judgments.

In summary, we make the following contributions:

- We propose MUFASSA, a novel automatic evaluation metric that measures summary faithfulness by the extent to which the generation of summary tokens relies on information in the document.
- In addition, to leverage MUFASSA during training, we design word truncation, a novel training objective that discards less faithful tokens identified by MUFASSA from the training samples to induce more faithful summarizers.

2 Related Work

Faithfulness Metrics. Recent analyses have shown that summaries with high ROUGE scores (Lin, 2004) can contain information that is not faithful to the source documents (Falke et al., 2019; Kryscinski et al., 2020). This observation has prompted the development of a number of faithfulness metrics that measure the extent to which summarization models produce unfaithful outputs. Existing faithfulness metrics largely fall under two broad categories: (1) entailment-based metrics, and (2) QA-based metrics. Entailment-based metrics evaluate the faithfulness of summaries by computing entailment levels of the sentences (Laban et al., 2022), dependency arcs (Goyal and Durrett, 2020), or semantic graphs (Ribeiro et al., 2022) of the summaries against the corresponding documents. QA-based metrics use models for question generation and question answering to determine whether questions derived from the summary can be answered using the document (Wang et al., 2020; Durmus et al., 2020) or questions derived from the document can be answered using the summary (Scialom et al., 2019). Results are enhanced using a combination of both approaches (Scialom et al., 2021) and adding a question filtering stage (Fabbri et al., 2022).

In this work we pursue an alternative approach that detects unfaithful outputs by analyzing differences in token probabilities when conditioning on different views of the source document. This

¹Our code is available at <https://shuyangcao.github.io/projects/mufassa/>.

approach was first proposed by Xie et al. (2021), whose CoCo metric measures probability differences on pre-specified sets of key terms in the output of models conditioned on partially masked sequences. Our proposed metric, MUFASSA, builds upon CoCo in two ways. First, we eschew the need for key terms, instead providing an approach for assessing faithfulness of different types of tokens (e.g., entities, relations). This not only makes MUFASSA easier to use, but, as we will see in Section 4, also results in better performance. Secondly, we introduce a strategy for incorporating these metrics into training, and demonstrate in Section 5.2 that this training scheme produces more faithful summarizers.

Faithful Summarization. In parallel with advancements in faithfulness metrics, researchers have also investigated approaches to train more faithful summarizers. One class of approaches propose to modify model architectures to leverage external knowledge graphs (Zhu et al., 2021) and OpenIE triplets (Cao et al., 2018). Another class of approaches investigates modifications to training data, either by removing unfaithful training examples (Wan and Bansal, 2022) or training models to differentiate between faithful and unfaithful summaries (Liu et al., 2021; Cao and Wang, 2021). In this paper, we study a third class of approaches that modify the model’s loss function. Our work builds upon the method of loss truncation (Kang and Hashimoto, 2020), which omits a fraction of low confidence predictions from the loss function during training. We show that loss truncation can better improve faithfulness by using MUFASSA to determine which predictions to ignore, and that even better results can be obtained using our novel word truncation objective that omits removed tokens from the input (Tables 2 and 3).

3 MUFASSA: Multi-View Information Ablation

In this section, we first introduce the formulation of faithfulness estimation by MUFASSA (§3.1) and the construction of inputs with different information ablated (§3.2). We then describe how MUFASSA can be incorporated into model training through loss truncation and our proposed word truncation (§3.3). We fine-tune BART (Lewis et al., 2020) for all summarization models in this paper.

3.1 Information Ablation

Let T denote the set of tokens in the model vocabulary, and T^* the set of all sequences of tokens in T . Given a summary $y \in T^*$ of document $x \in T^*$, let $\mathcal{I}_{y_i} : T^* \rightarrow T^*$ denote a "view function" that ablates out information from the source document necessary for generating token y_i (i.e., a summarization model conditioned on $\mathcal{I}_{y_i}(x)$ should *not* produce token y_i). We hypothesize that if y_i is not faithful to the source document, then y_i can be generated with $\mathcal{I}_{y_i}(x)$ by a summarization model, i.e., the output probability $p(y_i|y_{<i}, \mathcal{I}_{y_i}(x))$ should remain high. Based on this hypothesis, we propose the faithfulness level of summary token y_i estimated by:

$$m(y_i) = p_{\theta}(y_i|y_{<i}, x) - p_{\theta'}(y_i|y_{<i}, \mathcal{I}_{y_i}(x)) \quad (1)$$

where a higher $m(y_i)$ suggests a higher faithfulness level, and p_{θ} and $p_{\theta'}$ denote summarization models parameterized by θ and θ' . We train p_{θ} and $p_{\theta'}$ on the experimented summarization dataset by maximizing $p_{\theta}(y_i|y_{<i}, x)$ and $p_{\theta'}(y_i|y_{<i}, \mathcal{I}_{y_i}(x))$ with the cross-entropy objective. To obtain the sample-level faithfulness score, we aggregate the faithfulness estimation over all summary tokens: $\frac{1}{L} \sum_{i=1}^L m(y_i)$, where L is the length of the summary. Notably, the token-level faithfulness scores aggregated by MUFASSA are based on the generation probabilities given the *already generated tokens*. The contextual nature of the token-level faithfulness scores allows MUFASSA to account for unfaithfulness of phrases and sentences in the generated summary.

3.2 Multi-View Ablation

Careful construction of \mathcal{I}_{y_i} is crucial to accurate faithfulness estimation of y_i . To reduce the computational cost, instead of creating a unique ablated document $\mathcal{I}_{y_i}(x)$ for every y_i , MUFASSA groups the summary tokens into three different sets— Y_{ent} , Y_{rel} , and Y_{other} —according to their part-of-speech (POS) tags and entity labels,² and constructs a single view of the source document I_Y to compute $m(y_i)$ for each token $y_i \in Y$.³ In the following paragraphs, we describe the construction strategies and their corresponding token sets.

²We use SpaCy (Honnibal and Montani, 2017) for named entity recognition and part-of-speech (POS) tagging.

³Thus, all of the token-level scores are computed using only 4 forward passes of the model: one for each set, and one for the original source document.

Mask Entities and Proper Nouns. Named entities and proper nouns are important components of facts and events that constitute summaries, so our first set of tokens, Y_{ent} is comprised of all tokens that are part of a proper noun or named entity. Since the faithful production of these tokens in the summary relies on the entity and proper noun information available in the document, we replace all named entities and proper nouns in the document with [MASK] tokens. E.g.:

$$\mathcal{I}_{Y_{\text{ent}}}(x_j) = \begin{cases} [\text{MASK}], & \text{if } x_j \text{ is a proper noun} \\ & \text{or named entity.} \\ x_j, & \text{otherwise} \end{cases}$$

where we adopt the convenient abuse of notation $\mathcal{I}_{Y_{\text{ent}}}(x_j)$ to denote the j th output of $\mathcal{I}_{Y_{\text{ent}}}(x)$.

Shuffle Tokens. Besides entities and proper nouns themselves, faithful summaries require correct resolution of their *relations* and *modifications*. Thus the second set of tokens we consider Y_{rel} is comprised of all of the verbs, adjectives, adverbs, and adpositions in y . To drop the relation and modification information, we randomly shuffle all the tokens in the document, i.e., $\mathcal{I}_{Y_{\text{rel}}}(x) = \sigma(x)$ where σ is a random permutation.

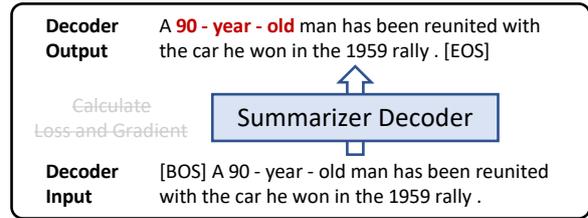

Empty Document. Lastly, for the remaining tokens not covered by the two aforementioned strategies, Y_{other} , we discard all tokens in the document, i.e., $\mathcal{I}_{Y_{\text{other}}}(x) = \emptyset$. Stopwords and punctuation are not included in Y_{other} . With empty documents, the summarizer resembles an unconditional language model. While empty documents have been used in previous work (Xu and Durrett, 2021; Xie et al., 2021), we argue that some spurious correlations might emerge from tokens that imply the document topic (e.g., tokens that usually occur with the topics) and aggressively taking empty documents for measuring the faithfulness level of any token would prevent the exposure of such spurious correlations.

3.3 Using MUFASSA during Training

We modify loss truncation (Kang and Hashimoto, 2020) to enable MUFASSA for training summarization models. Loss truncation considers tokens that still yield high training losses after several training epochs as noisy tokens and ignores their training losses.⁴ For each sample, the training objective with loss truncation is formally defined as:

⁴The loss truncation method is proposed at the sample level. We follow Goyal et al. (2022) to extend loss truncation to the token level.

① Faithfulness Estimation with MUFASSA

② Training with Truncation

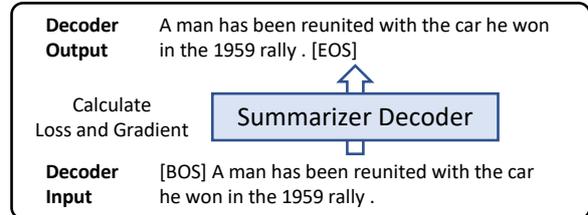

Figure 2: Illustration of our proposed word truncation training objective. In the first pass, model optimization is disabled and MUFASSA detects less faithful summary tokens. In the second pass, the summarizer is trained on the summary with these tokens discarded.

$$-\frac{1}{L} \sum_{i=1}^L \mathbb{1}_{[-\log p_{\theta}(y_i|y_{<i}, x) < Q_c^l]} \cdot \log p_{\theta}(y_i|y_{<i}, x) \quad (2)$$

where Q_c^l is the c percentile of the list Q^l tracking past training losses.

However, high loss might not well estimate the faithfulness level of each token. Thus, we propose to instead use faithfulness scores output by MUFASSA to identify unfaithful tokens to omit from the loss computation. That is, we replace Q^l with Q^m that records the faithfulness levels of past tokens measured by MUFASSA. The resulting training objective is:

$$-\frac{1}{L} \sum_{i=1}^L \mathbb{1}_{[m(y_i) > Q_c^m]} \cdot \log p_{\theta}(y_i|y_{<i}, x) \quad (3)$$

where the summarizer p_{θ} that is being optimized is also used for obtaining $m(y_i)$ as in Equation (1). Before switching to our modified training objective, we first optimize the summarization model for several epochs with the traditional cross entropy objective (henceforth, warm-up stage) following Goyal et al. (2022). The number of epochs for the warm-up stage is set to 3 in our experiments. We tune the percentile c on validation sets to achieve a balance of summary faithfulness and coverage.

Word Truncation. Although loss truncation avoids optimizing the likelihood of less faithful

tokens, they are retained in the generation context for the remaining tokens. Thus, the summarization model might insist on generating them in order to generate the remaining content, yielding unfaithful summaries. To this end, we extend loss truncation by additionally removing tokens that are less faithful from the decoder input during training. As illustrated in Figure 2, after feeding the original decoder input to the model, the faithfulness levels of summary tokens are first estimated by MUFASSA in the decoder output. At this step, we do not calculate the loss or perform any gradient back-propagation. With the less faithful tokens detected, we remove them from both the decoder input and output of the training sample. Finally, we train the summarizer with the truncated decoder input and output.

4 Metric Experiments

We first test how well MUFASSA agrees with human judgments on summary faithfulness.

Datasets. We experiment on AGGREGFACT (Tang et al., 2022), a benchmark consisting of document-summary pairs and their binary faithfulness labels annotated by most recent work (Kryscinski et al., 2020; Maynez et al., 2020; Huang et al., 2020; Fabbri et al., 2021; Pagnoni et al., 2021; Cao and Wang, 2021; Goyal and Durrett, 2021; Cao et al., 2022). We use the SOTA subset of AGGREGFACT where the summaries are produced by state-of-the-art summarizers built from large pre-trained models. The SOTA subset contains 1,335 and 1,018 samples annotated on XSum (Narayan et al., 2018) and CNN/DailyMail (Hermann et al., 2015) respectively.

Comparisons. For comparison, we include results of existing state-of-the-art faithfulness evaluation metrics:

- QUESTEVAL (Scialom et al., 2021) is a QA-based metric that answers questions created from the summary using the document and vice versa. To obtain the evaluation score, the word overlaps between the answers given by the pre-trained QA model and the ground-truth answers used for generating the questions are aggregated over all questions.
- SUMMAC (Laban et al., 2022) is an entailment-based metric that first computes the entailment

Metric	AGGREGFACT-	AGGREGFACT-	Average
	XSUM	CNN	
QUESTEVAL	61.6	71.5	<u>66.5</u>
SUMMAC	66.3	66.7	<u>66.5</u>
CoCo	59.3	68.4	63.8
PROBABILITY	54.7	68.5	61.6
EMPTY	<u>65.1</u>	67.0	66.1
MUFASSA	64.8	<u>69.2</u>	67.0

Table 1: The Area Under the ROC Curve (AUC) of different faithfulness metrics on AGGREGFACT. The top two results on each split are highlighted with a **boldface** and underline, respectively. MUFASSA achieves better average performance than existing metrics.

score between each pair of document and summary sentences. For each summary sentence, its entailment scores with document sentences are then binned into a histogram and transformed into the sentence-level faithfulness score via a 1-D convolutional layer. The mean of the sentence-level scores is then taken as the evaluation score.

- CoCo (Xie et al., 2021) is a model causality-based metric. We use its best-performing variant that masks document sentences that contain words in the summary. The difference between summary output probabilities given by a trained summarizer using the original document and the masked document is taken as the evaluation score.

We also compare with two variants of MUFASSA that: (1) directly take the output probability given by the original input as the faithfulness estimation (PROBABILITY), which no longer calculates the difference in Equation 1; or (2) only use the empty document as the ablated input (EMPTY).

Results. The performance by each metric is measured with the Area Under the ROC Curve (AUC). As shown in Table 1, when solely taking the empty document as the ablated input, the resulting metric already matches the performance of the other existing metrics except for QUESTEVAL on CNN/DailyMail, showing the effectiveness of ablation.

Furthermore, boosted by multi-view information ablation that provides model interpretation of finer granularity, MUFASSA *yields the best average performance on AGGREGFACT*, even without leveraging models obtained from other datasets.

We also observe that the average performance of CoCo is worse than the empty document ablation,

though COCO employs a more sophisticated masking strategy. As their masking strategy is based on exact word matching, it might struggle to ablate information for abstractive summaries, leading to less accurate faithfulness estimation.

5 Summarization Experiments

To verify the effectiveness of our methods to produce more faithful summaries, we train summarizers on popular summarization datasets with our proposed loss truncation and word truncation methods equipped with MUFASSA.

5.1 Experimental Setup

Datasets. We conduct experiments on XSum (Narayan et al., 2018) and CNN/DailyMail (Hermann et al., 2015) datasets. Both datasets are built from news articles, with the XSum summaries tending to be more abstractive than its counterpart. We follow the official data splits of XSum and CNN/DailyMail, which respectively contain 204,045/11,332/11,334 and 287,113/13,368/11,490 samples in the train/validation/test sets.

Evaluation Metrics. For faithfulness evaluation, we use SUMMAC and QUESTEVAL, which respectively obtain the best performance on the XSum and CNN/DailyMail splits of the AGGREFACT benchmark in §4. In addition, we report ROUGE scores, including variants based on the unigram overlap (ROUGE-1), bigram overlap (ROUGE-2), and longest common subsequence (ROUGE-L)⁵.

Comparisons. Besides the models fine-tuned only with the cross entropy objective (BART) and additionally with loss truncation (LOSSTRUNC), we also compare with DAE-based loss truncation (Goyal and Durrett, 2021) and CLIFF (Cao and Wang, 2021). Specifically, DAE assesses the entailment level of each dependency arc in the summary and then locates less faithful tokens by aggregating the entailment levels of their attached dependency arcs, where the training losses are discarded. By contrast, without using truncating losses, CLIFF augments the model training with negative samples (i.e., synthetic incorrect summaries) and adopts contrastive learning (Khosla et al., 2020) to help model distinguish incorrect summaries from correct summaries.

⁵Please refer to Appendix B for ROUGE-1 and ROUGE-2 scores

Model	SUMMAC	QUESTEVAL	R-L
<i>XSum</i>			
BART	24.36	36.66	37.19
CLIFF	24.60*	36.94	36.43
DAE	23.81	36.38	30.32
LOSSTRUNC	24.52	37.12*	34.60
+ MUFASSA	24.63*	37.22*	33.77
+ WORDTRUNC	24.85*	36.75	34.66
<i>CNN/DailyMail</i>			
BART	80.54	60.17	41.14
CLIFF	78.95	59.03	41.06
LOSSTRUNC	80.50	60.22	41.36*
+ MUFASSA	81.84*	60.04	40.69
+ WORDTRUNC	83.01*	60.44*	40.40

Table 2: Evaluation of summary generation on XSum and CNN/DailyMail. R-L: ROUGE-L. MUFASSA-based loss and word truncation yields summarizers with the best faithfulness scores. *Significantly better than BART with approx. randomization test ($p < 0.005$).

5.2 Results

We report results on XSum and CNN/DailyMail in Table 2. Our modified loss truncation produces summarizers with better performance than all comparisons on faithfulness metrics on both datasets, except for QUESTEVAL on CNN/DailyMail, which suggests the usefulness of MUFASSA in training summarization models with improved faithfulness. Moreover, additionally truncating the less faithful tokens in the decoding context during training consistently advances the SUMMAC scores, achieving the best SUMMAC scores on both datasets.

Though DAE trains a dependency arc entailment scorer with augmented negative samples, the external dependency parser requires processing the summarization dataset into a text format that does not align with the natural text format used by large model pre-training, yielding worse performance.

Additionally, we observe that summaries from our models have less competitive ROUGE scores. This could be due to unfaithful content in the human reference summaries, which has been identified as an issue in previous work (Maynez et al., 2020). In this regard, further human evaluation is conducted in the next section.

Human Evaluation. We hire human annotators on Amazon Mechanical Turk⁶ to rate system summaries on three aspects:

⁶<https://www.mturk.com/>

Model	Faith.	Cover.	Coher.
BART	3.32	3.22	5.00
CLIFF	3.45	3.22	4.97
LOSSTRUNC	3.41	3.17	4.97
+ MUFASSA	3.45	3.21	4.97
+ WORDTRUNC	3.59*	3.35	4.92

Table 3: Human evaluation results on XSum. Faith.: faithfulness; Cover.: coverage; Coher.: coherence. Our model using word truncation guided by MUFASSA achieves the best summary faithfulness and coverage. Krippendorff’s $\alpha \geq 0.35$ for all aspects.

- **Faithfulness:** How well the factual information in the summary accurately matches the information in the article;
- **Coverage:** How well the summary covers the important information in the article; and
- **Coherence:** How coherent the summary is on its own.

Each aspect is rated on a Likert scale from 1 (worst) to 5 (best).

We randomly select 80 articles from XSum, where models are more prone to errors (Pagnoni et al., 2021), and ask annotators to judge summaries generated by our models as well as comparisons including BART, CLIFF, and the original loss truncation. During annotation, the order of the system summaries is shuffled and each system summary is evaluated by three annotators. Details of the human evaluation such as payment, annotator qualification, and interface screenshots are included in Appendix C.

According to human judges (Table 3), without word truncation, MUFASSA improves the identification of less faithful tokens, outperforming the original loss truncation and matching CLIFF on summary faithfulness and coverage. Adding word truncation further encourages the summarizer to generate summaries with promoted faithfulness and content coverage, leading to the best scores on both aspects. We also find that removing less faithful summary tokens from the training samples only has minor effects on the summary coherence.

Case Study. Figure 3 displays an example article from XSum and its corresponding summaries generated by summarizers trained with different methods. The model trained with the original loss truncation does not attempt to modify the unfaithful entity “the Six Nations”, as training losses do not accurately reflect faithfulness levels. While the unfaithful entity is removed from the output when

Article: Amos dislocated a shoulder in the 32-8 defeat by Australia and will have an operation in the next week. The 22-year-old Dragons wing tweeted: "Operation set for Monday, aiming to be back in February". "It’s unlucky for Hallam but a great opportunity for Keelan," said Wales assistant coach Neil Jenkins ... "We’re going to miss him, but back-three is a position where we have strength in depth." Giles has been in outstanding form for Ospreys, scoring eight tries in five appearances for the region this season ...

BART: Ospreys wing Keelan Giles could make his Wales debut after Hallam Amos was ruled out of **the Six Nations** with a shoulder injury.

LOSSTRUNC: Ospreys wing Keelan Giles has been named in Wales’ back-three after Hallam Amos was ruled out of **the Six Nations**.

LOSSTRUNC + MUFASSA: Ospreys wing Keelan Giles could make his Wales debut after Hallam Amos was ruled out for **the rest of the season**.

LOSSTRUNC + MUFASSA + WORDTRUNC: Ospreys wing Keelan Giles is in line to replace injured Hallam Amos in Wales’ back-three.

Figure 3: Example generated summaries. Unfaithful information is shaded with red. Our model trained with word truncation signaled by MUFASSA generates a faithful summary.

the original loss truncation is augmented with MUFASSA, the summarizer produces another piece of unfaithful information. After applying word truncation, the model learns to stop generation, producing the faithful summary.

6 Additional Experiments

In this section, we inspect the effects of important design choices in MUFASSA (§6.1). Furthermore, to show the possibility of applying MUFASSA to other tasks, we train data-to-text generation models with our proposed methods (§6.2).

6.1 Ablation Study

We examine the effects on faithfulness estimation by the source ablations with masked entities and proper nouns, and shuffled tokens. For the faithfulness levels of summary tokens induced by each ablated input, when the ablated input is not used,

Metric	AGGREGFACT-		Average
	XSUM	CNN	
MUFASSA	64.8	71.2	68.0
<i>Not Using All Source Ablations</i>			
w/o Mask	64.5	69.8	67.1
w/o Shuffle	65.3	69.9	67.6
w/o Mask & Shuffle	65.1	67.0	66.1
<i>Not Assigning Ablations to Different Summary Tokens</i>			
Average	62.4	67.6	65.0
Minimum	53.5	51.3	52.4
Maximum	65.2	68.2	66.7

Table 4: The Area Under the ROC Curve (AUC) by variants of MUFASSA on AGGREGFACT. The best results on each split is highlighted with **boldface**. Removing any component of MUFASSA reduces its robustness, leading to lower average AUC.

we instead obtain their faithfulness levels with the empty document input. Moreover, we investigate the benefits of assigning each ablated input to different summary tokens. Concretely, we consider three variants, where the faithfulness level of each token is calculated by either taking the average, minimum, or maximum value of the faithfulness levels measured with the three source ablations.

Including multiple source ablations enhances the robustness of MUFASSA, as indicated by its best average performance on AGGREGFACT in Table 4. Compared to the source ablation with shuffled tokens, the source ablation with masked entities and proper nouns contributes more to the accurate faithfulness estimation by MUFASSA, dropping which leads to a larger performance degradation.

Simple aggregations (i.e., average, minimum, and maximum) of the faithfulness levels measured by the three source ablations produce lower AUC scores, justifying MUFASSA’s design of leveraging different token-specific source ablations.

6.2 Extension to Data-to-Text Generation

While this work focuses on summarization, we also explore extending our methods to other tasks. Specifically, we conduct experiments on a data-to-text dataset, WikiPerson (Wang et al., 2018) which requires the generation model to produce a natural language description for a person’s career, given the infobox in the corresponding Wikipedia biography article. Details of the dataset and experiment setup are included in Appendix A.2.

We evaluate outputs with faithfulness-aware data-to-text metrics, including: PARENT (Dhingra et al., 2019) that additionally aligns n-grams

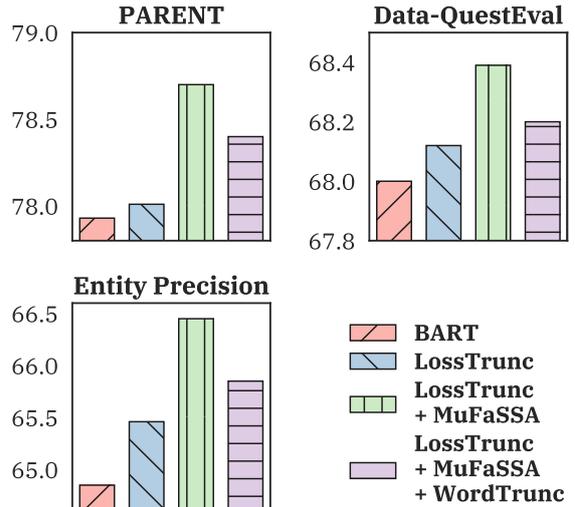

Figure 4: Automatic evaluation results on WikiPerson. Our models achieve better performance than comparisons with the cross entropy objective and original loss truncation objective, implying the effectiveness of MUFASSA on other generation tasks.

from the reference and the system generation to the source table; and Data-QuestEval (Rebuffel et al., 2021) which replaces the text-based question generation and answering models in the original QUESTEVAL with table-based models to adapt to data-to-text tasks. Moreover, we compute the precision of named entities in the generated text, suggested by recent work on text generation (Logan IV et al., 2022).

Our models outperform comparisons on all metrics, as shown in Figure 4, indicating the potential adaptations of MUFASSA on conditional generation tasks other than text summarization to improve output faithfulness. Word truncation does not further improve the performance on WikiPerson. We suspect that data-to-text tasks might require more samples to learn coherent generation due to the modality difference between the input and output, while word truncation reduces the number of tokens that the model can learn from.

7 Conclusion

We studied improving faithful summary evaluation and generation. Our proposed method, MUFASSA, estimates the faithfulness level of a summary token by the decrease in its generation probability after ablating crucial information from the source document. Multiple ablation strategies are used by MUFASSA for different summary tokens to achieve accurate faithfulness estimation. We also

designed word truncation for improved integration of MUFASSA into model training. Experiments on AGGREFACT show that MUFASSA better aligns with human faithfulness labels than existing metrics. When used for highlighting less faithful tokens during summarizer training, MUFASSA leads to summaries with enhanced faithfulness, which is further boosted by word truncation, achieving better faithfulness than competitive comparisons, as measured by both automatic metrics and human annotators.

Limitations

While MUFASSA does not rely on textual entailment or question answering models, the construction of ablated inputs in MUFASSA still requires some existing NLP tools such as named entity recognizers and POS taggers. Therefore, the accuracy of the faithfulness estimation would be limited by the performance of these tools. Also, construction strategies other than the ones presented in this paper might rely on more advanced NLP tools, further amplifying the limitation. This could be a significant issue for low-resource languages where basic NLP tools have not been established.

In addition, our word truncation training objective incurs some computational overhead. First, it takes two forward passes, though gradient back-propagation is not performed in the first pass. Second, similar to the original loss truncation, word truncation maintains a list for storing the faithfulness levels of past tokens and needs to calculate the threshold of faithfulness levels for truncating less faithful tokens.

Ethical Consideration

Previous studies have shown that large pre-trained models embed biases and might create harm to certain populations. While MUFASSA is built with large pre-trained models, we do not study if the faithfulness estimation by MUFASSA is biased towards any population in this work (e.g., produce higher scores for texts including a population than text including another population). As recent work finds that BERTScore which is also based on large pre-trained models has biases (Sun et al., 2022), we suggest users carefully investigate the potential biases in the model before applying it in real-world situations.

Table 5: Numbers of samples collected from previous work in the SOTA subset of AGGREGFACT.

A Details of Datasets

We include additional details for datasets we use in our paper.

A.1 AGGREGFACT

We show the numbers of samples included in the SOTA subset of AGGREGFACT (Tang et al., 2022) from different studies in Table 5.

A.2 WikiPerson

WikiPerson (Wang et al., 2018) extract Wikipedia articles and the corresponding infoboxes about person entities. For each article, they remove sentences that do not contain any value in the corresponding infobox or only contain entities not in the infobox. The remaining sentences of the article are then taken as the generation target for the infobox.

Statistics. We use the official data split provided by the original paper, which contains 250,186/30,487/29,982 samples in the train/validation/test sets. On average, each infobox contains 7.3 attribute-value pairs and each target output contains 86.3 words.

Experiment Details. On WikiPerson, MUFASSA masks the values in the infoboxes for estimating the faithfulness levels of entities and proper nouns in the outputs. For the remaining tokens in the outputs, we use empty infoboxes as the ablated inputs. We do not consider shuffling tokens of values in infoboxes, as they are mainly entities and proper nouns.

Model	R-1	R-2	Density	Coverage
<i>XSum</i>				
BART	45.41	22.29	1.65	75.70
CLIFF	44.52	21.40	1.69	76.71
DAE	38.94	15.00	1.50	74.80
LOSSTRUNC	42.98	19.13	1.74	78.78
+ MUFASSA	41.93	18.09	1.85	77.95
+ WORDTRUNC	42.36	19.13	1.75	76.82
<i>CNN/DailyMail</i>				
BART	44.32	21.32	20.81	99.00
CLIFF	44.18	21.14	18.89	98.91
LOSSTRUNC	44.50	21.48	20.16	99.02
+ MUFASSA	43.88	20.96	21.52	99.15
+ WORDTRUNC	43.63	20.77	24.57	99.32

Table 6: ROUGE-1 and ROUGE-2 on XSum and CNN/DailyMail. The best result of each metric on each dataset is **bolded**.

Given an infobox, to create the textual input to the model, we first concatenate attributes and their corresponding values with “=” . Then we concatenate all attribute-value pairs together with “|” inserted at the beginning of each attribute-value pair. An example of the converted textual input: “| Name_ID = Thorsten Barg | date of birth = 25 August 1986 | country of citizenship = Germany” .

B Additional Results

We report ROUGE-1 and ROUGE-2 scores on XSum and CNN/DailyMail, which are omitted in §5.2. Both scores follow the trend of ROUGE-L in Table 2. We also examine the abstractiveness of the summaries generated by each system by calculating the density and coverage (Grusky et al., 2018), where we find our system tends to be more extractive on CNN/DailyMail compared to other systems.

C Details of Human Evaluation

Our human evaluation is conducted on Amazon Mechanical Turk (AMT). In the annotation interface (Figure 5 to 8), we provide a detailed instruction of the annotation task, including rubrics, examples, and explanations.

Before launching all annotation samples on AMT, we run two batches for qualification. Each qualification batch contains one article and its corresponding system summaries, and is annotated by 20 workers. We manually inspect the annotation results and filter out workers that return abnormal annotations (e.g., giving high faithfulness scores to

for summaries containing unfaithful content or giving very different scores to identical summaries). We also require the annotators to be located in the US or the UK, with 100 tasks previously completed, and have an approval rate of 100%. A pool of 8 workers for our human evaluation is obtained after the qualification.

For compensation, we pay each annotator \$2.5 for each task (i.e., evaluating system summaries generated for an article) of our human evaluation to approximate an hourly payment of \$15.

D Details of Implementation

We use Fairseq (Ott et al., 2019)⁷ for setting up the training and decoding pipelines. The BART model (Lewis et al., 2020) in our paper is initialized from the `bart.large`⁸ checkpoint provided by Fairseq. We conduct training and decoding on 4 NVIDIA V100 GPUs with 16GB memory.

Training. We use the training hyperparameters in the training script provided by the BART paper⁹. The percentile for obtaining the threshold of faithfulness levels is tuned on the validation set of each dataset. For XSum, we search for the best threshold percentile within [30, 40, 50]. The model with the best SUMMAC score while having a ROUGE-1 score of at least 42 is selected. 40, 50, and 30 are chosen as the percentiles for the models respectively trained with the original loss truncation objective, our loss truncation guided with MUFASSA, and our word truncation objective. For CNN/DailyMail, we search for the best threshold percentile within [5, 10, 20]. The model with the best SUMMAC score while having a ROUGE-1 score of at least 44 is selected. 10, 10, and 5 are chosen as the percentiles for the models respectively trained with the original loss truncation objective, our loss truncation guided with MUFASSA, and our word truncation objective. To avoid incoherent summaries, we only apply word truncation to proper nouns. Due to the computational cost, we train all models for one run.

Decoding. We follow the original BART paper and decode using beam search with beam sizes of 4 and 6 on CNN/DailyMail and XSum. During

decoding, the maximum decoding lengths are 140 and 60 for CNN/DailyMail and XSum.

Running Time. We report the running time on XSum. Training our models with loss truncation or word truncation on XSum takes 10 hours and the decoding takes half an hour.

Model Parameters. Our methods do not increase the number of model parameters. Therefore, our models have 400M parameters, which is the same as the original BART.

E Output Examples

We include more examples of system outputs in Figure 9 and 10.

Task Instructions

There will be many similar HITs for you to perform if you do well at this task. Please follow the instructions carefully for each HIT; we will be reviewing your HITs periodically and if we note any unusual responses, you might not see any additional tasks from us.

During this task, you will read a news article and six different summaries for the article. You will rate the quality of each of the six summaries by four axes: *coherence*, *accuracy*, *coverage*, and *overall quality*.

The rubrics below give specific guidance on how each axis should be rated. Please read the rubrics carefully before continuing to the task.

Jump to [coherence rating](#)

Coherence

For each summary, answer the question "how coherent is the summary on its own?" (on a scale from 1 to 5). A summary is *coherent* if, when read by itself, it's easy to understand and free of English errors. A summary is not coherent if it's difficult to understand what the summary is trying to say. Generally, it's more important that the summary is understandable than it being free of grammar errors. Please **do not penalize incomplete punctuation** (e.g., when there exists only one quote mark in the sentence).

Rubric:

- Score of 1: The summary is impossible to understand.
- Score of 2: The summary has many mistakes or confusing phrasing.
- Score of 3: The summary has some mistakes or confusing phrasing that make it hard to understand.
- Score of 4: The summary has only one or two mistakes or confusing phrasing.
- Score of 5: The summary is perfectly clear.

Jump to [accuracy rating](#)

Accuracy

For each summary, answer the question "how well does the factual information in the summary accurately match the information in the article?" (on a scale of 1 to 5) A summary is *accurate* if it doesn't say things that aren't in the article, it doesn't contradict information in the article, and generally is not misleading.

Even if a piece of information is true according to your knowledge, if it is not mentioned in the article it should not be included in the summary.

Rubric:

- Score of 1: The summary is completely wrong, made up, or exactly contradicts what is written in the article.
- Score of 2: The summary says many things not mentioned in or contradicting the article.
- Score of 3: The summary says at least one substantial thing that is not mentioned in the article, or that contradicts something in the article.
- Score of 4: The summary says anything at all that is not mentioned in the article or contradicts something in the article.
- Score of 5: The summary has no incorrect statements or misleading implications.

Jump to [coverage rating](#)

Coverage

For each summary, answer the question "how well does the summary cover the important information in the article?" (on a scale of 1 to 5). A summary has good *coverage* if it mentions the main information from the article that's important to understand the event described in the article. A summary has poor coverage if someone reading only the summary would be missing several important pieces of information about the event in the article.

Rubric:

- Score of 1: The summary contains no information relevant to the article.
- Score of 2: The summary is missing many important pieces of information required to understand the event.
- Score of 3: The summary is missing at least one crucial piece of information required to understand the event.
- Score of 4: The summary is missing any information (no matter how small) required to understand the event.
- Score of 5: The summary covers all of the important information required to understand the event.

Jump to [overall quality rating](#)

Overall quality

For each summary, answer the question "how good is the summary overall at representing the article?" (on a scale of 1 to 5). This encompasses all of the above axes, as well as the information included in the summary and if it has helped you understand the event. If it's hard to find ways to make the summary better, give the summary a high score. If there are lots of different ways the summary can be made better, give the summary a low score.

Figure 5: Screenshot of our annotation interface (1/4).

Rubric:

- Score of 1: The summary is terrible.
- Score of 2: The summary is a pretty bad representation of the article and needs significant improvement.
- Score of 3: The summary is an okay representation of the article, but could be significantly improved.
- Score of 4: The summary is a pretty good representation of the article, but it's not perfect.
- Score of 5: The summary is an excellent representation of the article.

Example

Now you will review an example article and three associated summaries.

- For each of the summaries, we have provided ratings on the four axes: coherence, accuracy, coverage, and overall quality with explanations for why those ratings were chosen.
- Please review the summaries and their ratings carefully, so you understand how to rate the summaries during the task.
- If you have any questions about how to rate the summaries, please consult the rubric (above).

Example Article

Welsh and UK ministers have been rowing since March over how to finance the commuter lines in and out of Cardiff. Mr Crabb said the scheme - estimated at £309m to £463m - was "probably the most knotty" problem between the two governments but was solvable. The valleys rail electrification is due to be completed between 2019 and 2024. Planned rail improvements will see the upgrade of the main line from London Paddington to Cardiff, which is due to be completed by 2017, and extended to Swansea by 2018 at a cost of £850m. The electrification of the Valleys lines was due to follow, but the plan was thrown into doubt in March by a row over the financing of the project. Speaking on Radio Wales' Sunday Supplement programme, Mr Crabb said rail electrification was the "number one issue" for him. He said: "It's something that I've been spending quite a bit of my summer working on. "There's a bit more work to be done between the two governments on where we think the solution lies, but I think when I go around talking to businesses in south Wales they are desperate to see this problem answered, they want the two governments to be working effectively together." Describing the issue as "a bit of a litmus test" for joint working between Wales and Westminster, he warned the issue "can't drag on indefinitely". "There are engineering teams involved in Network Rail who need to get tasks assigned to them if this huge, enormous, financially-challenging project is to go ahead," he said. "There are some quite hard deadlines in that. But we are talking a short number of months hopefully."

Example summary #1

The electrification of the Valleys rail lines is the "number one issue" for Welsh Secretary Stephen Crabb.

Ratings for Example Summary #1

The summary should be rated as follows:

How coherent is the summary on its own?

It is impossible to understand. 1 2 3 4 5 The summary is perfectly clear.

Explanation for rating: This summary is easy to understand and read with clear language and no grammatical errors and therefore coherent, so we rate it a 5 (of 5).

How well does the factual information in the summary accurately match the article?

The summary is completely wrong, made up, or exactly contradicts what is written in the article. 1 2 3 4 5 The summary has no incorrect statements or misleading implications.

Explanation for rating: The position and first name of Mr. Crabb is unknown from the article. So we rate this summary as 3 (of 5).

How well does the summary cover the important information in the article?

The summary contains no information relevant to the article. 1 2 3 4 5 The summary covers all of the important information required to understand the event in the article.

Explanation for rating: This summary has a fair coverage of the article, but it misses the mention of the underlying reason for the rail line electrification issue. So we rate this summary as 4 (of 5).

How good is the summary overall at representing the article?

It is terrible. 1 2 3 4 5 It is an excellent representation of the article.

Explanation for rating: This summary is okay but it could be **significantly improved** by mentioning the underlying reason for the rail line electrification issue and not including extraneous information about Mr. Crabb. So, we rate this summary as 3 (of 5).

Example Summary #2

Mr. Crabb has said he is "desperate" to see the electrification of the Valleys rail line.

Ratings for Example Summary #2

The summary should be rated as follows:

How coherent is the summary on its own?

It is impossible to understand. 1 2 3 4 5 The summary is perfectly clear.

Explanation for rating: This summary is easy to understand and read with clear language and no grammatical errors and therefore

Figure 6: Screenshot of our annotation interface (2/4).

coherent, so we rate it a 5 (of 5).

How well does the factual information in the summary accurately match the article?

The summary is completely wrong, made up, or exactly contradicts what is written in the article. 1 2 3 4 5 The summary has no incorrect statements or misleading implications.

Explanation for rating: It could be inferred that Mr. Crabb is "desperate", but it is not explicitly stated in the article. So we rate this summary as 4 (of 5).

How well does the summary cover the important information in the article?

The summary contains no information relevant to the article. 1 2 3 4 5 The summary covers all of the important information required to understand the event in the article.

Explanation for rating: This summary has a fair coverage of the article, but it misses the mention of the underlying reason for the rail line electrification issue. So we rate this summary as 4 (of 5).

How good is the summary overall at representing the article?

It is terrible. 1 2 3 4 5 It is an excellent representation of the article.

Explanation for rating: This summary is pretty good, but it can be **somewhat improved** by providing the underlying reason for the rail line electrification issue. So we rate this summary as 4 (of 5).

Example Summary #3

The electrification of the Valleys rail lines interrupted by the finance plan is the "number one issue" for Crabb.

Ratings for Example Summary #2

The summary should be rated as follows:

How coherent is the summary on its own?

It is impossible to understand. 1 2 3 4 5 The summary is perfectly clear.

Explanation for rating: This summary is easy to understand and read with clear language and no grammatical errors and therefore coherent, so we rate it a 5 (of 5).

How well does the factual information in the summary accurately match the article?

The summary is completely wrong, made up, or exactly contradicts what is written in the article. 1 2 3 4 5 The summary has no incorrect statements or misleading implications.

Explanation for rating: Information in this summary is accurately grounded in the article. So we rate this summary as 5 (of 5).

How well does the summary cover the important information in the article?

The summary contains no information relevant to the article. 1 2 3 4 5 The summary covers all of the important information required to understand the event in the article.

Explanation for rating: This summary contains all important information in the article. So we rate this summary as 5 (of 5).

How good is the summary overall at representing the article?

It is terrible. 1 2 3 4 5 It is an excellent representation of the article.

Explanation for rating: This summary is an excellent representation of the article. So we rate this summary as 5 (of 5).

Test

Answer the following question to start the task. If you are unsure of the answer, review the rubrics above. The task section will appear when you've completed the test.

Which axis measures whether the summary information is grounded in the article information? Enter your answer and click "Start task".

Task

Instructions:

1. Read the article and when you are finished reading, click "Yes".
2. Write a short title for the article then click "Submit title".

Figure 7: Screenshot of our annotation interface (3/4).

3. You will then rate six summaries of the article for their coverage, accuracy, coherence, and overall quality.

article

\$(article)

Have you finished reading the article?

Give a short title to the article to describe what it is about

You may now rate the summaries below.

Note: consult the rubric if you are unsure of a rating.

How *coherent* is the summary on its own?

Figure 8: Screenshot of our annotation interface (4/4).

Article: Downing Street backed a report by think tank Policy Exchange which said selling high value homes when they become vacant would raise £4.5bn a year. That would be enough to build 80,000 to 170,000 social homes, the report said. Labour said new homes were urgently needed but "driving out hard-working families on low wages from whole neighbourhoods" was not the answer. In its Ending Expensive Social Tenancies report, Policy Exchange argues the move could create the largest social house building programme since the 1970s - giving the economy a kickstart. Neil O'Brien, the think tank's director, told the BBC that social housing would still exist in very expensive areas under its proposal, but there would just be "less of it". "The truth is I don't believe anybody has the right to live in the most expensive parts of town. "People do have a right to get housed, just not in the very most expensive areas," he said. He also suggested that the overall number of people waiting for social housing, currently around 1.8 million, could be reduced by about 500,000 if the scheme was implemented. The prime minister's official spokesman said: "This is something that councils can choose to do already. "Councils should be looking for ways to use their social housing stock as efficiently as they can. The waiting list for social housing has increased a lot over passing years. "They need to think about how they can use that social housing stock efficiently. "If they can sell high-value housing to invest in more social housing and find more homes for more people, then that is certainly something they should look at." But Labour said the coalition's "failed" policies were "making the housing crisis worse not better". Shadow housing minister Jack Dromey said: "Councils and housing associations should make effective use of their housing stock but the government should not force them to arbitrarily sell off social homes, breaking up mixed communities and driving out hard-working families on low wages from whole neighbourhoods." He said the government should use a bank bonus tax to fund 250,000 affordable homes and "put unemployed builders back to work" and boost the construction industry. 'Lucky family' Expensive social housing - which Policy Exchange defines as housing worth more than the average property in each region - accounts for 21.8% of the total social housing stock in the UK, it says. This equates to 816,000 properties - out of a total of 3.78 million - which the think tank says could raise up to £159bn if sold. It says London alone has more than £70bn of expensive social housing. About 3.5% of the total stock becomes vacant every year owing to people moving out or dying, the think tank said. This meant the government could sell a total of 28,500 properties each year, raising £5.5bn a year. The figure would stand at £4.5bn after paying off the debt held against the stock, the report said. Mr O'Brien argued that many hard-working people might want to live in a nicer area or in a bigger house but could not afford to. "Rather than having one lucky family with a very expensive house, you would have two families perhaps desperately waiting for social housing, now having a roof over their heads. "That seems fairer to me," he added. The think tank also said the move would be "extremely popular" with all sections of society, claiming that 73% of people, including social tenants, think people should not be given council houses worth more than the average property in a local authority. 'Dramatic erosion' Critics say such a move would push the least well-off out of expensive streets, and into new ghettos. The National Housing Federation, which represents housing associations, says many towns would be "cleansed" of "hardworking people who can't afford to pay high prices". Labour MP Karen Buck, who represents Westminster North, is concerned that lower income families, particularly in London, will be forced out of more affluent areas creating segregated communities of rich and poor. Ms Buck also argued that the Labour government's £8bn social and affordable housing building programme was cut by 60% when the coalition came to power. Housing Minister Grant Shapps - who is in favour of a sell-off - said the government had introduced "radical reforms" to "get Britain building" and to reduce social housing waiting lists. They included investing £19.5bn public and private funding into an affordable housing programme "set to exceed expectations and deliver up to 170,000 homes". Councils could now offer fixed-term tenancies to new tenants to make sure "social housing goes to those in greatest need", he added.

BART: Prime Minister David Cameron has said councils should be allowed to sell off expensive social housing to fund more affordable homes.

LOSSTRUNC: The government has said it would be "appropriate" for councils to sell off social housing in very expensive areas.

LOSSTRUNC + MUFASSA: Councils should sell high-value social housing to help build more homes, the prime minister's office says.

LOSSTRUNC + MUFASSA + WORDTRUNC: Councils should be allowed to sell council houses worth more than the average property to fund new homes, the government says.

Figure 9: Output examples on XSum.

Article: Following Raheem Sterling's interview on Wednesday, in which he said he was not ready to sign a new contract at Liverpool, blogger David Tyrer of Live4Liverpool gives the view from Merseyside. While I hate to use social media as a gauge of opinions, Raheem Sterling's interview didn't go down well at all. It was ill-timed and, regardless of what Sterling and his agent hoped, he didn't come across very well. Some of his answers only fuelled the fire really. I'm hoping that that wasn't the whole point, as we've seen these sorts of situations engineered by agents before. The interview has almost certainly changed the way the fans feel about him. There will be a lot of fans that are of the opinion: 'let him go'. Obviously, with the caveat that we get our money's worth! Raheem Sterling returns to Liverpool training after the international break and shakes hands with manager Brendan Rodgers. Sterling risked angering Liverpool fans after he said in an interview he was not ready to sign a contract. Sterling trains ahead of the weekend's game with Arsenal. It's always disappointing when a young player gets his head turned, but there's a sense of ungratefulness about the whole situation, considering how the club has nurtured him and paid him well throughout. Personally, I think he has the potential to be worth so much more than the £100,000-a-week contract he's turned down. But it's only that: potential. At present, he's arguably in the top five best young players in the world but, obviously at his age, he's also prone to bouts of inconsistency and prolonged poor form. He hasn't been great recently and was awful against Man Utd. Sterling has been linked with a move to Arsenal - the team he is preparing to face at the weekend. Raheem Sterling played for England in the 4-0 Euro 2016 qualifier against Lithuania. And while I'd be willing to see the club give him £100k a week - possibly £120k a week - the club shouldn't do everything it can to keep him. Definitely not. Liverpool fans have a popular mantra: no player is bigger than the club. Admittedly, we stretch the rules for truly great players (Suarez, a recent example) but Sterling is nowhere near. If he wants out, I'm sure the club will handle it the way they have before. Frustration over Sterling's situation has been building for a while, and many fans are now of the belief that if he wants to go he's welcome to. Personally, I don't like players holding the club to ransom. He has as much chance of winning trophies here as he does anywhere (other than money-rich clubs such as Chelsea or Man City). Sterling did not have his best game in a Liverpool shirt during the defeat at Manchester United. Liverpool fans have a mantra that no player is bigger than the club. If Sterling was to move to Arsenal then it would not go down well with Liverpool fans. But if he does end up going, he's worth a lot more than many established players. His ability is so raw but he has almost limitless potential. At the moment, we've seen it in fits and starts but even so, he's easily worth £25-30 million. If I was FSG, I'd hold any interested club to ransom, though - double it. But a move to Arsenal wouldn't go down well. Perhaps better than if it was Chelsea or Manchester United, but honestly there's little Arsenal can offer that we can't. Sure, they're more financially stable but what - in terms of trophies - do Arsenal have to show for the last 12 years? Sterling speaks to the BBC and reveals he is not ready to sign a new contract. I think we're somewhat ahead on that front. Much like Alexis Sanchez, any move to Arsenal will be more about location than anything else. People have drawn comparisons with when Suarez wanted to leave for Arsenal, but the situation is different. Suarez says he wanted Champions League football and we weren't offering that at that time. Not only that, but Suarez was an established top-class player at the time, one of the best in the world. Sterling is purely potential and, given all the club have done for him (cliched, as that sounds), it makes little sense. If he's going to be nurtured into the world-class talent he can become, it won't happen at Arsenal. It may not necessarily happen at Anfield either, but a manager like Brendan Rodgers will give him the best shot of improving to that level over the next two to three years. You can read more from Live4Liverpool [HERE](#) and follow the Twitter account [HERE](#).

BART: Raheem Sterling said he was not ready to sign a new contract at Liverpool. The England winger has been linked with a move to Arsenal. Liverpool fans have a mantra that no player is bigger than the club. But a move to Arsenal would not go down well with the Anfield faithful.

LOSSTRUNC: Raheem Sterling said he was not ready to sign a new contract at Liverpool. The England winger has been linked with a move to Arsenal. Liverpool fans have a mantra that no player is bigger than the club. Sterling has the potential to be worth more than the £100,000-a-week contract.

LOSSTRUNC + MUFASSA: Raheem Sterling has said he is not ready to sign a new contract at Liverpool. The England winger has been linked with a move to Arsenal. Liverpool fans have a mantra that no player is bigger than the club. But a move to Arsenal would not go down well with the fans.

LOSSTRUNC + MUFASSA + WORDTRUNC: Raheem Sterling said he was not ready to sign a new contract at Liverpool. Sterling has been linked with a move to Arsenal - the team he is preparing to face at the weekend. Liverpool fans have a mantra that no player is bigger than the club. If Sterling was to move to Arsenal then it would not go down well with Liverpool fans.

Mining Effective Features Using Quantum Entropy for Humor Recognition

Yang Liu and Yuexian Hou

College of Intelligence and Computing, Tianjin University, Tianjin, China
{lauyon, yxhou}@tju.edu.cn

Abstract

Humor recognition has been studied with several different methods in the past years. However, existing studies on humor recognition do not understand the mechanisms that generate humor. In this paper, inspired by the incongruity theory, any joke can be divided into two components (the setup and the punchline). Both components have multiple possible semantics, and there is an incongruous relationship between them. We use density matrices to represent the semantic uncertainty of the setup and the punchline, respectively, and design Quantum Entropy Uncertainty (QE-Uncertainty) and Quantum Entropy Incongruity (QE-Incongruity) with the help of quantum entropy as features for humor recognition. The experimental results on the SemEval2021 Task 7 dataset show that the proposed features are more effective than the baselines for recognizing humorous and non-humorous texts.

1 Introduction

Humor is one of the most distinctive features of human behavior and a sign of mental maturity (Pasquali, 1990). The study of humor has received extensive attention in the fields of linguistics, philosophy, psychology, and sociology (Mihalcea et al., 2010). Computational humor is of particular interest, with the potential to transform computers into creative and motivational tools (Nijholt et al., 2003).

This paper restricts research to humor recognition in computational humor, which aims to recognize whether a piece of text is humorous. As shown in Figure 1, a joke usually includes two components: the setup and the punchline. The reader generates an expectation of the following text (the punchline) based on the content of the setup, and if the following text violates the reader’s expectation, humor is generated, and vice versa.

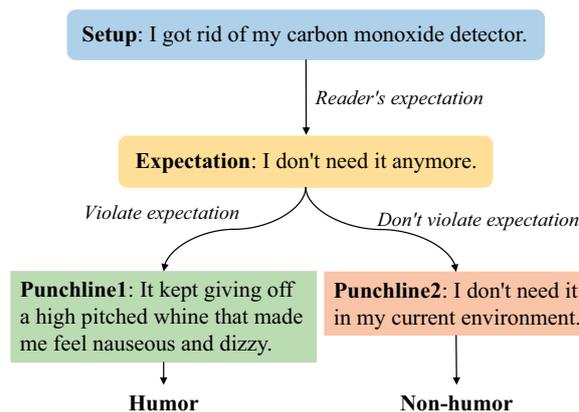

Figure 1: A humor and non-humor example containing the setup and the punchline.

In fact, the incongruity theory of humor can explain the above process of producing humor. The incongruity theory states that humor is generated because a thing (the setup) has multiple underlying concepts, and there is an incongruity between the concept involved in the situation and the real object it represents (the punchline).

Features based on semantic similarity (Mihalcea et al., 2010; Yang et al., 2015) and word association (Liu et al., 2018; Cattle and Ma, 2018) have achieved certain results, but they lack consideration of humorous mechanisms. Xie et al. (2021) calculated the uncertainty and the surprisal values of the joke with the help of the GPT-2. But they did not model the semantic incongruity between the setup and the punchline. While the above approaches are somewhat effective, the incongruity theory requires us to model semantic uncertainty and the incongruity between the setup and the punchline. We take inspiration from quantum theory and use density matrices to represent the uncertainty of text semantics. Specifically, the setup and the punchline are represented as density matrices, respectively. Then, take the quantum entropy of the setup as **Quantum Entropy Uncertainty (QE-Uncertainty)** and the conditional quantum entropy

between the setup and the punchline as **Quantum Entropy Incongruity (QE-Incongruity)**. Experiments conducted on a manually-labeled dataset demonstrate that these two features are better than existing baselines in distinguishing between humorous and non-humorous texts, confirming the necessity of correlating semantic uncertainty with quantum theory.

2 Background

2.1 The Incongruity Theory

The most widely accepted theory for explaining humor is the incongruity theory. The theory suggests that laughter is caused by an incongruity between the understanding of the text and its actual meaning (Mulder and Nijholt, 2002). Immanuel Kant describes humor as “*the sudden transformation of a strained expectation into nothing* (Hickey-Moody and Laurie, 2017).” Schopenhauer (1966) also believed that perceived incongruity exists between a concept and the real object it represents. The incongruity theory has also been developed in the field of linguistics. The Semantic Script-based Theory of Humor (SSTH) proposed by Raskin (1979) is a scripted expression of the incongruity theory. SSTH is our bridge to mathematically model the incongruity theory. SSTH requires humorous texts to meet the following conditions: (1) The text is compatible, fully or in part, with two different (semantic) scripts. (2) The two scripts with which the text is compatible are opposite.

2.2 Density Matrix

The mathematical form of quantum mechanics represents the probability space as a vector space (i.e., the Hilbert space \mathbb{H}^n) (Von Neumann, 2018). Researchers often use Dirac’s notation to represent unit vectors in this space. For example, a unit vector \vec{u} and its transpose \vec{u}^T are represented as $|u\rangle$ and $\langle u|$, respectively. The inner product of two unit vectors $|u\rangle$ and $|v\rangle$ is written as $\langle u|v\rangle$. The projector onto the direction $|u\rangle$ is its own outer product $|u\rangle\langle u|$. The rank of each projector is one and each projector represents a quantum fundamental event, often called a *dyad*. The density matrix (Nielsen and Chuang, 2010) is a generalization of the classical probability distribution. A density matrix ρ can be defined as a mixture of dyads:

$$\rho = \sum_{i=1}^n p_i |\psi_i\rangle\langle\psi_i| \quad (1)$$

where $|\psi_i\rangle$ represents a pure state with probability p_i . The density matrix ρ is symmetric, positive semi-definite, and its trace is one.

2.3 Quantum Entropy

Quantum entropy is a generalization of the quantum case of classical Shannon entropy (Shannon, 1948). If a quantum system is described by a density matrix ρ , its quantum entropy (Von Neumann, 2018) is defined as:

$$S(\rho) = -\text{tr}(\rho \ln \rho) \quad (2)$$

The conditional quantum entropy (Cerf and Adami, 1999) of the density matrix σ given the known density matrix ρ is defined as:

$$\begin{aligned} S(\sigma|\rho) &= S(\sigma\rho) - S(\rho) \\ &= -\text{tr}(\sigma\rho \ln(\sigma\rho)) + \text{tr}(\rho \ln \rho) \end{aligned} \quad (3)$$

unlike classical conditional entropy, conditional quantum entropy can be negative.

3 Methodology

The incongruity theory holds that the prerequisite for humor is that the text has multiple semantic aspects. The reader does not understand one meaning but expects one while the punchline provides another, leading to incongruity. According to the incongruity theory, we should design features to represent the multiple semantic overlaps of the setup, as well as the incongruity of the semantics of the setup and the punchline.

Normalize each word $w_i \in V$ as follows:

$$|w_i\rangle = \frac{\vec{w}_i}{\|\vec{w}_i\|} \quad (4)$$

where $\|\cdot\|$ represents the L_2 -norm. The representation of each word can be viewed as a superposition in Hilbert space.

A sentence of length l is represented by an n -by- n density matrix ρ :

$$\rho = \frac{1}{|l|} \sum_{i=1}^l |w_i\rangle\langle w_i| \quad (5)$$

where the diagonal values of ρ reflect the superposition semantics of sentences, and the non-diagonal values encode the correlation between semantics in a quantum way.

3.1 QE-Uncertainty

We take evidence of humor recognition from the setup, model the setup as a density matrix to represent its uncertainty semantics, and use the quantum entropy of the density matrix to represent the value of uncertainty. Formally, the QE-Uncertainty is calculated as follows:

$$U(\rho) = -\text{tr}(\rho \ln \rho) \quad (6)$$

where ρ represents the density matrix of the setup. The value of QE-Uncertainty reflects the amount of information contained in the text and the uncertainty of semantics. The larger the value, the more information the text contains, and the more likely the text is humorous.

3.2 QE-Incongruity

Another aspect of the incongruity theory is how different the semantics of the punchline is from expectations when the semantics of the setup are known (i.e., how much information we don't know about the punchline). In other words, how much information about the punchline is included in the setup? Specifically, the QE-Incongruity is defined as follows:

$$\begin{aligned} I(\sigma|\rho) &= U(\sigma\rho) - U(\rho) \\ &= -\text{tr}(\sigma\rho \ln(\sigma\rho)) + \text{tr}(\rho \ln \rho) \end{aligned} \quad (7)$$

where ρ and σ represent the density matrices of the setup and the punchline, respectively. The value of QE-Incongruity describes how unknown the semantics of the punchline is when the setup is known. We argue that when the setup contains less semantics in the punchline, there will be incongruity, and there will be humor.

4 Related Work

The existing text humor recognition methods are mainly divided into feature-based methods and deep learning-based methods. [Mihalcea and Strapparava \(2005\)](#) use automatic classification techniques to integrate humor-specific features (alliteration, antonymy, slang) and content-based features into a machine-learning framework for humor classification tasks. [Mihalcea et al. \(2010\)](#) divide the humor text into two components: the setup and the punchline. Humor recognition is performed by calculating the semantic correlation between the setup and the punchline based on the incongruity theory. [Morales and Zhai \(2017\)](#) use a generative language

model combined with background text resources to construct multiple features to identify whether a comment is a humorous text. [Liu et al. \(2018\)](#) combine discourse analysis and sentiment analysis to extract sentiment-related features to address humor recognition. [Xie et al. \(2021\)](#) developed uncertainty and superisal with the help of the prediction results of the pre-trained language model GPT-2. In recent years, with the development of deep learning, some deep learning-based methods have been proposed. [Chen and Lee \(2017\)](#) use convolutional neural networks to identify humor in the TED talks corpus. [Chen and Soo \(2018\)](#) used the highway network architecture to implement deep convolutional neural networks to predict humor on datasets of different types and different languages. [Weller and Seppi \(2019\)](#) used pre-trained BERT for the humor classification task. [Fan et al. \(2020\)](#) combine the Bi-GRU network with phonetic structure and ambiguity for humor recognition.

5 Experiments

5.1 Settings

We build a Support Vector Machine (SVM) classifier for humor classification. Experiments are performed on the SemEval 2021 Task 7¹ dataset modified by [Xie et al. \(2021\)](#). The dataset consists of a total of 3,052 labeled samples, half of which are humor and the other half are non-humor. The text of each sample in the dataset is split into two parts (the setup and the punchline). For each sample in the dataset, the lengths of the setup and the punchline are both below 20, and the percentage of alphabetical letters is greater than 75%, all of which start with alphabetical letters. We use Accuracy(Acc), Precision(P), Recall(R) and F1-Score(F1) as the evaluation metrics. P, R and F1 are macro-averaged. The experiments adopt 10-fold cross-validation, and the result is the average value of repeated experiments.

5.2 Baselines

Semantic similarity and semantic distance are the most commonly used text features, and we choose three such features as our baselines:

- **Path similarity** ([Rada et al., 1989](#)) is a similarity measure based on the shortest path, defined as follows:

$$\text{Sim}_{path} = \frac{1}{1 + D(c_1, c_2)} \quad (8)$$

¹<https://semeval.github.io/SemEval2021/>

where $D(c_1, c_2)$ represents the shortest path in WordNet between concepts c_1 and c_2 .

- **Disconnection** (Yang et al., 2015) is defined as the maximum distance between word pairs in the text.
- **Repetition** (Yang et al., 2015) is defined as the minimum distance between word pairs in the text.

In addition, we consider two GPT-2 based features proposed by Xie et al. (2021) as baselines. They feed the text into GPT-2 model to predict the next token. While predicting the tokens of y , GPT-2 produces a probability distribution v_i over the vocabulary.

- **Uncertainty** is obtained by calculating the average entropy of the probability distribution v_i on the vocabulary, defined as:

$$U(x, y) = -\frac{1}{|y|} \sum_{i=1}^n \sum_{w \in V} v_i^w \log v_i^w \quad (9)$$

where n represents the length of y and V is the vocabulary.

- **Surprisal** describes the degree of surprise when the language model generates the punchline, which is defined as follows:

$$\begin{aligned} S(x, y) &= -\frac{1}{|y|} \log p(y|x) \\ &= -\frac{1}{|y|} \sum_{i=1}^n \log v_i^{y_i} \end{aligned} \quad (10)$$

5.3 Predict Using Individual Features

Table 1 shows the results of individual feature prediction. Compared with the baselines, our proposed features QE-Uncertainty and QE-Incongruity achieve higher scores on all four metrics, with QE-Incongruity achieving the best results. In particular, compared with Uncertainty based on classical Shannon entropy, QE-Uncertainty under our quantum framework is greatly improved. This shows the necessity of quantum generalization for semantic uncertainty problems.

5.4 Boost a Content-Based Classifier

To demonstrate the effectiveness of our proposed features combined with content-based classifiers. We use the 50-dimensional GloVe (Pennington

Table 1: Experimental results of individual features. The results for features with an asterisk are reported by Xie et al. (2021).

et al., 2014) embedding as the baseline. We encode the setup and the punchline as the average of their respective word embeddings, resulting in two vectors with dimensions 50. Concatenate these two vectors with our features to form a vector with dimension 101. Finally, put it into an SVM classifier for humor classification. The results are shown in Table 2, our features achieve higher improvements on content-based classifiers compared to baselines.

Table 2: Experimental results of concatenating a content-based classifier. The results for features with an asterisk are reported by Xie et al. (2021).

GloVe+QE-U	0.8361	0.8363	0.8355	0.8359
GloVe+QE-I	0.8363	0.8365	0.8356	0.8360

5.5 Feature Visualization

Figure 2 shows the distribution histograms of the values of QE-Uncertainty and QE-Incongruity for the joke and non-joke samples. From the figure, it can be found that jokes have higher QE-Uncertainty and QE-Incongruity values than non-jokes, which is consistent with what we stated in Section 3.

6 Conclusion

In this paper, we model semantic uncertainty with a quantum framework. Inspired by the incongruity theory, we design two features, QE-Uncertainty and QE-Incongruity. We conduct experiments on the humor dataset, and the experimental results

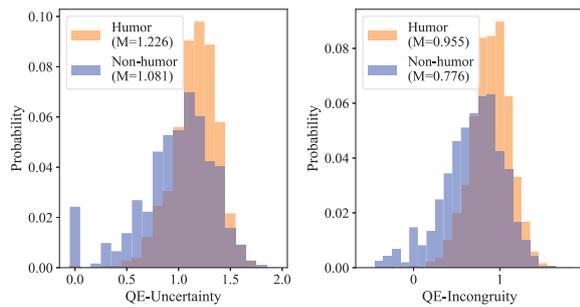

Figure 2: Histograms of our proposed features. The x-axis is the value of the feature, and the y-axis is the proportion of the feature in the total number of samples. **M** is the Median of the current feature.

demonstrate the effectiveness of our proposed features. This suggests that the density matrix is an excellent framework for describing uncertainty and that the quantum entropy of the density matrix is a better feature to distinguish jokes from non-jokes than previously proposed features. We believe that the quantum framework can also be used for semantic uncertainty modeling for other tasks in the future.

Limitations

In this paper, the density matrix representation of text is constructed in an averagely weighted manner, without considering the influence of weights on words. In addition, the density matrix as a text representation does not consider the position information of words. Furthermore, quantum generalization on the problem of multimodal humor recognition is also an interesting topic compared to unimodal humor recognition.

AdapterSoup: Weight Averaging to Improve Generalization of Pretrained Language Models

Alexandra Chronopoulou^{*†∇} Matthew E. Peters[‡] Alexander Fraser[∇] Jesse Dodge^{*‡}

[∇]Center for Information and Language Processing, LMU Munich, Germany

[∇]Munich Center for Machine Learning, Germany

[‡]Allen Institute for Artificial Intelligence, Seattle, WA

Abstract

Pretrained language models (PLMs) are trained on massive corpora, but often need to specialize to specific domains. A parameter-efficient adaptation method suggests training an adapter for each domain on the task of language modeling. This leads to good in-domain scores but can be impractical for domain- or resource-restricted settings. A solution is to use a related-domain adapter for the novel domain at test time. In this paper, we introduce *AdapterSoup*, an approach that performs weight-space averaging of adapters trained on *different* domains. Our approach is embarrassingly parallel: first, we train a set of domain-specific adapters; then, for each novel domain, we determine which adapters should be averaged at test time. We present extensive experiments showing that AdapterSoup consistently improves performance to new domains without extra training. We also explore weight averaging of adapters trained on the *same* domain with different hyper-parameters, and show that it preserves the performance of a PLM on new domains while obtaining strong in-domain results. We explore various approaches for choosing which adapters to combine, such as text clustering and semantic similarity. We find that using clustering leads to the most competitive results on novel domains.

1 Introduction

Large LMs are pre-trained using massive amounts of data in a self-supervised way (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Radford et al., 2019) and obtain general-domain knowledge. In order to adapt them to a new domain, continuing training using in-domain data has been shown to be helpful (Han and Eisenstein, 2019; Lee et al., 2020; Gururangan et al., 2020). To avoid fine-tuning all parameters, efficient methods such as domain-specific mixtures-of-experts (Gururangan et al., 2022) and

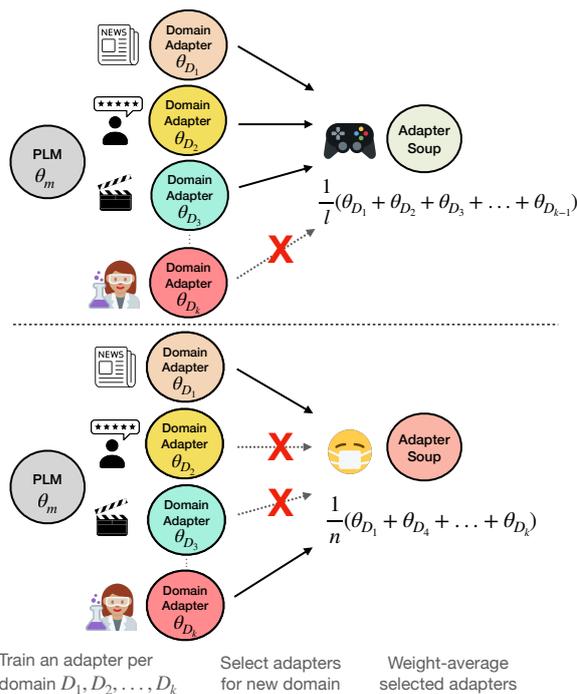

Figure 1: Illustration of AdapterSoup. Starting from the same random seed, an adapter is trained for each domain (*domain adapter*) on top of a PLM. AdapterSoup averages the weights of the adapters that are **most related** to the new domain to improve out-of-domain performance of a PLM at **test time**. The inference cost is independent of the number of adapters (l or n) used.

hierarchical domain adapters (Chronopoulou et al., 2022) have been proposed. Additional in-domain gains can be obtained using weight-space averaging (Wortsman et al., 2022a; Matena and Raffel, 2021). Motivated by this, we propose using weight-space averaging at test time to improve performance on *novel domains without extra training*.

Our approach, AdapterSoup, ensembles adapters in the *weight space* to improve performance on novel domains at test time without parameter updates. To this end, we train adapters on top of a PLM, each in a different domain. We compare several methods for selecting which adapters to

^{*}Correspondence to achron@cis.lmu.de or jessed@allenai.org

[†]Work done during an internship at Allen AI

use for each novel domain at test time and propose weight-space averaging models selected using text clustering. We find that AdapterSoup improves performance on novel domains. We also explore weight averaging adapters trained in the *same* domain, each with a different hyper-parameter configuration, and find that combining models trained with a low learning rate provides competitive in-domain scores, while averaging models trained with high learning rates performs similarly to a general-purpose PLM on novel domains.

Our contributions are the following: **1)** We propose combining domain-adapted PLMs at inference time using adapters. Our approach leads to consistent gains in novel domains. We compare several methods for choosing the models of the AdapterSoup, concluding that text clustering provides the best performance across all domains. **2)** We perform weight-space averaging of PLMs adapted to the same domain with varied hyper-parameters using adapters. We find that we can obtain competitive in-domain scores but also preserve the generalization ability of a PLM.

2 Proposed Approach

Problem Statement. Assuming we have a PLM adapted to k domains D_1, \dots, D_k , we want a model that performs well in a novel domain D_{k+1} without training more parameters. We use the provenance of a piece of text (that is, the *website* from which the text was scraped) as a proxy for *textual domain*. This follows Chronopoulou et al. (2022); Gururangan et al. (2022).

If we assume that we have a PLM fine-tuned on a single domain D_i with different hyper-parameters, we want to combine the fine-tuned models in order to both obtain good in-domain performance and preserve the generalization ability of the PLM to novel domains.

2.1 Cross-Domain AdapterSoup

An illustration of the cross-domain AdapterSoup is provided in Figure 1. Let $f(x, \theta_m)$ be a PLM with input data x and parameters $\theta_m \in \mathbb{R}^d$. We add adapters with a parameter initialization θ_α . While in this work we parameterize θ_α with adapters, our method is general and could be extended to other efficient fine-tuning methods. We only fine-tune the adapters, without updating the parameters θ_m of the PLM, for language modeling using cross-entropy loss. Let us assume that $\theta =$

$\text{FineTune}(\theta_m, \theta_\alpha, \phi, D)$ denote the parameters obtained by fine-tuning a PLM with adapters in a domain D , using hyper-parameters ϕ .

Let ϕ be a fixed hyper-parameter configuration. We vary only the *textual domain*. We first train k different adapters, one for each of the training domains. Then, we combine their weights:

$$\text{AdapterSoup}(x) = f\left(x, \frac{1}{l} \sum_{i=1}^l \theta_i\right), \quad (1)$$

i.e., we use the average of the parameters of l fine-tuned models, selected by one of the methods described in §2.3 ($l \leq k$). If $l = k$, this model is a *uniform soup* (Wortsman et al., 2022a).

2.2 Single-Domain AdapterSoup

In this setup, we want to learn an LM that performs well in a single training domain D , while *maintaining* the performance of the initial PLM θ_m in novel domains. To this end, we train adapters on the same domain, varying the *hyper-parameter configuration*. Each of the n models is optimized with different hyper-parameters ϕ_i , with $i \in 1, \dots, n$. We then compute the weight-space average following Equation 1, with $l = 3$. This is similar to logit ensembling, but only adds to the PLM the inference cost of a single adapter, while the added inference cost of logit ensembling scales linearly with the number of adapters.

2.3 Model Selection for AdapterSoup

In this section we describe two methods for selecting the combination of models to create our AdapterSoup (by weight-space averaging) which will be evaluated on a *novel* domain D_{k+1} . Following standard practice (Gururangan et al., 2022; Li et al., 2022) we use a small amount of validation data from the novel domain D_{k+1} for each of the below approaches. We note that we keep the test data unseen and only use it to perform our test-set evaluations.

Sentence similarity. We use pretrained sentence-BERT (Reimers and Gurevych, 2019), an approach that modifies BERT (Devlin et al., 2019) using siamese and triplet networks (Schroff et al., 2015) to obtain sentence embeddings. We compute the embeddings for 100 sentences from each of the training domains D_1, \dots, D_k , plus the novel domain D_{k+1} . Then we compute the average cosine similarity between each of D_1, \dots, D_k and D_{k+1} . We add up to 5 adapters to the AdapterSoup in order of highest cosine similarity (only considering models

Method	10 Evaluation Domains										Avg.

Table 1: Perplexity (\downarrow) scores on 10 evaluation domains. All single adapter and AdapterSoup experiments have the same inference cost; bold indicates the best perplexity for each novel domain and best average. We find that AdapterSoup using clustering as a selection method on average leads to the best out-of-domain performance.

trained on domains with cosine similarity greater than 0.15 to D_{k+1}). We experimented with several values to define the threshold (3, 5, 10, 15). We did not observe significant improvement when scaling up from 5 to 10 adapters and for that reason, we used up to 5 adapters in each AdapterSoup.

Domain clustering. Our domain clustering approach follows Aharoni and Goldberg (2020). We encode 100 sequences from each of the training domains using a PLM and fit a Gaussian Mixture Model (GMM) with 21 components (equal to the number of training domains), which gives us a domain clustering. We then use 100 sequences from our held-out set (not used for test-set evaluation) and find which clusters they are closest to. We add up to 5 adapters to the AdapterSoup in order of which clusters the most held-out domain text is mapped to. If at least 10% of the sequences of the D_{k+1} is mapped to the cluster of D_i , we add the model trained on D_i to the AdapterSoup.

In-domain. To select the models that perform best in-domain, we exhaustively combine all models trained on a single textual domain (in this case, text found in the website *booking.com*), using combinations of size 3. Each model has been trained with a different hyper-parameter configuration. Specifically, we vary the learning rate and data order. We compare them to the best-performing single model per domain and to a uniform soup.

3 Experimental Setup

Datasets. We assume that text found in a specific website (e.g., *tripadvisor*) can be used as a proxy of a textual domain. We use 21 training domains and 10 evaluation domains (text from 21 and 10 websites accordingly) from the released version

(Dodge et al., 2021) of C4 (Raffel et al., 2020) (details in the Appendix). We hypothesize that the variety of training domains plays an important role in this setting. We randomly sampled domains that belong to the 100 high-resource domains of C4, but further work could consider using M2D2 (Reid et al., 2022), a multi-domain language modeling dataset released concurrently to this work.

Model Architecture. We use GPT-2 (Radford et al., 2019); specifically, we use a publicly available pretrained checkpoint of the small version, i.e., gpt2 from the HuggingFace library (Wolf et al., 2020). We add an adapter to each Transformer (Vaswani et al., 2017) layer after the feed-forward layer. We train only the adapters for language modeling in each training domain. The adapters follow the Bapna and Firat (2019) architecture and have bottleneck size 64. For the cross-domain AdapterSoup, we train all models with an initial learning rate $1e-4$. For the single-domain AdapterSoup, we use different learning rates and data seeds shown in the Appendix.

4 Results

Results are presented in Table 1. For each experiment, we evaluate both perplexity and efficiency.

4.1 Cross-domain

As a first baseline, we use *GPT-2 (zero-shot)*, without further training or additional parameters. This has worse perplexity than all other approaches but is most efficient at inference.

Single Adapters. We then evaluate *Sentence similarity* and *Clustering* in the scenario where only a single adapter is chosen using each approach (this can be thought of as a soup of size 1). This is an

evaluation of how well these two approaches measure similarity between the novel domain D_{k+1} and the training domains; this baseline shows the performance of a single model which can be directly compared to AdapterSoups. Both approaches are significantly better than GPT-2 (zero-shot), and *Clustering* outperforms *Sentence similarity*, suggesting it is better at identifying related domains.

AdapterSoup. We evaluate three types of *AdapterSoup* which differ only in how the models added to the soup are selected. All three are equally as efficient at inference as using a single adapter. *Uniform* is a uniform soup (weight-averaging all trained models). This performs worse than all approaches except GPT-2 (zero-shot); we hypothesize that it performs worse due to negative interference between adapters trained on unrelated domains. Using *Sentence similarity* as described in §2.3 leads to marginally better scores than the single-best adapter per domain, indicating even relatively naively-created soups can outperform the best (oracle) single model. On 8/10 novel domains, the sentence similarity AdapterSoup outperforms the single adapter chosen by Sentence similarity, indicating that the soup leads to better performance. Next, using *Clustering* as described in §2.3 leads to perplexity improvements in 8/10 novel domains compared to sentence similarity, indicating that the method for selecting models for the soup has a large impact. On 9/10 novel domains, the Clustering AdapterSoup outperforms the single adapter chosen by clustering, indicating that our approach leads to better performance.

Oracle Experiments and Larger Models. *Best adapter per domain* shows the performance of the single-best adapter on each novel domain. This is the upper bound for a single adapter, and we see that our *Single Adapter Chosen Using Clustering* matches these scores on 3/10 novel domains, and is close on the rest, suggesting the clustering approach is reasonably good. *Clustering + 2 best* shows the performance of adding the two (oracle) best models to our AdapterSoup made by clustering; our clustering approach is close to these scores, but there is room for future work on better choosing models for the AdapterSoup. *Hierarchy adapter* is taken from Chronopoulou et al. (2022), and is less efficient in terms of both data and parameters.

Selecting Models for the Soup. We qualitatively compare the selection methods for choosing adapters to include in the AdapterSoup for 3 novel

Novel Domain i	Sentence Sim.	Clustering

- lr $1e-4$	10.4	27.4	30.0	48.9
Best AdapterSoup:				
- in-domain	10.0	26.3	29.1	47.5
- out-of-domain	26.8	22.9	24.5	37.3
Logit ensemble	9.2	25.0	27.7	47.7

Table 3: Perplexity scores in- and out-of-domain (respectively ID and OOD) of models trained on *booking.com*. Low learning rates lead to good in-domain scores, while high learning rates improve the out-of-domain performance.

domains in Table 2. In the case of *tripadvisor*, 2/3 domains *Sentence similarity* and *Clustering* select are identical, while for *ncbi* (science domain) both methods select the same domains. When selecting domains similar to *reuters* (news), clustering seems to find a good match, choosing news domains. However, *Sentence similarity* selects domains that are not quite as related to the novel domain. *Reuters* contains heterogeneous data, so the average cosine similarity on the sentence level is not a suitable metric to find related domains.

4.2 Single-domain

In this section we evaluate how models trained on the same domain can be combined into an AdapterSoup. We train a set of models using adapters on *booking.com* by varying the data order and the learning rate (see Appendix A.3, note our experiments kept the initialization of each adapter fixed), then evaluate all combinations of adapters of size 3, and evaluate the performance of the AdapterSoup both in-domain (*booking.com*) and on 3 held-out domains. We explore this controlled setting to bet-

ter understand the setup described in [Wortsman et al. \(2022a\)](#), who also noted that the learning rate is important; their experiments indicated that smaller learning rates led to better model soups.

Our experiments in Table 3 show a more nuanced result: AdapterSoups made from adapters trained with small learning rates ($5e-4$) performed best in-domain (confirming the result from [Wortsman et al., 2022b](#)), but AdapterSoups made from adapters trained with larger learning rates ($7e-3$, $4e-3$, and $7e-4$) generalize better to novel domains. The number of updates for each adapter is the same, and they all have the same initialization, so we hypothesize that AdapterSoups made from small learning rates act similarly to averaging across steps in gradient descent, leading to a model that is closer to a local optimum. As for why larger learning rates leads to better generalization to novel domains, we hypothesize that each model in the AdapterSoup travels a farther distance from the initialization, leading to learning somewhat more diverse representations. We leave further exploration to future work.

5 Related Work

As training large models from scratch has a severe computational and environmental cost ([Strubell et al., 2019](#); [Dodge et al., 2022](#)), efficient methods such as mixtures-of-experts (MoE) ([Shazeer et al., 2017](#); [Fedus et al., 2021](#); [Artetxe et al., 2022](#)), adapters ([Rebuffi et al., 2017](#); [Houlsby et al., 2019](#); [Pfeiffer et al., 2020](#)), and LoRA layers ([Hu et al., 2022](#)) have recently been proposed. Both adapters and MoEs have shown to work well for domain adaptation ([Cooper Stickland et al., 2021](#); [Gururangan et al., 2022](#); [Chronopoulou et al., 2022](#)). The hierarchy adapter ([Chronopoulou et al., 2022](#)) outperforms our approach but is significantly more expensive. It adds a training cost of $4Ld_{\text{model}}dT$ (following [Kaplan et al., 2020](#)) over the cost of running GPT-2 for a model with L layers, dimension d_{model} , adapter bottleneck size d , average tree depth T ($T = 8$ in the hierarchy adapter paper), while AdapterSoup needs $4Ld_{\text{model}}d$ flops. As a result, training the hierarchy adapter is a factor of T slower than our approach. At inference time, the hierarchy adapter activates 2 paths in the tree and invokes a cost $4Ld_{\text{model}}dT \times 2$, i.e., inference is a factor of $2T$ slower than our approach.

Averaging *weights* of models independently fine-tuned on the same task ([Wortsman et al., 2022a](#)) has shown to improve in-domain performance. [Matena](#)

and [Raffel \(2021\)](#) weight-average fine-tuned PLM models using Fisher merging to avoid intermediate task training and then perform downstream fine-tuning. [Wang et al. \(2022\)](#) fine-tune MoEs using adapters on a downstream task and average their weights at test time. Our paper, however, focuses on improving test-time scores of a model on *novel* domains.

[Wang et al. \(2021\)](#) improve performance in an unseen (target) language by ensembling the source language adapter and language adapters similar to the target language. This approach uses weighted ensembling of the *outputs* of adapters, whereas we ensemble the *weights* of the adapters. AdapterSoup has the inference cost of a single adapter, while [Wang et al. \(2021\)](#) require inference time that scales linearly to the number of adapters.

Contemporaneous work ([Li et al., 2022](#)) also explores performance in novel domains using weight averaging, but uses MoEs instead of adapters.

6 Conclusion

A PLM can be adapted to new domains using adapters. However, this requires training a new set of adapters for each domain. We propose a method based on weight-space averaging of adapters selected using text clustering. Our approach improves performance on novel domains without updating parameters or increasing the inference cost. Future work could explore more sophisticated selection methods to try to match the performance of the oracle experiments.

Limitations

The conclusions we draw in this work about how our approach compares to other approaches (e.g., our baselines) are only supported by evidence on the task of language modeling, with textual domains taken from the C4 dataset. We expect such results to hold more generally, but do not have experimental evidence to support any other scenarios. As with all work on language modeling, the models we have trained could be used to generate language, but we do not have evaluations of generated text (e.g., on fluency, factuality, or other common metrics used to evaluate generated language). Our paper focuses on using adapters; while we expect similar approaches to work for other types of models, we only have evidence to support AdapterSoup working for adapters.

Acknowledgements

We thank Ayyoob Imani for feedback on the final version of the paper and Jonas Pfeiffer for helpful discussions. We also thank Mitchell Wortsman and Ludwig Schmidt for preliminary comments on the first version of this idea.

A Appendix

A.1 Training details

We build our code using PyTorch (Paszke et al., 2019) and the HuggingFace library (Wolf et al., 2020). Each model is trained on a single NVIDIA A100 GPU with 40GB of RAM, batch size 64 and gradient accumulation over 5 steps. We train each model for 20 epochs, without using early stopping. We compute semantic similarity using sentence-transformers¹ and a publicly available pretrained model.²

We noticed from preliminary experiments that the choice of random seed is important when averaging weights of domain adapters. We empirically found that averaging domain adapters initialized from different random seeds led to poor performance of AdapterSoup. We suggest initializing the adapters from the same random seed in order to effectively combine adapters trained on various domains.

A.2 Dataset sizes

We use textual corpora from 31 of the 100 most high-resource internet domains of C4. The sizes of the training domains are shown in Table 4, while the sizes of the evaluation domains are shown in Table 5.

A.3 Single-domain AdapterSoup

We present the hyper-parameters we tried in Table 6. In this setup, we computed in- and out-of-domain scores for 455 different combinations (there are 15 models and computed all AdapterSoups of size 3). The trend we observed is that higher learning rates improved results out-of-domain, while lower learning rates provided the best in-domain scores.

A.4 Cross-domain AdapterSoup

We present in Table 7 the evaluation scores of each of the single adapter models. Each adapter has been trained in a different training domain (column 1), and evaluated in 10 novel domains.

Abstract

In open-retrieval conversational machine reading (OR-CMR) task, machines are required to do multi-turn question answering given dialogue history and a textual knowledge base. Existing works generally utilize two independent modules to approach this problem's two successive sub-tasks: first with a hard-label decision making and second with a question generation aided by various entailment reasoning methods. Such usual cascaded modeling is vulnerable to error propagation and prevents the two sub-tasks from being consistently optimized. In this work, we instead model OR-CMR as a unified text-to-text task in a fully end-to-end style. Experiments on the ShARC and OR-ShARC dataset show the effectiveness of our proposed end-to-end framework on both sub-tasks by a large margin, achieving new state-of-the-art results. Further ablation studies support that our framework can generalize to different backbone models.

1 Introduction

In a multi-turn dialogue comprehension scenario, machines are expected to answer high-level questions through interactions with human beings until enough information is gathered to derive a satisfying answer (Zhu et al., 2018; Zhang et al., 2018; Zaib et al., 2020; Huang et al., 2020; Fan et al., 2020; Gu et al., 2021). As a specific and challenging dialogue comprehension task, conversational machine reading (CMR) (Saeidi et al., 2018) requires machines to understand the given user's initial setting and dialogue history before the machine itself is able to give a final answer or inquire for more clarifications according to rule texts (see Figure 1).

In terms of acquisition of rule texts which are the main reference for tackling the CMR, there

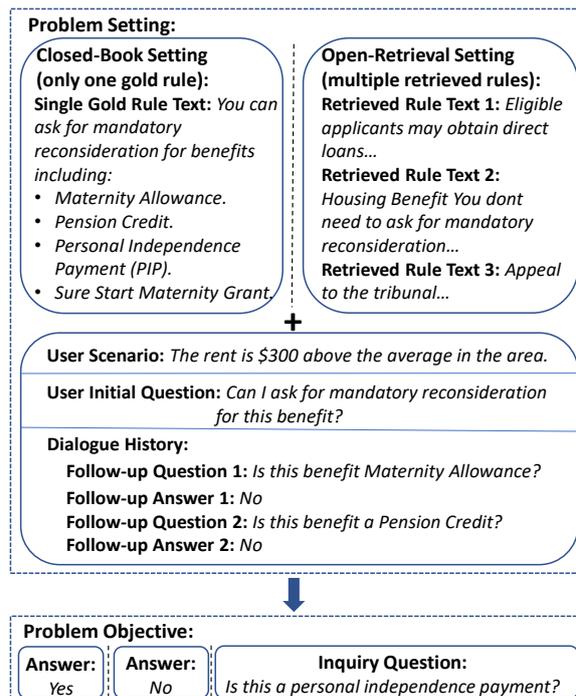

Figure 1: CMR and OR-CMR Task Overview

is closed-book setting where the rule texts are all given and there is correspondingly open-retrieval setting where the rule texts need to be retrieved from a knowledge base (Gao et al., 2021) (see Figure 1). In terms of problem objectives, current approaches in general divide the targets into two categories, one as decision making and one as question generation (Zhong and Zettlemoyer, 2019; Lawrence et al., 2019; Verma et al., 2020; Gao et al., 2020b,c). For decision making sub-task, the machine is required to give decisions to directly answer the user question which concludes the dialogue or generate clarifying questions which continues the dialogue. For question generation sub-task, the machine is required to generate the clarifying questions that are essential to the later final decision making. Following this line of approaching the CMR task, a variety of works

have been proposed mainly based on modeling the matching of elementary conditions (Henaff et al., 2017; Zhong and Zettlemoyer, 2019; Lawrence et al., 2019; Verma et al., 2020; Gao et al., 2020b,c; Ouyang et al., 2021; Zhang et al., 2021) in either a sequential encoding or graph-based manner.

However, by tackling the CMR task with two divided sub-tasks, the corresponding division of the optimization on decision making sub-task and the optimization on the question generation sub-task may result in problems including error propagation, thus hindering further performance advance. Ouyang et al. (2021) has shown that transferring some knowledge between the training of two sub-tasks is beneficial for better performance. However, reducing the gap between two sub-tasks to achieve an end-to-end optimization CMR task still needs further and more comprehensive attempts.

In this work, we propose a completely Unified end-to-end framework for Conversational Machine Reading tasks (UNICMR¹) to tackle the division of optimization challenge by formulating the CMR/OR-CMR task into a single text-to-text task. Our contributions are summarized as follows:

(i) We completely unify two sub-tasks of OR-CMR into a single task in terms of optimization, achieving a fully end-to-end optimization paradigm.

(ii) Experimental results on the OR-ShARC dataset and ShARC dev set show the effectiveness of our method, especially on the question generation sub-task with a relatively small amount of parameters. Furthermore, our method achieves the new state-of-the-art results on all sub-tasks.

(iii) By further ablation studies, we have shown that our proposed framework largely advances the decision making performance, and reduces error propagation thus boosting the question generation performance. We have also shown that our proposed framework can generalize to different backbone models. Qualitative analysis including case study has further verified the effectiveness of our framework.

2 Related Work

2.1 Conversational Machine Reading

The mainstream of research on the conversation-based reading comprehension task focuses on either the decision making (Choi et al., 2018;

Reddy et al., 2019; Sun et al., 2019; Tao et al., 2019; Cui et al., 2020; Yang et al., 2020) or the follow-up utterance generation (Wu et al., 2019; Bi et al., 2019; Ren et al., 2019; Gao et al., 2020a). However, the decision making centered approaches leave out cultivating the machine’s capability to reduce the information gap by clarifying interactions. While the question generation centered approaches neglect exploring the machine’s capability to concentrate on target-oriented information and make vital decisions. In contrast, our work focuses on a more challenging conversation-based reading comprehension task called conversational machine reading (CMR) task (Saeidi et al., 2018; Gao et al., 2021), which requires machines to make decisions and generate clarifying questions in a dialogue given rule texts and user scenarios.

2.2 Open-Retrieval CMR

Most of the current studies on CMR concentrate on the closed-book setting of CMR where the essential reference for the final decision, a piece of rule text corresponding to each dialogue, is given (Zhong and Zettlemoyer, 2019; Verma et al., 2020; Gao et al., 2020b,c). One typical example benchmark is called ShARC (Saeidi et al., 2018). However, in a more realistic and also more challenging setting, the machine is required to retrieve rule texts based on different scenarios. Similar to the open domain question answering setting where the supporting texts are retrieved from external documents to answer factoid questions (Moldovan et al., 2000; Voorhees and Tice, 2000), open-retrieval conversational machine reading (OR-CMR) task is established by requiring the machine to retrieve useful information from a given knowledge base composed of rule texts. In contrast to most of the previous works on CMR, we focus on OR-CMR in pursuit of a more realistic and more challenging setting.

2.3 Joint Optimization of CMR

Existing studies generally approach conversational machine reading task by separating it into two sub-tasks (Zhong and Zettlemoyer, 2019; Verma et al., 2020; Gao et al., 2020b,c), decision making and question generation. Therefore, existing approaches generally focus on different methods to extract the fulfillment of rule-related conditions and conduct explicit entailment reasoning on tracking the conditions in the dialogues. This includes applying attention mechanisms on the sequentially

¹Our source codes are available at <https://github.com/KevinSRR/UnicMR>.

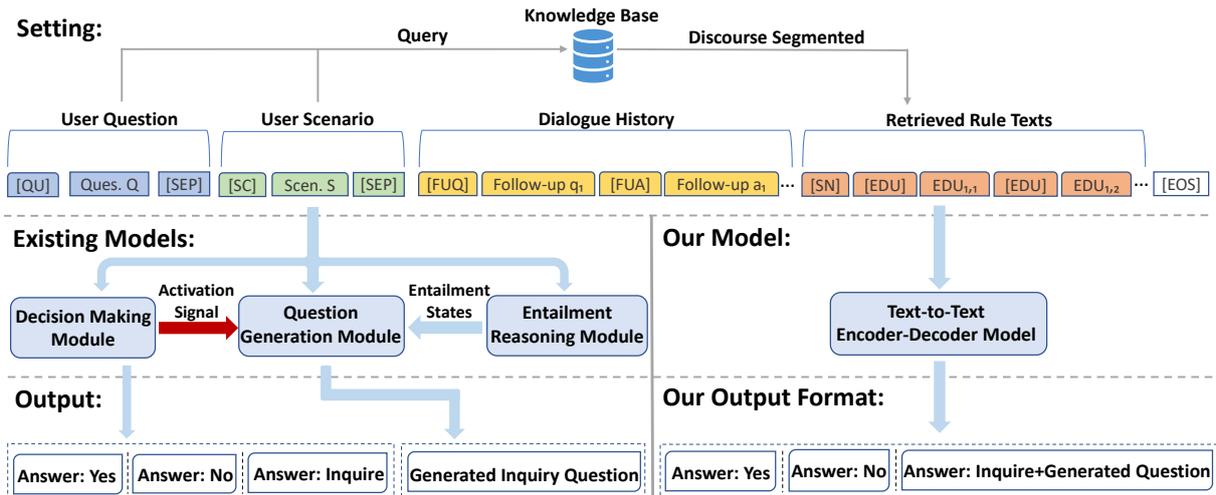

Figure 2: The overall framework for our proposed model (bottom right part) compared with the existing ones (bottom left part). Note that the ways of preprocessing the problem setting input vary from model to model, but they are generally similar. And the setting part only shows our preprocessing overview. Also note that [QU], [SEP], [SC], [SEP], [FUQ], [FUA], [SN], [EDU] are added special tokens while [EOS] is the end-of-sequence token for encoder-decoder model.

encoded user setups and the dialogue (Zhong and Zettlemoyer, 2019; Lawrence et al., 2019; Verma et al., 2020; Gao et al., 2020b,c) and extract discourse structures for better fulfillment matching (Ouyang et al., 2021).

However, one of the major challenges emerges as the division of the optimization of decision making sub-task and the optimization of the question generation sub-task. Zhang et al. (2021) have taken the initial attempt to mitigate the division between two sub-tasks by considering the encoded hidden states from decision making in question generation module. However, it still lacks synergy of optimization and relies on separate feature extractions including the entailment reasoning. In contrast, our work approaches the conversational machine reading task by unifying the two sub-tasks into one, enabling an end-to-end joint model optimization on both the decision making target and question generation target.

3 Problem Formulation

As shown by Figure 1, in traditional CMR task, the machine will be given: user scenario S , user initial question Q , a gold rule text R , and dialogue history $D := \{(q_1, a_1), (q_2, a_2), \dots, (q_n, a_n)\}$ which consists of n follow-up question-answer pairs. The machine is required to do the two sub-tasks:

- **Decision Making.** The machine makes a decision to either answer the user initial question

with *Yes* or *No*, or give *Inquire*² which activates the second sub-task to generate the inquiry question for more clarification.

- **Question Generation.** The machine generates an inquiry question aimed at essential clarifications to answer the user’s initial question.

Beyond CMR, open-retrieval conversational machine reading (OR-CMR) (Gao et al., 2021) further mimics the more challenging second scenario, which is the focus of this work. As shown by Figure 1, the difference between the CMR and OR-CMR lies in the rule text part R . In CMR, the machine is provided with a gold rule text in a closed-book style. While in OR-CMR, the machine needs to retrieve rule texts from a knowledge base in an open-retrieval style alternatively. The machine is given a knowledge base B containing rule texts. Therefore, under the OR-CMR setting, the machine needs to first retrieve m rule texts R_1, R_2, \dots, R_m to complete the input for the same downstream decision making and question generation sub-tasks.

4 Framework

Our model is composed of two main modules: a retriever and a text-to-text encoder-decoder model.

²For the completeness of the conversational machine reading task, there is an additional decision making answer *Irrelevant* which states that the user question is unanswerable. This is the case for CMR task. However, in our work, we mainly follow the setting of OR-CMR and assume that no such answer will be encountered.

The retriever is applied to retrieve rule texts R_1, R_2, \dots, R_m from a given knowledge base B . The text-to-text encoder-decoder model will take in the preprocessed textual input and generate the textual answer directly as a whole. Subsequent extraction methods will be applied for decision making and question generation sub-tasks to obtain the predictions for each sub-task respectively.

4.1 Retriever

To obtain the rule texts, the user scenario S and user initial question Q are concatenated as the input query to the retriever. Our retriever employs the MUDERN TF-IDF-based method (Gao et al., 2021), which takes account of bigram features and scores the similarity between rule texts and queries in the form of bag-of-words vectors weighted by the TF-IDF model. Top-scored m rule texts R_1, R_2, \dots, R_m will then be chosen for the following text-to-text encoder-decoder model.

4.2 Text-to-Text Encoder-Decoder

One of the major challenges of the CMR or OR-CMR task is the division of sub-task optimizations. Motivated by T5 (Raffel et al., 2020) which formulate several traditional NLP tasks into a unified text-to-text generation task, we unify the two sub-tasks by formulating the input and output to our encoder-decoder model as follows.

4.2.1 Input Formulation

Discourse Segmentation. We employ the discourse segmentation approach (Shi and Huang, 2019) to parse the retrieved rule texts into explicit conditions for the model. After discourse segmentation, each retrieved R_i is parsed into N_i elementary discourse units (EDUs) $EDU_{i,1}, EDU_{i,2}, \dots, EDU_{i,N_i}$. Formulation of the final input I is shown by the setting part in Figure 2.

4.2.2 Output Formulation

The output of the text-to-text encoder-decoder will be a sequence of textual tokens $O := \{o_1, o_2, \dots, o_k\}$ where the length k is determined by the model itself but within the maximum generation length hyperparameter. To extract the prediction of the decision making sub-task and the question generation sub-task respectively, we assume the first output token o_1 is model’s prediction, and the following tokens $\{o_2, \dots, o_k\}$ are the generated

follow-up question, which is only meaningful when o_1 represents the *Inquire* decision.

4.2.3 Training Objective

In training stage, the labels $Y := \{y_1, y_2, \dots, y_k\}$ are formulated as: {Yes Token, [EOS]}, {No Token, [EOS]}, and {*Inquire* Token, Follow-up Question Tokens, [EOS]}.³ The training objective is defined as:

$$\mathcal{L} = - \sum_{j=1}^k \log P(y_j | y_{<j}, I; \theta), \quad (1)$$

where I is the input to our encoder-decoder model and θ is all the parameters of our model.

5 Experiments

5.1 Experiment Setups

Datasets. Our training and evaluation is based on the OR-ShARC dataset (Gao et al., 2021). Original dataset ShARC (Saeidi et al., 2018) contains 948 dialogues trees which is then flattened into 32,436 examples with entries composed of rule documents, user setups, dialogue history, evidence, and decision. Derived from ShARC, OR-ShARC modifies the *initial question* to be self-contained and to be independent of gold rule texts. Then the gold rule texts are removed to form the knowledge base B of 651 rules. The train and dev set of ShARC are further split into train, dev, and test set, with sizes 17,936, 1,105, and 2,373, respectively.

The dev and test set each satisfies that around 50% of examples ask questions based on the rule texts used in training (seen) and the remaining asks questions based on the unseen rule texts in training. This feature of the datasets aims to mimic more realistic scenario where user may asks questions on information that the machine has encountered or has never encountered (Gao et al., 2021).

Evaluation Metrics. For decision making sub-task, the evaluation is Micro- and Macro- Accuracy of the decisions. For question generation sub-task, we adopt the $F1_{BLEU}$ (Gao et al., 2021) which calculates the F1 score with precision of BLEU (Papineni et al., 2002) when the predicted decision is *Inquire* and recall of BLEU when the ground truth decision is *Inquire*.

³To make sure Yes Token, No Token and *Inquire* Token have the same length after tokenization, we set the valid tokens of “1”, “2” and “3” to serve as Yes Token, No Token and *Inquire* Token respectively without loss of generality.

Implementation Details. Following the MUDERN model, we employ T5 as our text-to-text encoder-decoder model and initialize the model with the pretrained T5-base and T5-large weights⁴. For the main model either base or large, we set the max generation length as 30, number of beams in generation as 5, and use the first 8 top scored retrieved rule texts in preparing input. The training process utilizes AdamW (Loshchilov and Hutter, 2017) optimizer for 16 epochs with a learning rate of 3e-5. Max gradient norm of 1 is used to conduct gradient clipping. The batch size is 4 with a gradient accumulation step as 8. Random seeds 19, 27, and 95 are applied. Experiments are conducted in two RTX TITAN GPU’s with 24G memory⁵. In training stage, the model with best F1_{BLEU4} score on dev set is kept.

⁴<https://huggingface.co/t5-base>, and <https://huggingface.co/t5-large>, respectively.

⁵Average training run time for UNICMR_{large} is approximately 12 hours with one GPU. Average inference run time for UNICMR_{large} is approximately 10 minutes on dev set and 21 minutes on test set with one GPU.

5.2 Quantitative Results

The effectiveness of our proposed method is verified on both the OR-ShARC and the original ShARC datasets. In addition, we compare the number of parameters with related studies. Tables 1-3 present our main experimental results. We will discuss our findings in the following part.

5.3 Decision Making and Question Generation performance on OR-ShARC.

Referring to our results reported in Table 1, our large unified model has achieved new SOTA question generation performance in both dev and test sets by a large margin. In terms of decision making results, our large model lags behind in the dev set but prevails in the test set performance by maintaining a stable and consistent performance when transferring from dev set to test set.

5.4 Performance on ShARC.

As a reference, the performance of the UNICMR_{large} together with the current SOTA model OSCAR on the dev set of ShARC is reported on Table 2. Note that, in contrast with OR-ShARC (Gao et al., 2021), ShARC benchmark (Saeidi et al., 2018) is in the closed-book setting with the evaluation metric of the question generation sub-task as BLEU. Based on the results in Table 2, it can be seen that UNICMR_{large} maintains a new SOTA performance on dev set by a large margin for both the decision making and the question generation sub-tasks. This shows our unified method is effective for the model’s performance

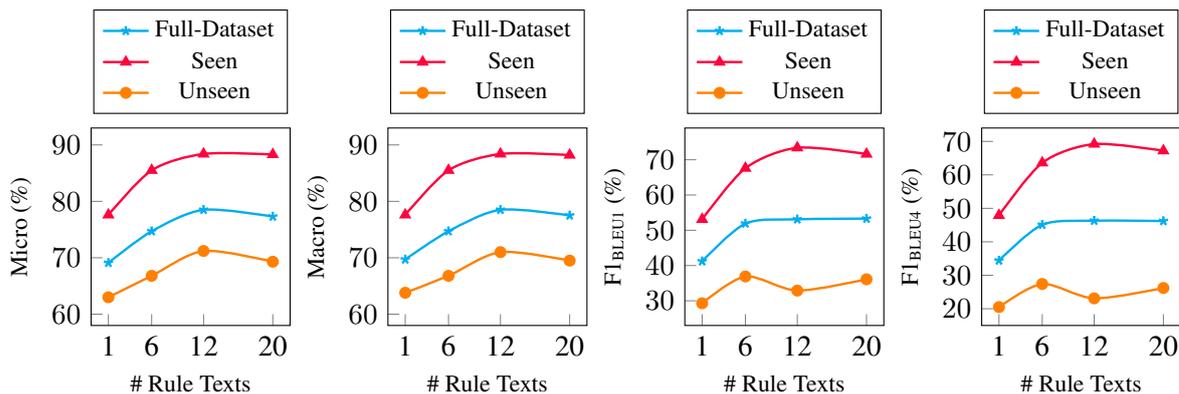

Figure 3: Evaluation performance of our model under different number of retrieved rule texts on test set.

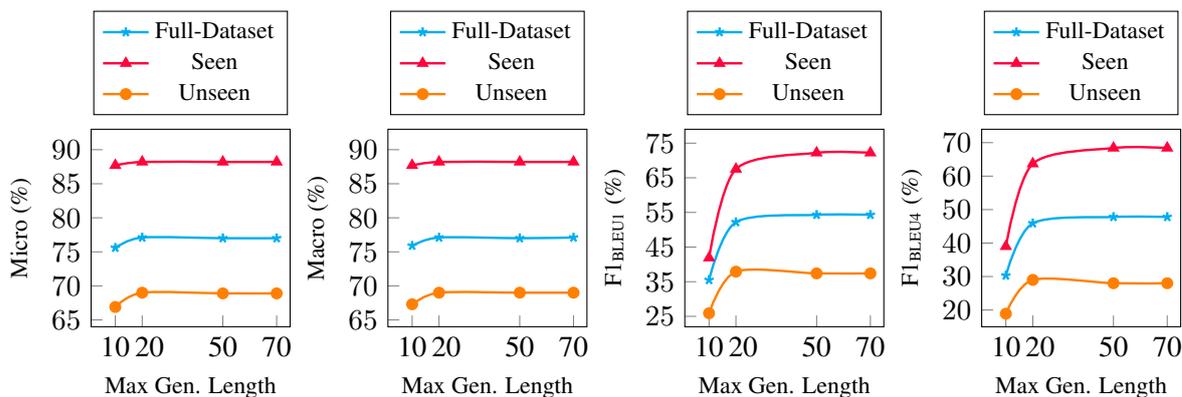

Figure 4: Evaluation performance of our model under different max generation length on test set.

beyond OR-ShARC.

	DISCERN	OSCAR	UNICMR (base/large)
#Param.	330M	1100M	220M/770M

Table 3: The comparison of approximate number of parameters of some current models.

5.5 Comparison of Model Parameter Numbers.

We have approximated total parameters of current high performance models. The information is shown in Table 3. By comparison of the parameter numbers used in current high performance models in Table 3, our UNICMR_{large} (based on T5-large) uses around 770M parameters which generally prevails the current SOTA model OSCAR using around 1100M parameters. Our UNICMR_{base} (based on T5-base) uses 220M parameters but prevails models like DISCERN which uses around 330M parameters. UNICMR_{base} also achieves a close performance to OSCAR in terms of question generation. The above observations verify that our method of unifying optimizing the two sub-tasks

is effective, which enables each sub-task to benefit from the optimization of the other task.

6 Analysis

6.1 Number of Retrieved Rule Texts

The model performance under different choices of the number of retrieved rule texts is shown in Table 7 in Appendix B whose visualization is shown by Figure 3. We see that generally, when the number of rule texts increases, there will be more information which improves our model while also introducing more noise which harms our model. In terms of decision making, our model is quite stable in seen test dataset when the number of rule texts varies. That means our model well captures the useful and trash conditions in rule texts and fulfillment states in dialogue history in the training stage. Besides, The unusual boost of question generation performance in the unseen test set might suggest that using more than the necessary number of rule texts possibly pushes the model to gain more power of generalization in the training stage.

Model	Dev Set				Test Set

UNICMR _{large}	77.7	78.0	59.3	52.8	76.7	76.7	54.2	47.9
Closed-Book	82.1	82.1	67.8	62.8	79.4	79.5	60.5	54.8
w/ DPR++	76.8	77.4	56.8	50.4	75.2	75.2	54.8	48.8
w/o Retriever	71.0	70.9	42.1	35.2	65.8	65.7	35.2	28.7

Table 4: Results of our UNICMR_{large} and UNICMR_{large} with different retriever module setting on the dev and test sets of OR-ShARC benchmark. For Closed-Book setting, the OR-ShARC is turned into a closed-book setting by given the rule texts. For w/ DPR++ setting, the TF-IDF retriever is replaced with DPR++ retriever. For w/o Retriever setting, the OR-ShARC is approached without rule texts.

6.2 Maximum Generation Length

The model performance under the different choices of the maximum generation length is shown in Table 8⁶ in Appendix B whose visualization is shown by Figure 4.

In terms of decision making and question generation, redundant max generation length will not affect the performance of the model but insufficient max generation length will limit the model performance. This means the model well learns the difference between different forms of answers and is able to generate answers of suitable length accordingly. This verifies the feasibility of our end-to-end framework design.

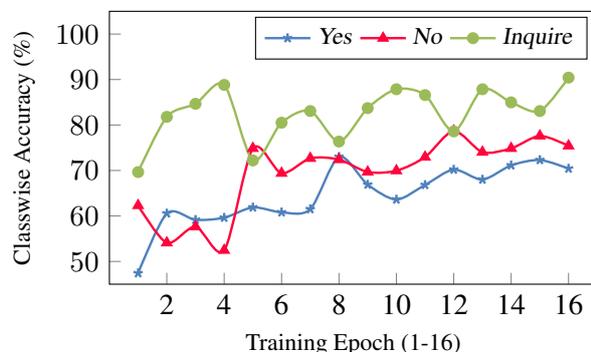

Figure 5: Classwise accuracy on dev set of each epoch.

6.3 Generation Quality Gain Across Training

The classwise accuracy evaluated in the training of the decision making sub-task is shown by Figure 5. By the initial gap between the accuracy for

⁶In Table 7, the hyperparameter m (number of retrieved rule texts) is varied to compare our model performance on the OR-ShARC test set, test set seen and test set unseen divisions respectively. In Table 8, the hyperparameter maximum generation length of the backbone encoder-decoder model is varied to compare our model performance on the same datasets. The corresponding performance of the above two experiments on dev set is shown by Table 9 and Table 10 in Appendix B for reference. Note in these experiments, all the hyperparameters remain the same unless explicitly stated.

“Inquire” and the accuracy for other decisions, our model tends to predict the decision as *Inquire* and generate question when not well fine-tuned. This is due to a gap between the length for the answer *Yes/No* and the length for the answer “*Inquire+Generated Question*”. And also the innate property of pre-trained T5 generation model before well fine-tuned at the beginning which is hence biased towards the longer answer. As the training continues, the accuracy for *Yes* and *No* gradually catches up with *Inquire* even though is slightly lower. This observation shows the existence of the bias of our backbone model and also the effectiveness of our training which large reduces such bias. This also suggests future improvements on more targeted training to eliminate the bias and lessening the discontinuity between the length of output for *Yes/No* and the length of output for “*Inquire+Generated Question*”.

6.4 Contribution of the Retriever Module

To quantify the contribution of the retriever module, we conducted an additional experiment where OR-ShARC is turned into a closed-book setting (see Closed-Book in Table 4). Also, we replaced the TF-IDF retriever with the DPR++ retriever introduced in UNICMR_{large} for reference (see w/ DPR++ in Table 4). Performance of UNICMR_{large} without retriever is also shown (see w/o Retriever in Table 4). The results verify that using the retrieval is beneficial, which reduces the gap between the challenging open-retrieval task and the closed-book task with gold rule texts.

6.5 Discussions of Performance Improvement

To further investigate the source of performance improvement of our method, more comprehensive experimental results are shown here following the deduced conclusions.

First, UNICMR’s unified training format advances the performance of training T5 separately

Model	Dev Set				Test Set			
	BLEU1	BLEU4	F1 _{BLEU1}	F1 _{BLEU4}	BLEU1	BLEU4	F1 _{BLEU1}	F1 _{BLEU4}
<i>w/ T5-large</i>								
UNICMR	67.5	59.1	59.3	52.8	55.8	48.3	54.2	47.9
QG-only whole-evaluation	53.3	47.5	49.5	43.1	45.2	40.1	47.0	39.7
QG-only partial-evaluation	71.1	61.0	47.9	40.8	69.4	59.5	45.8	38.9
<i>w/ BART-base</i>								
UNICMR	58.4	50.2	52.3	45.1	47.3	40.2	46.9	39.8
QG-only whole-evaluation	62.6	51.4	44.1	37.3	60.4	48.9	40.3	33.5
QG-only partial-evaluation	69.2	57.7	43.3	35.3	66.8	56.7	39.9	33.3

Table 5: Question generation performance of UNICMR compared with models trained only on question generation sub-task on OR-ShARC. For QG-only whole-evaluation setting, we use all samples by assigning empty generated question to samples with Yes/No decisions. For QG-only partial-evaluation setting, we use samples only with inquiry questions. The results are generally divided into two parts, one using T5-large as backbone model and one using BART-base as backbone model.

Model	Dev Set		Test Set	
	Micro	Macro	Micro	Macro
<i>w/ T5-large</i>				
UNICMR	77.7	78.0	76.7	76.7
DM-only	73.9	73.7	72.9	72.3
<i>w/ BART-base</i>				
UNICMR	74.8	75.7	71.5	71.8
DM-only	72.5	72.4	68.6	68.3

Table 6: Decision making performance of UNICMR compared with models trained only on decision making sub-task on OR-ShARC. For DM-only setting, we use all samples to train our model only on decision making sub-task. The results are generally divided into two parts, one using T5-large as backbone model and one using BART-base as backbone model.

on decision making. See the performance of T5-large trained for decision making separately (DM-only in Table 6) compared with the original UNICMR_{large} (UNICMR in Table 6) performance. The comparison indicates that UNICMR’s stronger form of unified training improves the model’s decision making ability.

Second, UNICMR’s unified training format advances the performance of training T5 separately on question generation in F1_{BLEU}. Ablation studies here include the T5-large trained with all examples (assign empty to examples with Yes and No decisions) for question generation only (QG-only whole-evaluation in Table 5), T5-large trained with examples with gold inquiry questions for questions generation only (QG-only partial-evaluation in Table 5), and T5-large-based UNICMR (UNICMR in Table 5). The results indicate that:

(i) In terms of F1_{BLEU}, UNICMR has dominantly higher performance than other separately trained models.

(ii) In terms of BLEU⁷, UNICMR is not the best, which shows its source of F1_{BLEU} dominance includes reduction of error propagation.

(iii) For T5-large backbone, UNICMR is higher in BLEU than QG-only partial-evaluation, which means UNICMR’s integration of decision making labels in training is effective.

6.6 Generalizability on Different Backbone Models

Replacing the T5-large backbone with BART-base, and repeating the same experiments (see the same settings but with BART-base as backbone models in Table 6 and Table 5), leads to same general conclusions. This shows the effectiveness of UNICMR’s unified format can well generalize to different end-to-end architectures.

6.7 Error Analysis and Case Study

To reveal more insights into UNICMR, we randomly collect test samples and conduct error analysis (see Figure 6) and case study (see Figure 7 in Appendix A). The ground truth answers are indicated in red, the TF-IDF scores are indicated in green, and the predictions of UNICMR_{large} are indicated in blue. The retrieved rule texts are in descending order in terms of TF-IDF scores.

Error Analysis. The observed test errors are summarized into four aspects: (1) *Noisy Retrieved Rule Texts* which is caused by the innate deficiencies of TF-IDF retriever with bigram

⁷Note that BLEU is measured on samples with *Inquire* as gold labels only while F1_{BLEU} is measured on all samples considering both the BLEU when prediction is *Inquire* and the BLEU when gold label is *Inquire*. For F1_{BLEU} calculation of all QG-only settings, decision making predictions of model trained only on decision making sub-task are used.

Error Type	Dialogue Setups	UniCMR Output
Noisy Retrieved Rule Texts	<p>Scen.: It was a donation of stuff I wasn't using that I gave to Gift Aid and they got me 25% more than anyplace else would.</p> <p>Ques.: Will I have to pay more tax than I've paid?</p> <p>His.: (empty)</p> <p>Gold Rule: Charity donations: tax relief. If the charity or CASC gets back more tax than you've paid, HMRC may ask you to pay more tax to cover the difference.</p> <p>Gold Answer: No</p>	<p>Retrieved Rules:</p> <p>(1) [78.43] Donations through Gift Aid: Charities and community amateur sports clubs (CASCs) can register with HM Revenue and Customs (HMRC) to be part of the Gift Aid scheme. When they're registered, they can claim back the tax you've already paid on your donation.</p> <p>(2) [39.25] Charity donations: tax relief. Donations to charity from individuals are tax free. You can get tax relief if you donate: * through Gift Aid * straight from your wages or pension, through Payroll Giving</p> <p>.....</p> <p>Prediction: Can a charity or community amateur sports club (CASC) register with HM Revenue and customs (HMRC)?</p>
Losing Track of Some Conditions	<p>Scen.: I married my husband Bob when he was 50 in the year 2014. Unfortunately he died of a heart attack in 2015 and never reached the age where he was eligible for a state pension.</p> <p>Ques.: Could I inherit part of my deceased partner's Additional State Pension?</p> <p>His.: Q: Did you partner reach state pension age before April 6 2016? A: No</p> <p>Gold Rule: (same as the first retrieved rule)</p> <p>Gold Answer: Would your partner have reached state pension age on or after 6 April 2016?</p>	<p>Retrieved Rules:</p> <p>(1) [149.46] Inheriting Additional State Pension. You might inherit part of your deceased partner's Additional State Pension if your marriage or civil partnership with them began before 6 April 2016 and one of the following applies: * your partner reached State Pension age before 6 April 2016 * they died before 6 April 2016 but would have reached State Pension age on or after that date</p> <p>(2) [99.16] Inheriting or increasing State Pension from a spouse or civil partner. You may inherit part of or all of your partner's extra State Pension or lump sum if: * they died while they were deferring their State Pension (before claiming) or they had started claiming it after deferring * they reached State Pension age before 6 April 2016 * you were married or in the civil partnership when they died</p> <p>.....</p> <p>Prediction: Did they die before April 6 2016?</p>
Different Condition Ordering	<p>Scen.: I require assistance in turning a local agricultural area into a hunting and gaming area.</p> <p>Ques.: Do I get the Additional State Pension automatically?</p> <p>His.: (empty)</p> <p>Gold Rule: (same as the first retrieved rule)</p> <p>Gold Answer: Have you contracted out of the state?</p>	<p>Retrieved Rules:</p> <p>(1) [49.66] Overview. You get the Additional State Pension automatically if you're eligible for it, unless you've contracted out of it.</p> <p>(2) [41.62] Inheriting Additional State Pension. You might inherit part of your deceased partner's Additional State Pension if your marriage or civil partnership with them began before 6 April 2016 and one of the following applies: * your partner reached State Pension age before 6 April 2016 * they died before 6 April 2016 but would have reached State Pension age on or after that date</p> <p>.....</p> <p>Prediction: Are you eligible for it?</p>
BLEU's Inability on Phrase Variants	<p>Scen.: (empty)</p> <p>Ques.: Can I get payment in lieu?</p> <p>His.: (empty)</p> <p>Gold Rule: (same as the first retrieved rule)</p> <p>Gold Answer: Are you leaving your job?</p>	<p>Retrieved Rules:</p> <p>(1) [21.83] Getting paid instead of taking holidays. The only time someone can get paid in place of taking statutory leave (known as 'payment in lieu') is when they leave their job. Employers must pay for untaken statutory leave (even if the worker is dismissed for gross misconduct).</p> <p>.....</p> <p>Prediction: Did you leave your job?</p>

Figure 6: Error analysis of UNICMR_{large} by comparison with ground truth answers.

features. (2) *Losing Track of Some Conditions* which shows in rare cases UNICMR_{large} might miss some condition fulfillment as UNICMR_{large} does not explicitly model condition fulfillment. (3) *Different Condition Ordering* which is caused by multiple unsatisfied conditions and the flexibility to inquire any of them. (4) *BLEU's Inability on Phrase Variants* which means predictions are penalized by BLEU even if they only differ in unimportant and semantically harmless words.

Case Study. Qualitative improvements of generated inquiries of UNICMR_{large} are summarized into two aspects: (1) *Exactness* which means the capability of capturing the self-contained yet elementary condition units that need to be clarified. (2) *Robustness to Noisy Retrieved Rules* which means the model can filter noisy retrieved rule texts to extract unsatisfied conditions. From the results in Figure 7, it can be seen that UNICMR_{large} generate more suitable inquiries in terms of *Exactness* and achieves excellent performance in terms of *Robustness to Noisy Retrieved Rules*. This suggests that our fully end-to-end framework enables the accurate focus on target conditions and the implicit feature engineering of UNICMR is powerful to filter noisy retrievals regardless of the retriever quality.

7 Conclusion

In this paper, we study open-retrieval setting of the conversation machine reading task and promote a novel framework to first unify the optimizations of the two sub-tasks to achieve optimization synergy. With a retriever module and a parameter-efficient text-to-text encoder-decoder module, we have achieved new SOTA results in both the CMR and the OR-CMR benchmarks. Further experiments shows that our unified training form with an end-to-end optimization method largely contributes to the advanced performance in decision making and reduces the error propagation to boost question generation performance. It's also shown that our framework well generalize to other backbone models. Further qualitative analysis also verifies our framework's effectiveness.

Limitations

Under the challenging open-retrieval setting, a retrieval is required to find the related rules texts. However, the performance of our model may be hindered by the noise introduced by the irrelevant rule texts from the retrieval. To conquer this deficiency, it is beneficial to develop additional filtering methods to alleviate the influence of irrelevant rule texts.

A Case Study

To reveal more insights into our framework, we randomly collect test samples and conduct the case study (see Figure 7). The ground truth answers are indicated in red, the TF-IDF scores are indicated in green, and the predictions of UNICMR_{large} are indicated in blue. The retrieved rule texts are in descending order in terms of TF-IDF scores. For the analysis on cases, please refer to Section 6.7.

B Hyperparameter-Related Experiments

In this section, additional experiments related to the hyperparameter m (number of retrieved rule texts) and the hyperparameter maximum generation length are conducted with their results shown in Table 7-10.

In Table 7, the hyperparameter m (number of retrieved rule texts) is varied to compare our model performance on the OR-ShARC test set, test set seen and test set unseen divisions respectively. In Table 8, the hyperparameter maximum generation length of the backbone encoder-decoder model is varied to compare our model performance on the same datasets. The corresponding performance of the above two experiments on dev set is shown by Table 9 and Table 10 respectively. Note in these experiments, all the hyperparameters remain the same unless explicitly stated.

Case Type	Dialogue Setups	UniCMR Output
Exactness	Scen.: (empty) Ques.: Could I authorize the use of marijuana for this patient? His.: (empty) Gold Rule: (same as the first retrieved rule) Gold Answer: If it medically appropriate?	Retrieved Rules: (1) [50.51] Patient Information. Healthcare practitioners may authorize the use of marijuana for any patient as long as it's medically appropriate under the law and the profession's standard of care. The Department of Health doesn't keep a list of those specific practitioners that are authorizing, however there is a list of healthcare practitioners that are allowed to authorize marijuana for medical marijuana. Prediction: Is it medically appropriate under the law and the profession's standard of care?
	Robust to Noisy Retrieved Rules	Scen.: (empty) Ques.: Is this item eligible for the zero rate? His.: Q: Is it rescue equipment? A: No Gold Rule: Items that qualify for the zero rate. Generative Knowledge Selection for Knowledge-Grounded Dialogues

Weiwei Sun, Pengjie Ren, Zhaochun Ren*

Shandong University, Qingdao, China

sunweiwei@gmail.com, {renpengjie, zhaochun.ren}@sdu.edu.cn

Abstract

Knowledge selection is the key in knowledge-grounded dialogues (KGD), which aims to select an appropriate knowledge snippet to be used in the utterance based on dialogue history. Previous studies mainly employ the classification approach to classify each candidate snippet as “relevant” or “irrelevant” independently. However, such approaches neglect the interactions between snippets, leading to difficulties in inferring the meaning of snippets. Moreover, they lack modeling of the discourse structure of dialogue-knowledge interactions. We propose a simple yet effective generative approach for knowledge selection, called GENKS. GENKS learns to select snippets by generating their identifiers with a sequence-to-sequence model. GENKS therefore captures intra-knowledge interaction inherently through attention mechanisms. Meanwhile, we devise a *hyperlink* mechanism to model the dialogue-knowledge interactions explicitly. We conduct experiments on three benchmark datasets, and verify GENKS achieves the best results on both knowledge selection and response generation.

1 Introduction

To improve the informativeness in open-domain dialogue agents (Freitas et al., 2020), knowledge-grounded dialogues (KGD) are proposed to leverage external structured (Liu et al., 2019) and unstructured (Dinan et al., 2019) knowledge to dialogue responses. In KGD, it is pivotal to embed factual and conversationally appropriate knowledge in responses. Two classes of approaches are considered to embed knowledge: *end-to-end* and *pipeline*. End-to-end models, such as FiD (Izacard and Grave, 2021), process the document and generate the response in one shot. However, they tend to misuse knowledge (Adolphs et al., 2021). Pipeline models address this problem by explicitly identifying a specific knowledge snippet to

*Corresponding author.

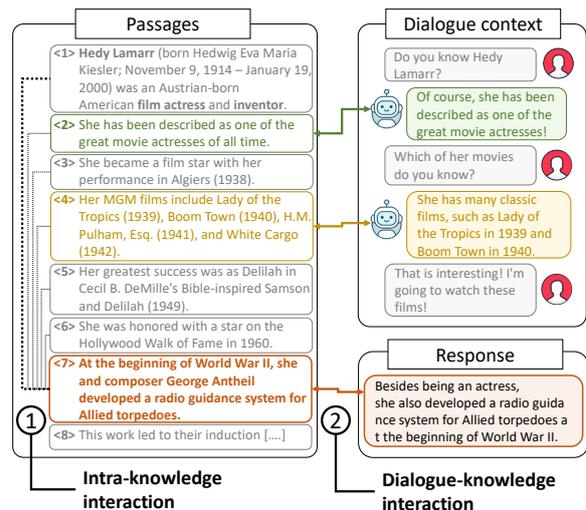

Figure 1: An example of knowledge-grounded dialogues. The dialogue agent selects a knowledge snippet (i.e., <7>) from passages and generates a response based on it. Intra-knowledge interactions and dialogue-knowledge interactions are denoted by ① and ②, respectively.

be used in the response (Adolphs et al., 2021). Typically, pipeline KGD approaches have two sub-steps, i.e., knowledge selection and response generation (Dinan et al., 2019; Kim et al., 2020): The former aims to select knowledge snippets from passages, and the latter generates responses based on them. Knowledge selection plays a vital role in KGD as it directly determines the content of the response (Lian et al., 2019; Meng et al., 2020). In this paper, we focus on selecting knowledge snippets for dialogue to enhance pipeline KGD models.

The *Classification* paradigm dominates knowledge selection studies. In this paradigm, each snippet is independently classified as “relevant” or “irrelevant” (Dinan et al., 2019; Zhao et al., 2020b). However, these approaches ignore *knowledge interactions*, which refer to flows of information within the knowledge or between knowledge and dialogues. As shown in Figure 1, we identify two

types of knowledge interactions in KGD:

Intra-knowledge interaction Intra-knowledge interaction refers to the interactions between snippets. It is worth noting that the meaning of a knowledge snippet is context-dependent and can be ambiguous when taken individually. For example, the <8> snippet in Figure 1 “*This work led to their*” has a referential element *their*, and is difficult to identify its meaning without knowing the remaining context of the sentence. However, with the existence of the remaining context, we can quickly infer that it refers to *Lamarr and George Antheil. This problem challenges existing methods when selecting knowledge on new topics.*

Dialogue-Knowledge interaction Previous works also neglect interactions between dialogue and knowledge. There is a discourse structure and smooth transition of involved knowledge in multi-turn dialogue. For example, *Lamarr’s* profession mentioned in the dialogue in Figure 1 is demonstrated in a parallel and multi-perspective manner, while some other cases follow a shallow-to-deep structure in dialogue.

Some recent efforts attempt to fix these problems within the classification paradigm; for example, [Li et al. \(2022\)](#) build a semantic graph for passages to capture intra-knowledge interaction, [Kim et al. \(2020\)](#) propose sequential knowledge selection to model the dialogue-knowledge interaction as latent variables. However, they are complicated, lack deep semantic interactions, and are challenging to model the two types of knowledge interaction simultaneously.

In this work, we propose **GENKS (Generative Knowledge Selection)**, a simple yet effective *generative* model that addresses these challenges. GENKS first assigns an identifier to each snippet, feeds all the snippets into the model simultaneously, and then selects snippets by generating their identifiers with a sequence-to-sequence Transformer model (e.g., BART ([Lewis et al., 2020a](#))). Compared with KGD methods with the *classification* paradigm, GENKS captures interactions between knowledge snippets through the *self-attention* mechanism in Transformer ([Vaswani et al., 2017](#)). Therefore, GENKS can obviate the ambiguity in snippets with the existence of the rest context and improve the understanding of knowledge. Moreover, we propose a *hyperlink* method to

capture the dialogue-knowledge interactions explicitly and effectively. Finally, we propose to joint knowledge selection and response generation within one generative model.

We evaluate our proposed method on three public KGD datasets: Wizard of Wikipedia ([Dinan et al., 2019](#)), Holl-E ([Moghe et al., 2018](#)), and CMU_DoG ([Zhou et al., 2018](#)). The experimental results show that GENKS significantly improves the accuracy of knowledge selection as well as the quality of response generation, by establishing new state-of-the-art on KGD benchmarks. Improvements are particularly significant on unseen topics, outperforming the BART classification model by up to 8.1% absolute. GENKS also achieves the best results as the number of dialogue turns increased, with an average of 10% improvements over the BART classification model in the last three turns. We also compare our model with recent SOTA end-to-end methods ([Shuster et al., 2021](#)), and find our model can generate responses with fewer hallucinations while having better controllability and interpretability. The effectiveness of the proposed method is also validated through human evaluation and ablative experiments.

Our contributions are summarized as follows: (1) We propose GENKS, which is the first attempt at generative knowledge selection in KGD. (2) GENKS captures intra-knowledge and dialogue-knowledge interactions simultaneously. (3) We propose a hyperlink method to enhance the interactions between dialogue and knowledge. (4) Experiments verify that GENKS establishes a new state-of-the-art on KGD¹.

2 Related work

Knowledge-grounded dialogues With the advances in large-scale language models, dialogue agents can now generate high-quality responses using parametric knowledge ([Thoppilan et al., 2022](#); [Freitas et al., 2020](#); [Bao et al., 2021](#)). However, hallucination remains a challenge, which means that the language model tends to generate plausible-looking statements that are factually incorrect ([Shuster et al., 2021](#)). To address this problem, knowledge-augmented approaches are applied in dialogue generation ([Lewis et al., 2020b](#)). In knowledge-grounded dialogues (KGD), the dialogue models first select a knowledge snippet from

¹The code is available at: <https://github.com/sunweiwei/GenKS>

passages and then generate the responses (Liu et al., 2018; Dinan et al., 2019).

Knowledge selection As the critical step in KGD, knowledge selection has received many studies. The existing methods mainly employ *classification* model with dual-encoder (Dinan et al., 2019; Kim et al., 2020) or cross-encoder (Zhao et al., 2020b) architecture. However, the classification paradigm is unable to capture the knowledge interaction in KGD (Kim et al., 2020; Li et al., 2022). To address this problem, Li et al. (2022) propose a graph-based method to capture the relationship between candidate snippets, Zhan et al. (2021a) and Wu et al. (2021) employ machine reading comprehension model to extract span from long document. Sequential knowledge selection has also been proposed to capture the topic transition in conversations (Kim et al., 2020; Zhan et al., 2021b; Zheng et al., 2020; Meng et al., 2020; Yang et al., 2022). Despite their effectiveness, the existing methods have two drawbacks: (1) they use compact vectors to represent dialogue and knowledge and thus lack deep semantic interactions; (2) they are complicated and challenging to capture intra-knowledge and dialogue-knowledge interactions simultaneously. We address these drawbacks by shifting the modeling paradigm of knowledge selection to identifier generation (Sun et al., 2022), and propose GENKS to capture the two types of interaction simultaneously using Transformer (Vaswani et al., 2017).

Generative knowledge selection A generative paradigm for knowledge selection is not foreign to the NLP community; for example, sequence-to-sequence models have been applied on entity retrieval (Cao et al., 2021), document ranking (Nogueira et al., 2020; Tay et al., 2022), multi-evidence retrieval (Min et al., 2021; Yavuz et al., 2022), and etc. Our proposed model GENKS differs from existing methods in the following ways: (1) we are the first to explore generative knowledge selection in KGD; (2) we consider the effectiveness of intra-knowledge interaction; (3) we design hyperlinks to capture the interaction between knowledge and dialogue.

3 GENKS

We provide an overview of GENKS in Figure 2. As shown in Figure 2, the dialogue data is first serialized into a sequence. Then a sequence-to-sequence model (i.e., BART) is employed to select knowl-

edge and get the response by generating the target sequence autoregressively. In this section, we first formulate the task in Section 3.1. Then, we detail the serialization (Section 3.2) and optimization (Section 3.3) methods.

3.1 Problem formulation

Suppose that we have a case of knowledge-grounded dialogues (C, \mathcal{K}, r) , where $C = (c_1, \dots, c_{|C|})$ is a dialogue context that contains $|C|$ utterances, r is the response to C , $\mathcal{K} = (K_1, \dots, K_{|\mathcal{K}|})$ denotes $|\mathcal{K}|$ passages that are relevant to C ; for each i , $K_i = (k_{i,1}, \dots, k_{i,|K_i|})$ denotes a passage that contains $|K_i|$ snippets. We define $m = \sum_{i=1}^{|\mathcal{K}|} |K_i|$ as the total number of snippets in \mathcal{K} . A knowledge-grounded dialogue agent is decoupled into two modules: a knowledge selection module $P(k|C, \mathcal{K})$ that selects a snippet from \mathcal{K} ; a response generation module $P(r|C, \mathcal{K}, k_s)$ where k_s is the selected snippet from knowledge selection module.

3.2 Serialization

We formulate the knowledge selection task as a procedure of sequence generation. As shown in Figure 2, the dialogue context C and knowledge candidates \mathcal{K} are mapped into a sequence and then fed into a sequence-to-sequence model. The model’s output is converted back to the selected knowledge k or the response r .

Specifically, we first assign an identifier to each snippet in \mathcal{K} , sequentially starting from $\langle k1 \rangle$ to $\langle km \rangle$. Then we convert passages \mathcal{K} into a sequence using a template that packages snippets with the corresponding identifiers and concatenates them in order; see the green block in Figure 2. Similarly, the dialogue context C is serialized by adding task prompts, i.e., task description and speaker name, as shown in the blue block in Figure 2.

In multi-turn dialogues, the knowledge appearing in the dialogue history prompts the discourse structure of knowledge transition and knowledge expression. Hence we propose a *hyperlink* method to capture the dialogue-knowledge interaction explicitly. We provide an example of the hyperlink method in Figure 2. We see that the first utterance of User1 refers to a snippet (whose identifier is $\langle k2 \rangle$) in the passage “Skateboarding”. We thus add a hyperlink to the utterance. The hyperlink includes the identifier and the title of the snippet, i.e., annotating [Skateboarding] $\langle k2 \rangle$ at the beginning of

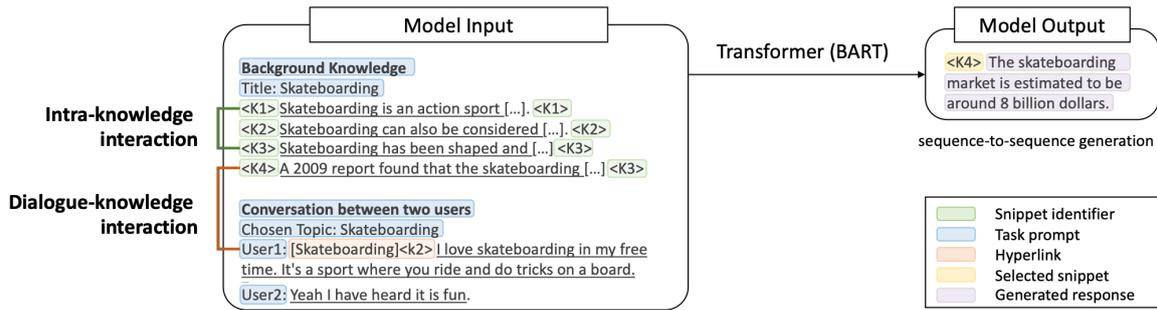

Figure 2: Overview of GENKS. The dialogue context and the knowledge are serialized and fed into a seq-to-seq model, BART. The outputs are the identifier of the selected snippet (i.e., <k5>) and the response.

this utterance (as shown in the red block in Figure 2). Finally, we splice the passages and dialogue context sequences as input for a Transformer model (i.e., BART). Therefore, the model can capture the intra-knowledge and dialogue-knowledge interactions through a *self-attention* mechanism (Vaswani et al., 2017).

3.3 Optimization

The knowledge selection model is optimized by the cross-entropy loss: $\mathcal{L} = -\log P(k_{true}|C, \mathcal{K})$, where k_{true} denotes the label knowledge. Since k_{true} needs to be labeled manually and is not available in some scenarios (Zhou et al., 2018), we construct pseudo-labels for model training following Zhao et al. (2020b) in cases the knowledge label is absent. In particular, we calculate the F1 score (Dinan et al., 2019) between each knowledge snippet and the response. We use the snippet with the highest score as the pseudo label. Such a method is based on the intuition that human responses provide hints regarding the relevance of the snippets (Zhao et al., 2020b; Li et al., 2020).

Since both knowledge selection and response generation are modeled with the *generative* paradigm, we unify the two modules with one joint generative model. In this joint model, the knowledge selection and the response generation are optimized jointly, with shared parameters. To this end, we splice the knowledge identifier k_{true} and response r into one sequence (as shown in Figure 2). Then, we optimize the sequence-to-sequence model using cross-entropy loss on all the tokens of the target sequence. In inference, the model generates knowledge identifier k_s and responses r in an autoregressive fashion. We note that the end-to-end model allows the two tasks to be mutually enhanced and improves the model’s efficiency.

4 Experimental setup

4.1 Datasets

We conduct experiments on Wizard of Wikipedia (WoW) (Dinan et al., 2019), Holl-E (Moghe et al., 2018), and CMU_DoG (Zhou et al., 2018). The statistical details on these three datasets are shown in Table 7 in the appendix.

- **WoW** is an open-domain KGD dataset using Wikipedia passage as background knowledge. The test set of Wizard is split into seen and unseen versions, where the unseen test set contains 58 new topics not discussed in the training data.
- **Holl-E** focuses on the movie domain. The background knowledge consists of plots, comments, and movie reviews collected from different websites. Holl-E has two versions of the test set: single test and multi-reference test. In the multi-reference test, there are multiple human-annotated ground-truth knowledge and corresponding responses for each instance.
- **CMU_DoG** focuses on the domain of movies. The workers discuss a movie in depth given the background knowledge (e.g., introduction, plots, and key scenes).

4.2 Baselines

We compare GENKS with baselines of two categories: (i) *End-to-end methods* that generate response directly without explicit knowledge selection, and (ii) *Pipeline methods* that explicitly select knowledge snippet to be used in response.

The end-to-end methods we consider are:

- **BART** (Lewis et al., 2020a) that generates responses without access to the external passage and uses knowledge inside model parameters instead.
- **BART FID** (Izacard and Grave, 2021) concatenates and encodes each candidate knowledge

with dialogue separately and fuses all the encoded representation in the decoder to generate the response.

- **BART RAG-DPR** is a baseline adopted by Adolphs et al. (2021), which uses DPR-retrieved passages and produces response using RAG.
- **BART FiD-RAG DPR-Poly** (Shuster et al., 2021) uses DPR-Poly to retrieve passage and uses FiD-RAG to generate the response.

Regarding the pipeline baselines, according to their knowledge selection modeling paradigm, we sub-categorize pipeline baselines into four groups:

(1) The *Classification methods*, includes:

- **SKT** (Kim et al., 2020) proposes sequential knowledge selection.
- **DiffKS** (Zheng et al., 2020) captures the knowledge differences between adjacent turns.
- **DukeNet** (Meng et al., 2020) models the knowledge shift and tracking processes with a dual learning scheme.
- **KnowledGPT** (Zhao et al., 2020b) exploits pre-trained language models in KGD.
- **MIKe** (Meng et al., 2021) distinguish user-initiative and system-initiative.
- **K-Mine** (Lotfi et al., 2021) proposes a score-and-aggregate module.
- **TAKE** (Yang et al., 2022) propose a topic-shift aware network.

(2) The *MRC methods*, includes:

- **CoLV** (Zhan et al., 2021a) proposes a collaborative latent variable model.
- **DIALKI** (Wu et al., 2021) proposes a MRC-based model to extract span from passage.

(3) The *Graph-based methods*, includes:

- **Graph** (Li et al., 2022) builds a semantic graph upon candidate documents and employs a GNN model.

(4) And the *Knowledge generation methods*, includes:

- **K2R** (Adolphs et al., 2021) uses the RAG-based model to generate knowledge text and then generates dialogue response based on it.

4.3 Evaluation metrics

In WoW, we choose perplexity (**PPL**) of the ground-truth responses, unigram **F1**² (Dinan et al., 2019), **Knowledge-F1** (Shuster et al., 2021), and **BLEU-4** (Papineni et al., 2002) score as metrics. In Holl-E, we additionally use **ROUGE-1**, and **ROUGE-2** following Meng et al. (2020). In

²<https://github.com/facebookresearch/ParLAI>

CMU_DoG, we additionally use embedding-based metrics includes **Average**, **Extreme**, and **Greedy** following Zhao et al. (2020b).

In addition, we randomly sample 100 examples from the WoW test seen and WoW test unseen, respectively, and recruit three experts for human evaluation. The annotators are asked to judge the model-generated response in four ways:

- **Fluency**, which measures whether the response is fluency in expression;
- **Coherence**, which measures whether the response is coherence to the dialogue context;
- **Relevance**, which measures whether the knowledge used in the response is relevant to the dialogue; and
- **Factuality** measures whether the response’s content is factual. In Factuality evaluation, the experts check the content using Google.

The annotators are asked to assign a score in {0, 1} (representing “nonfactual” and “factual”) for factuality, and a score in {0, 1, 2} (representing “bad”, “fair”, and “good”) for the others.

4.4 Implementation details

We implement the GENKS using BART large (with 400M parameters) (Lewis et al., 2020a) in HuggingFace’s Transformers library. We truncate the dialogue context to 256 tokens, then truncate the knowledge so that the total length is less than 1024 tokens. During inference, the responses are decoded using a greedy search. See Appendix A for more details.

Typically, the number of passages in \mathcal{K} is large, so that the input sequence exceeds the maximum input length of BART (i.e., 1024 tokens). To address this problem, we take advantage of a lightweight passage selector based on DistilBERT (with 66M parameters) (Sanh et al., 2019), which aims to rank the passages in \mathcal{K} . Specifically, we concatenate each passage with dialogue context and encode the sequence using DistilBERT. Finally, the representation of [CLS] token is used to estimate the relevance score of the passage through a learnable MLP classifier. The passage selector is optimized via contrastive learning objective (Nogueira and Cho, 2019), in which the model learns to assign a higher score to positive passages than negative passages. During inference, we keep only the top-1 passage ranked by the passage selector. The passage selector gets Recall@1 of 75.5%, 76.5%, and 68.0% for the WoW test seen, WoW test unseen,

Table 1: Knowledge selection accuracy on WoW (seen and unseen test set) and Holl-E (single reference and multi-reference test set). **Bold** denote the best results with significant improvements over the previous SOTA (t-test, $p < 0.05$). Underline denote second best results.

and Holl-E, respectively.

5 Experimental results

5.1 Performance on knowledge selection

We evaluate the knowledge selection effectiveness of GENKS on WoW and Holl-E, respectively³. In Table 1, we compare the knowledge selection accuracy of GENKS with previous pipeline methods. Results show that GENKS achieves the best knowledge selection accuracy on both datasets and consistently outperforms baselines.

We find that GENKS particularly excels at topics that do not appear during training (see WoW unseen test split). For example, the classification models both have noticeable accuracy drops on the unseen topic. In contrast, models that model the intra-knowledge interaction (e.g., GENKS, Graph, DIALKI) can better understand the knowledge of unseen topics⁴.

To evaluate the Performance of GENKS as dialogue goes deeper, we compare GENKS with

³We cannot evaluate the knowledge selection accuracy on CMU_DoG because the knowledge snippets used in responses are not manually labeled.

⁴The higher results on unseen than seen might be due to the smaller number of topics in the unseen test set.

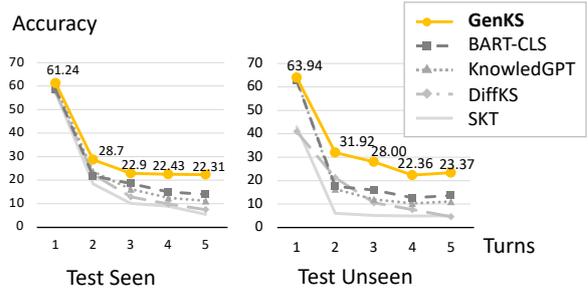

Figure 3: Knowledge selection accuracy over different dialogue turns. BART-CLS represents a text-matching model with cross-encoder architecture.

four classification baselines (SKT, DiffKS, KnowledGPT, and BART-CLS) overturns. Figure 3 shows the results. Both methods achieve good accuracy in the first few turns. However, as the conversation dives deeply into a topic, a significant performance decline can be seen in baseline methods. In contrast, GENKS that explicitly captures the multi-turn dialogue-knowledge interaction, achieves a relatively high accuracy (around 22%-23%).

5.2 Quality of generated responses

We report response generation evaluation results on WoW in Table 2. The results on Holl-E and CMU_DoG are available in Table 8 and Table 9 in the appendix. The results of baselines are cited from original papers or re-evaluated using officially released checkpoints.

Compared with previous pipeline models, GENKS achieve the best Performance on almost all metrics. For example, GENKS surpasses KnowledGPT by 0.7% and 2.4% in terms of F1 on WoW seen and WoW unseen, respectively. Note that the improvements on the unseen test set are more notable than on the seen test set, which agrees with the experimental results regarding knowledge selection. GENKS also achieve competitive results compared to SOTA end-to-end models. For example, GENKS performs comparably to BART FiD-RAG DPR-Poly on WoW seen and outperformed on WoW unseen.

5.3 Ablation study about knowledge selection

To analyze the effect of each component in GENKS, we designed several variants and conducted an ablation study about knowledge selection. Results are listed in Table 1, “Variants for comparison”. The details of compared variants and the findings are as follows:

BART classification We use BART to classify each

Methods	WoW Seen				WoW Unseen

Table 2: Evaluation results on WoW seen and unseen test set in terms of response quality. We compare against the ground-truth dialogue response in terms of perplexity (PPL), F1, Knowledge F1 (KF1), and BLEU-4 (B4). The four groups lists previous end-to-end models, previous pipeline models, GenKS, and ablative variants. The best results are highlighted with **bold**, and the second-best results are highlighted with underline. * indicates significant improvements over all baselines with p-value < 0.05.

candidate snippet into two classes: “relevant” or “irrelevant”. The results show that BART in the classification paradigm performs worse than GENKS by a large margin.

BART classification w/ position To understand the influence of position bias, we splice the snippet’s position into the classification model’s input. We find that the results are improved to a certain extent (about 1% improvement), but there is still a clear gap compared with GENKS.

Hierarchical classification This variant first uses the passage selector model of GENKS to rank the passages and then selects the snippets in the top-ranked passage using BART classification w/ position. The results show that the passage selector does not affect the classification model’s Performance.

Without passage selector When the passage selector model of GENKS is removed, the model has more probability of truncating the label knowledge, resulting in an evident decline in Performance.

Unorder knowledge snippets To disable the intra-knowledge interaction, we unorder the snippets so that order of the snippets is inconsistent with the original passages. This variant shows a decline in selection accuracy, especially on unseen topics, indicating that keeping the order of the snippets in

the passage is necessary.

Without hyperlinks We remove the hyperlinks in the dialogue context. About a 1% accuracy drop is seen, indicating the effectiveness of hyperlinks.

5.4 Ablation study about response generation

As shown in Table 2, we also conduct an ablation study about response generation. The details of compared variants and the findings are as follows:

With BART classification knowledge When replacing the generated identifier with the knowledge selected by BART classification, a performance decline is witnessed—the F1 value drops by 0.7% and 1.8% on Wizard seen and unseen, sustaining the effectiveness of the knowledge selection of GENKS.

Without identifier generation This variant removes the identifier generation by directly generating the response. We see notable performance drops, especially in the KF1 metric. The results indicate that explicit training and inference about knowledge selection enable to use of more appropriate knowledge in response generation.

Without hyperlinks This variant removes hyperlinks from GENKS. It performs worse than GENKS, probably due to its lower accuracy of knowledge selection than GENKS.

Use the oracle knowledge We replace the model-predicted snippet identifier with the oracle one

Methods	WoW Seen				WoW Unseen			
	Flu.	Coh.	Rel.	Fact.	Flu.	Coh.	Rel.	Fact.
BART	1.82	1.51	1.45	0.82	1.76	1.50	1.47	0.76
BART FiD	1.88	1.70	1.55	0.84	1.85	1.67	1.53	0.82
TMN	1.59	1.41	1.08	0.62	1.42	1.30	0.98	0.59
DukeNet	1.69	1.56	1.22	0.71	1.66	1.47	1.10	0.72
KnowledGPT	1.89	1.67	1.58	0.87	1.87	1.68	1.51	0.83
GenKS	1.90	1.72	1.69	0.89	1.91	1.71	1.67	0.91

Table 3: Human evaluation results. Flu, Coh, Rel, and Fact denote Fluency, Coherence, Relevance, and Factuality, respectively.

	KS	RG	ACC	F1
BART RAG (Adolphs et al., 2021)	0	11.5	-	21.5
BART FiD* (Shuster et al., 2021)	0	25.4	-	21.1
KnowGPT (Zhao et al., 2020b)	12.5	7.4	25.4	20.5
K2R* (Adolphs et al., 2021)	11.8	8.2	-	19.9

Graph* (Li et al., 2022)	15.4	-	30.8	-
GenKS	2.9	8.8	36.6	22.9

Table 4: Inference time (minutes) on one GPU on WoW unseen test set. The values of model with * are estimated based on the model size and input/output length. KG and RG denote inference time for knowledge selection and response generation stage, respectively.

(knowledge used by ground-truth response). The results (e.g., KF1=74) suggest that GENKS can effectively locate and incorporate the corresponding knowledge into the responses following the guidance of the identifier.

5.5 Human evaluation

Table 3 shows the human-evaluating results. Results show that GENKS consistently outperforms baselines on all datasets. The Fleiss’ kappa value is above 0.60, indicating substantial agreement among the annotators. GENKS outperforms KnowledGPT by about 0.02 and DukeNet by about 0.20 in terms of response generation evaluation metrics (i.e., *Fluency* and *Context Coherence*). Moreover, for the *Knowledge Relevance*, the annotators agree that GENKS is capable of selecting knowledge that is more relevant to the dialogue and generating more informative responses than baselines. The *Factuality* results show that by explicitly identifying the knowledge snippet used in response, GENKS can reduce the hallucination of response generation.

Methods	WoW Seen			WoW Unseen		
	F1	KF1	B4	F1	KF1	B4
GenKS	22.9	29.5	4.5	22.7	28.1	4.6
GenKS-2	22.4	29.3	4.2	22.2	27.6	4.2
GenKS (5 Snippets)	22.3	27.6	4.2	21.8	25.5	4.1
GenKS (3 Snippets)	21.1	29.3	3.2	20.0	20.9	2.9
GenKS (128 Tokens)	21.5	25.6	3.5	20.7	22.9	3.4
GenKS (64 Tokens)	20.7	23.3	3.0	20.1	20.6	2.9

Table 5: Analytical experiment results on WoW. The first group compares GENKS and its variant GENKS, which selects two snippets instead of one. The second group includes the results of GENKS with different maximum number of snippets inputs or maximum input tokens.

5.6 Efficiency evaluation

To evaluate the efficiency of GENKS, we compare the model with previous end-to-end models and pipeline models. The results listed in Table 4 show that GENKS is more efficient than previous pipeline models. We infer that this phenomenon is because GENKS jointly models knowledge selection and response generation, avoiding repeated encoding of dialogue history and knowledge. As a pipeline method, we also find that GENKS achieves comparable efficiency compared to end-to-end models like RAG, but benefits from explicit knowledge selection.

5.7 Analytical experiment

Multi-snippets selection GENKS select a single snippet following the experimental setup outlined in the baselines (Dinan et al., 2019), but it can also select multiple snippets by generating multiple identifiers. We test a variant of our GENKS model, GENKS-2, which selects two snippets by generating two identifiers consecutively. We compared its performance with the original GENKS on the WoW dataset. The results are listed in Table 5 group 1. GENKS-2 performs slightly worse than the original GenKS, likely because the WoW dataset only uses one snippet in response annotation and therefore does not benefit from using multiple snippets (Dinan et al., 2019). Nevertheless, the results suggest that the proposed generative knowledge selection approach has the ability to select multiple knowledge.

Hyper-parameter analysis We also conduct ablation experiments on the number of input snippets to the model and maximum input tokens. The results are listed in Table 5 group 2. We find that

Topic	Budweiser
User	I think Budweiser taste terrible. Have you ever had it?
Know 1	Produced in various breweries around the world, Budweiser is a filtered beer available in draft and packaged forms.
Res 1	Yes, I have. It is produced in various breweries around the world!
Know 2	Budweiser is an American-style pale lager produced by Anheuser-Busch, currently part of the transnational corporation Anheuser-Busch InBev.
Res 2	Yes, I have. I know that it is an American-style pale lager produced by Anheuser-Busch.

Table 6: Examples of GENKS outputs on the WoW.

reducing the number or length of knowledge reduces model effectiveness.

5.8 Case study

To better understand end-to-end baselines and our model, we provide an example in Table 6, which shows that GENKS appropriately changes its response prediction when providing different knowledge snippets⁵. Therefore, GENKS is more controllable and interpretable than end-to-end models, where the end-to-end system is a black box. We provide more case studies in Appendix B.

6 Conclusion

In this paper, we have proposed GENKS, a simple yet effective knowledge-grounded dialogue model. GENKS is a generative model, which learns to select knowledge snippets by generating their identifiers. Benefiting from the modeling of intra-knowledge interaction and dialogue-knowledge interaction, GENKS effectively addresses the challenges of *ambiguity* and *discourse structure*. Our experiments have shown that GENKS establishes a new state-of-the-art on three knowledge-grounded dialogue benchmarks. Notably, GENKS particularly excels at new topics and as the dialogue goes deeper. GENKS also outperforms SOTA end-to-end models. Hence, we believe GENKS reveals a new paradigm for knowledge selection in open-domain dialogue.

⁵Note that this example only aims to show the output of the model. In fact, according to <https://en.wikipedia.org/wiki/Budweiser>, Budweiser is also a famous lager from the Czech Republic, and the American Budweiser being sold and known as Bud through most of the European Union.

Limitations

The limitations of this work include the modular modeling of passage reranks, which reduces the efficiency of the approach. Besides, we only conduct human evaluation on one popular dataset, i.e., Wizard of Wikipedia. Furthermore, the effectiveness of GENKS is only verified in the English dataset. Research on other languages establishes a new challenge, especially for languages with limited knowledge and annotated data. In future work, we would like to explore more efficient passage rerank techniques on knowledge-grounded dialogues. We will also conduct human evaluation for more datasets. Besides, generative knowledge selection can be extended to future studies about conversational recommendation.

Ethics statement

The paper proposes a knowledge-grounded dialogue system to generate a response using external knowledge. The intended use of this system is to perform chit-chat with the user on topics such as books and movies. The system is developed using large pre-trained language models (i.e., BART), who are trained on large-scale web data known to contain biased or discriminatory content. The datasets (i.e., WoW, Holl-E, CMU_DoG) that we train on also include subjective knowledge (comments on movies) that may express the bias of the writers. Although the system is able to reduce the hallucination of response compared to end-to-end models, the outputs from our system may still contain non-factual information and should not be considered as advice for any critical decision-making.

A Implementation details

We use gradient clipping with a maximum gradient norm of 0.1. We optimize the model for up to 5 epochs with a batch size of 16 on 4 3090 GPUs with 24G memory. We choose the model checkpoints by evaluating the metrics on the validation set for each epoch. During inference, the responses are decoded using a greedy search. We have tried some advanced decoding algorithms (e.g., nucleus sampling) and found no improvement. The training of the model can be completed within 5h, and the latency of the model inference for one example is within 0.1s. The passage rerank model gets Recall@1 of 75.5%, 76.5%, 61.0% for WoW test seen, WoW test unseen, and Holl-E, respectively.

	PPL	F1	Avg.	Ext.	Greedy

Topic	Nickelback
User	Do you like Nickelback?
...	
User	Yes, what more can you tell me about Nickelback?
System	Chad Kroeger is the leading vocalist of the group.
User	Amazing. What about the other group members
Passage	The band is composed of guitarist and lead vocalist <i>Chad Kroeger</i> , guitarist, keyboardist and backing vocalist <i>Ryan Peake</i> , bassist <i>Mike Kroeger</i> , and drummer <i>Daniel Adair</i> .
TMN	i think the song is a very popular song
DukeNet	chad kroeger is a great band
KGPT	the lead vocalist is chad kroeger. he is also the drummer.
GenKS	Chad Kroeger, Ryan Peake, Mike Kroeger and Daniel Adair.
Human	Ryan Peake is the keyboardist an Mike Kroeger is the bassist.

Table 10: Case study on the Wizard Test Unseen dataset. This table shows an example where both GENKS and baselines select the proper knowledge.

Topic	List of national parks of the United States
User	I love national parks dont you
...	
User	I live in Arkansas and love the Hot Springs National Park and have been there many times, really it is beautiful
DukeNet	i have heard the city is located in the ouachita mountains among the us
KGPT	i've been to the ouachita mountains, too! i've been to the ouachita mountains in the ouachita mountains.
GenKS	I've never been to Hot Springs, but I've always wanted to go to there.
Human	I've never been to that one! I bet its beautiful!

Table 11: Case study on the Wizard Test Unseen dataset. This table shows an example where both models select the wrong knowledge.

B Case study

To better understand baselines and our model, we present two examples in Table 10 and Table 11. Table 10 show example where both GENKS and baselines select out the proper knowledge (i.e., the knowledge snippet shown in green). We see that the response generated by GENKS is more appropriate to the dialogue context than baselines, while KnowledGPT's response does not answer User2's question and is also factually incorrect. In Table 11, we observed that although neither GENKS nor the baselines selected the label knowledge, the response generated by GENKS is still more natural and coherence. We also find that KnowledGPT is more colloquial than GENKS but has problems with hallucinations.

Evaluating the Tradeoff Between Abstractiveness and Factuality in Abstractive Summarization

Abstract

Neural models for abstractive summarization tend to generate output that is fluent and well-formed but lacks semantic faithfulness, or factuality, with respect to the input documents. In this paper, we analyze the tradeoff between abstractiveness and factuality of generated summaries across multiple datasets and models, using extensive human evaluations of factuality. In our analysis, we visualize the rates of change in factuality as we gradually increase abstractiveness using a decoding constraint, and we observe that, while increased abstractiveness generally leads to a drop in factuality, the rate of factuality decay depends on factors such as the data that the system was trained on. We introduce two datasets with human factuality judgements; one containing 10.2k generated summaries with systematically varied degrees of abstractiveness; the other containing 4.2k summaries from five different summarization models. We propose new factuality metrics that adjust for the degree of abstractiveness, and we use them to compare the abstractiveness-adjusted factuality of previous summarization works, providing baselines for future work.¹

1 Introduction

Summarization is the task of generating a semantically faithful, well-formed and concise text representation of the input. Automatically generated summaries have traditionally been *extractive* (Luhn, 1958; Edmundson, 1969; Neto et al., 2002; Erkan and Radev, 2004; Wong et al., 2008), leading to issues with readability and coherence, as different extracted fragments may not fit well when taken out of their original contexts (Poibeau and Sag-gion, 2012). Researchers have also invested in methods for *abstractive* summarization, aiming to paraphrase the input documents' main points

*Work conducted during his position at Amazon.

¹Code and data are available at <https://github.com/amazon-science/abstractive-factual-tradeoff>.

Input: The National Zoo's giant panda cub made his debut Wednesday in a five-minute explosion of cuteness confined to a live stream because of the coronavirus pandemic. (...) The zoo is closed because of the pandemic and has not said when it will reopen. (...)

Summary 1: The National Zoo's giant panda cub made his debut Wednesday in a five-minute video live-streamed from the zoo's live stream because it's closed due to the pandemic. The zoo has not said when it will reopen.

Summary 2: The National Zoo's giant panda cub made its debut Wednesday in a five-minute video live-streamed from the zoo's live stream because it's closed due to the pandemic. It's not clear when the zoo will reopen.

Summary 3: The National Zoo is still closed due to the pandemic, but the National Zoo's giant panda cub has made its debut—and it was a pretty cute moment. The cub was born Wednesday, and the live-streamed birth lasted just five minutes.

More abstractive
↓

Figure 1: Three successively more abstractive summaries generated from the same input article, with MINT abstractiveness scores (Section 2.1) of 46.1%, 67.2%, 79.5%. Fragments extracted from the input are marked from red (longer fragments) to yellow (shorter fragments). The bottom summary has factual errors.

without borrowing their exact lexical expressions (Radev and McKeown, 1998; Saggion and Lapalme, 2002; Ganesan et al., 2010; Genest and Lapalme, 2012; Radford et al., 2019; Gehrmann et al., 2019; Lewis et al., 2019; Zhang et al., 2020). Abstractive summaries generated by today's neural models tend to be fluent and well-formed, but lack semantic faithfulness (Cao et al., 2017; Kryscinski et al., 2019). Observed rates of factual errors in abstractive summaries have ranged from 30% to over 75% (Cao et al., 2017; Maynez et al., 2020). The research community is developing automatic factuality metrics (Wang et al., 2020; Kryscinski et al., 2020; Goodrich et al., 2019; Goyal and Durrett, 2020; Ribeiro et al., 2022) and methods that attempt to increase factuality (Fan et al., 2018; Scialom et al., 2019; Zhang et al., 2019; Falke et al., 2020; Cao and Wang, 2021). However, the factuality problem of abstractive summaries cannot be well understood without considering the *degree* of abstractiveness of a given summary: Any summary is on a spectrum between *extractive* and

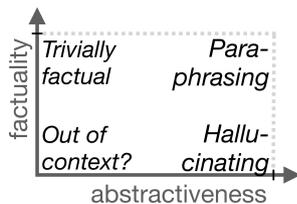

Figure 2: Four extremes at the abstractiveness-factuality spectrum.

paraphrasing, which results in summaries that are more *abstractive*, is harder and prone to semantic errors. As an example, Figure 1 shows part of a Washington Post article and three summaries with increasing abstractiveness, which we have generated using our abstractiveness constraints (Section 2.2). The first two summaries are correct, but the third, most abstractive, summary has factual errors, misinterpreting the input.

Few authors have discussed this connection explicitly. Lebanoff et al. (2019) observe that abstractive summaries consisting of concatenated extracted fragments tend to be more factual than those created by more complex fusion. Durmus et al. (2020) observe that models trained on the more *extractive* CNN/DM dataset (Hermann et al., 2015) create more factual summaries than models trained on the more *abstractive* XSum dataset (Narayan et al., 2018). We show that such models differ in factuality even when we bias them to generate summaries that have similar levels of abstractiveness. Our analysis (Section 4) situates summarization models on the spectrum outlined in Figure 2, where factual summaries range from “trivially factual” (extractive) to truly “paraphrasing” (abstractive). We make the following contributions:

1. We systematically explore the relationship of abstractiveness and factuality and show how factuality decays with increasing abstractiveness. We argue that factuality rates of different systems cannot be compared without taking their degrees of abstractiveness into account.
2. We introduce new factuality metrics that take abstractiveness into account and evaluate the abstractiveness-factuality tradeoff across various datasets and summarization models. We establish baselines that will allow others to demonstrate progress on mitigating the abstractiveness-factuality tradeoff.
3. We introduce a new dataset containing 10.2k summaries with systematically varied degrees

abstractive (See et al., 2017). Summaries that are extractive to a larger extent tend to be more factual since copying text from the input into the summary rarely introduces factual errors while the task of

of abstractiveness along with human factuality judgements, and a second dataset containing 4.2k summaries from five summarization models with their human factuality judgements.

2 Abstractiveness

2.1 Measuring Abstractiveness

In this paper, we wish to analyze the relationship of abstractiveness and factuality of generated summaries. We start by proposing a comprehensive abstractiveness metric. Abstractiveness measures the amount of rephrasing, i.e., the degree to which the words, phrases and sequences of the generated text have *not* been extracted from the corresponding input; a fully abstractive summary method expresses the main points of the input in its own words. To measure abstractiveness, most authors list the proportions of summary n -grams of varying lengths that are novel, i.e., do not occur in the corresponding inputs (See et al., 2017; Narayan et al., 2018; Gao et al., 2019). Grusky et al. (2018) proposed a new metric also based on contiguous overlapping text spans, *density*, measuring the average length of extracted fragments in a summary. Others have proposed metrics that take common *non-contiguous* subsequences into account, e.g., *perfect fusion_k* (Durmus et al., 2020) measures the percentage of summary sentences that assemble substrings from k source sentences in their original order.

Based on these previous works, we define a comprehensive abstractiveness metric that combines measures of contiguous and non-contiguous extractive summary fragments, making it sensitive to different kinds of abstractiveness and therefore suitable as a general abstractiveness metric. We define this metric as a ratio, in order to facilitate combining it with a factuality metric of the same $[0,1]$ range (Section 4). Let $\chi(\mathbf{x}, \mathbf{y}) = \text{hmean}(p_1, p_2, p_3, p_4, \text{lcsr})$ be a measure of *extractive* overlap between input \mathbf{x} and summary \mathbf{y} , using the harmonic mean of multiple component measures. Each p_n , short for $p_n(\mathbf{x}, \mathbf{y})$, is the n -gram precision of the n -grams in \mathbf{y} with respect to \mathbf{x} , i.e., the percentage of n -grams in \mathbf{y} that are extracted from \mathbf{x} .² Following common practice (Papineni et al., 2002), we use n -grams up to length four. We do not include density in $\chi(\mathbf{x}, \mathbf{y})$ as its range is unbounded. The measure lcsr (longest common sub-

²We smooth all n -gram counts (Chen and Cherry, 2014) to avoid undefined or zero harmonic mean values in highly abstractive summaries. See Appendix A for details.

x the supreme court reserved its verdict on a batch of pleas which have raised questions

y the supreme court reserved its decision on a batch of pleas that have raised questions

Figure 3: Example of input and highly extractive generated output. The color coding is the same as in Fig. 1.

sequence ratio), short for $\text{lcsr}(\mathbf{x}, \mathbf{y})$, is the length of the longest common subsequence (LCS) between \mathbf{x} and \mathbf{y} divided by the length of \mathbf{y} . lcsr , inspired by ROUGE-L (Lin, 2004), generalizes perfect fusion_k to consider *all* instances of non-contiguous overlaps between input and summary. Adding a measure of non-contiguous overlap is important as it detects overlaps that are long but broken up by minor changes, such as synonyms, as in the example in Figure 3. Finally, the MINT (Metric for lexical independence of generated text) abstractiveness measure is defined as $\text{MINT}(\mathbf{x}, \mathbf{y}) = 1 - \chi(\mathbf{x}, \mathbf{y})$. For a set of inputs and their summaries, we report the average MINT score. See Figure 1 for the MINT scores of three increasingly abstractive example summaries. In Section 5, we show that MINT scores correlate highly with density scores.

The described MINT score capitalizes on prior work to provide a comprehensive and unified metric for abstractiveness of conditionally generated text, combining measures of contiguous and non-contiguous overlap into a single percentage score. The implementation of MINT we provide will facilitate standardized comparisons of abstractiveness across different works.

2.2 Nonlinear Abstractiveness Constraints

We now introduce nonlinear abstractiveness constraints (NAC), which enable us to control the degree of abstractiveness at decoding time; it will allow us to use a trained summarization model to decode input multiple times while applying constraints to control the abstractiveness of the generated text output (e.g., see Figure 1). We will use this technique to analyze the impact of abstractiveness on factuality (Section 4).

Let $\mathcal{F}(\mathbf{x}, \mathbf{y})$ be the set of the longest extractive fragments in the decoding output \mathbf{y} with respect to the input \mathbf{x} . In Figure 1, such fragments are marked in color for each summary. We define a function $\lambda_h(|\mathbf{f}|)$ that assigns a discount probability to any extractive fragment $\mathbf{f} \in \mathcal{F}(\mathbf{x}, \mathbf{y})$:

$$\lambda_h(|\mathbf{f}|) = 2^{-|\mathbf{f}|^2/h^2} \quad (1)$$

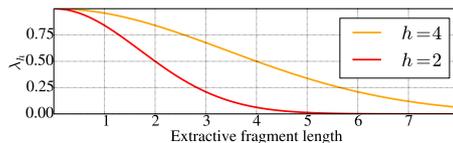

Figure 4: λ_h defines discounts for extractive fragments based on their lengths. Smaller h values lead to more abstractive summaries.

We configure this function³ with h , interpreted as the length of an extracted fragment for which $\lambda_h = 0.5$. Decreasing h results in a λ_h that discounts shorter extractive fragments more strongly, leading to increased abstractiveness (see Figure 4). Our discount penalty grows nonlinearly, affecting longer extractive fragments more strongly than multiple shorter ones with the same combined length. To see why we choose a **nonlinear penalty**, consider for example that extracting a 10-gram makes a summary more extractive than using ten words from the article separately, since an extracted 10-gram will be highly recognizable as stemming from the input. This nonlinearity is in contrast to Weber et al. (2018), which used a linear penalty to control the amount of copying in a pointer network.

In decoding, we search for the summary $\hat{\mathbf{y}}$ that maximizes the product of the summarization model probability, $p_M(\mathbf{y} | \mathbf{x})$, and the discount probabilities of the extractive fragments $\mathcal{F}(\mathbf{x}, \mathbf{y})$:

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{y}} p_M(\mathbf{y} | \mathbf{x}) \times \prod_{\mathbf{f} \in \mathcal{F}(\mathbf{x}, \mathbf{y})} \lambda_h(|\mathbf{f}|) \quad (2)$$

Beam Decoding. The model probability $p_M(\mathbf{x}, \mathbf{y})$ in neural text generation models (Section 5.1.1) decomposes for token-by-token decoding as $\prod_{i=1}^{|\mathbf{y}|} p_M(y_i | \mathbf{x}, y_1, \dots, y_{i-1})$. Similarly, we decompose the application of the λ_h function for any partial or completed extractive fragment \mathbf{f} :

$$\lambda_h(|\mathbf{f}|) = \prod_{l=1}^{|\mathbf{f}|} \frac{\lambda_h(l)}{\lambda_h(l-1)} \quad (3)$$

Therefore, to successively apply λ_h at each output position i in beam decoding, each candidate for token y_i is evaluated to check whether choosing it would extend an extractive fragment to length l . If so, its model probability $p_M(y_i | \dots)$ is multiplied with $\lambda_h(l)$ and the $\lambda_h(l-1)$ that was applied to the previous token y_{i-1} is divided out. We are not

³Additionally, the exponent used in $|\mathbf{f}|^2$ and h^2 could be configured, but we keep it at 2 in our experiments. A larger exponent would result in a steeper descent around h .

Figure 5: Screenshot (part) of a Mechanical Turk task (HIT) to judge the factuality of a summary sentence (in blue) with respect to news articles. Darker green article sentences are more similar to the blue summary sentence. The full task showed sentences from two more articles in the same cluster; from the Multi-News test set.

aiming to control the length of the generated output; instead we penalize the model in proportion to the length of any phrases it would extract from the input and encourage it to use novel phrases instead. **Extraction Rewards.** We can choose to apply an extraction *reward*, rather than a penalty, by using the inverse $1/\lambda_h$; smaller values of h then result in summaries that are more *extractive*.

3 Factuality

We now describe metrics for factuality, before we can describe the relationship between abstractive-ness and factuality (Section 4). By factuality of a summary y , we mean factual consistency with the input x , rather than objective factuality or universal truth. Measuring factuality automatically is an active area of research (Gabriel et al., 2020). Factuality is most naturally measured by human annotators; we describe our setup for human factuality annotation first, then move to automatic metrics.

3.1 Human-annotated Factuality

We use Amazon’s Mechanical Turk (AMT) to measure the factuality of automatically generated summaries with human annotators. These annotators are untrained, so we use multiple mitigation strategies to obtain high-quality judgements. We simplify the task: To avoid overwhelming annotators with long text, we select a single sentence per summary and ask the annotators if it is factually consistent with the shown article(s). The other sentences of the summary are given as well for context, shown in gray (see Figure 5). The article(s) are shortened to show a total of 9 sentences that were determined to be semantically most similar to the selected summary sentence;⁴ the remaining article parts are replaced by “...”. The summary sentence is selected at random in proportion to its length.

⁴We measure cosine similarity of sentence encodings computed by the Universal Sentence Encoder (Cer et al., 2018).

For each summary, we get judgements only for the randomly selected sentence. Aggregated over a set of summaries, we measure the average chance of any randomly selected summary sentence to be factual. We have verified high correlation of these factuality rates with the factuality rates obtained through professional annotators who judged complete summaries with respect to the full articles (see Appendix C).

We provide detailed task instructions, including examples for intrinsic and extrinsic factual errors (Maynez et al., 2020). We require that potential annotators pass a custom qualification test of finding factuality errors. Only workers with at least 100 completed tasks on AMT with an acceptance rate of 95%+ may take the test; 15% of those pass, enabling them to work on our tasks. We use three annotators per task and use MACE (Hovy et al., 2013) to aggregate annotations and recover the most likely binary factuality judgement per summary. We add summaries for which we know the correct factuality annotation and repeatedly check the annotators’ accuracy on those summaries while they are annotating; all answers from annotators who fall below a threshold are replaced by answers from additional annotators. Appendix C describes more details on our setup and fair compensation.

For any set of generated summaries, we create the AMT tasks, get an aggregate binary judgement per summary based on the multiple answers as described, and report the mean of all human binary summary factuality judgements; we call this score **FACTH** (Table 1). We collect human factuality judgements for 10.2k BART summaries with varying degrees of abstractive-ness, and for 4.2k summaries from five different summarization models.

Released Datasets. We release these human judgements as datasets called **CONSTRAINTSFACT** (Section 5.1) and **MODELSFACT** (Section 5.2). Previous datasets with human factuality judgements

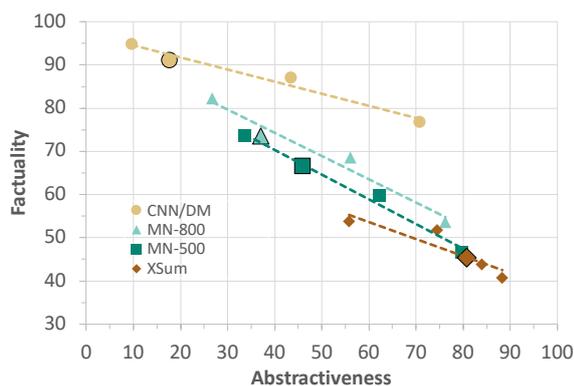

Figure 6: Human factuality judgements (FACTH) for different degrees of abtractiveness (MINT). Each color represents a BART model trained on a particular dataset, decoded with varying decoding constraints (Sec. 2.2); large outlined symbols mean no constraints.

(Wang et al., 2020; Kryscinski et al., 2020; Maynez et al., 2020; Pagnoni et al., 2021) are substantially smaller, with under 5k summaries each, and our CONSTRAINTSFACT dataset is the first that evaluates the factuality of summaries with systematically varied degrees of abtractiveness.

3.2 Automatically Measured Factuality

Measuring factuality *automatically* is an active research area; Pagnoni et al. (2021) gives an overview over recent metrics and compares their correlations to human judgements, where DAE (Goyal and Durrett, 2020, 2021) and FactCC (Kryscinski et al., 2020) perform well. DAE is an entailment model that classifies the factuality of the dependency arcs in the summary, resulting in fine-grained judgements at the subsentence level. FactCC is a BERT-based binary classifier trained on pairs of input and output sentences, where the output sentence is annotated as either factual or non-factual.

4 Abtractiveness-Factuality Tradeoff

The metrics for factuality and abtractiveness along with the abtractiveness constraints allow us to systematically explore the relationship between abtractiveness and factuality. We can control abtractiveness and observe the effect on factuality, i.e., we can vary the amount of lexical overlap between input and generated summary and observe the extent to which the summary preserves the input semantics.

Factuality Trend Lines. To explore this relationship, we train summarization models on different

datasets. For any trained summarization model, we decode the test set multiple times with different h values for λ_h (Equation 1), resulting in sets of summaries with varying degrees abtractiveness. For each of these test set decodings, we measure abtractiveness using MINT and the corresponding factuality using human annotations, unless otherwise noted. This results in a series of (abtractiveness, factuality) points for any trained summarization model, which can be plotted, along with a linear trend line. Figure 6 shows such a plot; Section 5.1.2 discusses its details.

F@50 Score. Given each trend line, we can read off the factuality at 50% abtractiveness, an intuitively interpretable metric, which we call F@50; it provides a comparison of the factuality of different models with a fixed degree of abtractiveness.

MINT-adjusted Factuality Scores. We characterize the tradeoff on any single decoding output using a weighted average between factuality and abtractiveness, $(\phi F + A)/(\phi + 1)$. To measure abtractiveness A , we use MINT; to measure factuality F , we use human-measured factuality or an automatic metric with $[0,1]$ range like DAE or FactCC, resulting in abtractiveness-adjusted factuality metrics μFactH , μDAE , μFactCC , etc.

We give factuality a higher weight, since factual semantic representation of the input is a fundamental requirement for summarization and low factuality can have negative societal impact (Zellers et al., 2019), while abtractiveness is a desirable stylistic property. When two measures are combined into one comprehensive evaluation metric there is no *a priori* correct mixture weight; we follow common practice to give the more important measure twice the weight (Kohonen et al., 2010; Li et al., 2020; Preuß et al., 2021; Opitz and Frank, 2021) and set ϕ to 2. By this definition, a system whose factuality decreases by x units, as compared to another system, must make up for the lost factuality by $2x$ units in abtractiveness to get the same score. When two systems have the same factuality, the score prefers the one with higher abtractiveness.

4.1 Discussion

The abtractiveness-adjusted factuality metrics address the issue that in the past, factuality rates of different systems have been compared without taking abtractiveness into account. However, if one system has a higher factuality rate than another, it may

	λ	MINT	FACTH	μ FACTH	F@50
CNN/DM	$1/\lambda_2$	9.7	94.8	66.5	84.4

Table 1: Abstractiveness and factuality on 600 test samples per setting. The 17 MINT and FACTH numbers are as shown in Figure 6; we add μ FACTH and F@50.

have achieved this by copying phrases from the input into the summary with minimal rephrasing, i.e., by having a low degree of abstractiveness. Such a system may produce high-quality summaries, but their factuality rate cannot directly be compared to the factuality numbers of more abstractive summarization systems. Summarization methods that are highly factual and abstractive are able to rephrase the input with few factual errors; when we compare the factuality of abstractive summarizers we must control for the amount of such rephrasing. The abstractiveness-adjusted factuality metrics we propose enable us to compare the factuality of abstractive summarization models even when they perform different amounts of rephrasings.

As an analogy, consider precision and recall. High precision can be trivially achieved with low recall, just as high factuality can be achieved with low abstractiveness. Therefore when comparing the precision of different retrieval systems, their recall numbers are taken into account by using the F-score.⁵ Similarly, we argue that factuality comparisons must take abstractiveness into account.

Dataset	Train	Valid	Test
CNN/DM	287,227	13,368	11,490
XSum	204,045	11,332	11,334
Multi-News	44,972	5,622	5,622

5 Experiments

5.1 Comparison Across Datasets Using NAC

Datasets. We use CNN/DM (Hermann et al., 2015), XSum (Narayan et al., 2018), and Multi-News (Fabbri et al., 2019), all of which contain English-only text. CNN/DM contains news articles from CNN and DailyMail paired with bullet point summaries. XSum contains articles from BBC News, using each article’s first sentence as summary.⁶ In Multi-News, each summary is written by a professional editor and paired with a cluster of news articles. For all three public datasets, we use the provided training/validation/test split. The sizes of the three datasets are listed in Table 2. From each of the three datasets, we use 600 samples to compare human and automatic factuality judgements.⁷

5.1.1 Setup

We use the BART (Lewis et al., 2020) sequence-to-sequence model, which was pretrained on 160GB of text and gives competitive results on CNN/DM and XSum. Our models use the provided model checkpoints for the CNN/DM and the XSum datasets as well as the recommended decoding settings. For Multi-News (MN), we train a model on the training set, starting from the `bart.large` pretrained model.⁸ For Multi-News, we truncate the input documents per cluster so that their combined length does not exceed N words, following Fabbri et al. (2019). We train models with $N = 800$ and $N = 500$, called MN-800 and MN-500, respectively. We measure the MINT scores for the reference summaries in these datasets; these can be compared to the MINT scores obtained in

⁵In our case, we use a weighted arithmetic mean instead because an F score would steeply decline to zero as abstractiveness goes to zero, which is undesirable for output whose factuality is high.

⁶Following Wang et al. (2020), we reinsert the first sentences whenever we measure factuality of XSum summaries on AMT or with automatic metrics.

⁷For Multi-News and XSum, we take the first 600 samples per test set. For CNN/DM, we take the first 300 and the last 300 test samples, from CNN and Daily Mail, respectively.

⁸We train for five epochs (learning rate: $2e-5$) and limit output to 50 to 300 tokens.

decoding (Section 5.1.2). The test set references for MN-500 have a MINT score of 78.2%, compared to 72.8% for MN-800. MINT is higher for MN-500 since the shorter truncation removes article content that could otherwise overlap with the summaries. The MINT scores for the CNN/DM and XSum references are 59.6% and 87.8%, respectively; XSum is the most abstractive dataset.

5.1.2 Results

We use each of the four BART models to decode its respective test set multiple times, with varying abstractiveness constraints, resulting in 17 outputs. For each one, we obtain human factuality judgements on the corresponding 600 samples, resulting in 17 x 600 human factuality judgements – our CONSTRAINTSFACT dataset –, which we aggregate into 17 mean FACTH scores; we also compute the corresponding 17 MINT scores. Figure 6 plots the resulting abstractiveness and human-measured factuality for each of the four models, thereby providing a visual representation of the abstractiveness-factuality tradeoff for these models. Table 1 shows the same 17 MINT and FACTH values, along with μ FACTH and F@50 scores.

The lower right of Figure 6 shows five lozenges (◆). The larger one represents the decoding with our **XSum**-trained model using default settings; the other four red points represent decodings under the same model, but with different abstractiveness constraints that result in more *extractive* ($1/\lambda_h$) or more *abstractive* (λ_h) summaries (Section 2.2). The five red points are associated with a dashed linear trend line. Compared to the other points in the figure, abstractiveness is high and factuality low – the model tends to paraphrase its input, often incorrectly. It took a strong extractive reward ($1/\lambda_1$), which we did not use for the models trained on other datasets, to bias this model toward lower abstractiveness and higher factuality.

For the **Multi-News** models, four decodings using MN-500 are shown as squares (■), decodings under MN-800 as triangles (▲). The MN-800 model is more factual across the abstractiveness spectrum. This can be explained by the fact that for MN-500, larger parts of the input are truncated (Section 5.1.1) that the untruncated reference summary in training may still refer to; the MN-500 model learns to hallucinate more.

The four decodings for **CNN/DM** are shown as bullets (●). Its model output without abstractiveness constraint (large bullet) is the most extractive;

the extraction reward to its left (using $1/\lambda_2$) cannot make it much more extractive; however, there is room to the right, and the abstraction rewards (λ_4 and λ_2) move its abstractiveness far into the abstractiveness level of Multi-News and XSum.

F@50 Scores. One of the main takeaways of this study is that different systems can have different factuality rates at the same level of abstractiveness. Previous authors have observed that XSum summaries are highly abstractive and less factual, and that CNN/DM summaries are at the opposite side of that spectrum. We confirm this; however, we add that we can bias the XSum model to create less abstractive summaries and the CNN/DM model to create more abstractive models, so that **their abstractiveness becomes comparable**, and the factuality rates still differ considerably: Based on the trend line, the F@50 score of the XSum model is 56.7%, while the CNN/DM model’s F@50 is 84.4%. MN-800 and MN-500 lie in the middle.

μ FACTH Scores. The μ FACTH scores adjust FACTH for abstractiveness. They penalize the CNN/DM model for its low abstractiveness and reward the XSum model for its high abstractiveness, bringing them closer together, compared to their more divergent FACTH scores. The μ FACTH scores for MN-800 and MN-500 are also close (59.6% versus 61.3% for λ =none), as MN-800 is more factual but also less abstractive.

Summary Quality and Abstractiveness. Table 3 lists ROUGE-L scores for the different decodings, along with abstractiveness metrics, measured on the *full* test sets. ROUGE scores aim to measure summary quality by comparing the generated summaries with the reference summaries, while abstractiveness metrics measure overlap between the generated summaries and the input. Decodings without abstractiveness constraints replicate previous works’ ROUGE scores (Lewis et al., 2020; Fabri et al., 2019) (Appendix H). The λ_4 constraint can **dramatically increase abstractiveness while leaving ROUGE scores virtually unchanged**. We also conduct a human evaluation of informativeness and coherence, comparing unconstrained summaries with summaries generated with the λ_4 decoding constraint; the unconstrained decoding is preferred for XSum but the constrained decoding is preferred for CNN/DM, and results are mixed for Multi-News, see Appendix D. The density scores (Grusky et al., 2018) in the table have high correla-

Table 3: Impact of λ on ROUGE-L F_1 (RL) and abstractiveness metrics on the full test sets. p3, p4, lcsr are component scores in MINT (Sec. 2.1), density is average length of extracted fragments (Grusky et al., 2018). ROUGE measures overlap with reference summaries, abstractiveness metrics measure input overlap.

tion with the MINT scores.

5.2 Comparison Across Different Models

We also compare the abstractiveness-factuality tradeoffs of summarization models from the literature. We obtain outputs of four summarization models other than BART: BERTSUM (Liu and Lapata, 2019) is a transformer model in which only the encoder is pretrained; PGCONV (See et al., 2017) is a pointer-generator network; BOTTOMUP (Gehrmann et al., 2018) and ABSRL (Chen and Bansal, 2018) select source fragments to constrain an abstractive generation model. We obtain human factuality judgements of the five model outputs on 600 samples of CNN/DM and XSum, respectively, and release this as our MODELSFACT dataset; we apply automatic metrics (e.g., DAE) as well as our abstractiveness-adjusted variants (e.g., μ DAE) to the *full* test sets. Table 4 shows the results. For CNN/DM, we find that the highly extractive model PGCONV receives the highest automatic and human factuality scores, while the abstractiveness-adjusted variants favor BART or ABSRL, whose outputs represent better tradeoffs between abstractiveness and factuality. On XSum, BART’s output is considerably more factual than BERTSUM’s across all factuality metrics, while BART has only slightly lower abstractiveness; as a result, BART is

	Model	MINT	μ FACTH	μ DAE	μ FactCC			
CNN/DM	BART	16.8	66.4	91.2	67.4	92.6	56.2	75.9
	BERTSUM	14.1	64.7	90.0	57.8	79.6	57.0	78.5
	PGCONV	5.5	63.5	92.5	64.0	93.3	62.3	90.7
	BOTTOMUP	17.2	50.6	67.3	55.0	73.9	54.3	72.9
	ABSRL	18.9	60.6	81.5	62.3	84.0	64.1	86.8
XSum	BART	80.2	56.9	45.3	67.3	60.8	53.9	40.8
	BERTSUM	82.8	52.1	36.8	61.5	50.8	50.8	34.8

Table 4: Abstractiveness (MINT) and factuality of different models. For each factuality metric, we first list its MINT-adjusted variant in green. Example: BART’s μ FACTH is 66.4, while the unadjusted FACTH is 91.2. All numbers are percentage scores $\in [0,100]$.

also favored by all MINT-adjusted factuality metrics. Detailed results including additional factuality metrics are described in Appendix G.

The MINT-adjusted variants of factuality metrics put factuality rates into perspective. We encourage authors who compare factuality rates across summarization models to also compare MINT-adjusted variants (e.g., μ DAE), to account for differing levels of abstractiveness.

6 Related Work

Abstractiveness-Factuality Tradeoff: Durmus et al. (2020) observe that abstractiveness at test time depends on the abstractiveness of the training data and that highly abstractive summaries tend to be less factual. We control for abstractiveness and see that factuality rates between different systems can vary widely at the *same* abstractiveness levels. Recently, Ladhak et al. (2022) present an alternative framework to evaluate the faithfulness-extractiveness tradeoff, requiring training multiple models on subsets of the training data to measure the tradeoff, while we use constraints to analyze tradeoffs that a single model makes. **Increasing Abstractiveness:** Kryściński et al. (2018) use policy gradient with a novelty reward to encourage abstraction in a pointer-generator (PG) (Gulcehre et al., 2016; See et al., 2017). Weber et al. (2018) penalize copying tokens during PG decoding. Our constraints apply to general sequence-to-sequence models and include nonlinear penalties. Song et al. (2020) control copying in training abstractive summarization models by masking the summary tokens with different probabilities, depending on whether they are seen in the input document or not. In contrast, our technique does not require retraining to

obtain varying degrees of abstractiveness.

7 Conclusions

We presented new metrics and datasets for evaluating the relationship of abstractiveness and factuality. As part of our analysis, we presented abstractiveness constraints, which can bias a summarization model to increase or decrease the level of abstractiveness while generating summaries, using nonlinear penalties or rewards based on the length of summary fragments extracted from the source. Through automatic and human factuality evaluations, including 10.2k human factuality judgements of summaries with systematically varied abstractiveness, we shed light on how abstractiveness interacts with factuality, across multiple datasets and models. We proposed new metrics to measure the tradeoff, including F@50 and MINT-adjusted factuality rates, such as μ DAE and μ FactCC, and we established baselines for future research.

Limitations

The abstractiveness constraints we have presented can be used to increase or decrease the abstractiveness of the generated text. Dedicated code is needed to integrate such constraints into a decoder. The constraints are needed to obtain trend lines as in Figure 6, as well as the F@50 score. However, the MINT-adjusted factuality scores, such as μ FactH, μ DAE or μ FactCC can be computed for any summarization system, without the need for implementing abstractiveness constraints, as we have done in Section 5.2.

Ethical Considerations

We have analyzed the factuality of generated text in relation to the abstractiveness of the source texts; we have also proposed new metrics that let researchers compare the factuality of different generative models. As such, we consider our work a contribution toward text generation methods that make fewer factual mistakes and become therefore more reliable and responsible. However, any advance in text generation methods can be used by bad actors to cheaply generate misleading or harmful texts.

We hired annotators on the Mechanical Turk platform to judge machine-generated summaries. Our first ethical consideration with respect to this data collection is fair and prompt pay for the work of the annotators. We describe in Appendix C that

we paid all human subjects a fair average pay of \$12.50 USD per hour, based on observed median time spent per HIT. As described (Section 3.1), we automatically approved the annotators' work promptly and paid bonuses as appropriate. The annotators' privacy and confidentiality were respected at all times.

A Measuring Abtractiveness with MINT

***N*-gram Overlap.** Each p_n , short for $p_n(x, y)$, is the n -gram precision of the n -grams in y with respect to x , i.e., the percentage of n -grams in y that are extracted from x .⁹ For highly abstractive outputs, higher-order n -gram precision can be zero, leading to an undefined or zero harmonic mean value. We prevent this by smoothing the n -gram counts from which n -gram precisions are calculated, such that each n -gram count is the average of itself and the smoothed $(n - 1)$ -gram count and the unsmoothed $(n + 1)$ -gram count. The smoothed 0-gram count is defined as the 1-gram count plus one. We chose this method for its simplicity and effectiveness; it is described as method 5 in [Chen and Cherry \(2014\)](#).

Harmonic Mean. We use the harmonic mean, in analogy to the definition of the F_1 score, as it is a mean function designed to aggregate ratios with different denominators.

For a completely extractive summary that extracts sentences in the original order, the MINT score is 0. The score increases as the order of the extractive fragments is changed with respect to the input, their lengths are decreased and new words and fragments are introduced that are not part of the input x . The use of the length-normalized LCS score (lcsr) is inspired by ROUGE-L; it is a useful addition to the n -gram precisions as it can detect the extraction of longer n -grams broken up by minor edits. As an example, consider the (x, y) pair shown in Figure 3. Only 4 of the 12 summary four-grams match the input, i.e., $p_4=33.3\%$, although very high overlap is apparent due to the fact that a 15-word fragment from the input was extracted with only the words “verdict” and “which” minimally changed by synonym substitution. The lcsr score reflects this and measures $12/15=80.0\%$ overlap. On the other hand, the n -gram precisions used in the MINT score are valuable in detecting textual overlaps that are not part of the longest common subsequence.

⁹MINT has elements of ROUGE ([Lin, 2004](#)) and BLEU ([Papineni et al., 2002](#)). We do not use the *modified* n -gram precisions, like BLEU does, because n -grams extracted multiple times from x should count as such every time.

B Details on the Abtractiveness Constraints

Log Space. We have described the abtractiveness constraints in probability space. In practice, we equivalently search for \hat{y} in log space using log probabilities and the log of λ_h defined in Equation 1. It can be shown that $\log \lambda_h(|f|) = \frac{-|f|^2}{(1.20112 \times h)^2}$.

C Details on Our Mechanical Turk Setup

We provide additional details on the strategies we use to obtain high-quality judgements on Amazon Mechanical Turk. We give detailed instructions to the annotators, with definitions and examples of different factual errors (see Figure 7). We also add a request to write a short explanation when a sentence is judged as not factual.

Tasks with Known Answers. We add a number of tasks with known answers, enabling us to estimate the accuracy of workers who work on multiple of these.

Automatic Quality Checks. Workers who complete the tasks too quickly, write no or very short explanation texts or have low accuracy on the tasks with known answers are automatically removed from our worker pool. Their answers are replaced with new answers.

Bonus. We use a bonus incentive structure. Every worker who passes the automatic quality checks receives a bonus at the end.

Check Against Professional Annotators. We have seven sets of 150 automatically generated summaries each, which we had previously sent to professional news editors to annotate factuality. Those annotators rated the complete summaries with respect to the complete inputs – no sentences were preselected to simplify the task. We re-annotated these summary-article pairs using our Mechanical Turk setup, and the resulting per-set factuality rates correlated highly ($r=.88$) with those previously obtained from the professional annotators ($p < .05$).

As a further quality check, we sent one set of 600 summaries to Mechanical Turk twice, several weeks apart. The two factuality rates obtained for that same set were close – 91.2% and 92.0%.

Instructions (Click to collapse)

Please evaluate whether the **blue sentence** from the summary is consistent with the information in the articles. Select **no** if the blue sentence is not consistent, i.e., its facts are not supported by the articles.

Select **no** in cases like these:

- The blue sentence **contradicts** information in the articles. The blue sentence might say "A fire broke out in Seattle", but an article says it broke out in Portland. Or the blue sentence might say "the Republicans won the election", but the articles indicate that the Democrats won instead.
- The blue sentence **adds** a fact that is not mentioned anywhere in the articles. For example, the blue sentence might say that "A fire broke out at 2am", but the articles don't mention the time when the fire broke out.

Meaning of the colors:

- Summary:** The gray sentences in the summary are displayed to give context only. Please evaluate the **blue sentence** only.
- Articles:** The sentences in the articles have green background color to help you find information more quickly. Article sentences with **darker green** background color are more related to the blue sentence. The least related sentence have been removed, indicated by three dots (...).

Please evaluate the **blue sentence** in the summary. (See instructions above.)

Summary:
 A North Carolina couple is suing the producers of Hgtv's love it or list it because they say the show turned their dream home into a Shoddily constructed one, the Raleigh news& observer reports. **Deena Murphy and Timothy Sullivan say they agreed to take part in the show under the guise of moving into a rental property with their teenage foster children, but the reality show's principals -- designer Hilary Farr, real estate agent David Visentin, and contractor Eric Eremita -- are "actors or television personalities playing a role for the camera," not people who "played more than a casual role in the actual renovation process," according to the lawsuit filed against big coat TV and contractor Aaron Fitz construction.** The lawsuit claims the couple were "victims of shoddy work and unfair trade practices" that left their floors, windows, and other parts of their home damaged. The couple says they gave \$140,000 to big coat for renovations, but were told the rest of the money was used to pay Fitz and other Subcontractors. " One of the things they're doing in this lawsuit is kind of blowing the secrecy off of reality TV," today legal's hosts say. big coat denies the couple's claims. " We believe that this claim is in no way supported by any of the facts of the case, and we will be defending ourselves vigorously in this matter," the company says in a statement, per the Huffington Post.

Article 1
 ...
 Deena Murphy and Timothy Sullivan are suing the production company for HGTV's "Love It or List It," claiming the hit show turned their dream home into a nightmare. The lawsuit against Big Coat TV and one of its contractors alleges the couple were "victims of shoddy work and unfair trade practices" that left their floors, windows and other parts of their home damaged.
 ...
 TODAY The program's hosts, David Visentin and Hilary Farr "One of the things they're doing in this lawsuit is kind of blowing the secrecy off of reality TV," said TODAY legal analyst Lisa Bloom.
 ...
 TODAY North Carolina couple Deena Murphy and Timothy Sullivan are suing the show's production company.
 ...

Article 3
 A North Carolina couple is suing the producers of Love It Or List It, saying the show left them with a house that was shoddily constructed. The Raleigh News & Observer says that Deena Murphy and Timothy Sullivan agreed to participate in the hit HGTV series under the guise that they were considering a move to a rental property with their teenage foster children. The problem, according to the suit against Big Coat TV and Aaron Fitz Construction, was that the show's principals--designer Hilary Farr, real estate agent David Visentin,

Figure 7: Instructions for the factuality annotation task on Amazon Mechanical Turk, as well as the summary and part of the article text shown to the worker.

Qualification Test. For all our evaluations on Mechanical Turk (see Section 3.1), we first set up a short qualification test that can be taken by any worker from a country whose main language is English, who has completed 100 or more HITs so far with an acceptance rate of 95% or higher. The qualification test consists of just three questions from our factual consistency setup; two of which must be answered correctly, along with an explanation text (5 words or more) to explain when “not factually consistent” was chosen. 53% of workers who start the test provide answers to all three questions, and 27.6% of these answer at least two correctly and provide a reasonable explanation text, i.e., only 14.6% of the test takers are granted the qualification.

The qualification enables workers to work on our factual consistency HITs as well as our HITs judging informativeness and coherence.

Fair Compensation. The factual consistency task pays \$0.15 per HIT with a bonus of \$0.05. It can be done quickly, given the fact that a single summary sentence is evaluated and the related sentences in the article are highlighted. The task of evaluating informativeness and coherence (see Appendix D) pays \$0.50 per HIT with a bonus of \$0.25, as more text is displayed, compared to the factuality task. These amount to an average pay of \$12.50 per hour, including the bonus, based on median time spent per HIT. The bonus is paid to workers who spend at least 10 seconds per HIT, give short explanation texts for their decisions and maintain high accuracy on HITs with known answers.

	CNN/DM		MN-800		XSum	
	inf.	coh.	inf.	coh.	inf.	coh.
prefer off	36.5	36.7	39.8	35.8	18.8	18.7
prefer λ_4	46.5	39.2	34.7	39.8	16.5	16.3
both equal	17.0	24.2	25.5	24.3	64.7	65.0

Table 5: Human quality evaluation of summaries generated with no abstractiveness constraint (“off”) versus λ_4 . We asked which summary is more informative or coherent, respectively. MN-800 stands for Multi-News with the input documents truncated to 800 words total (Section 5.1.1).

D Human Evaluation of Informativeness and Coherence

We conduct a human evaluation to determine the informativeness and coherence of the summaries generated with the λ_4 decoding constraint (Equation 1), which increases abstractiveness, as compared to not using any abstractiveness constraint. We use the same setup as for the factuality task, including a qualification test, three annotators per task and aggregation using MACE.

We use the following definitions of *informativeness* and *coherence* for the human evaluation:

- *Informativeness*: The more informative summary is better at expressing the main points of the news story. It contains information that is more relevant and important. It has fewer unimportant details. Its content is more similar to the human-written summary.
- *Coherence*: The more coherent summary has better structure and flow, is easier to follow. The facts are presented in a more logical order.

The results are shown in Table 5. For the **CNN/DM** model, the output without decoding constraints is the most extractive, and the raters preferred the more abstractive version generated with the decoding constraint, both for informativeness and coherence. For the **XSum** model, where the output with the decoding constraint disabled is already highly abstractive, the result is reversed. For **Multi-News**, the result is mixed: Raters found the output with no decoding constraints more informative, but less coherent.

Data	Size	DAE	FactCC	FEQA	QAGS
All	4.2k	.44	.35	.27	.44
CNN/DM	3.0k	.35	.24	.05	.27
XSum	1.2k	.39	.17	†.01	.25

Table 6: Pearson correlations to human factuality judgements on the MODELSFACT dataset. The result with the † symbol is not significant.

E More On Automatic Factuality Metrics

When we apply FactCC to a summary, we apply it separately to each summary sentence and use the mean score per summary. For each sentence that we score with FactCC, we shorten the input document by selecting ten sentences with the highest cosine embedding similarity (Conneau et al., 2017), in order to fit the input to the length limits.

In the following two appendix sections, we use not only DAE and FactCC, as described in the main text, but also two metrics based on question answering: FEQA (Durmus et al., 2020) and QAGS (Wang et al., 2020). **FEQA** generates questions from masked summary sentences whose masked entities are used as “gold” answers; these are compared to the answers obtained from a QA model on the input. In **QAGS**, a question generation model generates questions from the summary, a QA model answers these questions from both summary and input, and the similarity of the answer pairs is evaluated.

F Correlating Human and Automatic Factuality Judgements

Table 6 shows correlations of the human judgements with different automatic metrics on the MODELSFACT dataset, complementing earlier studies (Gabriel et al., 2020; Pagnoni et al., 2021). We compute correlations at the level of individual summaries. To make meaningful comparisons between the human and the automatic scores, we apply the automatic metrics here to the *single* randomly selected sentence per summary that the human annotators judged. Overall, we observe here that DAE has the highest correlations with human judgements.

Data	Model	MINT	μ FACTH	μ DAE	μ FactCC	μ FEQA	μ QAGS
CNN/DM	BART	16.8	66.4 91.2	67.4 92.6	56.2 75.9	47.2 62.4	61.7 84.2
	BERTSUM	14.1	64.7 90.0	57.8 79.6	57.0 78.5	47.6 64.4	60.8 84.2
	PGCONV	5.5	63.5 92.5	64.0 93.3	62.3 90.7	45.2 65.0	58.1 84.4
	BOTTOMUP	17.2	50.6 67.3	55.0 73.9	54.3 72.9	47.3 62.3	58.2 78.7
	ABSRL	18.9	60.6 81.5	62.3 84.0	64.1 86.8	49.6 65.0	61.3 82.5
XSum	BART	80.2	56.9 45.3	67.3 60.8	53.9 40.8	50.9 36.2	53.4 40.1
	BERTSUM	82.8	52.1 36.8	61.5 50.8	50.8 34.8	46.6 28.4	46.0 27.6

Table 7: Abtractiveness (MINT) and factuality of different summarization models. For each factuality metric, we first list its MINT-adjusted variant in green. Example: BART’s μ FACTH is 66.4, while the unadjusted FACTH is 91.2. All numbers are percentage scores $\in [0,100]$.

G Comparison Across Different Models

Here we offer an extended description of our comparison of the abtractiveness-factuality tradeoffs of summarization models from the literature, including the use of additional automatic factuality metrics (see Appendix E).

Table 7 shows human and automatic factuality scores, as well as MINT-adjusted versions of these scores. We observe that all factuality metrics favor the output of the PGCONV model on **CNN/DM**; however, its low abtractiveness indicates that its output falls into the “trivially factual” quadrant (Figure 2). The MINT-adjusted variants (shown in green) penalize such low abtractiveness, favoring the BART or ABSRL models instead, whose outputs represent better tradeoffs between abtractiveness and factuality. Human factuality raters (FACTH) rank ABSRL in fourth place, while FactCC, FEQA and QAGS rank it highly; we hypothesize that ABSRL makes factual errors that these measures cannot detect well. On **XSum**, BART’s output is considerably more factual than BERTSUM’s across all factuality metrics, while BART has only slightly lower abtractiveness; as a result, BART is also favored by all MINT-adjusted factuality metrics. BART’s pretraining of both encoder and decoder may be contributing to its factuality, in accordance with [Maynez et al. \(2020\)](#). Note that for DAE, we apply the Ent-C model on CNN/DM output and the XSUM-HUMAN model on XSum output. Appendix H.2 shows **ROUGE** scores.

H ROUGE Scores

H.1 BART Models

The aim of this paper is not to improve ROUGE scores, but to gain insights about the tradeoff between abtractiveness and factuality. We do, however, stress that the BART models we use in our analysis are competitive with the start of the art. We list our ROUGE-1, ROUGE-2 and ROUGE-L F_1 scores, as well as their averages; see the RL scores in Table 3 as well:

- For CNN/DM, our λ =none decoding has 44.1/21.2/41.0 with an average of 35.4, same as the average of 35.4 in [Lewis et al. \(2020\)](#).
- For XSum, our λ =none decoding has 45.3/21.9/36.8 with an average of 34.7, compared to an average of 34.9 in [Lewis et al. \(2020\)](#).
- For Multi-News, our MN-800 λ =none decoding has 50.2/20.5/45.8 with an average of 38.8, compared to improved ROUGE F_1 results of 44.5/16.0/40.3 with an average of 33.6 by [Fabbri \(personal communication\)](#) for [Fabbri et al. \(2019\)](#).

H.2 Comparing Summarization Models

To complement our comparison of different models in Section 5.2, we list the ROUGE-L F_1 scores of the five models in Table 8.

I Additional Experimental Details

We used AWS p3.8x and p3.16x EC2 machines for all our experiments, except we ran FEQA on the Multi-News summaries on a p3dn.24xlarge machine, as it required more memory.

	Model	RL
CNN/DM	BART	41.0
	BERTSUM	39.2
	PGCONV	36.4
	BOTTOMUP	38.3
	ABSRL	37.3
XSum	BART	36.8
	BERTSUM	31.3

Table 8: ROUGE-L F_1 scores for the models compared in Section 5.2.

The BART model has 406,290,432 parameters. Fine-tuning BART on the Multi-News training set took about 2.5 hours on 4 GPUs; we fine-tuned for 5 epochs following instructions on the fairseq BART webpage, without further hyperparameter search. For CNN/DM and XSum we used the provided checkpoints.¹⁰ The minimum and maximum length for Multi-News decoding was determined by the lengths of the training reference summaries.

Fairness in Language Models Beyond English: Gaps and Challenges

Krithika Ramesh, Sunayana Sitaram, Monojit Choudhury

Microsoft Corporation

{t-kriramesh, sunayana.sitaram, monojitc}@microsoft.com

Abstract

With language models becoming increasingly ubiquitous, it has become essential to address their inequitable treatment of diverse demographic groups and factors. Most research on evaluating and mitigating fairness harms has been concentrated on English, while multilingual models and non-English languages have received comparatively little attention. In this paper, we survey different aspects of fairness in languages beyond English and multilingual contexts. This paper presents a survey of fairness in multilingual and non-English contexts, highlighting the shortcomings of current research and the difficulties faced by methods designed for English. We contend that the multitude of diverse cultures and languages across the world makes it infeasible to achieve comprehensive coverage in terms of constructing fairness datasets. Thus, the measurement and mitigation of biases must evolve beyond the current dataset-driven practices that are narrowly focused on specific dimensions and types of biases and, therefore, impossible to scale across languages and cultures.

1 Introduction

Language models are known to be susceptible to developing spurious correlations and encoding biases that have potentially harmful consequences in downstream tasks. Whilst prior work has documented these harms (Dev et al., 2021) (Bender et al., 2021) (Kumar et al.), there remains much to be studied and criticism for the existing research (or lack thereof) that remains to be addressed.

In the context of language models, fairness can manifest in two forms; *representational* and *allocational* harms. **Representational** harms generally refer to cases where demographic groups end up being misrepresented. This includes stereotypes and negative associations with these groups and even a lack of acknowledgment of certain groups that are underrepresented in the data. **Allocational** harms,

on the other hand, refer to the inequitable distribution of resources and opportunities to groups with different demographic attributes associated with them. The nature of allocational harms can vary based on the **sociocultural, economic, and legal** settings where the system has been deployed. However, it can also take shape in terms of the model’s functionality across languages with fewer resources (Choudhury and Deshpande, 2021; Liu et al., 2021). While current literature adopts a Euro-American-centric view of fairness, work such as Sambasivan et al. (2021) pushes to recognize algorithmic fairness from a more inclusive lens.

Bias crops up in multiple steps of the pipeline (Hovy and Prabhumoye, 2021) (Sap et al., 2022), including the annotation process, the training data, the input representations, model architecture, and the structure of the research design. Thus, measures to mitigate bias in one of these components alone will likely not suffice as a corrective measure, necessitating human intervention at different stages of the pipeline.

Most work that addresses fairness in NLP addresses it from an Anglo-centric context, with comparatively significantly less work done in grammatically-gendered and low-resource languages. Their inability to capture social and cultural nuances and demographic variations is well-documented (Talat et al., 2022). Despite this, they are ubiquitous, with applications ranging diverse fields, from legal contexts to healthcare. That said, there is insufficient documentation of the harms that could stem from unfair models trained for downstream tasks involving natural language generation, despite Arnold et al. (2018); Bhat et al. (2021); Buschek et al. (2021) indicating the influence of these systems on users. Apart from this, these NLP systems also reinforce and reproduce the social and racial hierarchies observed in society and fail to recognize underrepresented communities that are already marginalized (Dev et al., 2021;

Lauscher et al., 2022b). The ramifications of neglecting these issues are diverse and far-reaching, from minor inconveniences for users in less harmful contexts to compromising their privacy as well as depriving them of opportunities and resources (Cirillo et al., 2020; Köchling and Wehner, 2020).

Finally, while the interplay and tradeoff between privacy, efficiency, and fairness in tabular data has received extensive examination (Hooker et al., 2020; Lyu et al., 2020) comparatively fewer studies have been conducted in NLP (Tal et al., 2022; Ahn et al., 2022; Hessenthaler et al., 2022).

The contributions of this work center around drawing attention to the current state of research on fairness in the context of linguistic and cultural issues in non-English languages and in the context of multilingual models. While thorough survey studies such as Sun et al. (2019); Stanczak and Augenstein (2021); Bhatt et al. (2022) yield valuable insights into some of these aspects, none address the current state of the work in multilingual fairness. Our paper provides insights into the following:

- This work surveys and presents challenges and unanswered questions with respect to fairness in both monolingual and multilingual NLP.
- We analyze bias from both a linguistic and cultural lens for non-English languages and present a comprehensive overview of the literature in bias pertaining to grammatically gendered languages and multilinguality.
- We bring to the forefront challenges in multilingual fairness and begin a dialogue for creating more equitable systems for multilingual NLP.

2 Bias in Monolingual Setups for English

2.1 Metrics for Measurement

Prior to delving into the complexities of fairness in multilingual systems, it is essential to first examine the prevalent biases and challenges in monolingual systems. By prefacing the discussion on bias in multilingual systems with an overview of the current state of fairness evaluation and identifying areas for improvement, we aim to shed light on the potential for similar issues to arise in multilingual systems, as many of the biases present in monolingual systems are likely to persist in multilingual contexts. Some of the initial work on analyzing biases in NLP models (Bolukbasi et al., 2016) propose quantitative measures of evaluating bias in

word embeddings. Broadly speaking, bias measures are subcategorized into *i) intrinsic* and *ii) extrinsic* measures. Intrinsic metrics quantify bias in the model’s pre-trained representations, whereas extrinsic metrics deal with bias observed in the outputs of the downstream task the model is trained for.

Caliskan et al. (2017); May et al. (2019); Nadeem et al. (2021); Nangia et al. (2020) are commonly used in papers evaluating language models for fairness. Caliskan et al. (2017) proposes the Word Embedding Association Test (WEAT). A fundamental criticism of WEAT is that it can be exploited to overestimate the bias in a model (Ethayarajh et al., 2019). The Sentence Encoder Association Test (SEAT) metric (May et al., 2019) was proposed to address WEAT’s limitation of measuring bias only over static word embeddings. SEAT is an adaptation of WEAT that allows us to measure bias over contextualized embeddings.

StereoSet (Nadeem et al., 2021), and CrowS-Pair (Nangia et al., 2020) are crowdsourced datasets specifically geared toward measuring the model’s stereotypical proclivity over multiple dimensions, which are inclusive of gender, race, and religion, among others. Blodgett et al. (2021) points out the flaws in the data quality, such as invalid stereotype/anti-stereotype pairs, reliance on indirect group identifiers as a proxy for demographic identification, and logical incongruities in the sentence pairs.

Several other intrinsic measures and adaptations of the aforementioned ones have also been proposed (Kurita et al., 2019; Webster et al., 2020; Kaneko and Bollegala, 2021; Lauscher et al., 2021). Recent studies (Delobelle et al., 2022; Meade et al., 2022) that perform comparative evaluations across these measures provide valuable insights into how and where the metrics can be used, along with their potential drawbacks.

2.2 Intrinsic vs Extrinsic Evaluation

While intrinsic measures are valuable in that they indicate the existence of representational bias in systems, the current literature on fairness evaluation largely concentrates on intrinsic metrics alone. Considerably less work has been done on addressing bias in extrinsic evaluation, with several downstream tasks needing concrete metrics to evaluate bias in their outputs. This is a pressing issue due to the lack of correlation between intrinsic and extrin-

sis measures (Goldfarb-Tarrant et al., 2020; Cao et al., 2022; Delobelle et al., 2022). As emphasized in Orgad and Belinkov (2022), incorporating extrinsic evaluation measures is crucial for several reasons, including the greater relevance of these metrics to bias mitigation objectives. Aside from this, evaluating fairness on the downstream task’s outputs allows us to gauge more precisely how a particular demographic may be affected by the biases in the system.

Although work done in fairness evaluation in NLP primarily concentrates on monolingual studies, there remain several unanswered questions and inconclusive results. For instance, although May et al. (2019) claims to use semantically bleached templates, experiments in Delobelle et al. (2022) suggest that they retain some degree of semantic significance. While several bias evaluation methods use template-based data, recent findings (Alnegheimish et al., 2022) suggest that this approach may be unreliable and advocate the use of natural sentence prompts.

2.3 Fairness From the Lens of Multiple Social Dimensions

The focus of much of the existing body of literature is on gender bias, with little that covers other dimensions like race and religion. Evaluation metrics should be able to evaluate harms in language models over the intersectionality of multiple identities, akin to what would realistically be expected in real-world data. While previous research (Talat et al., 2022; Kirk et al., 2021) has emphasized the importance of fairness evaluation and mitigation over intersectional identities, there is relatively sparse work that attempts to address the same (Tan and Celis, 2019; Subramanian et al., 2021; Hassan et al., 2021; Lalor et al., 2022; Câmara et al., 2022). It is also crucial to gauge if reducing bias across one dimension could affect biases in the other dimensions. Most fairness measures do not account for the intersectionality of identities and standards of justice outside the predominantly Western sphere of distributive justice (Sambasivan et al., 2021; Lundgard, 2020).

Whilst there has been an increase in proposing novel methods to mitigate bias in language models, there needs to be more work in benchmarking these debiasing techniques to assess their relative effectiveness. Meade et al. (2022) represents a step forward in this direction. Despite criticism (Etha-

yarajh et al., 2019; Blodgett et al., 2021) of some evaluation metrics, they are still consistently used (and not always in conjunction with other metrics) in bias evaluation studies.

3 Linguistic Aspects

The linguistic variations between languages pose additional problems in the realm of multilingual NLP. Take, for example, the concept of gender, which has multiple definitions in linguistic terms (namely, **grammatical, referential, lexical and bio-social gender**) (Stanczak and Augenstein, 2021). Section 3.1 delves into how the grammatically gendered nature of languages can affect bias in multilingual and monolingual spaces alike. **Referential** gender, on the other hand, deals with terms that referentially address a person’s gender, such as pronouns. Terms that non-referentially describe gender fall under the umbrella of **lexical** gender, and the **bio-social** definition of gender involves a mixture of phenotypic traits, gender expression, and identity as well as societal and cultural aspects that influence them (Ackerman, 2019).

Although initial forays into this field investigate bias caused by grammatical gender, problems in these systems can also crop up due to the other definitions of gender. Referential gender terms are not always aligned when used in conjunction with lexically gendered terms, particularly with respect to pronoun-based anaphors for queer-identifying individuals. Several default assumptions regarding the individual’s gender identity are made as a consequence (Cao and Daumé III, 2021).

There are multiple varying forms of pronoun complexity (Lindström, 2008; Ballard, 1978). Apart from this, there are instances of substantial variations in their linguistic forms even among languages within a specific region, as highlighted in Nair (2013). Linguistics also involves the presence of constructs like deictic pronouns and honorific pronouns (Goddard, 2005), which in some cases can lead to the pronouns used to reference someone changing based on their social dynamic within the community (Lauscher et al., 2022c). These linguistic aspects represent another line of work that must be addressed for lower-resourced communities that communicate using languages that utilize these.

Lexical gender, while non-referential, finds its own challenges due to the variation of these terms across languages. For example, while certain relationships with individuals in a family may have an

exact mapping in other languages, more often than not (particularly with Southeast Asian languages), there is no precise mapping, and the system ends up making an approximation or ignoring the term altogether. Such issues may also be likely to perforate to other axes such as race, religion, caste, and so forth. In particular, considering that one method of training multilingual embeddings relies on alignment-based approaches, it is imperative that we keep in mind how these design choices could affect the representations of these terms.

Whilst utilizing linguistic features in methods to evaluate and mitigate gender bias is a relatively new field of study, previous work has demonstrated that additional linguistic context can result in performance gains (Volkova et al., 2013; Wallace et al., 2014), thus in alignment with the claim from Hovy and Yang (2021) that LMs must utilize social context to be able to reach human-level performance on tasks. Sun et al. (2021) utilizes linguistic features to capture cross-cultural similarities, and thus, to select languages that are optimal for cross-lingual transfer. However, it is essential to acknowledge that languages are susceptible to cultural and linguistic shifts that occur at both global and local levels over time, as noted in Hamilton et al. (2016). Pretrained models also have the capability to embed sociodemographic information, as evinced by Lauscher et al. (2022a).

It has also been noted that other linguistic forms of gender do not translate well to sociological gender (Cao and Daumé III, 2021). Furthermore, the scarcity of non-binary gender options in different languages can lead to the misgendering of non-binary individuals in these languages, as they may be constricted to fit into a binarized definition of sociological gender.

3.1 Grammatically Gendered Languages

Linguistics recognizes multiple forms of gender (Cao and Daumé III, 2020), as observed in grammatically gendered languages where most or all nouns, including those referring to inanimate objects, possess a syntactic concept of gender. These languages can have anywhere between 2 to 20 forms of grammatical gender divisions. There has been an almost exclusive focus on English for evaluating gender bias, even in the setting of monolingual models and systems. English, however, is not a grammatically-gendered language. This may limit the transferability of techniques used for bias

evaluation and mitigation to other languages that are grammatically gendered.

Zhou et al. (2019) examines bias from the view of grammatically gendered languages by decomposing the gendered information of words in the embedding space into two components; i) semantic and ii) syntactic. For instance, the Spanish word for "man" (*hombre*) is both semantically and syntactically gendered. However, the Spanish word for "water" (*agua*) is not semantically gendered but is considered a feminine noun. The proximity of female occupation words to the feminine side and male occupation words to the masculine side of the semantic gender direction suggests the presence of bias in these Spanish embeddings. Zhou et al. (2019) also demonstrates via experiments on bilingual embeddings that, post-alignment, masculine-gendered words are closer to the English equivalent of the occupation words than feminine-gendered ones. The paper also proposes bias mitigation methods and demonstrates that the quality of the embeddings is preserved via word-translation experiments. Nevertheless, the validity of these mitigation measures would need to be verified by testing them on downstream tasks. Gonen et al. (2019) show that grammatical gender affects the word representations in Italian and German and that inanimate nouns end up being closer to words of the same gender. They propose to address this through the precise use of a language-specific morphological tool and a careful approach to removing all the gender signals from a given text.

The grammatical properties of a language might show some interesting properties to be taken into account when dealing with the fairness of large language models, particularly for gender bias. Studies directed toward them could yield insights into observable trends across language families, with Gonen et al. (2019) demonstrating how the alignment of languages in the embedding space is negatively affected by grammatical gender. They could also prove helpful when analyzing bias in multilingual models, where both grammatically gendered and non-gendered languages are aligned to the same embedding space. The research and datasets available for extrinsic evaluation over other languages remain an area with scope for improvement.

Apart from these grammatical properties that affect the results we observe, the translation of existing bias evaluation datasets into other languages to create parallel corpora does not suffice

when dealing with languages apart from English. This is partly because most languages are inherently rooted in cultural context. Any data curated for these languages must incorporate socio-cultural and linguistic aspects unique to the language/region. Depriving NLP systems of cultural context could consequently lead to entire axes over which social biases are measured being ignored. The cultural significance of words and phrases in various languages can vary significantly, as demonstrated in [Mohamed et al. \(2022\)](#), as well as in characteristics such as metaphorical tendencies ([Gutiérrez et al., 2016](#)) and communication styles ([Miehle et al., 2016](#); [Suszczyńska, 1999](#)). [Hovy and Yang \(2021\)](#) includes an overview and critique of this in the current state of NLP literature, which they claim adopts an oversimplified view and focuses on the information content alone while ignoring the social context of this content. [Milios and BehnamGhader \(2022\)](#); [España-Bonet and Barrón-Cedeño \(2022\)](#) illustrate the inefficiency of direct translation methods, and [España-Bonet and Barrón-Cedeño \(2022\)](#) advocates for the creation of culturally-sensitive datasets for fairness assessment. However, [Kaneko et al. \(2022\)](#) proposes a way to generate parallel corpora for other languages that bears high correlation with human bias annotations.

4 Multilingual Models

Multilingual spaces allow the embeddings of multiple languages to be aligned so that the mappings of every word to its equivalent in other languages are close to each in these embedding spaces. There are numerous ways of training multilingual language models ([Hedderich et al., 2021](#)) using monolingual and unlabeled data. Multilingual language models can improve cross-lingual performance on low-resource languages leveraging the data available to higher-resourced languages up to a certain number of languages. Beyond a point, however, the performance across these languages on cross-lingual and monolingual tasks begins to dip as the number of languages increases ([Conneau et al., 2020](#)). However, few studies explore the impact of multilingual training on biases. [Hovy and Yang \(2021\)](#) illustrate how language and culture share a strong association, and [Khani et al. \(2021\)](#); [Sun et al. \(2021\)](#) reveal that geographical and cultural proximity among languages could enhance the performance of models.

Languages provide much insight into a society's

cultural norms, ideologies, and belief systems ([Hershovich et al., 2022](#); [Wilson et al., 2016](#)). Often, the properties unique to a language are not clearly mapped to other languages or even other dialects within a language, with no direct translations available for several phrases and terminology. Whether or not language models can retain this cultural information and context while utilizing information from higher-resourced languages still requires investigation.

4.1 An Outline of Fairness Evaluation in the Context of Multilinguality

Several datasets have been put forward for the purpose of multilingual evaluation, and [Table 1](#) describes these datasets along with details regarding their utility. These include the languages they cover, whether or not they evaluate bias over pre-trained representations or a downstream task, and the downstream tasks and dimensions they cater toward.

[Zhao et al. \(2020\)](#) was among the first papers to quantify biases in multilingual spaces and does so using both extrinsic and intrinsic evaluation techniques. Their findings indicate that some factors that influence bias in multilingual embeddings include the language's linguistic properties, the target language used for the alignment of the embeddings, and transfer learning on these embeddings induces bias. Additionally, there is the possibility that non-Germanic languages do not align well with Germanic ones, and further work would be required to derive conclusions as to how this affects fairness measurements.

[Huang et al. \(2020\)](#) released the first multilingual Twitter corpus for hate speech detection, annotated with the author's demographic attributes (age, country, gender, race/ethnicity), which allows for fairness evaluation across hate speech classifiers. Through experiments, they prove that variations in language, which are highly correlated with demographic attributes ([Preoțiuc-Pietro and Ungar, 2018](#); [Osiapem, 2007](#)), can result in biased classifiers. However, there are some promising results from [Liang et al. \(2020\)](#), which proposes a novel debiasing method using [Dufter and Schütze \(2019\)](#). While the multilingual model is originally debiased over English, results show its effectiveness for zero-shot debiasing over Chinese.

[Câmara et al. \(2022\)](#) measures both unisectional and intersectional social biases over gender, race,

and ethnicity in multilingual language models. This is particularly relevant, as in a practical setting, treating identities as composites of various demographic attributes is a necessity. Kaneko et al. (2022) measures gender bias in masked language models and proposes a method to use parallel corpora to evaluate bias in languages shown to have high correlations with human bias annotations. In cases where manually annotated data doesn't exist, this could prove helpful.

Although there has been research on fairness in multimodal contexts (Wolfe and Caliskan, 2022; Wolfe et al., 2022), in a first-of-its-kind study, Wang et al. (2022) looks at fairness from a multilingual view in multimodal representations. Whilst they find that multimodal representations may be individually fair, i.e., similar text representations across languages translate to similar images, this concept of fairness does not extend across multiple groups.

Talat et al. (2022) expresses criticism over the primary data source for multilingual large language models being English, which they claim is reflective of cultural imperialism. They also advocate for these models to be used only for languages they have been trained for to retain the cultural context unique to a language. The multilingual datasets commonly used tend to be parallel corpora derived directly from English translations, neglecting the socio-cultural nuances specific to a given language, as evidenced by the CommonCrawl corpora (Dodge et al., 2021).

Moreover, recent literature (Al Kuwatly et al., 2020; Parmar et al., 2022; Sap et al., 2022) presents us with yet another potential issue; lack of demographic variation in the annotation of these dataset results could contribute to bias in the pipeline. As of yet, several languages (Aji et al., 2022; Joshi et al., 2020) (such as Hindi, Arabic, and Indonesian, which have tens to hundreds of million of native speakers) have had little to no fairness benchmark-

ing datasets developed for them, an indicator that much remains to be done to develop more equitable language models.

4.2 An Outline of Fairness Mitigation in the Context of Multilinguality

Due to multilingual spaces being a composite of the embeddings of various languages with different linguistic and semantic properties, it would serve mitigation techniques well to consider these differences. Other methods could use these distinctions to reduce bias in downstream tasks. Zhao et al. (2020), for one, show that balancing the corpus and transferring it to a grammatically gendered language's embedding space could reduce bias, and that using debiased embeddings could also aid with bias mitigation.

Huang (2022) takes inspiration from the FEDA domain adaption technique (Daumé III, 2007) to use it to mitigate bias in multilingual text classification and compares this with other mitigation methods. These debiasing baselines involve adversarial training, masking out tokens associated with demographic groups, and instance weighting to reduce the impact of data instances that could lead to more biased classifiers. While Liang et al. (2020) show that zero-shot debiasing can be beneficial for this purpose, further study would be required to ascertain if this is a feasible possibility.

4.3 Problems in Multilingual Evaluation and Mitigation

A major challenge in multilingual fairness is the lack of datasets (including parallel corpora) and literature for evaluation across tasks. Much of the research conducted in monolingual contexts has yet to be replicated in a multilingual setting, which would enable us to determine whether or not bias trends in monolingual spaces are directly transferable to multilingual contexts. Research and data resources also tend to neglect less-represented

demographics, notably those local to a particular region. Further, datasets require thorough documentation, as variations in annotator information can result in different types of biases infiltrating the pipeline (Mohamed et al., 2022; Joshi et al., 2016; Bracewell and Tomlinson, 2012). These could include attitudes towards other cultures and languages, which must be assessed and reported during data collection. Multilingual users speak multiple languages, and there is no work on evaluating bias in language contact settings such as code-switching. Certain axes along which systems may discriminate may be contained to a given region. Due to the underrepresented nature of marginalized identities (such as immigrant communities), models will likely not learn useful representations of these identities.

5 Culture

Language and culture are intrinsically linked with each other. However, NLP research has historically placed a considerable emphasis on the information content of the data, as opposed to the contextual information surrounding the same data. Hovy and Yang (2021) propose a broad taxonomy of 7 social factors that encompasses various aspects of this contextual information. This could be incorporated into models to improve performance and make them aware from a socio-cultural perspective.

The differences between a pair of languages or even a pair of dialects could reflect across multiple attributes; this could lead to variations in language’s *phonology, tone, text, and lexical forms*. Some of these attributes are controlled by the speaker and receiver involved. Despite evidence of gains in performance by leveraging these features, systems still retain the potential to discriminate against marginalized communities, as evinced in Sap et al. (2019). This necessitates the proposal of evaluation methods to analyze the potential harms that people from different cultural backgrounds might expose themselves to via the use of such systems.

Multilingualism also entails the need to navigate the nuances of language, including the potential for stereotypes and discriminatory language, which may not have precise equivalents in other languages. Cultural taboos and stereotypes can be highly localized. As an example, pregnant or lactating women are discouraged from consuming nutritious food in certain cultures (Meyer-Rochow,

2009). Such contextual information might be underrepresented or nonexistent in the data that the model is exposed to. While some culture-specific behaviors may be prohibited or frowned upon in some parts of the world, there are yet other places that may encourage or remain indifferent to these very same behaviors.

Additionally, the axes we consider require to be treated differently in different cultural and linguistic settings. Take, for instance, gender. While gender has, for the most part, been treated as a binary variable in these studies, this does not echo what is observed in real-world settings, where several individuals have non-binary gender identities (Devinney et al., 2022). Non-binary gender identities encompass a broad spectrum of gender identities, and the term is generally considered an umbrella term for any identity outside the binary. The inability of models to incorporate this additional information on gender has subsequently led to them developing meaningless representations of non-binary genders in text (Dev et al., 2021). This translates to the systematic erasure of their identities. Baumler and Rudinger (2022) show that much remains to be done concerning addressing non-binary identities outside the Western context. For instance, several non-binary identities, such as the Aravanis and the Māhūs (local to India and Hawaii, respectively) are likely to have little to no meaningful coverage in the training data of the models. These identities can also have unanswered nuances in literature; for example, the Acaults of Myanmar do not consider transsexualism, transvestism, and homosexuality to be distinct categories. This is also applicable to languages such as Arabana-Wangkangurru, which make use of deictic pronouns (previously discussed in Section 3) (Lauscher et al., 2022c; Hercus, 1994).

Further, given that models are highly susceptible to the kind of data they are trained on, it is unlikely that our models can recognize that certain forms of prejudice are more frequent in specific socio-cultural environments than others. The targets of this discrimination are also likely to vary from region to region, another nuance that models find difficult to account for. India and Nepal, for instance, are two countries that still suffer from the effects of the hierarchy of a historically caste-based society that (despite sharing similar roots) bear differences in terms of representation of the various castes and how they are referred to (Jodhka et al., 2010; Rao,

2010). It is important to note that the ability of a system to incorporate information from these social factors to mitigate biases is task-dependent. Downstream tasks like machine translation and dialogue/response generation may depend more on cues related to speaker and receiver characteristics from the taxonomy proposed in [Hovy and Yang \(2021\)](#) than other tasks. Extrinsic metrics for machine translation focus primarily on the gender bias of the mappings of nouns and pronouns from one language to another ([Cho et al., 2019](#)). On the other hand, more open-ended, subjective tasks like NLG are prone to encoding underlying biases and stereotypes across multiple axes and reproducing these in their outputs ([Henderson et al., 2018](#)).

It is critical to consider intersectionality in these studies, as every individual is a composite of multiple identities across multiple axes. When conducting inquiries into the biased nature of these systems, we encourage researchers to use metrics that treat fairness as an intersectional concept and keep in line with the recommendations as suggested in [Talat et al. \(2022\)](#); [Blodgett et al. \(2020\)](#) to document the affected demographics. Testing the validity and reliability of bias measurement and debiasing metrics is essential to ensuring the effectiveness of proposed methods ([Blodgett et al., 2020](#)), and it is crucial to report any limitations of the same.

6 Moving Towards Inclusive Systems in All Languages

The issue of fairness in multilingualism presents a number of challenges. Although current practitioners encourage making systems multicultural and developing systems to be used only for specific cultural contexts ([Talat et al., 2022](#)), we posit that this may not be a viable solution due to various practical considerations. The vast diversity of cultures and ethnicities across the world presents significant difficulties in terms of creating equitable multilingual systems. Even within languages such as English, several dialectal variants, both of the regional and social kind ([Nguyen et al., 2016](#)), still need to be accounted for. [Blodgett and O'Connor \(2017\)](#) is an example of how this could further stigmatize oppressed communities. Language and various social aspects related to language are ever-evolving. Modeling aspects such as lexical variants and the syntactical difference between languages, elements like phonology, and speech inflections in spoken language could contribute to the complexity

of these systems.

Several countries have diverse concentrations of people from all regions of the world with unique backgrounds. The intricacies of the social interactions resulting from the population's diverse linguistic backgrounds and issues arising from language contact make the study of the fairness of multilingual systems that would be deployed to cater to these populations essential. It is not possible to make models agnostic to demographic attributes. Even with the omission of certain attributes, models can still exhibit bias based on factors such as linguistic variations in dialect, or the linguistic features employed, as demonstrated by [Hovy and Søgaard \(2015\)](#) who highlight the improved performance of NLP systems on texts written by older individuals. The data that large language models (LLMs) are trained on tends to be biased towards certain demographic strata ([Olteanu et al., 2019](#)). Although curating more diverse datasets and following recommendations to mitigate bias in the data pipeline would be a step forward to mitigating this problem ([B et al., 2021](#)), various resource constraints could hinder this or make it impractical.

Due to all these challenges and the ubiquity of language technologies that are used by large populations of non-English speaking users, addressing fairness and bias, taking into account diverse linguistic, socio-linguistic, and cultural factors, is of utmost importance. Interdisciplinary and multicultural teams are crucial to identifying, measuring, and mitigating harms caused by bias in multilingual models. Better evaluation benchmarks covering diverse linguistic phenomena and cultures will lead to better fairness evaluation.

Regarding data collection, as discussed in [Section 3.1](#), it would be prudent to avoid directly translating datasets for training or evaluation in applications where fairness is critical. As we have shown in this survey, it is not enough to collect datasets in multiple languages for measuring and mitigating bias, although even these are lacking for most languages worldwide. Zero-shot techniques that ignore the cultural nuances of a language should be used with care in fairness-critical applications, as linguistically similar languages may have different cultural values and vice versa. Finally, multilingual models and systems need to incorporate shared value systems that take into account diverse cultures, although some cultural differences may still go unacknowledged.

Limitations

Our work surveys fairness literature in languages other than English, including bias measurement and mitigation strategies. Although we call out the fact that bias in literature is studied from an Anglo-centric point of view, it is conceivable that we miss many diverse perspectives on linguistic and cultural aspects of bias in different languages and cultures of the world due to the relatively heterogeneous background (in terms of nationality, ethnicity and field of study) of the authors. There may also be other relevant work in the social science literature that we may have missed including in this survey.

Global-Local Modeling with Prompt-Based Knowledge Enhancement for Emotion Inference in Conversation

Renxi Wang and Shi Feng

realreasonwang@gmail.com, fengshi@cse.neu.edu.cn

Abstract

The ability to recognize emotions in conversations is necessary and important for the online chatbot to do tasks such as empathetic response generation and emotional support. Present researches mainly focus on recognizing emotions through a speaker’s utterance, while research on emotion inference predicts emotions of addressees through previous utterances. Because of the lack of the addressee’s utterance, emotion inference is more challenging than emotion recognition. In this paper, we propose a global-local modeling method based on recurrent neural networks (RNN) and pre-trained language models (PLM) to do emotion inference, which utilizes the sequence modeling ability of RNNs and abundant knowledge from PLMs. Moreover, we take the whole dialogue history as input of PLM to generate knowledge by in-context learning. Experimental results show that our model with knowledge enhancement achieves state-of-the-art performance on all three datasets.¹

1 Introduction

The task of emotion recognition in conversation (ERC) (Poria et al., 2019b) aims to identify emotion labels of an utterance, where the whole dialogue history along with the current utterance is given. However, in emotion inference in conversation (EIC) the current utterance is lacking but the dialogue history and the current addressee are known (Li et al., 2021a). For example, Figure 1 shows a conversation between A and B. In the third turn, ERC detects A’s emotion using all available information while EIC predicts A’s emotion using all the information except the last utterance. ERC is a popular task that has been explored widely and deeply, while EIC is a new task that measures the emotion understanding ability of models from a different perspective.

¹The code is available at <https://github.com/Reason-Wang/DialogueGLP>.

Person A

Person B

[neutral]: Hi, what are you doing here?

[happy]: Thank you! It’s so nice of you to invite me.

[happy]: I am celebrating my child’s birthday. Would you like to join us?

Figure 1: A conversation between A and B. The text in orange might be helpful for ERC. The text in green might be helpful for EIC.

In ERC, some previous works utilize sequence-based neural networks to model the context and speaking parties (Majumder et al., 2019; Hu et al., 2021a; Li et al., 2021a). These approaches first finetune a model on utterances to classify emotions. Then this model is used to extract features of utterances. As shown in Figure 1, B makes A happy because he/she is inviting A to join in a party. However, B feels happy because he/she is celebrating his/her child’s birthday. The finetuning tends to keep the semantics that is helpful to classify the current emotion and the feature extraction compresses the utterance’s information, which may cause information loss that is valuable to infer A’s emotion. Some works model dialogues at utterance-level with graph-based models (Ghosal et al., 2019, Shen et al., 2021). They have the same problem as sequence-based models. Also, it becomes difficult for them to distinguish similar emotions as their layers deepen (Li et al., 2022). Pre-trained language models do not need to do the feature extraction process and they contain knowledge suitable for EIC. However, these models can not naturally process sequential utterances from different parties. Motivated by this, we propose global-local modeling method to combine different abilities from these models. Specifically, we use a sequence-based model to get the representation

of the dialogue history and a pre-trained model to process utterances that are close to the addressee’s turn in which his/her emotion is to be inferred. In our framework, the global representation and local utterances can attend to each other, which we believe is helpful for EIC.

Some researchers introduce external knowledge to improve the performance of emotion detection (Ghosal et al., 2020, Li et al., 2021b). They generate commonsense knowledge using COMET (Bosselut et al., 2019) which is trained on ATOMIC (Sap et al., 2019). However, this knowledge is limited to certain event types. Also, it is generated based on a single utterance instead of the whole dialogue, which further limits the quality of the knowledge. Recent advancements of in-context learning (Liu et al., 2022) show that it is possible to generate high-quality knowledge when language models are provided with appropriate examples. Based on the above analysis, we propose a knowledge generation method specially designed for EIC task based on prompt learning. Specifically, we use templates to obtain two kinds of knowledge: I. We let GPT fill the dialogue, thus we get pseudo utterances that may be spoken by the addressee and take them as knowledge. II. We ask GPT how the addressee feels and take generated texts as knowledge. Our knowledge is more precise since we take the whole dialogue history as input. Also, it is more diverse because GPT is trained on a large number of texts in different fields.

2 Methods

2.1 Problem Definition

Given a dialogue $D = [(U_1, p_1), (U_2, p_2), \dots, (U_m, p_m), p_{m+1}]$, where U_i is the utterance in i -th turn and p_i is the participant in i -th turn. For $i = m + 1$, p_i is the addressee, otherwise p_i is the speaker. The task is to predict the addressee’s emotion e using D .

2.2 Global Model

We use DialogueInfer (Li et al., 2021a) as our global model. We first finetune a RoBERTa-Large (Liu et al., 2019) model to predict the emotion label of utterances as ERC task. Then we use the finetuned model to extract features of utterances and get a 1024-dimensional vector u_i for each utterance U_i . These representations of utterances are then put into DialogueInfer to get the representation of the dialogue. DialogueInfer is a model designed for

the EIC task. It adopts addressee-aware modules to capture the persistence and contagiousness of utterances. Formally, the output of the global model can be defined as:

$$h_t, c_t = \mathbb{1}\{p_t = p_{m+1}\}LSTM_a(u_t, (h_{t-1}, c_{t-1})) + \mathbb{1}\{p_t \neq p_{m+1}\}LSTM_o(u_t, (h_{t-1}, c_{t-1}))$$

$$h_g = h_{m+1} \quad (1)$$

where $t = 1, 2, \dots, m$ is the turn step, $\mathbb{1}\{\text{condition}\}$ is the indicator function and returns 1 if the condition is true otherwise 0, $h_t \in \mathbb{R}^{d_1}$ and $c_t \in \mathbb{R}^{d_1}$ are hidden state and cell state respectively, d_1 is the hidden dimension in LSTM unit, h_g is the global representation of the dialogue. The final output $h_g \in \mathbb{R}^{d_1}$ is then fed into the local model.

2.3 Local Model

We employ RoBERTa (Liu et al., 2019) as the local model. RoBERTa shares the same architecture as BERT (Devlin et al., 2019) and is trained with masked language modeling objective function. We concatenate the last k utterances to form the input. To make the local model addressee-aware as global model, we prepend a speaker prefix to indicate whether the utterance comes from the addressee. The final text input is:

$$U_t = \text{prfix}(p_{m-k+1})U_{m-k+1} </s> \text{prfix}(p_{m-k+2})U_{m-k+2} </s> \dots \text{prfix}(p_m)U_m \quad (2)$$

$$\text{prfix}(p_i) = \begin{cases} \text{"I:"}, & p_i = p_{m+1} \\ \text{"Other:"}, & p_i \neq p_{m+1} \end{cases} \quad (3)$$

where $</s>$ is the special token that indicates the separation of utterances.

To fuse the global information, we add the global representation h_g to the first token’s embedding of the text input. The whole process can be formulated as:

$$\hat{h}_g = W^T h_g + b \quad (4)$$

$$H = [\text{Emb}(U_t[0]) + \hat{h}_g; \text{Emb}(U_t[1 :])] \quad (5)$$

$$h_e = \text{RoBERTa-Model}(H) \quad (6)$$

where $W \in \mathbb{R}^{d_1 \times d_2}$ is the matrix to project dimensions, d_2 is the hidden dimension in RoBERTa model, Emb is the embedding layer of RoBERTa.

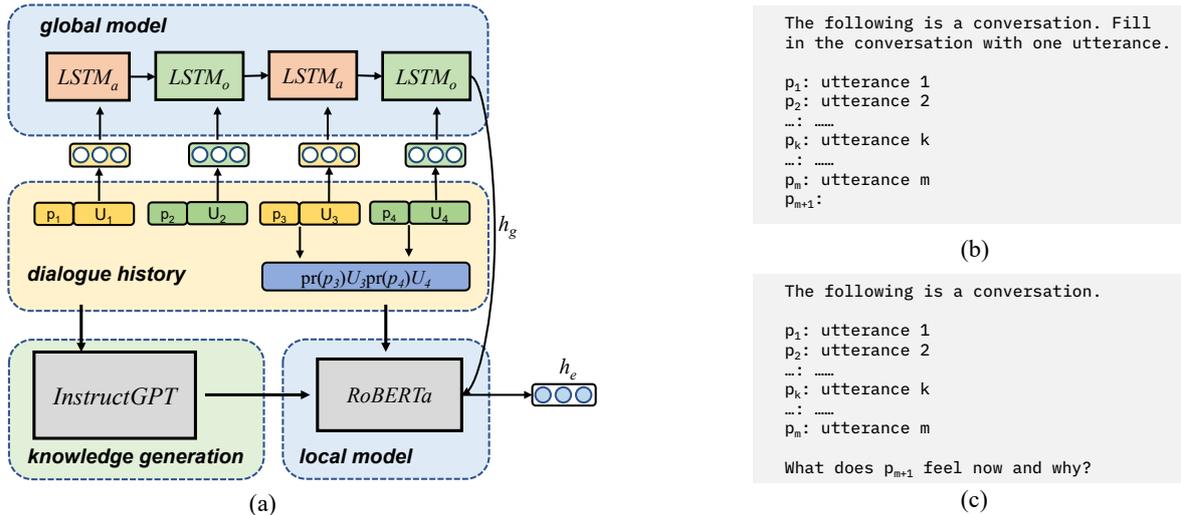

Figure 2: (a) Our framework to infer the emotion. (b) The template to generate pseudo utterances. (c) The template to generate feelings and corresponding reasons.

2.4 Prompt Based Knowledge Generation

GPT-3 (Brown et al., 2020) is a powerful model which generates informative and accurate texts when provided with appropriate examples. The model is further finetuned to align with users so the outputs are more truthful and less toxic (Ouyang et al., 2022). We use the resulting model, called InstructGPT, to generate two kinds of knowledge.

Pseudo Utterances We take the dialogue history as input and let InstructGPT generate the utterance that might be spoken by the addressee. Figure 2 shows the template to generate pseudo utterances. After obtaining these knowledge texts, we first prepend the addressee prefix to them. Then we append them to the text input in the local model.

Feelings and Corresponding Reasons Since InstructGPT is able to do many tasks, we ask InstructGPT directly about the addressee’s emotions and corresponding reasons. The output from the model is taken as knowledge and is used the same way as pseudo utterances. Figure 2 shows the template to generate this kind of knowledge.

2.5 Classifier

We use the first token’s representation h_e as the final output. A softmax layer is employed after a linear projection layer:

$$p_e = \text{softmax}(W^T h_e + b) \quad (7)$$

where $W \in \mathbb{R}^{d_2 \times c}$ is the projection matrix, c is the number of emotions, $p_e \in \mathbb{R}^c$ is the probability distribution over different emotions.

3 Experiments

3.1 Implementation

We train our model on three datasets: DailyDialog (Li et al., 2017), MELD (Poria et al., 2019a) and EmoryNLP (Zahiri and Choi, 2018). We first finetune a RoBERTa-Large model on the training set of each dataset. The batch size is set to 16 and the model with the best performance on the development set is saved. We then use this model to extract features of the datasets. For emotion inference, we set the learning rate to 1e-5. AdamW is used as the optimizer to update parameters. In the first two epochs, we only update the global model and freeze the local model. After that, we finetune the whole model. We find this updating scheme makes training more stable.

For other baselines, we adapted their official codes to make them applicable to EIC task. The parameters we used in training referred to their original paper. We select all the models based on their best performance on the development set. We use cross entropy as the loss function.

3.2 Main Results

Table 1 shows the main results of our experiments. Our base model without knowledge augmentation already performs best on DailyDialog and MELD. In most cases, the generated knowledge improves the performance. However, knowledge U (pseudo utterances) decreases the performance measured by macro F1 on DailyDialog. COMET decreases the performance measured by macro F1 on DailyDia-

w/o local model	71.37	35.44	20.93
w/o addressee-aware	73.51	36.58	20.07

Table 2: Ablation studies on three datasets.

log and MELD. Generally, knowledge F (feelings and corresponding reasons) are better than knowledge U. Our prompt-based knowledge generation method is better than COMET. We also concatenate the two generated prompt-based knowledge (U+F). The performance is further improved compared to single knowledge augmentation.

Knowledge F consists of emotions and reasons for those emotions. To explore whether only InstructGPT is enough to predict the emotions, we let it directly infer the emotions of addressees in DailyDialog. The resulting weighted F1 is 34.65, which shows that it is not good at inferring emotions and the main performance boost of DialogueGLP(F) comes from the part of reasons.

Ablation Analysis To explore the effectiveness of different modules in our model, we also do ablation studies on the three datasets. To remove the addressee information, we simply replace the global model with a single LSTM and the addressee prefix with the speaker’s name. The results show that the local model is generally more important than other modules. Since DailyDialog is dyadic, the second to last utterance in our input texts must be from the addressee. Therefore, the addressee information is less important in DailyDialog.

4 Related Work

Emotion recognition in conversation has been a popular area where different models have been proposed. We divide them into three categories: sequence-based, graph-based and transformer-based. DialogueRNN (Majumder et al., 2019) models different parties and global state by different recurrent neural networks. DialogueInfer (Li et al., 2021a) adopts two LSTMs to process utterances by whether they are from addressees. DialogueCRN (Hu et al., 2021b) iteratively does retrieving and reasoning process to extract and integrate emotional clues. DialogueGCN (Ghosal et al., 2019) utilizes graph neural networks to connect utterances with surrounding utterances. DAG (Shen et al., 2021) uses a directed acyclic graph network to gather information over long distances. CoG-BART (Li et al., 2022) adopts supervised contrastive learning and response generation as auxiliary tasks. CoMPM (Lee and Lee, 2022) combines speaker’s memory using a pre-trained model as an extractor.

Some works focus on introducing knowledge to help detect emotions. KET (Zhong et al., 2019) retrieve commonsense knowledge from ConceptNet (Speer et al., 2017) and NRC_VAD (Mohammad, 2018). COSMIC (Ghosal et al., 2020), DialogueInfer (Li et al., 2021b) and ToDKAT (Zhu et al., 2021) incorporates commonsense knowledge generated by COMET (Bosselut et al., 2019). GKP (Liu et al., 2022) generates knowledge from language models with prompt learning to do commonsense reasoning.

5 Conclusions

In this paper we combine the ability of sequence models and pre-trained models and propose global-local modeling method to do emotion inference in conversation. Moreover, we take the whole dialogue as input and generate knowledge with prompt learning. Experiments show that our model has achieved state-of-the-art performance on three datasets. Ablation studies show the effectiveness of different modules in our model.

Limitations

Since in our framework the global model needs to first compute the global representation then the local model outputs the emotion distribution, it takes longer time to train and inference than other models. We utilize a pre-trained model in our framework, which requires large GPU memory.

A Case Study

Figure 3 shows a dialogue example between A and B from DailyDialog (Li et al., 2017) dataset and generated knowledge by COMET (Bosselut et al., 2019) and prompt learning. The task is to infer A’s emotion. For COMET, we take each utterance as input and generate three types of knowledge as Li et al. (2021b), which are oReact, oWant and oEffect. For prompt-based knowledge generation, we formulate the input by the template and dialogue history and input it into InstructGPT. As a result, we get a pseudo utterance that may be spoken by A and feelings of A.

As Figure 3 shows, our knowledge summarizes the dialogue well and is much more human-readable. This property makes our knowledge more suitable to concatenate with text inputs. COMET trained on ATOMIC (Sap et al., 2019) generates knowledge based on events. Therefore only one utterance can be taken as input instead of longer contexts. If an utterance contains multiple events, the generated knowledge may not be accurate. Also, the knowledge generated by COMET often repeats.

B Datasets Preprocessing

The datasets can not be directly used. We take each dialogue as an example and the emotion of the last utterance as the label. In training, we do not use the last utterance. DailyDialog is a dyadic dialogue dataset for emotion recognition. It contains more than 10,000 dialogues. We take each dialogue as a training example and take the last speaker of the dialogue as the addressee and the corresponding emotion as the label. MELD (Poria et al., 2019a) is a multimodal multiparty dialogue dataset designed for emotion recognition. However, it contains less than 2,000 dialogues. To get more training examples, we cut one dialogue into more dialogues. We keep a dialogue at least three utterances and cut it wherever the next speaker is different from the current speaker. Figure 3 shows how we process a dialogue with eight utterances. EmoryNLP (Zahiri and Choi, 2018) is a ERC dataset collected from *Friends*. We preprocess it the same way as MELD. Table 3 shows the statics after we preprocess the three datasets. We get each split of datasets from their original splits.

C Adapting Codes to EIC

Since EIC is a new task, there are not many baselines for EIC. We adapt models that are original

Dataset	train	dev	test
DailyDialog	11118	1000	1000
MELD	6125	685	1540
EmoryNLP	8345	1124	1140

Table 3: Statics of processed datasets.

designed for ERC to do EIC. In our baselines, only DialogueInfer is designed for EIC. For other models, we mainly modify the code of their inputs and outputs.

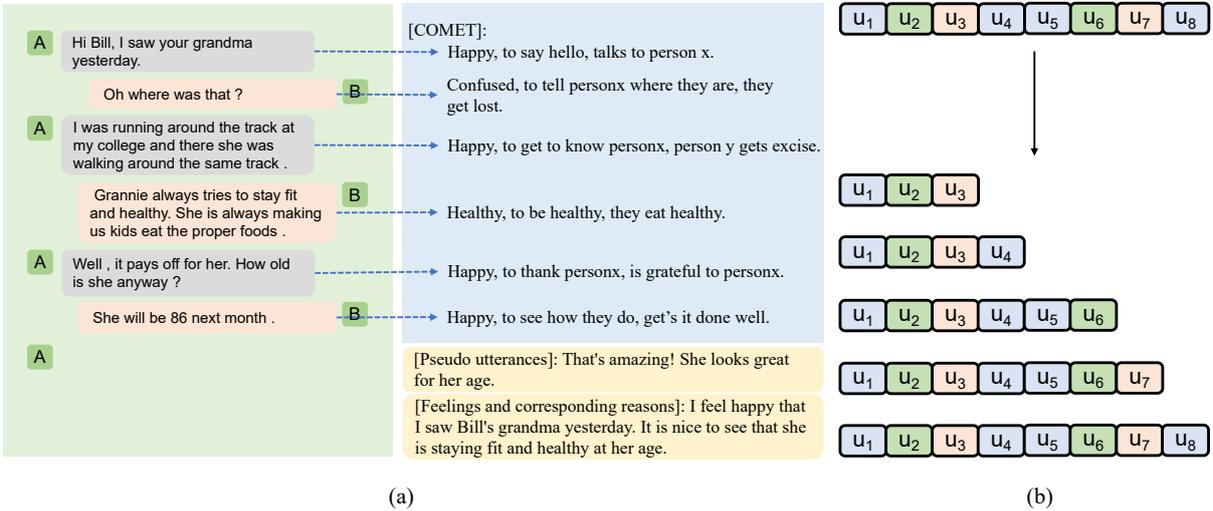

Figure 3: (a) A dialogue example from DailyDialog and generated knowledge from COMET and our method. (b) An example of how we cut dialogues. This dialogue contains eight utterances. Colors denote speakers. We cut it into five dialogues.

Headline Token-based Discriminative Learning for Subheading Generation in News Article

Abstract

The news subheading summarizes an article’s contents in several sentences to support the headline limited to solely conveying the main contents. So, it is necessary to generate compelling news subheadings in consideration of the structural characteristics of the news. In this paper, we propose a subheading generation model using topical headline information. We introduce a discriminative learning method that utilizes the prediction result of masked headline tokens. Experiments show that the proposed model is effective and outperforms the comparative models on three news datasets written in two languages. We also show that our model performs robustly on a small dataset and various masking ratios. Qualitative analysis and human evaluations also show that the overall quality of generated subheadings improved over the comparative models.

1 Introduction

The news headline summarizes the article to grab the attention and interest of the readers (Dor, 2003; Ifantidou, 2009; Ecker et al., 2014). However, the headline is written in a brief form of short sentences with topic-related phrases (Yamada et al., 2021), making it hard for users to grasp the entire content of the news article from the headline alone. To tackle this problem, some news vendors provide a *subheading*, usually located right below the headline, to convey its main content within several sentences. This component can provide a core and informative summary of a news article that cannot be conveyed by the headline alone. Mainly, subheadings are written by professional news writers with concise content that corresponds to the main body of the news.

Recently, Hasan et al. (2021) released XLSum, a multilingual news summary dataset, referring to subheading as a summary of the article. Therefore, generating subheadings can be considered an abstractive summarization problem that needs to cap-

ture the topical knowledge from the body of the article. The main approach is to add auxiliary signals to make the model aware of topical knowledge. Dou et al. (2021) and Aralikkatte et al. (2021) add an external guidance signal by lexical similarity between input text and summary. Yamada et al. (2021) extracts the context word sequences from the reference to reflect some important phrases from the article. Although these external auxiliary sources provide diverse topical signals, they are cost-intensive to heuristically manipulate and have limitations in guiding the overall topical information of the article. Other approaches incorporate contrastive learning into sequence-to-sequence (seq2seq) model, allowing the model to learn topical representation of the input text (Lee et al., 2021; Liu et al., 2021; Wu et al., 2020). They explicitly constructs positive or negative inputs to introduce contrastive loss as an augmentation of MLE training.

In this work, we propose a novel framework for generating compelling news subheadings by discriminating whether each token in the reconstructed headline is the same as the token in the original headline. Unlike previous approaches that use heuristically extracted topical information or positive and negative pairs, we utilize *headline* that fundamentally implies the topic of the entire article. We make full use of this indispensable object as a guide signal through token-based discriminative learning. We conducted comparative experiments on three datasets written in English or Korean to evaluate the performance of our model and verified our model through additional qualitative analysis with human evaluations.

2 Datasets

We used one English news summarization dataset and two Korean news summarization datasets.

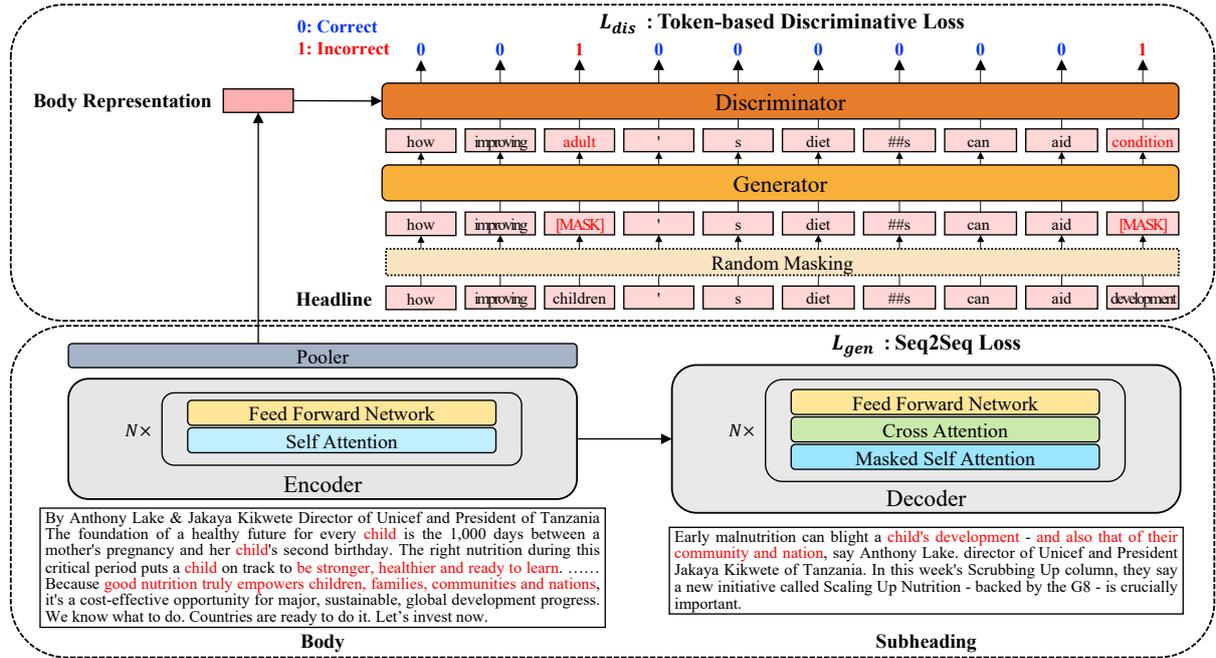

Figure 1: Framework of the proposed model. The lower part of the figure represents subheading generation, and the upper part of the figure represents token-based discriminative learning. Prediction results of discriminator encourage encoder to focus on the topical information.

2.1 XLSum

XLSum (Hasan et al., 2021) is a highly abstract multilingual news summarization dataset containing online articles crawled from the British Broadcasting Corporation (BBC). They regard a bold paragraph containing one or two sentences at the beginning of each article as a summary, a subheading. We use the English and Korean versions with train set, valid set, and test set pairs of $\{306522, 11535, 11535\}$ and $\{4407, 550, 550\}$, respectively.

2.2 YonhapNews

However, the size of the training dataset in XLSum’s Korean version is insufficient for fine-tuning. We construct a dataset from YonhapNews, one of the most reliable news outlets in South Korea, to evaluate the performance of the model with a sizable Korean dataset. In YonhapNews, the subheading is located right below the headline to condense the body in abstractly, like the BBC. Train set, valid set, and test sets in YonhapNews are $\{208750, 26094, 26094\}$ and will be released for academic use.¹

¹<https://github.com/Lainshower/Subheading-Gen>

3 Proposed Method

As shown in Figure 1, our proposed model consists of subheading generation (bottom) and token-based discriminative learning (top) parts. The loss occurring in each part is defined as L_{gen} and L_{dis} , and the model is trained by minimizing the following loss:

$$L = L_{gen} + \lambda \cdot L_{dis}, \quad (1)$$

where λ is a weighted hyperparameter for the two losses.

3.1 Subheading Generation

We use BART (Lewis et al., 2020) as our seq2seq model, where the encoder takes a body B as an input, generates an input representation of the body, and passes it to the decoder, which outputs the subheading \hat{S} . The loss of subheading generation is as follows:

$$L_{gen} = - \sum_{i=1}^M \log(p(s_i | s_{1:i-1}, B; \theta)), \quad (2)$$

where a body $B = (b_1, b_2, \dots, b_N)$ and its subheading $S = (s_1, s_2, \dots, s_M)$ consists of N token vectors b_i and M token vectors s_j , respectively, and the seq2seq model is optimized to learn the θ parameters to minimize the negative log-likelihood.

Dataset	Model	Size	Rouge-1	Rouge-2	Rouge-L	BERTScore
XLSum-ENG	BART	139M	36.52	15.33	30.49	77.68
	MT5	582M	37.81	14.59	28.30	74.48
	T5	220M	37.87	15.97	29.09	75.96
	Pegasus	571M	39.57	16.63	32.45	77.93
	T5 w/multi	247M	35.37	14.71	29.84	75.74
	Ours	282M	39.84	18.07	33.77	78.96
XLSum-KOR	BART	124M	25.23	15.91	23.37	74.60
	MT5	582M	29.16	14.03	25.40	69.94
	T5	247M	13.99	4.10	13.48	67.92
	T5 w/multi	247M	17.55	7.03	16.60	71.58
	Ours	269M	27.41	17.56	25.48	75.58
YonhapNews	BART	124M	21.41	11.00	19.21	72.19
	MT5	582M	25.24	11.28	21.13	70.70
	T5	247M	20.10	8.70	17.96	71.67
	T5 w/multi	247M	22.21	9.91	19.91	71.21
	Ours	269M	24.15	13.21	21.93	73.08

Table 1: Subheading generation performance for each dataset. Size represents the number of parameters in each model. Our model outperforms the comparative models except for Rouge-1 score for XLSum-KOR and YonhapNews.

3.2 Token-based Discriminative Learning

Inspiring by [Chuang et al. \(2022\)](#), we inject topical knowledge of the article by discriminating whether tokens in the reconstructed headline are the same as the original. As described in Appendix A, headline has high lexical similarity with subheading compared to other objects in the article. Therefore, headline reconstruction helps model to aware of topical information which is inherent in the headline. The loss of token-based discriminative learning is as follows:

$$L_{dis} = \sum_{i=1}^L \left(-\mathbb{1}(h'_i = h_i) \log D(H'|B, H) - \mathbb{1}(h'_i \neq h_i) \log(1 - D(H'|B, H)) \right), \quad (3)$$

where a headline $H = (h_1, h_2, \dots, h_L)$ consist of L tokens and the reconstructed headline H' is $H' = G(H_{masked})$ where G is the generator and a masked headline H_{masked} is obtained with random mask $M = [m_1, m_2, \dots, m_L], m_t \in [0, 1], H_{masked} = H \cdot M$. Using the compressed body representation of the encoder, the discriminator D predicts whether the tokens in the reconstructed headline H' are the same as the original headline H . As shown in Figure 1, the generator predicts the masked headline into “*how improving adult’s diet can aid condition*”. Using the encoded body representation and partially mispredicted headline, the model trains the incorrectly predicted “*adult*”, and “*condition*” and the correctly predicted rest of the tokens, respectively. Back-propagated gradients of the discriminator D cause the encoder to include the topical information of the article in the body representation by classifying whether the tokens

in the reconstructed headline H' come from the original headline or not.

Model	Generated Subheading
BART	The UK’s oil and gas industry generated negative tax receipts in 2015-16, according to HM Revenue and Customs (HMRC).
MT5	Have led to a fall in tax receipts from UK oil and gas production, according to HM Revenue and Customs (HRMC)
T5	revenues have fallen to their lowest level since records began in the 1960s, according to new figures from HM Revenue and Customs (HMRC)
Pegasus	tax receipts from oil and gas production in the UK have fallen to their lowest level, according to HM Revenue and Customs (HMRC)
Ours	Revenues from the North Sea oil and gas industry have fallen to their lowest level since records began, according to HM Revenue and Customs (HMRC).

Table 2: Example of generated subheading for each model. The original headline is “*North Sea receipts hit record low*” and the reference subheading is “*The UK government has incurred a loss from North Sea oil and gas production for the first time since records began nearly 50 years ago*”. The body of the article can be found in the XLSum-ENG test set with the corresponding id= ‘uk-scotland-scotland-business-36388621’.

4 Experiments

4.1 Experimental Setting

We use pretrained models BART and ELECTRA ([Clark et al., 2020](#)). Unlike [CLS] representation of BERT ([Devlin et al., 2019](#)), BART doesn’t have a special input representation token. As such, we use an average pooler to compress the output of the encoder and freeze the generator to keep generating noise headline for token-based discriminative learning. Optimal parameters

were obtained in the search spaces with learning rate $\{1e-5, 2e-5, 3e-5, 4e-5\}$, masking ratio $\{0.1, 0.2, 0.3, 0.4, 0.5\}$, and lambda $\{0.1, 0.01\}$.

4.2 Comparative Models

BART, T5 (Raffel et al., 2020), and MT5, (Xue et al., 2021) were used as comparative models in all datasets. Also, Pegasus (Zhang et al., 2020) for English were used as comparative models. For a fair comparison, we use the concatenated body with a headline in the input of the comparative models.

4.3 Experimental Results

Table 1 shows the results of subheading generation performance for each dataset. Model performance was evaluated using Rouge (Lin, 2004) and BERTScore (Zhang et al., 2019). In XLSum-ENG, our model outperforms all comparative models. In particular, our model performs better than MT5 or Pegasus, which have more than double the model size. In other words, token-based discriminative learning can improve generation performance more efficiently than simple concatenation. Our model outperforms the comparative models in all other metrics except the Rouge-1 score for the Korean language datasets. MT5 records the highest Rouge-1 score on both Korean datasets. However, because Korean is decomposed into many sub-words due to its morphological richness, it is not suitable to evaluate performance with Rouge-1 score alone. In particular, in terms of BERTScore, our model scored 5.64% and 2.32% higher than MT5 in XLSum-KOR and YonhapNews, respectively. This indicates that our model can generate semantically relevant subheadings. Moreover, good performance on small datasets (i.e., XLSum-KOR) demonstrate the robustness of our model.

Table 2 shows an example of the generated subheadings for each model. We can see that our model utilizes “North Sea” and “record low” from the headline to better condense topical information in the article. Additional qualitative results are described in Appendix C.

	XLSum-ENG	XLSum-KOR	YonhapNews
BART	2.53 (0.64)	2.00 (0.38)	3.53 (0.92)
MT5	2.71 (0.61)	2.07 (0.59)	2.60 (0.51)
T5	2.64 (0.74)	2.20 (0.41)	2.73 (0.46)
Pegasus	3.64 (0.50)	-	-
Ours	4.21 (0.70)	3.67 (0.49)	3.40 (0.74)

Table 3: The average score of human evaluation for XLSum-ENG, XLSum-KOR, and YonhapNews. Numbers in parentheses indicate the standard deviations.

4.4 Human Evaluations

We conduct human evaluations to verify whether the subheadings of the proposed method are more topically relevant than the baselines. Three samples were randomly selected from each test dataset, and subheadings generated along with their corresponding headlines and body were shown to the workers and evaluated on a five-point Likert scale. Table 3 shows that our model generates topic-relevant subheadings better than the baselines on two datasets, and is particularly robust on a small dataset (i.e., XLSum-KOR). In the case of YonhapNews, BART showed the highest score, but the independent t-test showed that the average difference between Ours and BART was insignificant ($p > 0.663$).

4.5 Comparison with Multi-task Learning

To verify whether our model effectively learns topical information from the headlines, we conduct additional experiments with a multi-task learning. Different prefixes were used to know the model what the current training task is. One task maps news body text to subheading, and the other maps news body text to headline. We experiment with T5 because it has less discrepancy with our pre-training objectives. T5 w/multi rows in Table 1 show the multi-task learning results, demonstrating that our method is more effective in learning headline information.

4.6 Ablation Studies

We perform ablation studies in terms of masking ratio to analyze the effectiveness of token-based discriminative learning. Figure 2 shows the results of the Rouge-2 score and BERTScore according to the masking ratio for each dataset. We also plot the performance of the T5 with similar parameter sizes to ours. Our model outperforms T5 in all masking ratio ranges. This indicates that our model is not significantly sensitive to masking ratio. In particular, the large performance difference of XLSum-KOR demonstrates the robustness of our model on the small dataset. The original headline is completely incorrectly reconstructed if the masking ratio exceeds 0.4, limiting ability of the model to learn crucial topical information from the headline considering the token length of the headline. However, for small masking ratios such as 0.1, the generator can completely reconstruct the original headline, but it is limited in maximizing the benefits of token-based discriminative learning. Headline to-

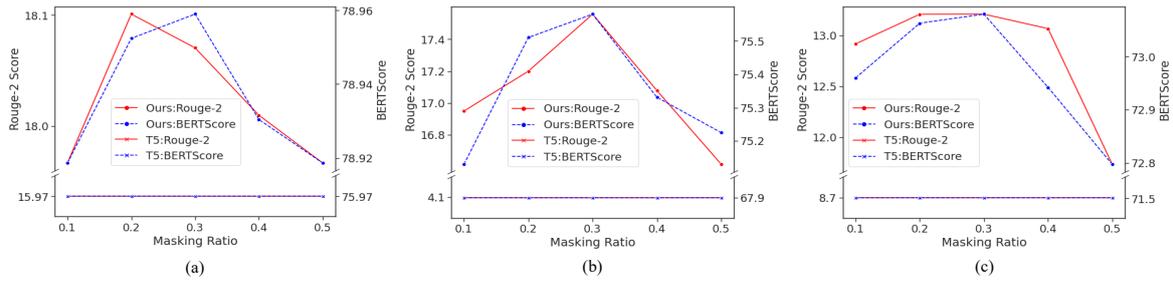

Figure 2: Rouge-2 score and BERTScore according to masking ratio for (a) XLSum-ENG, (b) XLSum-KOR, and (c) YonhapNews. The performance of the T5 in two Korean datasets is plotted with a ‘x’ marker. The masking ratio between 0.2 and 0.3 shows the best performance in all datasets.

ken length distribution is described in Appendix B. Therefore, it is recommended to set the masking ratio between 0.2 and 0.3 in order to utilize the token-based discriminative learning for subheading generation entirely.

5 Conclusions

In this paper, we propose a novel model for generating a subheading for news article. Along with token-based discriminative learning, our model can effectively utilize topical information from a headline that is essential in articles and does not require additional manipulated information. Experiments on three datasets written in two different languages show the effectiveness of the proposed model. Also, qualitative results and human evaluation show that the overall quality of generated subheadings is improved compared to comparative models. We expect that our model will be extended in future research to an abstractive summarization task that include both a headline and a body text, such as legal texts or papers.

Limitations

Our study outperformed all comparative models in generating subheadings through token-based discriminative learning. However, the experiments mainly used limited languages such as English and Korean due to a lack of large-scale multilingual training data and the need for significant GPU resources. We, therefore, encourage further investigations to expand the versatility of the proposed model by utilizing large-scale multilingual language datasets to verify expandable applications in various morphological characteristics.

Ethics Statement

As YonhapNews is one of the most reliable media outlets in South Korea, articles from YonhapNews are published through a rigorous verification process and will be deleted or revised if they contain any form of bias. However, the period of data collected is three years, and there may be past article content that has not been modified by new facts, so we cannot guarantee that all articles in YonhapNews dataset are completely unbiased. Nevertheless, this dataset has sufficient potential to develop into various studies and thus is released for academic uses.

Decipherment as Regression: Solving Historical Substitution Ciphers by Learning Symbol Recurrence Relations

Nishant Kambhatla Logan Born Anoop Sarkar

Abstract

Solving substitution ciphers involves mapping sequences of cipher symbols to fluent text in a target language. This has conventionally been formulated as a search problem, to find the decipherment key using a character-level language model to constrain the search space. This work instead frames decipherment as a sequence prediction task, using a Transformer-based causal language model to learn recurrences between characters in a ciphertext. We introduce a novel technique for transcribing arbitrary substitution ciphers into a common *recurrence encoding*. By leveraging this technique, we (i) create a large synthetic dataset of homophonic ciphers using random keys, and (ii) train a decipherment model that predicts the plaintext sequence given a recurrence-encoded ciphertext. Our method achieves strong results on synthetic 1:1 and homophonic ciphers, and cracks several real historic homophonic ciphers. Our analysis shows that the model learns recurrence relations between cipher symbols and recovers decipherment keys in its self-attention.¹

1 Introduction

Text may be considered a special kind of recurrent sequence, where letters repeat at intervals which conform to a language’s character n -gram distribution. The hidden mapping between cipher text and plain text can be viewed as a model that predicts this recurrent sequence. Can we use self-attention to recover the mapping from a sequence of recurrent symbols to crack the cipher?

In this work, we exploit this idea for decipherment by building upon recent successes of Transformer models (Vaswani et al., 2017) in reasoning-based regression tasks such as mathematical reasoning (Saxton et al., 2019; Li et al., 2021) and learning the mathematical function for recurrent

¹https://github.com/protonish/decipher_symbol_recurrence

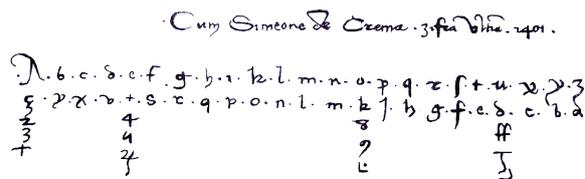

Figure 1: The homophonic substitution key for the *Simeone de Crema* written in Mantua in 1401 AD. The top line maps each character in the alphabet to its reversed-alphabet equivalent; each vowel is substituted by three additional symbols.

sequences (D’Ascoli et al., 2022). We rethink decipherment as a regression task that predicts a natural language plaintext by learning a recurrence relation between integer-coded ciphertext symbols.

There exist large collections of historical ciphers (see de-crypt.org)², in the form of encrypted letters and more informal communications, of which many remain undeciphered. Many of these texts employ complex *homophonic substitution ciphers*, which mask the frequencies of letters by using a larger alphabet than the underlying language. Figure 1 shows the first known homophonic cipher from 1401 AD³. Automated computational decipherment of such texts is challenging (Pettersson and Megyesi, 2019; Megyesi et al., 2020). Prior work has mainly focused on using clever heuristics and/or search algorithms to explore the space of cipher keys and score multiple candidate plaintexts under character language models (LMs) (Knight et al., 2006; Corlett and Penn, 2010; Hauer et al., 2014; Berg-Kirkpatrick and Klein, 2013; Nuhn et al., 2013, 2014; Kambhatla et al., 2018) In contrast Aldarrab and May (2021) train a sequence-to-sequence model to solve simple (one-to-one) substitution ciphers. This approach, however, cannot solve complex homophonic ciphers as it relies on frequency information which such ciphers obscure.

In this paper, in a departure from frequency and

³https://en.wikipedia.org/wiki/Francesco_I_Gonzaga

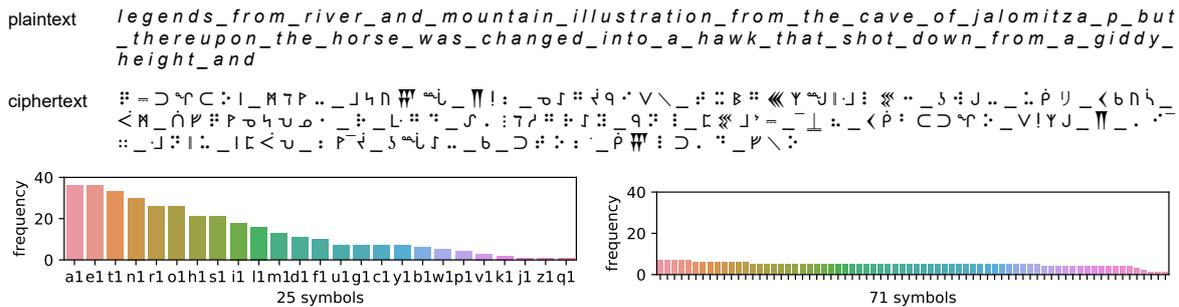

Figure 2: Part of an arbitrary 424 characters long homophonic cipher with 71 symbols and its plaintext. **Bottom** row juxtaposes symbol frequencies in 1:1 vs homophonic encipherments of the plaintext.

heuristic search-based techniques, we make the following **contributions**: ① We create a sequence-to-sequence dataset comprising 2 million unique homophonic ciphers and their plaintext. ② We propose a novel *recurrence encoding* which encodes information about the position and repetition of symbols in a cipher. This can be applied to both 1:1 and homophonic ciphers. ③ This encoding allows us to treat decipherment as a sequence prediction task conditioned on an integer sequence. We introduce a novel approach to solving homophonic ciphers by using a Transformer LM to translate integer-encoded ciphertexts to plaintexts. We also provide exhaustive analysis to show the strengths of our model. ④ We demonstrate near-perfect results on synthetic homophonic ciphers. Additionally, we show fully automated decipherment of TNA_SP106/5 and BnF-f01, two real historical ciphers.

Our analysis shows that reproducing the input ciphertext before generating the plaintext helps our model to learn the relations between cipher symbols. This enables it to implicitly learn the decipherment key with high accuracy, and to determine which symbols are homophones of one another. The decipherment is highly constrained by this implicit key even in the face of disfluent plaintexts, and as a result our model is able to produce decipherments into Latin and late Middle/early modern English, despite being trained on modern English.

2 Decipherment of Substitution Ciphers

A 1:1 or *simple substitution cipher*, the oldest known technique for obscuring written information, defines a 1-1 mapping between plaintext characters and ciphertext symbols. This mapping can easily be broken with frequency analysis (Hauer et al., 2014; Kambhatla et al., 2018; Aldarrab and May,

Method	Search	Train

Table 1: Summary of different methods used for solving homophonic ciphers. Prior approaches are predominantly search-based and use a frozen language model to score partial candidate hypotheses.

2021) which leverages the fact that these ciphers preserve the distribution of character frequencies in the underlying language.

Homophonic ciphers are substitution ciphers where one plaintext character may be encoded by more than one ciphertext symbol. In this way, frequent plaintext characters can be mapped to many infrequent ciphertext symbols, resulting in a flattened frequency distribution (Figure 2).

2.1 Background

Traditional approaches to natural language decipherment of homophonic substitution ciphers—the main focus of this work—are entirely search-based (Table 1). Nuhn et al. (2013) perform a beam search using an offline, frozen character language model to score candidate decipherments, and Nuhn et al. (2014) improve the rest-cost estimation for this technique. Kambhatla et al. (2018) further improve the rest-cost heuristic by using a frozen neural LM to score hypotheses. Corlett and Penn (2010), on the other hand, use A* search. Berg-Kirkpatrick and Klein 2013 uses 1 million random restarts to learn HMMs for decipherment.

The ability of such inference-only methods to generalize can be limited, as it depends on the underlying language model that is used to score the

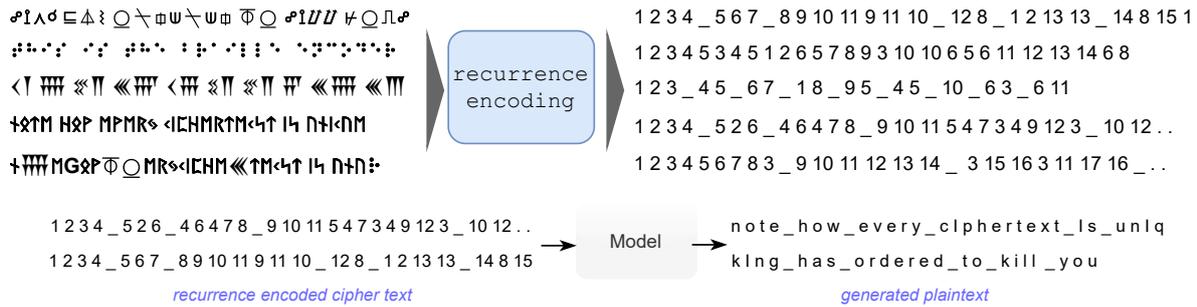

Figure 3: **Top-left:** Before *recurrence encoding*. Every ciphertext is unique with a different key, with distinct keys and plaintexts, and varying lengths. There is no relation between identical symbols in different ciphers (e.g. Φ in cipher 1 and 5). These dissimilarities make it nearly impossible to train a model to generalize to new, unseen homophonic ciphers. **Top-right:** After *recurrence encoding*. Arbitrary ciphertexts are converted to recurrent integer sequences. The encoding is applied to each cipher independently: the same symbol may receive different encodings in different ciphertexts depending on where it first occurs, and two ciphers may receive the same encoding despite using different alphabets. **Bottom:** Recurrence-encoded symbols decipher to different values depending on context.

constructed hypotheses. Even an efficient search can take a long time to find the whole cipher key (Nuhn et al., 2013; Kambhatla et al., 2018).

3 Our Generative Decipherment Model

We frame decipherment as a novel sequence generation task—we train a generative language model that learns the relations between recurring symbols in a homophonic cipher and generates the corresponding deciphered plaintext message.

3.1 Converting Arbitrary Ciphers into Recurrent Integer Sequences

In a substitution cipher, any character may be substituted for any other, limiting what one can generalize between different ciphertexts (Figure 3). However, unrelated ciphers may still exhibit similar patterns of letter distribution and repetition and display latent characteristics of the plaintext language. For example, the characters at the beginning of two unrelated ciphers are likely drawn from the same distribution of word-initial letters in the underlying plaintext language. So we can generalize better by treating ciphers as recurrent sequences.

We propose a novel *recurrence encoding* to highlight where cipher symbols first occur and how they are repeated within a ciphertext. This encoding replaces the n th unique symbol in a ciphertext with the number n wherever that symbol occurs (Figure 3). This converts arbitrary ciphertexts into integer sequences, and thus provides a coherent connection between ciphers with distinct keys or disjoint alphabets.

3.2 Modelling Symbol Recurrence Relations

In this section, *ciphertext* specifically refers to a recurrence-encoded integer sequence.

Following Wang et al. (2021) and Zhang et al. (2022) in MT, we use a causal language model (LM) as a replacement for a Transformer-based encoder-decoder model (Vaswani et al., 2017). For a source sequence X and the target Y ,

$$[X^l, Y^l] = \text{FFN} \circ \text{SelfAttn} \left([X^{l-1}, Y^{l-1}], \text{Mask} \right) \quad (1)$$

where l is the layer index, FFN is a feed-forward network, and *Mask* denotes the attention mask. Our **CausalLM** model is a unidirectional LM, with causal masking over both the source and the target. This optimizes the joint distribution of cipher (src) and plaintext (tgt) sequences:

$$\begin{aligned} \mathcal{L}^{\text{CLM}}(X, Y) &= \mathcal{L}^{\text{SRC}} + \mathcal{L}^{\text{TGT}} \\ &= -\log P(X) - \log P(Y|X) \end{aligned} \quad (2)$$

CausalLM is therefore forced to sequentially predict the ciphertext just as it predicts the plaintext. This formulation encourages the model to learn a coherent relationship between the ciphertext and plaintext characters within each training sample.

Baseline Models. To understand the importance of causal attention masking, we also consider the following models which do not generate the ciphertext:

Seq2Seq Following (Aldarrab and May, 2021), this is a character level Transformer architecture that is only optimized on the target-side (plaintext) loss: $\mathcal{L}^{\text{Seq2Seq}}(X, Y) = \mathcal{L}^{\text{TGT}} = -\log P(Y|X)$

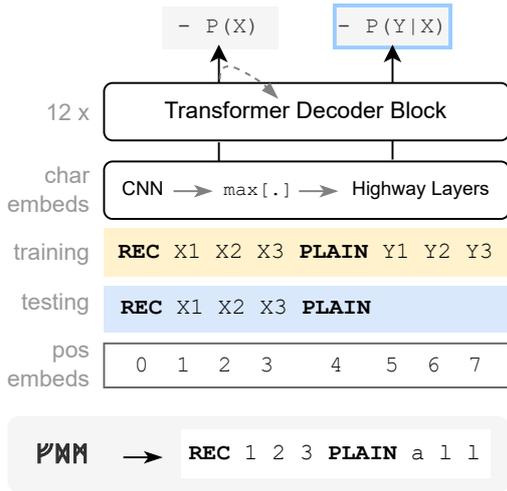

Figure 4: Schematic depiction of our Transformer LM model for an example ciphertext. X denotes the recurrence encoded ciphertext and Y is the plaintext, prepended by REC and PLAIN tags respectively.

Target-Only CausalLM is only optimized on the target-side loss \mathcal{L}^{TGT} , and incurs no loss when generating the source text.

PrefixLM combines SelfAttn and masked-SelfAttn: the ciphertext is attended at all times, while the plaintext uses a causal mask:

$$Mask(i, j) = 1, \text{ if } i \geq j \text{ or } j \leq |X|; \text{ else } 0 \quad (3)$$

where $1 \leq i, j \leq (|X| + |Y|)$. This setting mimics an encoder-decoder by modelling the conditional distribution of the plaintext target given the ciphertext source with target-only objective $\mathcal{L}^{PLM}(X, Y) = \mathcal{L}^{TGT}$.

All models build character embeddings with a convolutional neural network and highway networks over character inputs (Kim et al., 2016).

4 Experimental Setup

4.1 Data

Length	Keys	#Train	#Valid	#Test
300-400	30-45	460,467	25,582	25,581
	45-60	503,695	25,582	25,581
	30-85	542,611	25,582	25,581
300-700	30-45	460,467	25,582	25,581
	45-60	542,611	25,582	25,581
	30-85	1,046,306	25,582	25,581

Table 2: Summary of the synthetic homophonic ciphers used in our experiments. All ciphers are unique.

    sym_count += num_sym
    sym_per_char[char] = num_sym
  return sym_count, sym_per_char

```

Gutenberg⁴ to create training, validation and test sets. We also use $\sim 200k$ English sentences from news-commentary v9 from WMT14 En-De. Combining these, we generate homophonic ciphers with lengths and keys summarized in Table 2.

Synthetic Homophonic Ciphers. To train a model that can generalize to unseen ciphers, we first generate synthetic homophonic ciphers using Algorithm 1 to flatten the frequency distribution of a text. This technique allocates multiple less-frequent ciphertext symbols to common plaintext letters to yield strong homophonic ciphers.

For simple substitution ciphers, we use the same English data as above to create 1.2M synthetic substitution ciphers with lengths up to 256. Following previous work on 1:1 ciphers (Nuhn et al., 2013; Kambhatla et al., 2018; Aldarrab and May, 2021), we evaluate on 50 test ciphers of lengths up to 128 (16,32,64) and beyond 128 (128,256) from the Wikipedia page on History⁵. All our experimental settings include data with word boundaries denoted by the space symbol ($_$). We train our multilingual model on length 256 1:1 ciphers from the 13 language data in Aldarrab and May (2021)⁶ which includes training, validation and test splits.

4.2 Model Details

Our main model uses a Transformer decoder-based auto-regressive language model. Our model comprises a 12 layer decoder with 12 attention heads and a feed-forward dim. of 1536, totalling 23M trainable parameters. We use character filters of

⁴<https://github.com/pgcorpus/gutenberg>

⁵<https://en.wikipedia.org/wiki/History>

⁶<https://github.com/NadaAldarrab/s2s-decipherment>

[(1, 64), (2, 128), (3, 192), (4, 256)] with a character dim of 4 and 2 highway layers. For the seq2seq model, we implement a 6 layer encoder-decoder Transformer with the same settings as above. All models are implemented using the fairseq toolkit (Ott et al., 2019).

All models train for about 30 iterations over the data at ~ 100 minutes per epoch on 4xA6000 GPUs. Inference uses a beam size of 200 unless otherwise stated. Inference speed is about 400 chars/second on a single Titan RTX.

Evaluation Following prior work (Kambhatla et al., 2018; Aldarrab and May, 2021), we evaluate on Symbol Error Rate (SER), the proportion of ciphertext symbols which are wrongly recovered.

5 Homophonic Substitution Ciphers

We experiment on solving our own synthetic homophonic ciphers, and on automatically deciphering two real world homophonic ciphers that have previously only been cracked manually.

5.1 Results on Synthetic Ciphers

Table 3 reports results on synthetic homophonic data using recurrence encoding. On 400- and 700-character long ciphers, our best model with causal attention and up to 65 keys achieves near perfect decipherment. As expected, we observe the best results on long ciphers, which provide more context. Even on challenging ciphers with up to 85 keys over 400 characters (4.5 chars/symbol), our model attains an average error rate of 2.25%, averaging only 1 wrong character each. As will be shown in Section 8 (Table 7), our model also implicitly recovers decipherment keys with $> 98\%$ accuracy.

#keys	Model	Max Len.	
		400	700
30-45	Seq-to-Seq	72.30	fail
	PrefixLM	54.73	69.50
	CausalLM (tgt)	29.99	37.20
	CausalLM	0.40	0.21
40-65	PrefixLM	69.50	54.73
	CausalLM (tgt)	29.99	37.20
	CausalLM	0.83	0.80
30-85	PrefixLM	70.52	71.82
	CausalLM (tgt)	42.05	42.69
	CausalLM	2.25	2.19

Table 3: SER% on synthetic, homophonic, recurrence-encoded ciphers. All plaintexts use 26 unique letters.

These results show the strength of recurrence encoding together with a causal LM objective.

Generating cipher + plaintext vs. plaintext only:

The best results by a significant margin are obtained through language modeling with a causal attention mask—the only model that is trained to generate the ciphertext before the intended plaintext. All other approaches fail to give adequate results in any setting. A sequence-to-sequence model obtains poor results on ciphers of 400 characters and fails to converge on 700 char long ciphers.⁷ Prefix attention is consistently worse than causal attention, and its performance varies unpredictably across input length and number of keys. Causal attention with target-only loss is worse than causal attention, suggesting that reproducing the source text may play an important role in solving this task. We consider this idea further in our analysis of the model’s attention in Section 8.

5.2 Results on Zodiac 408 Cipher

We compare our method on the famous Zodiac 408 cipher that has 408 characters written with 54 different symbols (~ 7.5 characters per symbol). For this particular cipher, all models including ours are trained on the English Gigaword corpus for fair comparison with other models in Table 4. From Table 4, our generative LM is both better, and faster by orders of magnitude.

Method	Search	SER (%)	Speed
LM+EM (2013)	1M restarts	11.0	–
n -gram LM (2013)	beam 100K	94.6	4000
	beam 1M	2.7	35000
LSTM LM (2018)	beam 100K	2.4	5600
	beam 1M	1.9	50000
Ours (greedy)	beam 1	1.9	1 sec
Ours (best)	beam 200	1.9	2 sec

Table 4: Zodiac 408. Methods for simple (1:1) substitution ciphers can not be used on Zodiac408. The last column shows inference speed in seconds. Our method is much faster because it auto-regressively generates the decipherment whereas previous methods perform an exhaustive search to find the mapping for each symbol.

5.3 Solving historical substitution ciphers

Most historical ciphers are centuries old and can be challenging to solve—the encipherment scheme may be peculiar to the author; the language may be

⁷NMT models are known to suffer from long sentences (Neishi and Yoshinaga, 2019; Varis and Bojar, 2021)

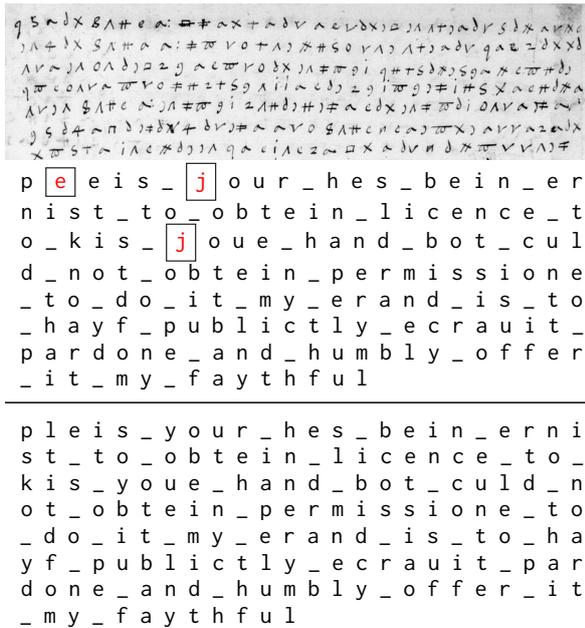

Figure 5: Predicted (middle) vs true (bottom) decipherment of the first few lines of BnF-f01 cipher (top). Errors in red and boxed.

archaic or unstandardised, and thus out-of-domain for models trained on modern data; or there may be human errors in the transcription.

Though our model is trained only on synthetic ciphers with no further finetuning, we hypothesize that it may nonetheless see success on real medieval ciphers. This section demonstrates those successes. **1. TNA_SP106/5** Also called CharlesI_(0096),⁸ this is a strong homophonic cipher that was written in 1624 in the United Kingdom, during the reign of King Charles I of England. It is a very difficult cipher which is 171 characters long, using 47 unique symbols to encipher 27 plaintext letters (each cipher symbol appears 3.6 times on average).

Using our homophonic 40-65 key model with beam size 1000, we attain a readable decipherment with a symbol error rate (SER) 18%.

2. BnF_fr2988_f01 BnF-f01⁹ (Fig. 5) is a 2 page long enciphered letter from between 1524–1549 in Italy, believed to be addressed to King Henry VIII. This homophonic cipher uses 35 symbols, with archaic spellings in the underlying plaintext that make it a challenging target due to the different character distribution from our training set. Examples include pleis→(please), faythful→(faithful),

⁸de-crypt.org/decrypt-web/RecordsView/420

⁹de-crypt.org/decrypt-web/RecordsView/2323

obtein→(obtain) and gretast→(greatest). Our best homophonic model trained with ciphers between [30-45] keys is able to crack it with SER 1.13%. The first few lines of model output and corresponding plaintext are shown in Figure 5. Although our model was never explicitly trained for robustness, the recurrence encoding helps it to overcome the unexpected plaintext distribution and maintain a consistent key to recover the message.

6 Does our technique generalize to 1:1 substitution ciphers?

To exploit the well-known weakness of simple substitution ciphers, Aldarrab and May (2021) proposed *frequency ranking* whereby cipher symbols are replaced by their frequency ranks across all 1-1 substitution ciphers. We use recurrence encoding and frequency ranking with our best performing causal LM architecture¹⁰ and compare with several baselines, including Aldarrab and May (2021).

cipher length →	<128	>128
Beam + 6-gram (Nuhn et al., 2013)	22.00	0.00
Beam + LM ((Kambhatla et al., 2018))	10.89	0.00
Beam + LM + Freq. Match (ibid.)	11.32	0.00
Seq2Seq + Freq. (Aldarrab and May)	7.68	0.00
Causal LM + Freq.	10.56	0.00
Causal LM + Rec.	11.30	0.02

Table 5: On simple substitution ciphers of length >128, our performance equals or exceeds all baselines. Freq. and Rec. denote frequency and recurrence encodings.

Our model performs well on simple substitutions (Table 6) using frequency ranking. While the scores on very short ciphers (16, 32, 64) only match the performance of beam-search based methods, on ciphers longer than 128, our model achieves close to 0 SER. Recurrence encoding is less effective in shorter sequences (< 128) and requires more context to be effective compared to frequency ranks which more directly indicate the plaintext character distribution. However, recurrence encoding is not required in this context as the character distributions are not flattened.

7 Unknown Plaintext Language

As Megyesi et al. (2020) reports, several historical ciphers in libraries and archives have no information on the plaintext language. We evaluate on the

¹⁰Recall that recurrence encoding doesn’t work well with an encoder-decoder model (Table 3).

Latin Borg Cipher¹¹, a ca. 17th century manuscript, to learn if our model can decipher without explicit knowledge of the underlying language.

7.1 Multilingual model with no language ID

Following Aldarrab and May (2021), we train our decipherment model on ciphers from 13 different languages without language ID and apply it to the Borg cipher (page 0011v). Both models are trained on frequency based encoding. Compared to 5.47% SER in the baseline, our model achieves a better SER of 4.1%.

	SER (%)
Multilingual Seq2Seq (2021)	5.47
Multilingual Causal LM (ours)	4.10

Table 6: Using our multilingual model trained on 13 languages to solve the 1:1 Borg cipher.

7.2 Zero-shot decipherment in an unseen language

Though the Borg MS uses a simple substitution cipher, the plaintext language (Latin) is out-of-domain for our main model which was trained on English only (Sec. 5). Zero-shot inference on the first 400 characters of page 0011v results using our recurrence-encoding based model in an SER of 45.14%. A mere 3 manual interventions—fixing two words (*aperitione*, *emorrhoidarum*) and correcting one (*cumo* to *cum*)—however, are sufficient to solve the entire cipher with **SER 3.89%**. See Appendix B for details on human-in-the-loop decipherment.

This shows that our model learns to consistently produce the same output for a given symbol regardless of the plaintext distribution, which is crucial for cracking ciphers and separates this from a conventional text generation model.

8 Analysis

8.1 On the significance of learning the distribution of ciphertext characters

Section 5 demonstrated that CausalLM significantly outperforms other models on synthetic homophonic data. This is the only approach which must model the distribution of ciphertext characters: Seq2Seq and PrefixLM allow the model to freely attend to the full ciphertext, while target-only loss gives no penalty for mistakes in the ciphertext. These settings remove the incentive to learn

¹¹<https://cl.lingfil.uu.se/~bea/borg/>

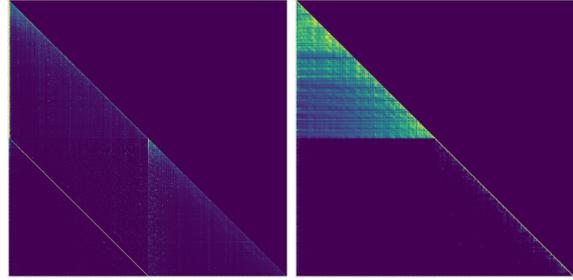

Figure 6: **Left:** self-attention map from our causal LM. **Right:** self-attention map over the same sentence from our causal LM with target-only loss.

the distribution of ciphertext characters, whereas CausalLM must sequentially predict the ciphertext just as it predicts the plaintext.

Figure 6 illustrates the impact of target-only loss by showing the final layer of self-attention scores for an example input. CausalLM exhibits a strong diagonal pattern in the lower-left of the attention matrix, showing that it attends monotonically to cipher symbols when producing corresponding plaintext symbols. With target-only loss, attention is roughly uniform over all ciphertext symbols when reproducing the input, as there is no penalty for mistakes in this section and consequently no need to attend to relevant context cues. This model does not strongly attend to the ciphertext at any point when generating the plaintext.

Key Recovery The model’s self-attention implicitly recovers decipherment keys. We construct a $n_{\text{plaintext_symbols}} \times n_{\text{cipher_symbols}}$ matrix where cell (p, c) sums the mean attention over all layers paid to c when producing p . More common symbols receive more attention, so we divide each column by the frequency of the corresponding symbol. Figure 7 depicts such a matrix, normalized so that the largest value in each row is 1: the largest value in most columns clearly corresponds to the decipherment key. Table 7 reports key error rate (KER) using this technique, as well as variants without adjusting for frequency or normal-

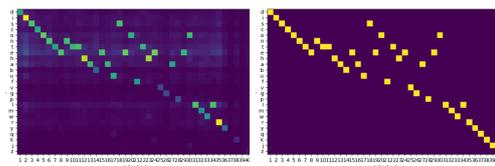

Figure 7: **Left:** Avg. attention paid to ciphertext symbols when generating plaintext symbols in one test case. **Right:** True key, where a dark cell indicates which character the symbol in each column deciphers to.

	KER (%)
Row-norm.	3.40
Col-norm.	3.63
Row-norm. + Frq. adj.	1.54
Col-norm. + Frq. adj.	3.63

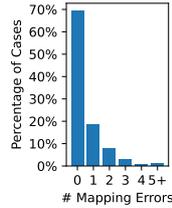

Table 7: (l) Key error rate (%) averaged over 2000 homophonic test cases. Values multiplied by 100 for readability. (r) Distribution of mapping errors.

izing by column rather than by row; the distribution of errors is shown beside the table. With our best technique, the median and mode number of erroneous mappings is 0, i.e. we perfectly recover the key from the self-attention in most cases.

Our model’s ability to accurately produce Latin highlights that it learns to obey the inferred key even in the face of conflicting signals from an out-of-domain plaintext.

8.2 Recovering character recurrence relations

Homophone Recovery Attention from ciphertext symbols to other ciphertext symbols reveals which characters are homophonic. Figure 8 (left) shows, for a sample input, the average self-attention from a ciphertext symbol towards other ciphertext symbols; Figure 8 (right) shows which of these symbols are homophones. The largest self-attention scores roughly correlate with cells representing homophonic symbol pairs. Comparing to Figure 7 (left) we see that the homophone pairs which are *not* recovered involve those symbols for which the model lacks a confident plaintext mapping.

This behaviour arises as the model reproduces the input ciphertext. This can be observed by averaging self-attention over chunks of successive time-

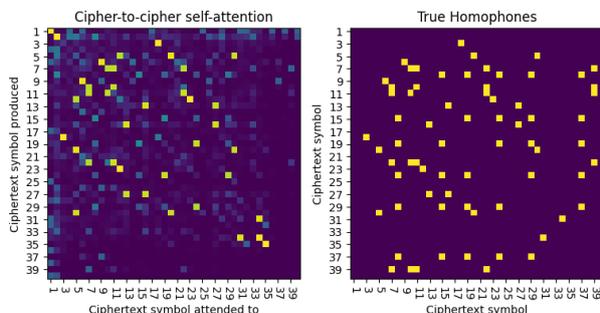

Figure 8: **Left:** Avg. attention from ciphertext symbols to other ciphertext symbols when reproducing one test case. **Right:** Dark cells indicate homophonous symbols.

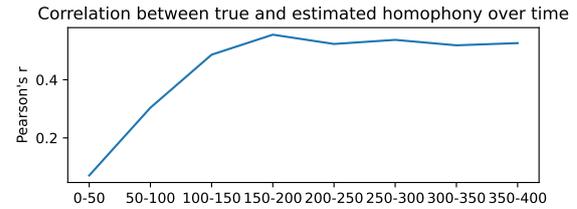

Figure 9: Pearson’s r between self-attention scores at different time-steps and reference matrices encoding homophones (cf. Figure 8). Averaged over 50 ciphertexts.

steps (rather than the entire input) and measuring Pearson’s r between the resulting matrices and a reference matrix as in Figure 8 (right). As seen in Figure 9, the correlation between homophony and self-attention grows steadily as the model reproduces the input, reaching a plateau after ~ 200 tokens. (See also Figure 13 in Appendix C.) This demonstrates the importance of CausalLM, as it shows that the model makes crucial inferences about its input as it reproduces that input.

We emphasize that our model learns homophony relations and recovers decipherment keys *implicitly*, in just a single pass over the input ciphertext. Prior search-based techniques required a search over many candidate plaintexts in order to recover these same relations explicitly.

9 Other Related Work

Computational decipherment based techniques have seen a wide range of applications ranging from identifying unknown languages and scripts (Hauer and Kondrak, 2016), writing systems (Born et al., 2019, 2021, 2022) and lost languages (Snyder et al., 2010; Luo et al., 2019), offensive language detection (Wu et al., 2018; Qian et al., 2019), and, more recently, towards improving neural machine translation (Kambhatla et al., 2022). While decipherment has strong connections to cryptography research, we limit the scope of this work to natural language based decipherment. Knight et al. (2006) proposed an unsupervised noisy channel based technique for decipherment. Hauer et al. 2014 solved short ciphers with Monte-Carlo tree search. Greydanus (2017) train a seq-to-seq LSTM to solve polyalphabetic substitution ciphers including Enigma, but only explore supervised known-plaintext attacks. CipherGAN (Gomez et al., 2018) exploits learned letter embedding distributions, but requires a large volume of ciphertext and only handles 1:1 substitution and Vigenère ciphers. Luo et al. (2021) and Aldarrab and May (2022) pro-

pose techniques to decipher undersegmented ciphers. Aldarrab and May (2021) train a sequence-to-sequence neural translation model to decipher from character frequencies. In contrast, we introduce a novel encoding which is suitable for homophonic inputs, and demonstrate that a causal LM is more effective than a seq-to-seq model in a homophonic setting.

Cross-attention from encoder-decoder architectures has been shown to have limited explanatory power in translation settings (Moradi et al., 2019, 2021). In spite of this, Born et al. 2022 show that encoder self-attention implicitly captures information which replicates expert intuitions about document structure in an undeciphered script. In a similar vein, our key recovery experiments offer evidence of yet another way self-attention may be fruitfully exploited in the decoder in a decipherment setting.

10 Conclusion and Future Work

We introduce a novel recurrence encoding to represent distributional information which is invariant across plaintexts and ciphertexts, even under homophonic ciphers. This allows us to train a Transformer LM for decipherment using synthetic ciphertext-plaintext pairs. Our model achieves strong results on unseen homophonic substitution ciphers, and achieves the first fully-automatic decipherment of several historical ciphers. We show that language models vastly outperform sequence-to-sequence models on this task, and that causal attention masking (which forces our model to reproduce the ciphertext before deciphering it) is crucial to solve homophonic inputs. Our analysis shows that our model implicitly learns homophony relations and the decipherment key while reproducing the input. In a zero-shot setting, our model accurately deciphers into Latin despite being trained on English; This work marks a successful departure from search-based solutions to homophonic substitution ciphers, and introduces language models as a viable tool for future decipherment work.

Acknowledgements

We would like to thank the anonymous reviewers for their helpful comments. The research was partially supported by the Natural Sciences and Engineering Research Council of Canada grants NSERC RGPIN-2018-06437 and RGPAS-2018-522574 and a Department of National Defence

(DND) and NSERC grant DGDND-2018-00025 to the third author, and by an NSERC award CGSD3-547773-2020 to the second author.

Limitations

A key limitation of our model is the combined sequence length of the ciphertext and the plaintext. As the standard self-attention mechanism of the Transformer uses $O(n^2)$ time and space with respect to sequence length, modelling longer ciphers (eg. 1500 chars) is extremely compute inefficient. This also restricts our model’s ability to handle ciphers such as the Beale Pt. 2 cipher. A possible avenue for an extension of this work is to address this issue by leveraging more sophisticated self attention mechanisms like the linformer (Wang et al., 2020).

Ethics Statement

This work is concerned with decoding encrypted correspondences, and therefore the techniques in the paper are designed to reveal information that has been purposefully obscured and might violate the privacy of the authors. However, an encryption system such as the homophonic substitution cipher is primarily seen in centuries old historical ciphers, and is both relatively weak and obsolete. The methods might have little impact beyond any applications intended towards decipherment of ancient ciphers or machine translation. Further, the more standard encryption techniques such as the AES/RSA are very sophisticated and cannot be attacked with the model discussed in the paper.

We note that our proposal of this method is not as a replacement to expert code-breakers, but as a new tool at their disposal. Our model cannot “cheat” except by disobeying the key, and we’ve shown that it does consistently follow the key (Section 8.2). Thus our model output is no more or less trustworthy than the equivalent produced by a human. Since there is no guarantee that the model will always produce the right decipherment, it is imperative that domain experts assess the text produced by this model in the same way they would assess proposals from an amateur decipherer with little/no domain knowledge.

A Hyperparameters and Settings

Preprocessing Following the previous work (Kambhatla et al., 2018; Aldarrab and May, 2021), we preprocessed the Project Gutenberg data by stripping the text of all non text elements, then lower-casing all characters, and removing all non-alphabetic and non-space characters. Our final plaintexts consists of the 26 letters of English alphabet and the `_` symbol to denote space only.

Multilingual Data. The 13 language multilingual data¹² released by Aldarrab and May (2021) consists of 2.2M ciphers in Catalan, Danish, Dutch, Finnish, French, German, Hungarian, Italian, Latin, Norwegian, Portuguese, Spanish, and Swedish languages.

B Towards Decipherment with Human Intervention

In a realistic decipherment setting, the nature of the cipher under attack will not be known. It is possible that some symbols will be polyphonic, that the plaintext language will be out-of-domain, or that the text will be short or corrupted (intentionally, to prevent decipherment, or as a result of damage in the case of historical documents). In such cases, the outputs from an automated decipherment may require manual emendation; real computer-assisted decipherments have previously relied on post-editing by domain experts, as in the decipherment of the Copiale cipher Knight et al. 2011. We demonstrate two examples of how our model can be used for human-in-the-loop decipherment in this more realistic setting.

Zodiac 408 A famous cipher from the Zodiac killer of the 1970s, this text contains 408 characters written with 54 different symbols (~7.5 characters per symbol). There are six polyphonic¹³ symbols, making the text out-of-domain for our model which was only trained on homophonic ciphers. Table 9 shows an example of assisted decipherment based on corrected words. When a correction is identified, it can be appended to the model input, for example:

```
orig. input: REC <cipher> PLAIN
user prompt: REC <cipher> PLAIN i _ l i k e
```

Since our model is a left-to-right language model on both cipher and plaintext, we can interrupt it at any point during plaintext generation to introduce a correction, which is then used as a new constraint on decoding the plaintext. Correcting only 5 polyphonous characters gives **SER 0.4%**, establishing a new state of the art on this cipher.

Borg Cipher The Borg Cipher¹⁴ is a ca. 17th century manuscript written in enciphered Latin. Though the text uses a simple substitution cipher, the plaintext language is out-of-domain for our model which was trained on English.

Since our model was never trained on Latin, zero-shot inference on the first 400 characters results in an SER of 45.14%. But fixing the words `aperitione _ emorrhoidarum` and correcting

¹²<https://github.com/NadaAldarrab/s2s-decipherment>

¹³Different from a homophonic symbol, a *polyphonic* cipher symbol encodes more than one plaintext character.

¹⁴<https://cl.lingfil.uu.se/~bea/borg/>

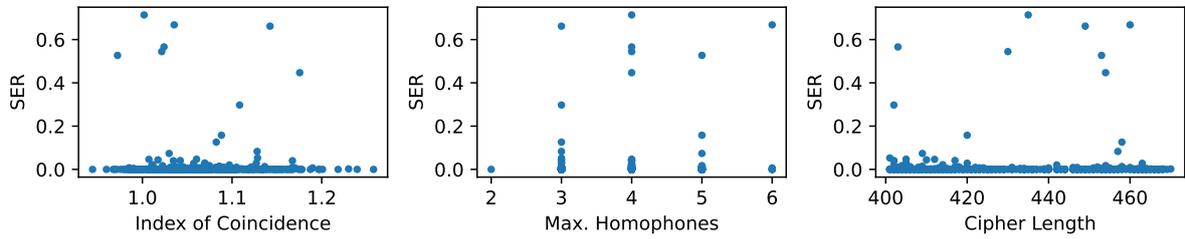

Figure 12: SER vs. index of coincidence, number of homophones of the most homophonic ciphertext symbol, and cipher length. SER is not significantly correlated with any of these metrics.

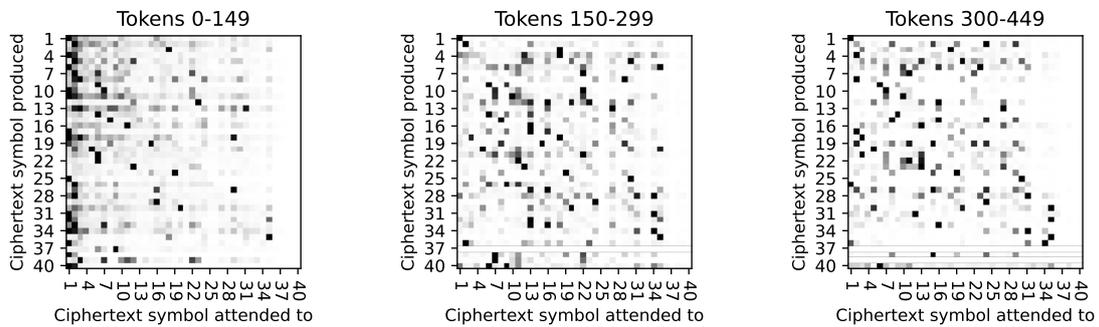

Figure 13: Mean self-attention from each ciphertext symbol to every other ciphertext symbol, averaged across different time-steps. This figure uses the same input as Figure 8. Note how the left subfigure, representing the earliest time-steps, does not meaningfully resemble the reference matrix from Figure 8, implying that the model has not learned which tokens are homophones at this early stage.

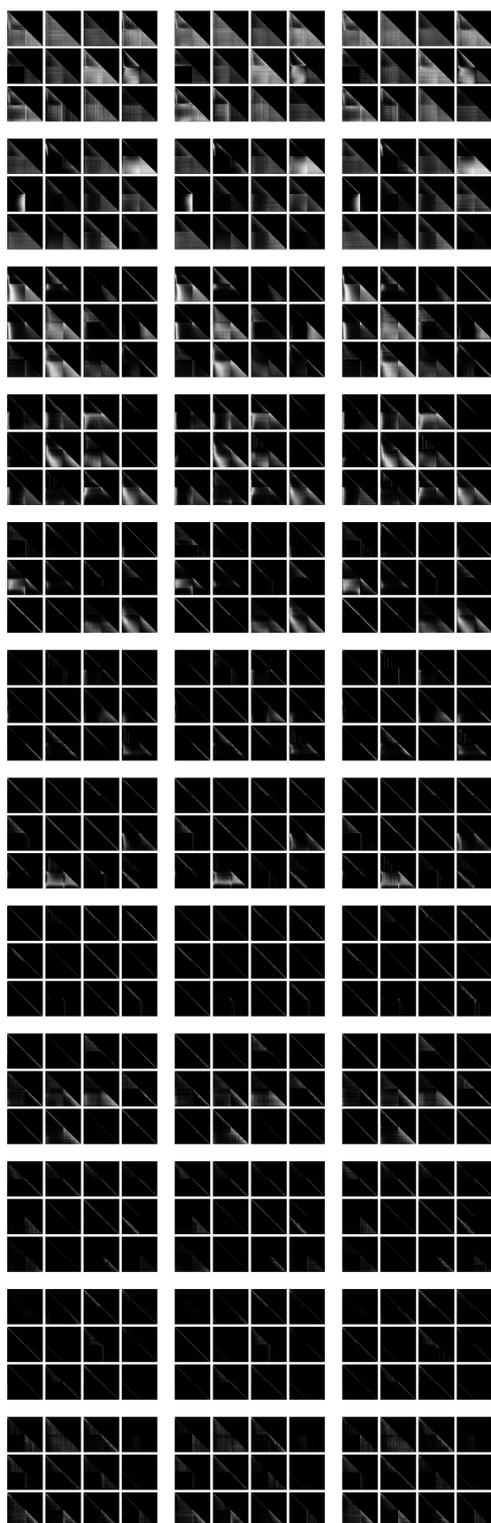

Figure 14: Attention maps for each head in each layer on three sample inputs. (Full-size figure available in supplemental material.) Each column represents a distinct ciphertext, and each row a Transformer layer, with the output layer on the bottom. Each cell is divided into 12 sub-figures, showing the self-attention maps from each of the 12 heads in the corresponding layer on the corresponding input.

Figure 15: The original full version of the **Zodiac-408** cipher published by the San Francisco Examiner on August 3rd 1969.

Figure 16: Page 1 of the BnF-f01 cipher from 1500s.

Handwritten text in a ciphery script, likely a form of the BnF-f01 cipher. The text is arranged in approximately 20 lines, written in a dense, slanted hand. The characters are a mix of letters and symbols, including what appears to be a Cyrillic 'X' and various combinations of letters and numbers. The script is highly stylized and difficult to decipher without a key.

Figure 17: Page 2 of the BnF-f01 cipher from 1500s.

A Survey on Recent Advances in Keyphrase Extraction from Pre-trained Language Models

Mingyang Song, Yi Feng and Liping Jing*

Abstract

Keyphrase Extraction (KE) is a critical component in Natural Language Processing (NLP) systems for selecting a set of phrases from the document that could summarize the important information discussed in the document. Typically, a keyphrase extraction system can significantly accelerate the speed of information retrieval and help people get first-hand information from a long document quickly and accurately. Specifically, keyphrases are capable of providing semantic metadata characterizing documents and producing an overview of the content of a document. In this paper, we introduce keyphrase extraction, present a review of the recent studies based on pre-trained language models, offer interesting insights on the different approaches, highlight open issues, and give a comparative experimental study of popular supervised as well as unsupervised techniques on several datasets. To encourage more instantiations, we release the related files mentioned in this paper¹.

1 Introduction

Keyphrase extraction is a fundamental task in NLP for identifying and extracting a set of keyphrases from the document that could summarize the important information discussed in the source document (Hasan and Ng, 2014; Papagiannopoulou and Tsoumakas, 2019). Keyphrases have enabled accurate and fast searching for the document from a large text corpus and have exhibited their potential in improving many NLP tasks, such as text summarization (Zhang et al., 2004). Various information filtering and extracting techniques are becoming critical with the ever-increasing amount of text data. Owing to its potential importance, keyphrase extraction has received more and more attention from

NLP researchers. However, the keyphrase extraction task is far from being solved: state-of-the-art performance on keyphrase extraction is still lower than other core NLP tasks. Our goal in this paper is to investigate the state-of-the-art models in keyphrase extraction, examine the primary sources of errors made by existing systems, and discuss the challenges ahead.

The first keyphrase extraction task was organized by Turney (1999), which defines the keyphrase extraction task as “the automatic selection of important and topical phrases from the body of a document”. Since then, there have been numerous keyphrase extraction models (Witten et al., 1999; Turney, 2000; Tomokiyo and Hurst, 2003; Hulth, 2004; Wan and Xiao, 2008a; Jiang et al., 2009; Liu et al., 2009; Grineva et al., 2009; Nguyen and Phan, 2009; Bougouin et al., 2013; Caragea et al., 2014; Danesh et al., 2015; Bougouin et al., 2016; Florescu and Caragea, 2017a; Campos et al., 2018a; Alzaidy et al., 2019). In the past two decades, keyphrase extraction methods have experienced the development from traditional approaches to deep learning methods (Hasan and Ng, 2014; Papagiannopoulou and Tsoumakas, 2019). With the recent development of Pre-trained Language Models (PLMs) (Devlin et al., 2019; Liu et al., 2019), many NLP tasks have significantly changed, that is, how to adopt and leverage pre-trained language models in the specific task. Therefore, many keyphrase extraction models (Sun et al., 2020a; Song et al., 2021) adopt PLMs as the embedding layer.

We present a comprehensive survey of recent advances in neural keyphrase extraction. We describe the neural keyphrase extraction systems based on pre-trained language models, which depend on different paradigms (e.g., one-stage (Wang et al., 2020) and two-stage (Sun et al., 2020a)), various tasks (e.g., classification and ranking (Mu et al., 2020; Sun et al., 2020a)), different learning strategies (e.g., supervised (Song et al., 2021) and un-

* Corresponding author.

¹<https://github.com/MySong7NLP/KeyphraseExtractionSurvey>

supervised (Ding and Luo, 2021)), and variants of pre-trained language models (e.g., BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)).

Furthermore, we re-implement and collect the results of the mentioned models on several benchmark keyphrase extraction datasets. We illustrate the results in Table 3 and Table 2 and discuss in Section 6 how neural keyphrase extraction systems have improved performance over past works, including supervised and unsupervised models. Furthermore, we provide resources, including links to share the current neural keyphrase extraction systems and links to share the code for each category of the neural keyphrase extraction approaches. To the best of our knowledge, this is the first survey focusing on the keyphrase extraction task based on recent pre-trained language models.

Overall, this paper first discusses previous surveys on keyphrase extraction in Section 2.1 and give a briefly introduction about pre-trained language models in Section 2.2. Then we highlight standard, past, and recent benchmark keyphrase extraction datasets (from shared tasks and other research) in Section 3 and evaluation metrics in Section 4. We then describe neural keyphrase extraction systems in Section 5. Next, we give the analysis and discussion in Section 6. Finally, we summarize the conclusions and future directions of neural keyphrase extraction in Section 7. The limitations of our work is presented in Section 8.

2 Preliminary

In this section, we claim the differences between the current survey and the existing surveys. Next, we present the background of pre-trained language models and their importance in NLP.

2.1 Previous Surveys

The first comprehensive keyphrase extraction survey was Hasan and Ng (2014), which covered a variety of unsupervised and supervised keyphrase extraction models, highlighted common features used by existing models during that time, and explained evaluation metrics that are still in use today. Papagiannopoulou and Tsoumakas (2019) present a more recent keyphrase extraction survey that mainly included many unsupervised and supervised models based on deep learning. Furthermore, Papagiannopoulou and Tsoumakas (2019) also provides a list of popular keyphrase extraction datasets and a thorough empirical study.

The existing keyphrase extraction surveys primarily cover early feature-engineered and neural-based keyphrase extraction models (Hasan and Ng, 2014; Papagiannopoulou and Tsoumakas, 2019). There is not yet, to our knowledge, a comprehensive survey of keyphrase extraction based on pre-trained language models.

2.2 Pre-trained Language Models

Recently, pre-trained language models have advanced the state-of-the-art in many NLP tasks ranging from textual similarity to text summarization (Zhang et al., 2019; Liu and Lapata, 2019; Zhong et al., 2020) and named entity recognition (Zhou et al., 2021). State-of-the-art pre-trained models include LSTM-based language models (e.g., ELMo (Peters et al., 2018)) and Transformer-based language models (e.g., BERT² (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)). Specifically, the transformer-based models learn bidirectional representations for words based on a masked language model and sentence adjacency training objective (Devlin et al., 2019). Simply using contextualized embeddings obtained from the transformer-based pre-trained language models in place of traditional embeddings has resulted in state-of-the-art performance on a range of NLP tasks. Therefore, pre-trained language models have been employed as encoders for obtaining word-, sentence-, and document-level representations to assist the downstream tasks.

3 Keyphrase Extraction Dataset

Since the first shared task on KE (Turney, 1999), many shared tasks and benchmark datasets for KE have been created. Specifically, OpenKP (Xiong et al., 2019), Inspec (Hulth, 2003), NUS (Nguyen and Kan, 2007), Krapivin (Krapivin and Marchese, 2009), SemEval2010 (Kim et al., 2010), SemEval2017 (Augenstein et al., 2017), and KP20k (Meng et al., 2017) were created from scientific articles in English.

Compared with other datasets, KP20k contains a large amount of annotation data, so it is often used as the dataset to train the neural-based KE models recently. Meanwhile, in recent papers (Sun et al., 2020a; Song et al., 2021), Inspec (Hulth, 2003), NUS (Nguyen and Kan, 2007), Krapivin (Krapivin and Marchese, 2009), SemEval2010 (Kim et al., 2010), and SemEval2017 (Augenstein et al., 2017)

²<https://huggingface.co/bert-base-cased>

Dataset	Type	Long	# Doc.	Avg. # Words	Present KPs (%)
KP20k (Meng et al., 2017)	Scientific Paper Abstract	✗	568.00k	188.47	57.40
Inspec (Hulth, 2003)	Scientific Paper Abstract	✗	2.00k	130.57	55.69

OpenKP (Xiong et al., 2019)	Open Domain Web Content	✗	147.20k	900.40	100.00

Table 1: This table shows the statistics of different recent popular datasets. **Long** indicates whether the dataset belongs to a long document. **# Doc.** is the number of documents in the dataset. **Avg. # Words** is the average number of words for documents in the indicated dataset. **Present KPs (%)** indicates the percentage of keyphrases, which are presented in the documents.

datasets are often used as the zero-shot test sets to verify the robustness of the KE models trained by the KP20k dataset. Furthermore, KE tasks have also been organized on newswire articles in English, e.g., DUC2001 (Wan and Xiao, 2008b). Table 1 summarizes the statistics of several commonly used benchmark datasets.

4 Keyphrase Extraction Evaluation

This section describes evaluation metrics for measuring recent state-of-the-art keyphrase extraction baselines on commonly-used datasets. Designing a suitable evaluation metric for the keyphrase extraction task is by no means an easy study (Hasan and Ng, 2014). To score the output of a keyphrase extraction model, the traditional approach, which is also adopted by the SemEval-2010 (Kim et al., 2010) shared task on keyphrase extraction, is (1) to create a mapping between the keyphrases in the ground-truth keyphrases and those in the model output adopting exact and partial matching (Papagiannopoulou and Tsoumakas, 2019), and then (2) score the output using evaluation metrics such as precision (P), recall (R), and F1-score (F1).

As mentioned earlier, such evaluation usually operates based on exact matches between the predicted and ground-truth keyphrases. However, such a strategy cannot account for partial matches or semantic similarity. For example, if the prediction is "keyphrase extraction model" and the ground truth is "keyphrase extraction system", despite both semantic similarity and partial matching, the score will be 0. These minor deviations are ubiquitous in

keyphrase extraction, yet they are harshly penalized by the "exact match" evaluation metrics.

5 Neural Keyphrase Extraction Models with Pre-trained Language Models

There are two popular pipelines in the keyphrase extraction task, including one-stage and two-stage frameworks, as illustrated in Figure 1. The former mainly refers to using the task reformulation to address the keyphrase extraction task, which often treats the keyphrase extraction task as a sequence labeling task. The latter represents a more general framework, which usually operates in two procedures: (1) extracting a set of words/phrases that serve as candidate phrases using some heuristics and (2) determining which candidate phrases are keyphrases using supervised or unsupervised methods (Hasan and Ng, 2014; Papagiannopoulou and Tsoumakas, 2019).

Typically, supervised methods perform better on specific domain tasks. However, this kind of method takes a lot of labor to annotate the corpus, and the model after training may overfit and not work well on other KE datasets. On the contrary, unsupervised methods do not need to annotate the corpus and usually have better data generalization in different domains. Still, the performance is often insufficient due to the lack of annotated data. Overall, we defined the above two procedures as the candidate keyphrase extraction and keyphrase importance estimation. In this paper, we distinguish the existing methods into three categories depending on the recent state-of-the-art baselines (with

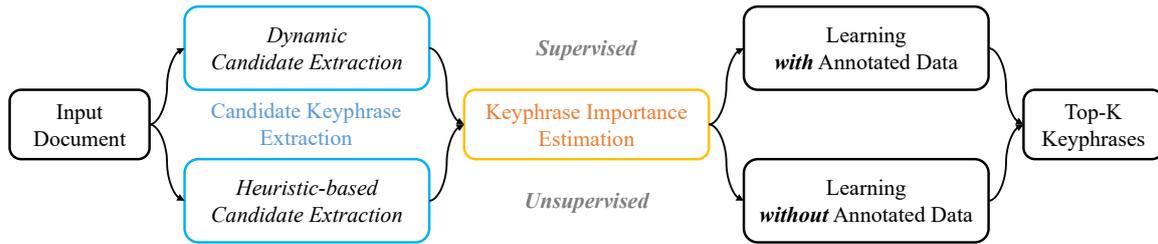

Figure 1: The overall architecture of the two-stage supervised and unsupervised keyphrase extraction framework.

pre-trained language models as the backbone), including two-stage unsupervised, two-stage supervised, and one-stage supervised models.

5.1 Two-Stage Unsupervised Keyphrase Extraction Models

As noted before, unsupervised keyphrase extraction systems generally extract a set of phrases from the source document as candidates by using heuristic rules. These rules are designed to avoid spurious instances and keep the number of candidates to a minimum (Hasan and Ng, 2014). The main steps of the commonly used candidate keyphrases extraction methods for the recent unsupervised keyphrase extraction models are as follows, (1) tokenizing the document and tagging the document with part-of-speech (POS) tags via the StanfordCoreNLP Tools³; (2) extracting candidate phrases based on part-of-speech tags by the regular expression via the python package NLTK⁴. Furthermore, different pruning heuristics have been designed for pruning candidates that are unlikely to be keyphrases to obtain a better candidate set (Huang et al., 2006; Kumar and Srinathan, 2008; El-Beltagy and Rafea, 2009; Newman et al., 2012; You et al., 2009). After obtaining candidates, keyphrases are determined by estimating the importance of each candidate through various strategies. Here, to facilitate the introduction, we divide the methods of importance estimation into two categories, namely, traditional methods and embedding-based methods.

Traditional unsupervised keyphrase extraction systems can be mainly divided into statistics-based (Jones, 2004; Campos et al., 2018b), topic-based (Liu et al., 2009; Jardine and Teufel, 2014), and graph-based (Mihalcea and Tarau, 2004; Wan and Xiao, 2008b; Bougouin et al., 2013; Florescu and Caragea, 2017b) methods. Generally, these

models primarily use different features of documents (e.g., word frequency, position, linguistic properties, topic, length, the relationship between words, external knowledge-based information, etc.) to estimate the importance of each candidate phrase and discriminate whether a candidate phrase is a keyphrase (Hasan and Ng, 2014; Papagiannopoulou and Tsoumakas, 2019).

However, these traditional unsupervised models estimate the importance scores of candidate phrases based on the surface-level features, ignoring the high-level features (e.g., syntactic and semantic information) of natural languages, which leads to extract wrong keyphrases. Therefore, recent studies focus on embedding-based models (Wang et al., 2015; Mahata et al., 2018a; Papagiannopoulou and Tsoumakas, 2018; Sahrawat et al., 2020; Kulkarni et al., 2022; Song et al., 2022b), which leverage pre-trained embeddings (containing high-level features) to obtain phrase and document embeddings and calculate the importance scores of candidate phrases for extracting keyphrases. Wang et al. (2015) is the first work to explore utilizing word embedding and frequency to generate weighted edges between words, then using the weighted PageRank algorithm to compute and rank candidate scores. Key2vec (Mahata et al., 2018a) proposes an effective way of processing text documents for training multi-word phrase embeddings that are used for topic representations of scientific articles and ranking of keyphrases extracted from them using the topic-weighted PageRank algorithm. Mahata et al. (2018b) uses a combination of theme-weighted personalized PageRank algorithm and neural phrase embeddings for extracting and ranking keyphrases. EmbedRank (Bennani-Smires et al., 2018) ranks candidate phrases by measuring the semantic similarity between each candidate phrase and document embeddings.

With the development of pre-trained language

³<https://stanfordnlp.github.io/CoreNLP>

⁴<https://github.com/nltk>

models (e.g., ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019)), SIFRank⁵ (Sun et al., 2020b) improves candidate phrase and document embeddings from EmbedRank with the pre-trained language model ELMo (Peters et al., 2018) and achieves better performance. JointGL⁶ (Liang et al., 2021) integrates boundary-aware phrase centrality (the semantic similarities are calculated between all candidate phrases for identifying which candidate is better) and phrase-document relevance (the semantic similarities are calculated between candidate phrases and their corresponding document) from both local and global views, then used both jointly to determine the importance of each candidate. AttentionRank⁷ (Ding and Luo, 2021) adopts a pre-trained language model to calculate the self-attention of a candidate within the context of a sentence, and the cross-attention between a candidate and sentences within the source document to evaluate the local and global importance of each candidate. MDERank⁸ (Zhang et al., 2021) proposes to rank candidates using the similarity between the BERT embeddings of the source document and the masked document. Totally, these models achieve state-of-the-art performance in the unsupervised keyphrase extraction task, benefiting from the development of representation learning.

5.2 Two-Stage Supervised Keyphrase Extraction Models

Different from two-stage unsupervised approaches, supervised approaches generally combine candidate keyphrase extraction and keyphrase importance estimation via *an end-to-end learning framework*, guide the whole model to rank and extract keyphrases through annotated data and optimize the two stages simultaneously. Therefore, to obtain sufficient candidates, the recent supervised models (Xiong et al., 2019; Sun et al., 2020a; Song et al., 2021, 2022a) directly extract n-grams from the document as candidates. Then propose, various approaches to estimate the importance scores of candidates. To estimate the importance of candidate phrases, similar to unsupervised models, supervised models (Xiong et al., 2019; Sun et al., 2020a; Song et al., 2021) also obtain phrase and document representations by adopting pre-trained

language models as the backbone, including ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), etc.

Firstly, BLING-KPE (Xiong et al., 2019) formulates keyphrase extraction as an n-gram level keyphrase chunking task to determine whether a candidate is a keyphrase, which incorporates pre-trained embeddings (i.e., ELMo (Peters et al., 2018)) into a convolutional transformer network to model n-gram representations. BLING-KPE achieves significant improvement over previous models. To leverage external knowledge to assist keyphrase extraction, SMART-KPE⁹ (Wang et al., 2020) also shows that incorporating multimodal information in web pages, such as font, size, and DOM features, can bring further improvement for open-domain web keyphrase extraction. Later, Ainslie et al. (2020) replaces the full self-attention of Transformers with local-global attention, which significantly boosts the keyphrase extraction performance for long documents. SKE-BASE-RANK (Mu et al., 2020) proposes a span-based keyphrase extraction model to model the relationships between candidates and the document in context.

JointKPE¹⁰ (Sun et al., 2020a) proposes an open-domain keyphrase extraction approach built on pre-trained language models (Devlin et al., 2019; Liu et al., 2019), which can capture both local phraseness and global informativeness when extracting keyphrases. JointKPE learns to rank keyphrases by estimating their informativeness in the whole document and is jointly trained on the keyphrase chunking task to guarantee the phraseness of keyphrase candidates. KIEMP¹¹ (Song et al., 2021) proposes estimating the importance score of each candidate from multiple perspectives and introducing a matching module to match the high-level concept between the document and candidates to enhance the relevance of extracted keyphrases. To extract more relevant keyphrases, HyperMatch¹² (Song et al., 2022a) proposes a new matching framework and explores keyphrase extraction in the hyperbolic space. Concretely, HyperMatch first maps phrase and document representations into the same hyperbolic space and explicitly models the relevance between candidate phrases and the document as the phrase-document relevance via the Poincaré distance to extract keyphrases.

Table 2: Performance of unsupervised keyphrase extraction models on the DUC2001, Inspec, SemEval2010 and SemEval2017 test sets. F1 scores on the top 5, 10, and 15 keyphrases are reported. The best results are bolded. The results of baseline models are those presented in the original papers or better results published in other papers recently.

5.3 One-Stage Supervised Keyphrase Extraction Models

A major limitation of the above two-stage supervised approaches is classifying the labels of each candidate phrase independently while ignoring the dependencies that could potentially exist between candidates. Therefore, recent studies (Golapalli et al., 2017; Basaldella et al., 2018; Wang et al., 2018; Alzaidy et al., 2019; Sun et al., 2019; Mu et al., 2020; Sahrawat et al., 2020) formulated keyphrase extraction as sequence labeling and showed that using linear-chain Conditional Random Fields improved the performance over baseline models for this task. Then, Mu et al. (2020) proposes SKE-BASE-CLS and -RANK, which directly extracts span-based phrase representations from all the document tokens via pre-trained language models and further learn to capture the interaction between them and their corresponding document to get better ranking results. Furthermore, this kind of model can extract overlapped keyphrases (Mu et al., 2020).

6 Discussion

In this section, we report the results of the recent unsupervised and supervised keyphrase extraction baselines, which all adopt pre-trained language

models as the backbone, as shown in Table 2 and Table 3. Specifically, Table 2 presents the results of the traditional unsupervised methods and the unsupervised embedding-based keyphrase extraction baselines discussed in Section 5.1 on the DUC2001 (Wan and Xiao, 2008b), Inspec (Hulth, 2003), SemEval2010 (Kim et al., 2010), and SemEval2017 (Augenstein et al., 2017) datasets. Embedding-based two-stage models without PLMs indicate that the models do not use pre-trained language models as the backbone to obtain representations. Table 3 shows the results of all the different categories of the supervised keyphrase extraction systems discussed in Section 5.2 and Section 5.3 on the KP20k (Meng et al., 2017) and OpenKP (Xiong et al., 2019) datasets.

Our first finding from the survey is those two-stage embedding-based systems with static embeddings outperform two-stage traditional methods, despite the latter’s access to different valuable features (e.g., word frequency, position, linguistic properties, topic, length, the relationship between words, external knowledge-based information, etc.). This further demonstrates the necessity of studying embedding-based methods.

Our second finding is those embedding-based systems with PLMs outperform embedding-based approaches with static embeddings in most cases.

Two-Stage Supervised Keyphrase Extraction Models					
BLING-KPE (Xiong et al., 2019)	-	-	26.7	29.2	20.9
SKE-BASE-CLS (Mu et al., 2020)	38.6	32.6	-	-	-
BERT-ChunkKPE [†]	41.2	33.7	34.0	35.6	31.1
RoBERTa-ChunkKPE [†]	40.8	33.7	35.5	37.3	32.4

SKE-BASE-RANK (Mu et al., 2020)	39.2	33.0	-	-	-
BERT-RankKPE [†]	41.3	34.0	34.2	37.4	32.5
RoBERTa-RankKPE [†]	41.7	34.3	36.1	39.0	33.7
HyperMatch (Song et al., 2022a)	41.6	34.3	36.4	39.4	33.8

BERT-JointKPE [†]	41.1	33.8	34.9	37.6	32.5
RoBERTa-JointKPE [†]	41.9	34.4	36.4	39.1	33.8
KIEMP (Song et al., 2021)	42.1	34.5	36.9	39.2	34.0

Table 3: Results of different categories of supervised keyphrase extraction models on two benchmark keyphrase datasets. F1 scores on the top 1, 3, 5, and 10 keyphrases are reported. [†] indicates the results are reported by their corresponding paper (Sun et al., 2020a), and [‡] denotes that these results are re-evaluated by ourselves via the code which is provided by its corresponding paper (Sun et al., 2020a). The best results are highlighted in bold. The results of baseline models are those presented in the original papers or better results published in other papers recently.

However, not all embedding-based systems with PLMs are superior to embedding-based systems with static embeddings. The former generally outperforms the latter when adopting the same importance estimation strategy, but the estimation strategy can significantly affect the results of keyphrase extraction. To sum up, effectively using pre-trained embeddings to estimate the importance score of each candidate is a critical part of improving the performance of keyphrase extraction. Furthermore, there is still interesting progress to be made by leveraging a self-supervised learning strategy to optimize embedding-based systems. MDERank uses a simple yet effective contrastive learning strategy to optimize embedding-based systems, achieving better performance.

Our third finding is that the embedding-based methods have slight improvement on long document datasets (e.g., SemEval2010), and all unsupervised methods have poor effects on long document datasets. This demonstrates that keyphrase extraction from long documents is still a challeng-

ing problem.

Our final finding is that two-stage supervised keyphrase extraction methods are superior to one-stage supervised keyphrase extraction methods, as illustrated in Table 3. In addition, the two-stage method has higher scalability and adaptability than the one-stage method, such as handling long and extremely long documents.

7 Conclusion and Future Directions

We summarize the recent neural keyphrase extraction models based on pre-trained language models. Our survey of models for keyphrase extraction, covering both unsupervised and supervised models, has yielded several important insights. The analysis revealed that there are at least six major challenges ahead.

7.1 Improving the Quality of Generated Candidate Keyphrases

Many heuristic rules have proven effective with a high recall to cover most of the gold keyphrases

of source documents, which determines the upper bound of the performance of keyphrase extraction (Hasan and Ng, 2014). Intuitively, better candidate keyphrase extraction strategies are required to generate a set of candidate keyphrases with a higher recall from the source document to improve the upper-bound performance of keyphrase extraction. Recent work (Jawahar et al., 2019) demonstrates that the intermediate layers of BERT encode a rich hierarchy of linguistic information, with surface features at the bottom, syntactic features in the middle, and semantic features at the top, as mentioned in Section 2.2. They also observe that BERT mostly captures phrase-level information in the lower layers and gradually dilutes this information in higher layers. In addition, the number of candidate keyphrases will increase as the document length increases. Therefore, how constructing candidate keyphrases using the potential knowledge of pre-trained language models is a valuable research direction.

7.2 Improving Evaluation Metric

As mentioned in Section 4, the existing evaluation metrics occur when a keyphrase extraction system extracts a keyphrase from candidates that is semantically equivalent to a ground-truth keyphrase but is considered erroneous by a scoring function because it fails to recognize that the predicted keyphrase and the corresponding gold keyphrase are semantically equivalent.

In other words, an evaluation error is not made by a keyphrase extraction system, but a mistake due to an unformed scoring function (Hasan and Ng, 2014). Therefore, a more suitable evaluation metric is required to evaluate the predicted keyphrases by adopting the semantic-based matching metric instead of the exact matching evaluation metric. In the future, using pre-trained language models (e.g., BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)) to construct a new semantic-aware evaluation metric similar to BERTScore (Zhang et al., 2020) may be an interesting and valuable research direction.

7.3 Reducing Over-Generation Error

Over-generation errors occur when a keyphrase extraction system correctly predicts a candidate as a keyphrase because it contains a word that frequently appears in the associated document but at the same time erroneously outputs other candidates

as keyphrases because they have the same word in the document.

As mentioned before, for example, if the prediction is "keyphrase extraction challenge" and the ground truth is "keyphrase extraction system", despite both semantic similarity and partial matching, the score will be 0. These minor deviations are ubiquitous in keyphrase extraction, yet they are harshly penalized by the "exact match" evaluation metrics. There are often some non-keyphrases in the candidates. Half of the content of such phrases is very relevant to the core information of the document, but the other half is meaningless. These candidate keyphrases are usually hard to extract and treated as hard samples, which is one of the main reasons for reducing keyphrase extraction performance. The above issues can be solved by modifying the traditional evaluation metrics with semantic weighting.

7.4 Handling Long Document

Generally, two main challenges exist in keyphrase extraction systems equipped with pre-trained language models (e.g., BERT (Devlin et al., 2019)) as the backbone when extracting keyphrases from a long document, especially for an extremely long document.

The first challenge is that pre-trained language models can not directly model the complete context information when facing long documents due to the length limitation of pre-trained language models.

The second challenge is that as the length of the document increases, the difficulty of estimating the importance scores of candidate phrases also increases (specifically for the number of candidates), resulting in the reduction of keyphrase extraction accuracy.

7.5 Improving Domain Generalization

For news or scientific documents, the authors usually annotate a set of keyphrases for their articles (Meng et al., 2017; Augenstein et al., 2017). However, there is typically a lack of keyphrases as the label information for their corresponding documents in other specific domains.

Most existing keyphrase extraction datasets and studies are based on news or scientific documents and lack datasets and research related to other domains. Therefore, the task worthy of investigation is to transfer the keyphrase extraction model from the scientific domain to other domains to build a

domain-specific keyphrase extraction model with various domain generalization strategies.

7.6 Probing Pre-trained Language Model for Keyphrase Extraction

In addition to using transformer-based pre-trained language models (e.g., BERT) in NLP tasks and end applications, research has also been done on BERT, especially to reveal what linguistic information is available in different parts of the model (Jawahar et al., 2019; de Vries et al., 2020; Chen et al., 2021). It has been noted that BERT progressively acquires linguistic information roughly in the same order as the classic language processing pipeline (Tenney et al., 2019a,b): surface features are expressed in lower layers, syntactic features more in middle layers, and semantic ones in higher layers (Jawahar et al., 2019). Making full use of the above hierarchy information may effectively improve the performance of keyphrase extraction.

8 Limitations

The main goal of this paper is to provide a survey of the existing models. Since we do not propose new models, there are no potential social risks to the best of our knowledge. Our work may benefit the research community by providing more introspection into the current state-of-the-art neural keyphrase extraction approaches with pre-trained language models.

Abstract

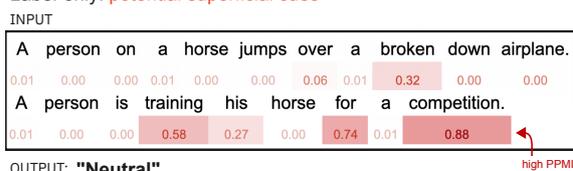

Explanation prompts ask language models to not only assign a label to a given input, such as *entailment* or *contradiction* in natural language inference (NLI) tasks, but also to generate a free-text explanation that supports this label. While explanation prompts originally introduced aiming to improve model interpretability, here we show that they also improve robustness to superficial cues. Compared to prompting for labels only, explanation prompting shows stronger performance on adversarial NLI benchmarks, outperforming the state of the art on ANLI, Counterfactually-Augmented NLI, and SNLI-Hard datasets. Analysis suggests that the increase in robustness is due to a reduction in the association strength between single tokens and labels, i.e., explanation prompting weakens superficial cues. More specifically, we find that single tokens that are highly predictive of the correct answer in the label-only setting become uninformative when the model also has to generate explanations.

1 Introduction

Explanation prompting requires language models to not only assign a particular label to a given input (henceforth: label-only prompting), but also to generate an explanation that supports this label. For example, given the natural language inference (NLI; Bowman et al., 2015) premise “A soccer game with multiple males playing” and the hypothesis “Some men are playing a sport”, in label-only prompting the model only has to generate a label such as *entailment*. With explanation prompting, the model has to generate not only the label but also an *explanation* that supports this label, such as “It is true because playing soccer is playing a sport”.

While explanation prompting was originally proposed for improving model interpretability (Narang et al., 2020), here we explore a different advantage: improved model performance on adversarial bench-

Label-only: **potential superficial cues**

Explanation prompting: **neutralizes superficial cues**

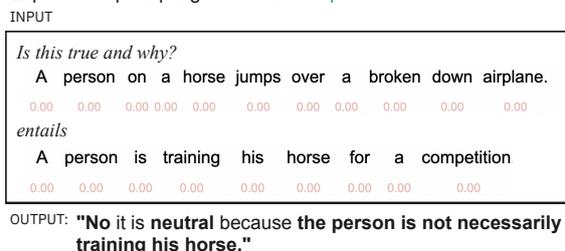

Figure 1: When models only have to predict class labels (top), some words in the input can become superficial cues, as indicated by high pointwise mutual information (shown in red) between words and class labels. With *explanation prompting* (bottom) the added requirement of generating explanations renders such shortcuts ineffective.

marks. Created in response to the discovery of superficial cues in many common datasets, adversarial benchmarks are designed to give a more realistic estimate of model performance. Non-adversarial benchmarks such as SNLI (Bowman et al., 2015) can contain superficial cues, i.e., single tokens that are predictive of the correct label and hence allow models to achieve high scores by taking “shortcuts” instead of acquiring and employing the capabilities intended by the task designers (Gururangan et al., 2018a; McCoy et al., 2019; Poliak et al., 2018; Niven and Kao, 2019; Sugawara et al., 2018; Schuster et al., 2019a; Kavumba et al., 2019). In contrast, adversarial benchmarks are created in a way that reduces or completely eliminates superficial cues, thus forcing models to solve tasks in the intended and generally more difficult manner.

In this work, we investigate the benefits of explanation prompting through the lens of adversarial benchmarks. Concretely, we finetune pre-trained language models on natural language inference datasets with explanation prompting and compare performance to label-only prompting. We find that explanation prompting improves performance across four adversarial NLI datasets and two non-adversarial NLI datasets (§5). Improvements are consistent across model architectures, model sizes, and prompt variations. Further analysis reveals that both the specific verbalization of the label (“*Yes, it is* {label} because...”) and the relation between explanation and label are important for model performance (§6). Finally, we verify that explanation prompting models do not rely on the kind of superficial cue that allows taking shortcuts in the label-only setting (§6). Source code is available at github.com/pkavumba/explanation-prompting.

2 Background and Related Work

2.1 Superficial Cues

In the original natural language inference setting, as exemplified by SNLI (Bowman et al., 2015), models are trained to assign a label, such as *entailment* or *contradiction*, to a given input. While models quickly achieved high evaluation scores, a line of research starting with Gururangan et al. (2018a) found that SNLI and other datasets contain superficial cues that models can exploit instead of learning the task as intended (Poliak et al., 2018; McCoy et al., 2019; Niven and Kao, 2019; Schuster et al., 2019a; Kavumba et al., 2019; Wang and Culotta, 2021; Srivastava et al., 2020; Wang et al., 2019b,c). For example, in SNLI, negations such as “not” are strongly associated with the *contradiction* label (Gururangan et al., 2018a). A model that predicts *contradiction* when the input contains the token “not” will achieve a high evaluation score without acquiring any capability to perform actual natural language inference. Having learned to rely on such shortcuts (Geirhos et al., 2020), models will be “right for the wrong reasons” (McCoy et al., 2019) on data that contains superficial cues, but will perform worse on data that does not.

There are several approaches to mitigate superficial cues. A direct countermeasure is to remove them from existing datasets and to take care not to introduce superficial cues when creating new datasets. The two dominant methods to do so are

removal of easy samples via adversarial filtering (Zellers et al., 2018, 2019; Sakaguchi et al., 2020; Bras et al., 2020; Nie et al., 2020) and augmentation with counterfactual examples that neutralize the association between existing superficial cues and labels (Kavumba et al., 2019; Schuster et al., 2019b; Kaushik et al., 2020). A complementary line of work aims to prevent models from relying on superficial cues, for example via adversarial training (Belinkov et al., 2019; Stacey et al., 2020, 2021) and adversarial attacks (Wang et al., 2019a; Liu et al., 2020; Zhu et al., 2020; Wang et al., 2021). Adversarial approaches suffer from drawbacks such as a more complex training scheme and higher computational costs. Another approach is multi-task training. Camburu et al. (2018) propose a “predict-and-explain” multi-task setup in which one model first predicts a label and a second model generates a free-form explanation for this label. However, this setup turns out to slightly degrade performance.

In this work, we study *explanation prompting* as a method for reducing the impact of superficial cues. While this form of prompting was originally introduced to enhance model interpretability (Narang et al., 2020), our work is most closely related to Chen et al. (2022), who studied the robustness of rationale models (Lei et al., 2016; Bastings et al., 2019; DeYoung et al., 2020) to adversarial attacks. Rationale models operate in a two-step “rationalize-then-predict” manner, where the model first selects a pertinent subset of the input, called a *rationale*, and then predicts a label given this rationale. Stacey et al. (2021) investigates using human annotated rationales for supervising attention mechanism. Their goal is to increase the attention given to annotated rationales.

2.2 Explanation Prompting

Explanation prompting requires models not only to predict a class label but also to provide an explanation of why that label is the correct answer. Previous work has explored explanation prompting as a way to improve model interpretability. Wiegreffe et al. (2021) analyzed the faithfulness of explanations obtained via explanation prompting. Since high-quality explanation are expensive to create and not available in large quantities, Marasovic et al. (2022) compare methods for generating high-quality explanations in limited data regimes, whereas Wiegreffe et al. (2022) investigate the fea-

sibility of using large language models such as GPT-3 (Brown et al., 2020) to automatically generate large amounts of explanations. In contrast to this strand of research, we use free-text explanations not to improve model interpretability, but to improve model robustness in adversarial settings.

3 Explanation Prompting for Adversarial NLI

In the original natural language inference setting, one trains a classifier to label the relationship between a *premise* and a *hypothesis* as *entailment*, *neutral*, or *contradiction*. When using a generative language model to generate a label and an explanation supporting the label, the task turns from classification into what we refer to as *explanation prompting*. Turning the original NLI instances into input-output pairs suitable for a generative language model necessitates choosing a *verbalizer*¹ that converts premise, hypothesis, label, and answer into an input prompt and target output, e.g.:

- *Input*: Is this true and why? {premise} implies {hypothesis}
- *Output*: {Yes or No} it is {label} because {explanation}

Note that the label prediction process is further broken down into two steps: first, the model must provide a *binary* answer to the question (in this case, whether the statements are entailed), then give the exact label. That is, the output starts with “*Yes it is ...*” for Entailment, or “*No it is ...*” for Neutral and Contradiction. We refer to this as *multi-step verbalizing*. This is a deviation from previous work that utilized single-step or single-word verbalizers. For example, entailment is often verbalized as *yes*, while contradiction and neutral are verbalized as *no* and *maybe*, respectively (Schick and Schütze, 2021a,b). Finally, the output is completed with a free-text explanation supporting the label.

4 Experimental Setup

4.1 Datasets

We compare label-only and explanation prompting on six NLI datasets.

e-SNLI (Camburu et al., 2018) extends SNLI (Bowman et al., 2015) with crowdsourced free-form explanations and annotated salient spans.

¹Verbalizer details are given in Appendix A.

Adversarial NLI (ANLI) (Nie et al., 2020) was created in an iterative, adversarial process where, in each iteration, human annotators create examples that a given model does not label correctly, which are then used to train a stronger model.

SNLI Hard (Gururangan et al., 2018a) is a filtered version of the SNLI test set and contains only instances that could not be labeled correctly by a model given only the hypothesis as input.

NLI Diagnostic (Wang et al., 2018) was carefully constructed to evaluate capabilities related to commonsense knowledge, logical reasoning, predicate-argument structures, and lexical semantics.

Heuristic Analysis for NLI Systems (HANS) (McCoy et al., 2019) was created to analyze and prevent several kinds of shortcuts found in prior NLI datasets, such as lexical overlap between premise and hypothesis.

Counterfactually-Augmented NLI (Counter-NLI) (Kaushik et al., 2020) augments a subset of SNLI with counterfactual instances, which were obtained by editing either the premise or hypothesis so that a counterfactual, i.e., different than the original, label becomes true. Models relying on superficial cues will perform well on original SNLI instances, but poorly on counterfactual ones.

4.2 Models and Training Details

The two main models selected for our comparison are T0 (Sanh et al., 2021) and T5-3B (Raffel et al., 2020). We chose these two models based on their good reported performance on NLI datasets while involving comparably low computational costs, which we further reduced by finetuning all models only on a third of the available e-SNLI and ANLI training data. Thus, test results on e-SNLI, ANLI, and SNLI Hard can be considered in-domain tests and results on the remaining datasets out-of-domain tests. Further training details and hyperparameter settings are given in Appendix B.

5 Results

Does explanation prompting improve robustness to adversarial attacks? *Yes.*

For both T0 and T5-3B, training with explanation prompting improved performance over label-only prompting on nearly all datasets, surpassing the reported state of the art on e-SNLI, SNLI-Hard,

Dataset	Subset	Current SOTA	T5-3B		T0 (11B)	
			Label-only	Explanation prompting	Label-only	Explanation prompting
e-SNLI	-	92.3	91.7	95.1	91.0	91.9
SNLI Hard	Hard	80.2	84.0	89.7	83.0	84.5

	Logic	58.7	63.7	73.9	60.7	64.5
	LS	66.5	69.6	79.3	63.0	70.4
	PAS	69.9	73.1	80.9	70.8	72.4

Table 1: Results by T5-3B and T0 (11B) models trained with label-only prompting and Explanation prompting. Current state-of-the-art results on each dataset are reported from: WT5 (Narang et al., 2020), BERT-Sup-ATT (Stacey et al., 2021), InfoBERT (Wang et al., 2021), RoBERTa-AFLITE (Bras et al., 2020), BERT (Kaushik et al., 2020), and RoBERTa-AFLITE (Bras et al., 2020), respectively. Note that T5-3B and T0 are trained with different batch sizes and sequence lengths, so the results are not comparable (§ 5).

ANLI, and Counterfactually-Augmented NLI (Table 1). For example, on the three ANLI subsets T5-3B achieves accuracies of 81.8%, 72.5%, and 74.8% with explanation prompting, compared to much lower accuracies of 74.9%, 58.9% and 57.9% with label-only prompting. Furthermore, since e-SNLI does not contain any adversarially chosen “hard” instances, strong results on this dataset show that explanation prompting does not necessarily hurt performance on datasets with superficial cues. Overall T5-3B achieves higher performance despite its smaller size, but this is due to T0 using a quarter of the batch size and sequence length of that used for T5 due to memory limitations.

The HANS dataset remains the most challenging dataset, indicating that the models may still be susceptible to such adversarial attacks. Surprisingly, the use of explanation prompting actually leads to *degraded* performance for certain subsets, such as the lexical overlap for T0, and subsequences and constituents for T5-3B. This discrepancy warrants further investigation, which we leave for future work.

On all other datasets, explanation prompting models show clear improvements over label-only models in both in-domain and adversarial out-of-domain settings. This demonstrates that us-

	Full	H-only	Δ
Label-only prompting	87.2	63.7	-23.5
Explanation prompting	90.9	33.1	-57.8
Random baseline	33.3	33.3	-

Table 2: The average prediction accuracy of T0 models on e-SNLI when trained with the full input compared to the hypothesis-only setting (H-only), which allows the models to solely rely on superficial cues to make accurate predictions. The explanation prompting-trained model’s performance degraded to random performance, implying that it did not learn to make use of superficial cues.

ing explanation prompting generally enhances the model’s robustness to adversarial attacks and improves the overall NLI prediction performance.

6 Discussion

In this section we vary experimental settings and conduct ablations in order to provide a more detailed analysis of how explanation prompting impacts NLI performance. Unless stated otherwise, reported results are obtained by finetuning T0 on 20K randomly-sampled instances from e-SNLI and averaging prediction accuracies from three runs

Explanation	Accuracy	BLEU
None	88.4	-
Random characters	21.00	0.02
Random words	0.00	0.90
Low-sim. sentences	0.04	0.03
High-sim. sentences	59.1	1.73
Original (e-SNLI)	91.6	36.1

Table 3: Impact of explanation content. Accuracies are shown for the e-SNLI dev set, averaged over three T0 models finetuned with different random seeds. Random characters and words or unrelated explanations significantly reduce performance, indicating that the models did not rely on superficial cues. Original explanations outperform extracted sentences with high similarity, demonstrating the benefit of related explanations. We also report BLEU scores with respect to the original explanations.

with different random seeds. Training details are given in Appendix B.

Does explanation prompting prevent models from exploiting superficial cues? *Yes.*

To see if models still exploit superficial cues, we employ the hypothesis-only setting of Gururangan et al. (2018b). Since the missing premise makes the task impossible, any performance above random chance can be ascribed to models picking up on superficial cues. After training one model with label-only prompting and one with explanation prompting (Table 2), we observe that the label-only model considerably exceeds random chance (63.7% compared to 33.3%). In contrast, the explanation prompting model does not exceed random chance, indicating that explanation prompting is not conducive to shortcut learning.

Do the explanations need to be related to the input? *Yes.*

To check if the content of the target explanation matters we replace it with unrelated text ranging from completely random characters to similar but unrelated sentences and find that explanation prompting with the original explanations still performs best (Table 3). Specifically, we choose the following target “explanations”: (i) random characters, (ii) random words, (iii) sentences extracted from the BookCorpus (Zhu et al., 2015) with *low* similarity with the input, and (iv) sentences extracted from the BookCorpus with *high* similar-

ity.² All similarities are computed with SentenceBERT (Reimers and Gurevych, 2019). We also compare to label-only prompting (*None* row in Table 3). Table 3 shows the mean prediction accuracy scores on the development set of e-SNLI over three random seeds. Performance degrades with random explanations or sentences extracted from BookCorpus, confirming that training the model to predict explanations improves adversarial robustness.

Does *Multi-step* verbalizing have an effect on the model performance? *Yes.*

A binary decision step may seem like a small change in prompt format, however, we found that this added step has partial merit to the improvement in performance. To verify this, we train label-only and explanation prompting models using *single-step*-verbalized prompts (*{label} because...*) and ones using *multi-step*-verbalized prompts (“*Yes it is {label} because...*”), both with an explanation (+Explain column in Table 5) and without added explanations (Label-only column in Table 5). The results show the prediction accuracy averaged over three random seeds. In both label-only and explained settings, adding a multi-step verbalizer brings an improvement over the single-step version.

Are the models sensitive to prompt wording in the input? *No.*

Previous work has demonstrated that language models can be very sensitive to the prompts (Schick and Schütze, 2021a,b; Brown et al., 2020). To examine this, we conduct experiments on five diverse crowdsourced prompts obtained from the Prompt Source project (Bach et al., 2022). For each model, we run three separate experiments using three different random seeds. We report the average accuracy across all five prompts on the development set of e-SNLI and Counterfactually-Augmented NLI. Due to resource constraints, we use T5-3B, a smaller model than T0, for these experiments. Furthermore, we limit the number of instances used from e-SNLI to twenty thousand randomly selected examples.

The results presented in Table 4 demonstrate that models trained with explanation prompting outperform those trained with label-only prompting across all five prompts in terms of accuracy (see Table 8 in Appendix C for results with different models). For instance, the explanation prompt-

²We use the BookCorpus instead of sampling random explanations to avoid accidentally sampling valid explanations.

Dataset	Prompt ID					Mean _(stddev)
	1	2	3	4	5	
e-SNLI	91.5 / 94.4	91.6 / 94.7	91.8 / 94.6	91.6 / 94.5	91.8 / 94.4	91.7 _(0.1) / 94.5 _(0.1)
CNLI (RP)	70.8 / 82.5	73.0 / 83.8	71.5 / 83.0	72.1 / 83.0	70.1 / 82.8	71.5 _(1.1) / 83.0 _(0.5)
CNLI (RH)	82.0 / 92.3	82.8 / 93.0	81.9 / 92.8	82.0 / 92.2	83.1 / 92.5	82.4 _(0.6) / 92.6 _(0.3)
CNLI (RP&RH)	76.4 / 87.4	77.9 / 88.4	76.7 / 87.9	77.0 / 87.6	76.6 / 87.7	76.9 _(0.6) / 87.8 _(0.4)

Table 4: Prompt sensitivity on the development set of e-SNLI and Counterfactually-Augmented NLI (CNLI). Values are accuracy of label-only/explanation prompting-trained T5-3B models averaged over three random seeds. Besides the consistently higher performance of the explanation prompting setting, the lower standard deviation indicates greater stability w.r.t. prompt format.

	Label-only	+Explain (e-SNLI)
Single-step	87.2	90.9
Multi-step	88.4	91.6

Table 5: Comparing the effects of single-step (“[label] because ...”) and multi-step (“Yes/no, it is [label] because ...”) verbalizing on T0 prediction accuracy, both with an explanation (+Explain) and without an explanation (Label-only) in the model output. Multi-step verbalizing improved the accuracy in both cases, with and without explanation, and the added task of providing an explanation (+Explain) further enhanced performance.

ing model achieves an overall average accuracy of 94.5% on e-SNLI compared to 91.7% for the label-only model. Additionally, the explanation prompting model exhibits better accuracy on all the individual prompts on the adversarial Counterfactually-Augmented NLI with an overall average accuracy of 83.0% on the revised premise (RP), 92.6% on the revised hypothesis (RH), and 87.8 on RP&RH, compared to 71.5%, 82.4%, and 76.9% respectively for the label-only model. The lower standard deviations for explanation prompting also indicate higher stability across all prompts.

Are the results dependent on the architecture/size of the model employed? *Yes.*

To study the impact of model size on performance, we repeat the experiments using six models ranging from 60 million to 11 billion parameters. These models comprise two versions of BART (Lewis et al., 2020) with 125M and 400M parameters, as well as three variants of T5 (Raffel et al., 2020) with 60M, 770M, and 3B parameters, and T0 with 11B parameters. The results, as depicted in Figure 3 for ANLI, indicate a clear correlation between model size and performance, with larger models demonstrating improved results. It is worth noting that

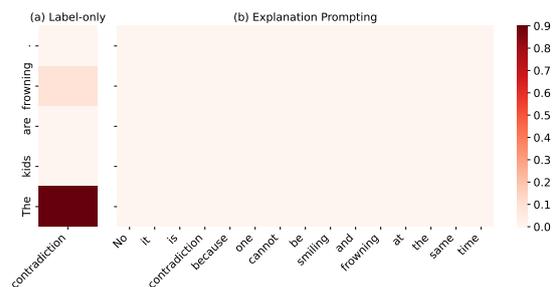

Figure 2: Positive Pointwise Mutual Information (PPMI) statistics for hypothesis words and labels with and without explanation prompting. Words in the hypothesis are strongly associated with the predict-only labels. With explanation prompting, the association between the hypothesis words and the labels drops to a zero. For example, while the negative word *frowning* is strongly associated with *contradiction* label, the association is eliminated with explanation prompts. The figure only shows the hypothesis because superficial cues are from the hypothesis, not the premise.

the highest achieved performance by T5-3B, exceeds that of the larger T0 model. This is due to the fact that T0 is trained using only a quarter of the batch size and the sequence length used for all other models, resulting in reduced performance. Comprehensive results for all models and datasets are presented in Table 6. For more information on the training details, see Appendix B.

Does explanation prompting weaken the association between word-level superficial cues and labels? *Yes.*

To investigate the impact of explanation prompting on the association between input words and their corresponding output labels in the training set, we compare the positive pointwise mutual information (PPMI) between them in both label-only and explanation prompting settings:

		Current	T5-Small (60M)		BART-Base (125M)		BART-Large (400M)		T5-Large (770M)		T5-3B (3B)		T0* (11B)

Table 6: Average prediction accuracy over three random seeds by models of increasing size trained with label-only (LP) and explanation prompting (EP). Current state-of-the-art results on each dataset are reported from: WT5 (Narang et al., 2020), BERT-Sup-ATT (Stacey et al., 2021), InfoBERT (Wang et al., 2021), RoBERTa-AFLITE (Bras et al., 2020), BERT (Kaushik et al., 2020), and RoBERTa-AFLITE (Bras et al., 2020), respectively. *Note that the T0 models were trained using only a quarter of the batch size and half the sequence length used for all other models due to computational limitations. This may be the cause for weaker performance compared to the smaller T5-3B models.

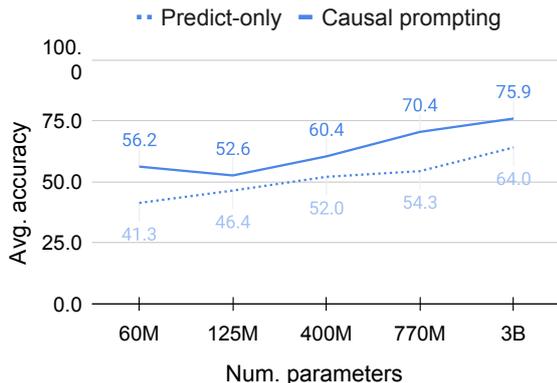

Figure 3: Average accuracy on ANLI depending on model size with label-only and explanation prompt training, respectively. See Appendix B for a comprehensive overview of performance, including on other datasets.

Figure 4: Crowd-sourced comparison of human-written explanations and those generated by a model. Overall, the crowd workers found that the model-generated explanations were either comparable to or better than the human-written ones.

$$PPMI(w, l) = \max(\log \frac{p(w, l)}{p(w)p(l)}, 0)$$

Where w represents the input word and l represents the output label. The PPMI analysis enables us to determine which words have a strong association with specific output labels, and how the use of explanation prompts modifies these associations. Following Gururangan et al. (2018b), we use add-100 smoothing in our PPMI calculations to highlight the input words that exhibit the strongest associations with the output labels.

The results, as presented in Figure 2, show that explanation prompts weaken the association between the input words and the output labels. For instance, in the absence of explanation prompting, the negative word *frowning* had a strong association with the label *contradiction*. However, when explanation prompting is used, this association is diminished from 0.1 to around 0. It's worth mentioning that only the hypothesis words are shown in Figure 2 as the superficial cues are mainly present in the hypothesis, not the premise. These findings align with the results obtained from the hypothesis-

only model, as presented in Table 2.

Are the explanations generated by explanation prompting models plausible? *Yes.*

While interpretability is not the primary objective of this study, we conduct a human evaluation of the model’s generated explanations to assess its performance within the intended framework. We use Amazon Mechanical Turk to gather assessments from 100 randomly selected T0 instances. To make the task easier for the crowd workers, we simplify it to only include two labels: Entailment and non-entailment. Instances labeled as Neutral or Contradiction are considered as non-entailment. We present the crowd workers with the gold label and request an evaluation of the quality of the *explanation* using a five-point Likert scale, ranging from “very bad” to “extremely good”. We gather three ratings per instance. Each Human Intelligence Task (HIT) features three explanations: the gold explanation authored by a human, the model-generated explanation, and an “attention check” explanation with a known expected annotation. The “attention check” explanation is included to ensure the quality of the annotations provided. This “attention check” explanation is randomly selected and unrelated to the *premise* and *hypothesis*, and therefore is expected to receive a lower score compared to the human-authored explanations that have already been validated by other crowd workers in previous work (Camburu et al., 2018). If the “attention check” explanation receives a high score or an equal score to a human-authored explanation, the HIT is flagged for review. Additionally, to prevent the use of simple heuristics, such as assuming that the last explanation is always the low-scoring one, the order in which the explanations are presented to the annotator is randomly shuffled during each HIT. An example of an NLI instance with an “attention check” explanation is shown below:³

- **Premise:** A man stands by an animal rights sign at an outdoor event.
- **Hypothesis:** A man is standing inside of his house
- **Human:** an outdoor event is not in his house
- **Generated:** The man cannot be standing inside of his house and at an outdoor event at the same time.

³The crowdsourcing study form can be found in the appendix D.

- **Attention Check:** It cannot be inferred that the young woman is an artist or that she is be finished soon.

The results of this evaluation are shown in figure 4. On the whole, crowd workers found model-generated explanations to be comparable to or better than human-written ones.⁴

This result suggests that the crowd workers found the generated reasons to be of similar quality to the human-authored reasons. This indicates that the model learns important features of the input data and is able to use them effectively to generate reasonable explanations.

7 Conclusions

In this study, we examined the influence of causal prompting on the adversarial robustness of natural language processing models. Our results indicate that using causal prompts can improve a model’s robustness to adversarial attacks. We also explored the performance of our models under various modified and ablated settings and found that explanation prompting-trained models (i) no longer rely on superficial cues, (ii) benefit most from both causally related explanations and multi-step verbalization, and (iii) are robust to differences in the input prompts. In addition, we observed that performance increases with model size and that the use of the explanation prompting format reduces the association between input words and output labels. Finally, human evaluation showed that the models generated plausible explanations.

Limitations

Explanation prompting requires datasets annotated with explanations, which may not always be available and it can be costly to collect explanations in a quantity suitable for model training or finetuning. Therefore, applying this method to datasets without explanations may be difficult.

Additionally, our analysis and evaluation are limited to English language benchmarks. Although we anticipate the method to be transferable to other languages, this requires further investigation.

Finally, experiments showed that training with explanation prompting did not improve the performance of T5 variants on the "Subsequence" and "Constituent" subsets of the HANS dataset. It is

⁴Refer to Appendix E for some example explanations.

currently unclear why all variants of BART performed better than random baselines, while T5 variants did not. Possible explanations include differences in training data, model architecture, and optimization goal, but this discrepancy requires further investigation.

Ethics Statement

In our human evaluation of the explanation quality, we took steps to ensure fair treatment of the crowd workers. To do this, we internally conducted experiments to determine the average completion time for one Human Intelligence Task (HIT). Our goal was to pay a fair wage of at least \$20 per hour to all participants involved in the study. As a result, all crowd workers received fair compensation for their work, and no HITs were rejected.

Acknowledgements

We thank the reviewers for their constructive feedback. We also thank all the crowd workers who have contributed to this research by rating the explanations. This work was supported by JST CREST Grant JPMJCR20D2 and JSPS KAKENHI Grant JP21K17814, Japan.

Appendix

A Prompt templates

Inspired by Unified Prompts (Sanh et al., 2021) and Prompt Source project (Bach et al., 2022), we express all explanation prompting input-output pairs in the jinja2 template language.⁵ This choice allows us to take advantage of the many features and benefits offered by jinja2.

A.1 Explanation prompting template

Input:

Is this true and why?

```
{{premise}} implies {{hypothesis}}
```

Output:

```
{% if label == 'entailment' %} Yes {%else%} No  
{%endif%} it is {{label}} because  
{{explanation}}
```

A.2 Alternative template for training samples lacking explanations

Input:

Is this true?

```
{{premise}} implies {{hypothesis}}
```

Output:

```
{% if label == 'entailment' %} Yes {%else%} No  
{%endif%} it is {{label}}
```

Note that ANLI provides explanations for only some of the questions; where missing, the prompt template was modified to accommodate this.

B Training details

We fine-tuned the models on an Nvidia A100 node with 8 x 40GB GPUs. We used the DeepSpeed library⁶ that implements ZeRo (Rajbhandari et al., 2020) and ZeRo-Offload (Ren et al., 2021); and the Huggingface transformers library (Wolf et al., 2019). We used an Adam optimizer (Kingma and Ba, 2015) with a learning rate of {1e-4, 5e-5}, with a per device batch size of {8, 16, 32, 64}, warm-up ratio of 0.08, max source length of 1024 except for T0 which uses 512 tokens with dynamic padding based on the longest sequence in the batch. We fine-tuned for a maximum of three epochs and selected the best checkpoint based on performance on the e-SNLI development set. Table 7 shows an overview of all used hyperparameters.

zero_optimization	
sub_group_size	1.00e9
stage3_max_live_parameters	1.00e9
stage3_max_reuse_distance	1.00e9

Table 7: Hyperparameter settings. Where multiple values were tried the final values used is shown with an asterisk. The batch size of 8 is only used for the 11Billion parameter model.

C Prompt Sensitivity Results

We present extended results on prompt sensitivity with a range of model sizes, with all values being averages over three random seeds. Table 8 shows the results on each prompt. The aim of the experiment is to examine the sensitivity of various models to prompt wording. To do this, we evaluated the models on five diverse crowdsourced prompts obtained from the Prompt Source project (Bach et al., 2022). We conducted three separate experiments for each model, using three different random seeds, and report the average accuracy across all five prompts on the development sets of e-SNLI and Counterfactually-Augmented NLI. We limited the number of instances used from e-SNLI to twenty thousand randomly selected examples. The results demonstrate that models trained with explanation prompting outperform those trained with label-only across all five prompts in terms of accuracy.

D Crowd sourcing Forms

In this section, we present the crowdsourcing form utilized for the human evaluation of explanation

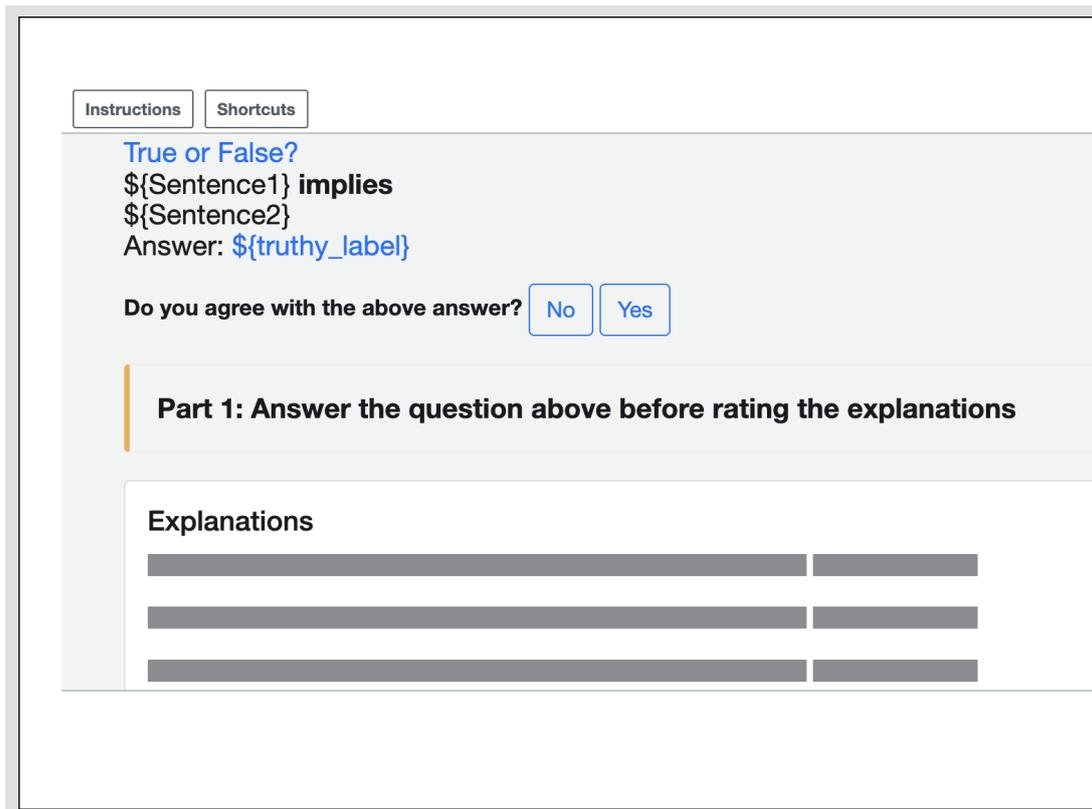

Dataset	Prompt_ID	T5-Small		T5-Large		T5-3B		BART-B		BART-L	
		LO	EP	LO	EP	LO	EP	LO	EP	LO	EP
e-SNLI	1	71.1	67.3	89.2	93.3	91.5	94.4	84.5	90.1	88.6	93.0
	2	66.7	69.3	89.6	93.3	91.6	94.7	84.3	90.3	59.1	93.4
	3	72.3	67.7	89.5	93.2	91.8	94.6	84.0	90.5	88.2	93.3
	4	69.0	66.4	89.6	93.6	91.6	94.5	84.1	90.5	72.3	93.4
	5	69.2	67.4	89.5	93.4	91.8	94.4	84.7	90.3	85.8	93.3
CNLI (RP)	1	44.8	60.3	64.4	79.6	70.8	82.5	50.1	72.3	60.1	77.9
	2	42.8	68.5	65.4	79.2	73.0	83.8	49.3	71.8	41.9	77.2
	3	47.5	68.4	65.9	79.0	71.5	83.0	49.3	72.0	59.9	76.6
	4	43.3	68.3	66.2	79.3	72.1	83.0	49.0	71.8	49.0	79.0
	5	43.4	68.8	65.9	79.7	70.1	82.8	48.8	71.6	58.3	77.2
CNLI (RH)	1	65.6	62.7	80.6	91.1	82.0	92.3	73.0	86.5	79.3	90.8
	2	54.8	70.6	81.1	91.8	82.8	93.0	72.2	86.2	54.1	90.5
	3	67.5	69.4	81.3	91.3	81.9	92.8	73.3	85.7	79.4	91.0
	4	63.2	68.8	81.6	91.4	82.0	92.2	73.0	87.3	65.6	90.8
	5	60.7	68.7	82.3	91.1	83.1	92.5	71.8	85.3	77.0	90.9
CNLI (RP&RH)	1	55.2	61.5	72.5	85.3	76.4	87.4	61.5	79.4	69.7	84.3
	2	48.8	69.5	73.3	85.5	77.9	88.4	60.7	79.0	48.0	83.8
	3	57.5	68.9	73.6	85.1	76.7	87.9	61.3	78.8	69.7	83.8
	4	53.3	68.5	73.9	85.3	77.0	87.6	61.0	79.5	57.3	84.9
	5	52.0	68.8	74.1	85.4	76.6	87.7	60.3	78.4	67.7	84.0

Table 8: Prompt-sensitivity results on the development set of e-SNLI and Counterfactually-Augmented NLI (CNLI). The values represent mean accuracy over three random seeds. The table compares the accuracy of a label-only prompting model (represented by the LO column) and the explanation prompting model (represented by the EP column). Explanation prompting models outperform the label-only model on almost all the prompts.

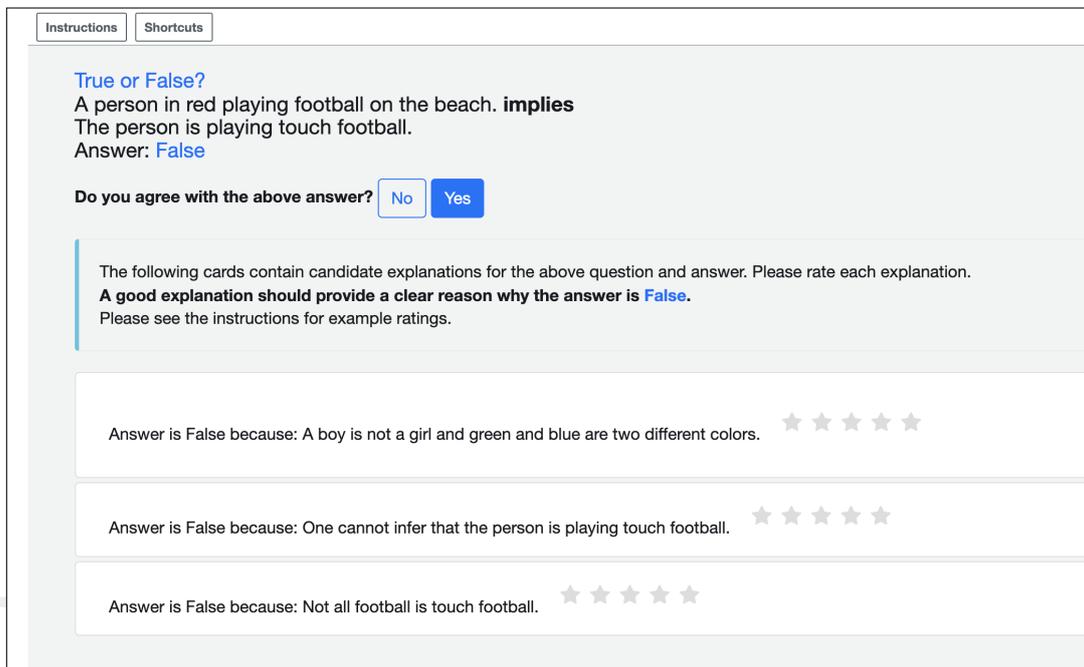

quality. To ensure unbiased assessments, the explanations were initially concealed from the crowd workers while they read the question and answer (as depicted in Fig.5a). Once the workers answered the first question, the explanations were then revealed (as shown in Fig.5b).

E Qualitative Results

Table 9 shows some qualitative examples of the *explanations* generated by the explanation prompting T0 model.

(a) The figure depicts the process of evaluating the quality of the explanations in the crowd-sourcing task. The first stage requires the user to carefully read both the premise and hypothesis presented. After familiarizing themselves with the information, the user is then tasked with answering the corresponding question. At this stage, the explanations for the question are initially hidden.

(b) The figure illustrates the stage of the crowdsourcing process where the explanations are reviewed after the first question has been answered (figure a). Hovering over the rating stars reveals the meaning of the star such as "Very bad" for 1 star and "Bad" for 2 stars. Upon choosing a star rating, the form displays its corresponding description, such as "Very bad" for 1 star, "Bad" for 2 stars, "Good" for 3 stars, "Very good" for 4 stars, and "Extremely good" for 5 stars.

#	Input	Reason	Target
1	<p>P: Two women are embracing while holding to go packages.</p> <p>H: The sisters are hugging goodbye while holding to go packages after just eating lunch.</p>	<p>Model: Two women are not necessarily sisters.</p> <p>Human: The to go packages may not be from lunch.</p>	N (o)
2	<p>P: Two women are embracing while holding to go packages.</p> <p>H: Two woman are holding packages.</p>	<p>Model: Two women are holding packages is the same as two women are holding packages.</p> <p>Human: Saying the two women are holding packages is a way to paraphrase that the packages they are holding are to go packages.</p>	E (o)
3	<p>P: Two women are embracing while holding to go packages.</p> <p>H: The men are fighting outside a deli.</p>	<p>Model: Women are not men.</p> <p>Human: In the first sentence there is an action of affection between women while on the second sentence there is a fight between men.</p>	C (o)
4	<p>P: Two young children in blue jerseys, one with the number 9 and one with the number 2 are standing on wooden steps in a bathroom and washing their hands in a sink.</p> <p>H: Two kids at a ballgame wash their hands.</p>	<p>Model: Bathroom and ballgame are different.</p> <p>Human: Two kids in jerseys watching their hands are not necessarily at a ballgame.</p>	N (x)
5	<p>P: A woman is doing a cartwheel while wearing a bikini in the sand next to the beach.</p> <p>H: A woman is doing a cartwheel and falls on her head.</p>	<p>Model: Just because a woman is doing a cartwheel doesn't mean she falls on her head.</p> <p>Human: A woman doing a cartwheel as opposed to a woman falling while doing a cartwheel.</p>	C (x)
6	<p>P: At an outdoor event in an Asian-themed area, a crowd congregates as one person in a yellow Chinese dragon costume confronts the camera.</p> <p>H: A single man is next to a camera</p>	<p>Model: A single man is a person.</p> <p>Human: The crowd can't be single man.</p>	C (x)

Table 9: Examples explanations generated by our models on the development set of e-SNLI, which consists of three labels: entailment (E), contradiction (C) and neutral (N). We show the first three correct and incorrect instances.

JobXMLC: EXtreme Multi-Label Classification of Job Skills with Graph Neural Networks

Abstract

Writing a good job description is an important step in the online recruitment process to hire the best candidates. Most recruiters forget to include some relevant skills in the job description. These missing skills affect the performance of recruitment tasks such as job suggestions, job search, candidate recommendations, etc. Existing approaches are limited to contextual modelling, do not exploit inter-relational structures like job-job and job-skill relationships, and are not scalable. In this paper, we exploit these structural relationships using a graph-based approach. We propose a novel skill prediction framework called JobXMLC, which uses graph neural networks with skill attention to predict missing skills using job descriptions. JobXMLC enables joint learning over a job-skill graph consisting of 22.8K entities (jobs and skills) and 650K relationships. We experiment with real-world recruitment datasets to evaluate our proposed approach. We train JobXMLC on 20,298 jobs and 2,548 skills within 30 minutes on a single GPU machine. JobXMLC outperforms the state-of-the-art approaches by 6% on precision and 3% on recall. JobXMLC is 18X faster for training tasks and up to 634X faster in skill prediction on benchmark datasets enabling JobXMLC to scale up on larger datasets. We have made our code and dataset public at <https://precog.iiit.ac.in/resources.html>.

1 Introduction

Online recruitment platforms such as LinkedIn and Glassdoor are extensively used to post jobs, find relevant candidates, and match resumes to the jobs posted. Recruiters create job positions mentioning skills, roles, and responsibilities to reach potential candidates. Among all these required fields, skills are crucial parameters to determine whether or not a candidate is suitable for a job position (Mehta et al., 2013). Recruiters often miss adding relevant and crucial skills required for the job due to

a communication gap between the domain experts and recruiters. According to statistics, 65% of the job descriptions (JDs) do not include relevant and popular skills, and 40% of JDs miss listing 20% or more explicitly-stated skills in the prose description (Bhola et al., 2020). It reduces the number of relevant applications for the job posting and affects the performance of major recruitment tasks such as job-to-resume matching. Therefore, it is imperative to recommend such missing skills to improve the quality of job postings. Figure 1 shows the sample (fictitious) job posted over the recruitment platform where some skills are missing from the textual JD. Prior works (Bhola et al., 2020; VERMEER et al., 2020) explored missing skill recommendation task using large-scale pre-trained language models. Document embedding and Graph-based systems (Gugnani and Misra, 2020; Kivimäki et al., 2013) are used for skill extraction and recommendations. However, these approaches have a few shortcomings- (a) they do not exploit the structural relationships between jobs and skills across the whole dataset. For example, assume jobs j_1 and j_2 share a common skill s_1 . If there is another skill s_2 relevant to j_2 and other similar jobs, we can infer that s_2 might also be relevant to j_1 . Such transitive cues can be extremely useful for identifying missing skills. Current deep extreme classifiers (You et al., 2019; Prabhu and Varma, 2014) find it hard to model such implicit relationships unless the training set explicitly contains a pair (j_1, s_2) , (b) they give equal importance to every skill corresponding to the job. However, each skill in the skill label set has different weights based on the frequency of their occurrence in job descriptions, (c) language models bring high computational costs at massive scales as a task not only involves predicting multiple missing skills but also requires to precisely organize the most relevant skills specific to the job posting. Graphs are naturally suitable to make the relationships explicit such as job-skill networks.

Job Title	Market Analyst					
Job description	Assist the Manager in sourcing the food industry and in conducting product research and analysis. Facilitate effective communication between the analytics and user experience teams. Evaluates customers' online behaviour and provide insights and recommendations for further enhancements to the guest experience. Strong research, data analysis and communication skills.					
Required skills	communication	data analysis	tableau	visualization	python	Excel
	Explicit Skills			Implicit Skills		

Figure 1: An example of a fictitious job posted over a recruitment platform. The job description does not include implicit and job-specific skills such as ‘*tableau*’, ‘*visualization*’, ‘*python*’, and ‘*Excel*’.

Two nodes (jobs) are likely to have common neighbors (skills) if the jobs have overlapping skills. To model these structural relationships between nodes (jobs and skills), a Graph neural network (GNN) is a well-known architecture for representing the knowledge and additional information (Wu et al., 2020). Missing skills applications also face extreme skill label sparsity; using label co-occurrence alone without graphs yields fractured correlations. To this end, we propose a framework called JobXMLC, which uses a GNN with label attention to jointly model the jobs and skills in the same space. Through the use of ubiquitous job description data, we aim to predict the missing skills using collaborative learning of jobs and skills. Therefore, we model our problem as an Extreme Multi-label Classification (XMLC) task as there is no existing dataset with manually-annotated labels from textual JDs, making it sub-optimal to train a sequence labeling task. The contributions of this work are summarized as follows:

- We construct a novel job-skill graph consisting of 22, 844 (jobs and skills) and 650K relationships that allow flexible integration of textual features and various pre-trained language representation models.
- We cast our problem as an XMLC using job-skill graph and propose JobXMLC comprising of graph neural networks with skill attention to learn multi-resolution graph neighborhoods with the sampling method.
- We also provide the performance comparison of JobXMLC, which outperforms by a margin of 6% from the best baselines.
- JobXMLC is lightweight, up to 18X faster in training and 634X in predicting than existing deep learning-based extreme classifiers to

scale up to thousands of labels.

2 Background and Related Work

Recently, several works (Bhola et al., 2020; Jiechieu and Tsopze, 2021) have been done for skill prediction using Extreme Multi-label Classification. XMLC refers to the classification of text where the number of the set of labels is large, i.e., thousands or millions. One-vs-All (OVA) is a well-known method for text classification tasks with high accuracy (Khandagale et al., 2020). The OVA approach is computationally efficient for the XMLC task for modest-sized label sets (up to a few thousand labels).

These methods are broadly classified as (a) Deep learning-based models, (b) Graph-based, and (c) Domain-specific methods.

Deep learning-based methods. Deep learning models that use powerful text representation capabilities have also been explored for the XMLC problems (You et al., 2019; Chang et al., 2019). XML-CNN (Liu et al., 2017) applies a dynamic max-pooling scheme and a family of CNN models to learn text representations. AttentionXML (You et al., 2019) uses the attentional bidirectional long short-term memory (BiLSTM) networks to extract embeddings from raw text inputs. However, the CNN-based models cannot capture the most relevant parts of the information on each label. The RNN-based methods fail to model long-term dependencies due to vanishing gradients. Research (Bhola et al., 2020) explores the language models such as ELMo, Transformer and BERT (Devlin et al., 2019), and X-BERT (Chang et al., 2019) for XMLC task. These approaches model input language’s syntactic and semantic structure to predict tokens based on the available contextual information. However, such models are computationally expensive and require a predefined meaning of la-

bels. In addition, the difficulty of scaling to the extreme label space remains in deep learning methods as the output layer scales linearly with the product of label size and feature dimension. The research gaps with deep-extreme classifiers motivate us to explore alternative approaches and techniques that do not require explicit label representation or predefined semantic meaning of labels and are scalable for extensive datasets.

Graph-based approaches. The recent proliferation of graph neural networks (Wu et al., 2020) allows using node neighborhoods to learn more discriminative features collaboratively. GraphSAGE (Hamilton et al., 2017) proposed the computation of node representations inductively by recursively aggregating over fixed-sized neighborhoods. Authors (Xu et al., 2018a) proposed the Graph Isomorphism Network (GIN) with discriminative power equal to that of the WL test. GraphSAINT (Zeng et al., 2020), a graph sampling-based inductive learning method, compute node representations based on the local graph structure and node attributes. However, job-skill graph-based collaborative learning at extreme scales is underexplored for missing skill prediction task.

Domain-specific methods. Research work identifies the skill bases used for analyzing the job market, the type of extracted skills (Khaouja et al., 2021), the skill identification methods, the studied sector and their granularity. Literature (Xu et al., 2018b) build a job-skill network to measure the popularity of the skills by exploring a large corpus of job postings. Research (Bhola et al., 2020) employs an Extreme Multi-label Classification method that utilizes the Transformer model to predict the required skills from a textual job descriptions. However, these approaches are computationally expensive and either predict frequent skills or miss rare crucial skills for recruiters. To address all the existing challenges and limitations, we propose JobXMLC that uses graph neural networks with skill attention to learn multi-hop job-skill network. To the best of our knowledge, this work is the first to exploit GNNs for the job-skill prediction task.

3 Problem Formulation

Consider the set of jobs $\mathcal{J} = \{j_1, j_2, \dots, j_i\}$. A job $j_i \in \mathcal{J}$ corresponds to its textual description and \mathcal{S}_i is the set of skill labels for the i^{th} job. The skill set is represented as, $\mathcal{S}_i = \{s_i^1, s_i^2, s_i^3, \dots, s_i^k\} \forall 1 \leq k \leq n$, where n

refers to total skills that vary differently for each dataset. The task of JobXMLC is to learn a function $f : \mathcal{J} \rightarrow 2^{\mathbb{S}}$ that maps a job $j_i \in \mathcal{J}$ to its target skill set $\mathcal{S}_i \in \mathbb{S}$, where $\mathbb{S} = \{\mathcal{S}_1 \cup \mathcal{S}_2 \cup \dots \cup \mathcal{S}_{|\mathcal{J}|}\}$.

4 JobXMLC: EXtreme Multi-label Classification of Job Skills

In this section, we introduce JobXMLC as shown in Figure 2. The architecture is inspired by the models proposed in (Saini et al., 2021).

The architecture comprises of three major components: 1) Job-skill graph 2) Graph Neural Network that learns multi-hop embeddings with neighbourhood selection approach on the job-skill graph 3) a scalable mechanism of extreme classifiers to predict skill labels in cold and warm-start scenarios.

4.1 Module I: Job-skill graph

We first formally define a job-skill graph, which is usually represented as a tuple $\mathbb{G} = (\mathbb{V}, \mathbb{E})$, where \mathbb{V} and \mathbb{E} are the set of nodes and edges respectively. Here \mathbb{V} consists of jobs belonging to \mathcal{J} and skill set \mathbb{S} (See Section 3). We construct an edge $e \in \mathbb{E}$ between j_i and s_i^k where $\mathbb{E} \subset \mathcal{J} \times \mathbb{S}$ iff s_i^k is relevant to j_i i.e., s_i^k is a positive label for j_i . Each node $v \in \mathbb{V}$, is initialized as a d -dimensional vector based on its textual features. We obtain initial embeddings by fine-tuning the fastText skip-gram model (Bojanowski et al., 2017) in an unsupervised manner. fastText is a lightweight embedding model that is well-suited when the document misses predicate-argument structure dependencies (Arora et al., 2020). We also leverage word-level information, including POS tagging (Kumawat and Jain, 2015) and word importance (TF-IDF), to parse the long document according to relevancy and structure. Since all the tokens present in job descriptions are not informative, we apply POS tagging to filter out verbs, adjectives, and adverbs, which are not indicators of skills in the job description. The underlying assumption is that skill labels would be mostly nouns such as ‘java’, ‘python’, etc. We found out that there are 60% nouns present in job descriptions. Further, we use an averaging technique to get the representation for every job. For each node v , its initial representation is \hat{f}_v^0 (with $\hat{f}_v^0 \equiv \hat{f}_j^0$ if the node v is the job $j \in \mathcal{J}$ and $\hat{f}_v^0 \equiv \hat{f}_s^0$ if node v is the skill label $s \in \mathbb{S}$).

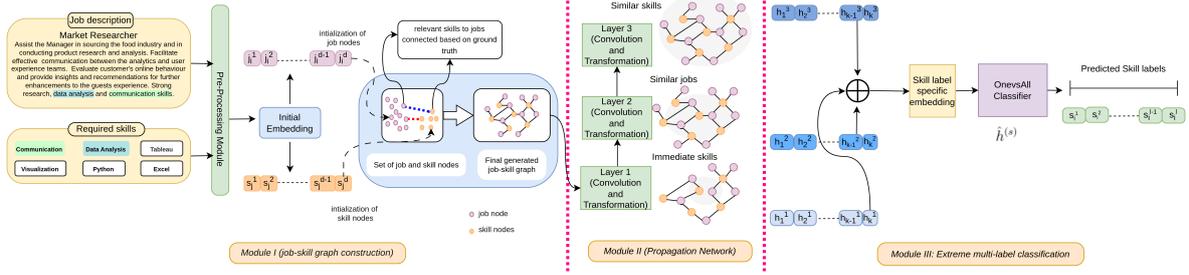

Figure 2: **JobXMLC** consists of three components: Module I consists of a mechanism to construct a job-skill graph, and Module II consists of a graph neural network-based architecture that learns embeddings using multi-hop neighborhoods using a job-skill graph effectively. Module III uses a scalable mechanism of extreme classifiers to predict missing skills.

4.2 Module II: Multi-hop job-skill graph neural network

To learn a job-skill graph, the module introduces the propagation network and neighborhood selection approach.

Propagation Network. This network captures higher-order job-skill graph structure using multiple layers of aggregation, each layer aggregating information from the previous layer’s node representations. Therefore, we utilize Graph Isomorphism Network (GIN) (Xu et al., 2018a) encoder for representations considering its outstanding expressive capacity and model simplicity. It consists of a convolution to aggregate information from a node’s neighbors and a transformation operation to update the node representation based on the convolved embeddings ($f_v^{(k)}$). To avoid over-smoothing, we utilize the skip connection operation that gathers information from historical representations of nodes. We also learn multi-hop representations with k -hop (fanouts) neighbors of each node, where k is a hyperparameter. For instance, if $k=1$, the encoder would only consider the immediate neighbors (skills) of each node (job) in the graph. If $k=2$, it would consider the neighbors (jobs) of the neighbors (skills) and so on. Equation 1 shows the graph neural network layer that updates the node representation using a weighted sum of neighboring node features:

$$f_v^{(k)} = (1 + \lambda_k) f_v^{(k-1)} + \sum_{j \in \mathcal{N}_v, j \neq v} f_j^{(k-1)} \quad (1)$$

where \mathcal{N}_v be the set of neighboring nodes of an i^{th} node; $f_v^{(k)}$ be the representation of the v^{th} node after layer k , and λ is a fixed scalar for layer k .

Equation 2 shows the final embeddings after transformation:

$$h_v^{(k)} = f_v^{(k)} + g(\delta(R_k * g(f_v^{(k)}))) \quad (2)$$

where $g(\cdot)$ is ReLU activation, $\delta(\cdot)$ is batch normalization and R_k is a parameter matrix for the residual layer.

Neighborhood selection. Instead of considering all k -hop neighbors of each node, we sampled a subset of the neighbors at each layer of the network. The goal of selection is to reduce the computational cost of the network and ensure that our model is scalable in dense settings. Therefore, we select the top l neighbors based on their frequency. Formally, for every node $v \in |\mathbb{V}|$, we accomplish frequency-based sorting where a set of fanouts $[k]$ neighbors are sampled for every node to construct $\mathbb{V}(n)$.

4.3 Module III: Extreme multi-label classification

In this module, we discuss skill attention and prediction pipeline for Extreme multi-label classification task.

Skill attention. We incorporate label-wise attention for every skill $s_i \in [\mathcal{S}]$ and layer $k \in [\mathcal{K}]$ in the propagation network. We obtain attention weights α_k using a softmax operation. $\alpha_{sk} = \exp(e_{sk}) / \sum_{k' \in [K]} \exp(e_{sk'})$. Given multi-resolution embeddings \hat{h}_v^k , $k \in [\mathcal{K}]$ for a job description, when calculating the score for a label $s \in [\mathcal{S}]$, first a label-specific embedding is calculated as given in Equation 3 and then One-vs-all classifier depicted as $C = [c_1, c_2, \dots, c_{\mathcal{S}}] \in \mathbb{R}^{\mathcal{J} \times \mathcal{S}}$ is used to obtain a score for the skill label as $score_s = \langle c_s, \hat{h}^{(s)} \rangle$.

$$\hat{h}^{(s)} = \sum_{k \in \mathcal{K}} \alpha_{sk} \cdot \hat{h}^{(s)} \quad (3)$$

Element	mycareersfuture.sg	StackOverflow Jobs
No. of job posts	20, 298	20, 320
# of distinct skills	2, 548	275
# of skills with 20 or more mentions	1, 209	50
Average skill tags per job post	19.98	2.8
Average token count per job post	162.27	200.8
Maximum token count in a job post	1, 127	800

Table 1: Dataset statistics for mycareersfuture.sg and StackOverflow Jobs.

Prediction pipeline. Initial representations are used to construct an Approximate Nearest Neighbors graph (ANNS). Suppose a test job appears at runtime, First, the relationships in the graph are introduced to its *prediction-introduce-edges* (See Table 8) nearest neighbors. These neighbors can be a part of \mathcal{J} or \mathcal{S} . New job nodes are first introduced into the graph for the standard cold start setting, where jobs are not part of the job-skill graph used for training. Relationships are introduced to the partially revealed skill labels in warm start settings. This setting is possible when the recruiter enters some skills before writing the job description. Then, JobXMLC is used to obtain multi-resolution embeddings $\hat{h}^k \in [\mathcal{K}]$ for the test job.

Shortlisting. Since evaluating skill scores for all skill labels would take $\Omega(\mathcal{J}\mathcal{S})$ time. To predict in milliseconds, the prediction time complexity should not be worse than $\Theta(\mathcal{J}\log(\mathcal{S}))$. Therefore, we utilize a shortlisted where a set of $\mathcal{O}(\log\mathcal{S})$ skill labels are shortlisted that seem most relevant to it. For a test job description, the label-wise embeddings $\hat{h}^{(s)}$ are created with respect to skill labels $s \in \mathcal{S}$. To create the shortlister, multi-resolution representations of skill labels are averaged and a second ANNS graph is created over these averaged embeddings. We rank the top *num_shortlist* (See Table 8) neighbors, based on their cosine similarity, for shortlisting to form the set \mathcal{S} of potential labels for which label-wise embeddings are calculated.

5 Experimental Setup

5.1 Datasets

We utilize two real-world recruitment datasets, namely mycareersfuture.sg (Bhola et al., 2020) and StackOverflow Jobs¹ collected from popular recruitment platforms. These datasets consist of

over 20,000 richly-structured job posts with 23 informative fields about the advertisement details and current status. Table 1 reports the statistics for recruitment domain datasets. Small-scale datasets vary from 100 to 300, whereas large-scale ranges from 300 to millions of labels. Similar scales for the XMLC task are demonstrated in (Jain et al., 2019; Liu et al., 2017).

Data Pre-processing. We filtered out *job descriptions*, *job title*, *required skills* corresponding to every job posting. From mycareersfuture.sg dataset, we consider concatenation of ‘*roles & responsibilities*’ and ‘*job requirements*’ fields as the ‘*job description*’, and ‘*required skills*’ as the set of target discrete labels. Similarly, for StackOverflow Jobs dataset, we consider the ‘*job description*’ and ‘*required skills*’ sections. We filtered out the jobs with either empty or single words in the textual content. We also perform lower-casing, stopwords removal, and removal of less important strings such as ‘*available*’, ‘*requirements*’, which are present in most JDs. StackOverflow Jobs dataset consists of 6M words with 298,729 unique words. We split the dataset into training, validation and testing datasets with an 80:10:10 proportion. Similar splits has been utilized by competitive methods (Bhola et al., 2020).

5.2 Implementation and Competing Methods

This section will discuss the training details and baselines.

Training details: We utilize binary cross-entropy loss and Adam optimizer. We use the drop out layer after every ReLU layer. We conducted our experiments using the list of hyperparameters reported in Table 8 and Table 9 (See appendix B) for details.

Baselines: We show the effectiveness of different aspects of JobXMLC and evaluate our model performance against competitive transformer-based baselines. These constitute CNN (Kim, 2014), LSTM (Rocktäschel et al., 2015), BiLSTM (Sun

JobXMLC (GraphSAGE)	16.84	29.18	56.89	67.36	58.36	37.93
JobXMLC	18.29	32.33	63.18	73.20	64.66	42.22

Table 2: Results of JobXMLC along with state-of-the-art approaches on mycareersfuture.sg dataset. For RNN-based models (†), we have limited all model architectures to two layers.

et al., 2017), BiGRU (Halder et al., 2018), BERT-XMLC (Bhola et al., 2020), RoBERT-XMLC (VERMEER et al., 2020), GalaXC (Saini et al., 2021), JobXMLC (GraphSaint) (Hamilton et al., 2017), and JobXMLC (GraphSAGE) (Hamilton et al., 2017). We discuss transformer-based approaches, BERT-XMLC (Bhola et al., 2020) encodes the words of the job descriptions using a pre-trained BERT model. The encoding of the [CLS] token is then used as representation of the job description. The job representation is passed to a bottleneck layer (i.e., an added linear layer before the output layer). The last layer treats every skill as a binary classification problem, so for each skill it calculates the probability that the skill is associated with JD.

State-of-the-art models such as CNN, LSTM, Bi-GRU, and Bi-LSTM are self-explanatory. We utilize two neural network layers for all RNN-based models. GalaXC (Saini et al., 2021) describes a novel framework for extreme classification using graph neural networks (GNNs). GraphSAGE (Hamilton et al., 2017) and GraphSaint (Hamilton et al., 2017) encodes the node information and useful for graphs that have rich node attribute information for extreme multi-label classification.

5.3 Evaluation metrics

We utilize Precision@ k (P@ k), Recall@ k (R@ k), Normalized Discounted NDCG@ k (N@ k), Mean Reciprocal Rank (MRR), EIM, REIM, RIIM (Bhola et al., 2020) as evaluation metrics for the skill prediction task.

Precision@ k : includes the proportion of skills in

the top- k skill prediction list that are relevant.

Recall@ k : includes the proportion of relevant skills found in the top- k skill prediction list.

NDCG@ k : discounts the true positives that occur later in the prediction rankings.

MRR: indicates the position (reciprocal) of the first true positive in the predicted set of skills.

EIM (Explicit Inference Measure): the micro, instance-based measure of explicit skills predicted by the model, compared against gold-standard explicit skills mentioned, for instance.

RIIM (Relative Implicit Inference Measure): macro, the recall-based measure of implicit skills predicted by the model, relative to the entire set of implicit skills.

REIM (Relative Explicit Inference Measure): macro, recall-based measure of explicit skills predicted by the model compared to the entire set of explicit skills.

6 Results and Analysis

Table 2 and Table 3 reports Recall@ k and Precision@ k for all state-of-the-art approaches and JobXMLC on both datasets. Compared to leading deep extreme classifiers, BERT-XMLC and RoBERTa-XMLC, JobXMLC is up to 18X faster to train on a single GPU. Compared to other baselines, JobXMLC is at least 3% better than Bi-LSTM (Sun et al., 2017) in R@5, which helps demonstrate the efficacy of modelling the sequence by JobXMLC. Further, fastText initialization in JobXMLC is 7-8% better than BERT-XMLC+CAB (Bhola et al., 2020) in R@5, indicating that the global relationships improve the model

Model	R@5	R@10	R@30	P@5	P@10	P@30

better in addition to local connections through joint learning. Compared to BERT-XMLC (Bhola et al., 2020) and RoBERTa (VERMEER et al., 2020), both utilize transformer-based embeddings and skill correlation-based features for training, JobXMLC is 4% better in recall and precision metrics. JobXMLC outperforms Graph-based methods such as GalaXC (Saini et al., 2021) across all metrics. Table 4 reports NDCG and MRR val-

Model	N@5	N@10	N@30	N@50	N@100	MRR
CNN	28.21	40.23	60.60	66.37	71.96	0.77
LSTM	29.27	40.66	59.43	69.61	71.53	0.70
Bi-LSTM	30.32	48.07	44.55	50.30	57.04	0.76
Bi-GRU	30.83	50.52	46.45	52.37	59.15	0.76
BERT-XMLC	28.05	38.81	57.62	64.68	71.28	0.83
BERT-XMLC+CAB	29.13	40.74	60.60	67.51	73.74	0.85
GalaXC	32.86	44.51	63.73	70.11	74.77	0.82
JobXMLC	37.91	49.63	67.83	73.81	78.94	0.90

Table 4: Normalized Discounted Cumulative Gain (NDCG) is represented by N and Mean Reciprocal Rank (MRR) comparison of JobXMLC along with State-of-the-art approaches on mycareersfuture.sg dataset.

ues for mycareersfuture.sg dataset. We observe that JobXMLC outperforms all state-of-the-art approaches by significant margin of 8% from deep extreme classifiers.

Inference time: Table 5 presents the results of JobXMLC and leading deep extreme classifiers like BERT, ROBERTa which shows that JobXMLC is 18X faster than BERT+XMLC+CAB for mycareersfuture.sg dataset.

Analysis on Implicit and Explicit skills: Table 6 shows the Explicit and Implicit Metrics for the skill prediction task. We are interested in the relevance

and implicitness of the retrieved implicit skills and false positives. We find the explicit and implicit skills underline the noisy nature of the skill labels. For example, ‘*machine learning*’ and ‘*python*’ are clear required (explicit) skills and ‘*communication*’ comes across as a vast skill. In terms of false positives, we note that the job description explicitly mentions ‘*good knowledge of python*’ as a required skill (for Data Scientist job). Most relevant skills are not very distinctive to the job role, causing the model to mispredict the skill.

7 Ablation Study

Initial embeddings: JobXMLC shortlisting criteria offered much better recall if we use the initial fastText embeddings to create shortlists. We observe that fastText worked best for our recruitment domain dataset in comparison to other recent pre-trained language representation models (See Appendix B) including BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), and Paraphrase-mini-LM-L6 (Reimers and Gurevych, 2019). For example, on the mycareersfuture.sg dataset, the recall for the top 100 labels shortlisted using the initial fastText and BERT embeddings are around 85.20% and 56.90%, respectively. Based on an average of 20.61 skills per job, about 4 skills were derived within the top 5 and 19 within the top 100 of derived skills. **Warm and Cold Start Scenarios:** Table 7 reports the results in warm-start and cold-start settings separately. JobXMLC is initialized with fine-tuned fastText embeddings which achieve P@k, R@k, and MRR of 72.86, 18.26, and 0.89 respectively in cold-start scenario. JobXMLC is initialized with

Datasets →	mycareersfuture.sg		StackOverflow Jobs

BERT+XMLC	5.50	1200	1.63	350
RoBERTa+ XMLC	4.72	1200	1.24	350
BERT+XMLC+CAB	9.20	1200	4.86	350
JobXMLC	0.51	1.89	0.31	1.71

Table 5: Comparison of JobXMLC with stronger baselines. JobXMLC is faster to train than leading Deep Extreme Classifiers like BERT at training and prediction time. Here TT= Train Time (in hours), PT= Prediction Time (in ms).

Metrics	EIM	RIIM	REIM
BERT+XMLC +CAB	115.89	64.60	25.73
JobXMLC	121.09	66.36	33.04

Table 6: Comparison of EIM, RIIM, and REIM metrics on JobXMLC on mycareersfuture.sg dataset.

fine-tuned fastText embeddings which achieve $P@k$, $R@k$, and MRR of 75.76, 22.09, and 0.91 respectively in warm-start scenario. In both scenarios, the value of $k=5$. These results show that partially reveal achieved comparable precision and relatively higher recall than cold-start settings.

Model	P@5	R@5	MRR
JobXMLC (cold-start)	72.86	18.26	0.89
JobXMLC (warm-start)	75.76	22.09	0.91

Table 7: Effectiveness of JobXMLC in warm-start and cold-start scenarios on mycareersfuture.sg dataset.

Qualitative Analysis: We compared the JobXMLC and analyzed the skills predicted correctly and incorrectly as shown in Figure 3. JobXMLC captures the structural relationships between jobs and skills effectively. JobXMLC predicts ‘Java’, ‘Software Development’, ‘XML’, ‘JavaScript’, ‘jQuery’, etc. as required skills whereas BERT-XMLC with CAB predicts ‘Java’, ‘C++’, ‘Linux’, ‘Python’ as skills where more relevant skills such as ‘JavaScript’ and ‘Web Applications’ are missed.

8 Discussion

We compare with existing graph-based methods such as GalaXC (Saini et al., 2021), which are more well-suited to handle short text inputs for product queries. JobXMLC leverages word-level

components, including syntactic roles (POS tags) such as nouns and verbs present in each job and word importance (TF-IDF), which explains the long document from the perspective of text relevancy and structure. We believe that JobXMLC is generalizable across many other applications. Our raw dataset is relatively preprocessed, simple and misses predicate-argument structure dependencies. Therefore, we hypothesize that non-contextual embeddings such as fastText (having 98.69% of words from our dataset present in vocabulary) outperformed BERT as it understands word-level information. Similar observations are made by (Arora et al., 2020) for classic embeddings with competitive (or even slightly better) performance than contextual embeddings.

9 Conclusion

In this work, we propose a JobXMLC framework, which uses a graph neural network to incorporate neighborhood information with the help of a collaborative graph over jobs and skills. JobXMLC leverages skill attention mechanism for more effective extreme classifiers and attends to multi-resolution representations of jobs and skills. JobXMLC outperforms leading deep extreme classifiers on precision and recall metrics by 6% and 3%. JobXMLC also operate in warm and cold-start scenarios effectively. JobXMLC is 18X faster on training and 634X faster on predicting than deep extreme classifiers and can be scaled efficiently to real-world datasets with thousands of labels. We believe that JobXMLC can be deployed on large-scale recruitment platforms for predicting missing skills using job descriptions.

10 Limitations

We perform experiments on jobs sampled from a popular Singaporean government job portal and StackOverflow, which is limited to the English lan-

guage. Our approach can handle missing skills which are part of our skill vocabulary, but it cannot infer new emerging skills from job descriptions, i.e., out-of-vocabulary. We will consider domain knowledge and the popularity of job skills to generalize our approach for job-candidate mapping applications for future work. We wish to expand our work to other recruitment domain applications with resumes and candidate profiles.

11 Ethical Considerations

The paper investigates the missing skills problem with the help of a graph-based framework by incorporating word-based embeddings that can be insightful for other researchers in academia and industry. Any biases present in the dataset or embedding model can creep into the proposed approach.

A Hyper-parameter Details

This section reports the set of hyperparameters used for experiments conducted in the paper.

1. **No. of Epochs:** refers to number of epochs for JobXMLC.
2. **num_HN_epochs:** number of hard negative epochs for JobXMLC.
3. **learning rate (lr):** is the learning rate for JobXMLC.
4. **attention_lr:** is the learning rate used by skill attention.
5. **dlr_factor:** defines factor by which learning rate is decayed.
6. **batch_size:** refers to batch size used during training of JobXMLC.
7. **num_HN_shortlist:** refers to number of hard negative labels to be selected by sampling from other data points from the same batch.
8. **num_shortlist:** refers to number of skills sampled by shortlister.
9. **prediction_introduce_edges:** refers to total edges that should be introduced to graph at prediction time.
10. **fanouts:** refers to number of neighbors to sample for layer k .

Hyperparameter	Value
No. of epochs	20
num_HN_epochs	20
learning rate (lr)	0.0003
attention_lr	0.0003
dlr_factor	0.5
batch_size	256
fanouts	5, 5, 5
num_HN_shortlist	500
embedding_type	fastText
num_shortlist	1500
prediction_introduce_edges	3

Table 8: Hyper-parameters for mycareersfuture.sg dataset for JobXMLC. fastText refers to 300-dimensional embeddings obtained by fine-tuning fastText model on job descriptions.

B Evaluation Metrics for different initializations

This section reports the EIM, RIIM, REIM measures for Mini-LM (Reimers and Gurevych, 2019) model initialization. We observe that Mini-LM is

Hyper-parameter	Value
No. of epochs	30
num_HN_epochs	20
learning rate (lr)	0.0003
attention_lr	0.0003
dlr_factor	0.5
batch_size	256

Abstract

We introduce ViLPAct, a novel vision-language benchmark for human activity planning. It is designed for a task where embodied AI agents can reason and forecast future actions of humans based on video clips about their initial activities and intents in text. The dataset consists of 2.9k videos from Charades extended with intents via crowdsourcing, a multi-choice question test set, and four strong baselines. One of the baselines implements a neurosymbolic approach based on a multi-modal knowledge base (MKB), while the other ones are deep generative models adapted from recent state-of-the-art (SOTA) methods. According to our extensive experiments, the key challenges are compositional generalization and effective use of information from both modalities¹.

1 Introduction

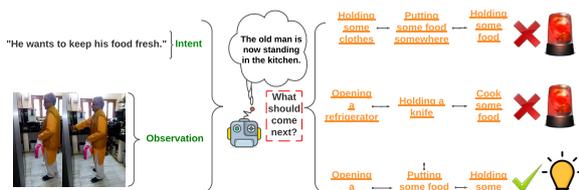

Figure 1: In daily life scenarios, an agent should be aware of future actions that will likely be taken by the user based on what it has observed. In this example, inputs of intent and observation are colored in green, while potential future action sequences are highlighted in orange. The first two sequences contain actions which do not align with the human intent. Thus, the agent needs to automatically detect which future actions are plausible by understanding the user’s intent.

One of the ultimate goals of Artificial Intelligence is to build intelligent agents capable of accurately understanding humans’ actions and intents,

*Corresponding authors: lizhen.qu@monash.edu, xuzenglin@hit.edu.cn

¹Our benchmark is available at <https://github.com/terryyz/ViLPAct>

so that they can better serve us (Kong and Fu, 2018). Newly emerging applications in robotics and multi-modal planning, such as Amazon Astro, have demonstrated a strong need to understand human behavior in multimodal environments. On the one hand, such an agent, e.g. an elderly care service bot, needs to understand human activities and anticipate human behaviors based on users’ intents. Here the intents may be estimated based on previous activities or articulated verbally by users. The anticipated behaviors may be used for risk assessment (e.g. falling of elderly people) and to facilitate collaboration with humans. On the other hand, recent advances in robotics show that it is possible to let robots learn new tasks directly from observed human behavior without robot demonstrations (Yu et al., 2018; Sharma et al., 2019). However, that line of work focuses on imitating observed human actions without anticipating future activities.

To promote research on action forecasting based on intents, we propose the *vision-language planning* task for human behaviors. As shown in Fig. 1, given an intent in textual form and a short video clip, an agent anticipates which actions a human is likely to take. We consider intents as given because there is already ample research on intent identification (Pandey and Aghav, 2020) and automatic speech recognition (Malik et al., 2021). To the best of our knowledge, there is no dataset to evaluate models for this task.

The task poses two major challenges. First, there are often multiple plausible action sequences satisfying an intent. Second, it is highly unlikely that a training dataset can cover all possible combinations of actions for a given intent. Hence, models need to acquire *compositional generalization* (Fodor and Pylyshyn, 1988), the capability to generalize to unseen action sequences composed of known actions.

In this work, we construct a dataset called ViLPAct for Vision-Language Planning of human Activities, which to the best of our knowl-

edge is the *first* dataset studying the above challenges. Specifically, we extend the Charades dataset (Sigurdsson et al., 2016) with intents via crowd-sourcing. As it is practically infeasible to find all possible future action sequences given an intent and a video clip of initial activities, we propose to evaluate all systems by letting each of them answer multi-choice comprehension questions (MQA) *without training them on those questions*. Given an intent and a video clip showing initial activities, each multi-choice question provides a fixed number of future action sequences as possible answers. A system is then asked to select the most plausible action sequence among them. We show that the rankings of all models using the MQAs correlate strongly with those obtained by asking human assessors to directly observe estimated action sequences. For training, we provide both a dataset for end-to-end training of sequence forecasting and a multimodal knowledge base (MKB) built from that dataset, which is also the *first* video-based multimodal knowledge base for human activities to the best of our knowledge.

We conduct the first empirical study to investigate compositional generalization for the target task. As baselines, we adapt three strong end-to-end deep generative models for this task and propose a neurosymbolic planning baseline using the MKB. The model is neurosymbolic because it combines both deep neural networks and symbolic reasoning (Garcez and Lamb, 2020). Given a video of initial activities and an intent, the deep models generate the top- k relevant action sequences, while the neurosymbolic planning model sends the intent and the action sequence recognized from the video as the query to the MKB, followed by retrieving the top- k relevant action sequences. Each model selects the most plausible answers by performing probabilistic reasoning over the relevant action sequences. We conduct extensive experiments and obtain the following key experimental results:

- We compare the evaluation results using MQA with the ones of human evaluation. The results of both methods are well aligned. Thus, MQA is reliable without requiring human effort.
- The likelihood functions of the deep generative models are not able to reliably infer which answers are plausible. In contrast, probabilistic reasoning is an effective method to improve compositional generalization.
- Despite information from both modalities be-

ing useful and complementary, all baselines heavily rely on intents in textual form but fail to effectively exploit visual information from video clips.

2 Related Work

Vision-Language Planning Task Vision Language Navigation (VLN) was among the first widely used goal-oriented vision-language tasks, requiring AI agents to navigate in an environment without interaction by reasoning on the given instruction (Anderson et al., 2018; Hermann et al., 2020; Misra et al., 2018; Jain et al., 2019). Recently, further goal-oriented vision-language tasks have been proposed. The Vision and Dialogue History Navigation (VDHN) task (De Vries et al., 2018; Nguyen and Daumé III, 2019; Thomason et al., 2020), which is similar to VLN, requires agents to reason on the instructions over multiple time steps. Other tasks such as Embodied Question Answering (EQA; Das et al. 2018; Wijmans et al. 2019), Embodied Object Referral (EOR; Qi et al. 2020b; Chen et al. 2019) and Embodied Goal-directed Manipulation (EGM; Shridhar et al. 2020; Kim et al. 2020; Suhr et al. 2019) rely on reasoning and interpreting the instruction with observation or object interaction in the environment. However, we argue that there are other ways to learn to plan without practising. Our task is one example of this, requiring agents to reason over the observation without performing actions.

Vision-Language Planning Datasets As existing vision-language planning datasets emphasize teaching embodied AI to perform the task like humans, they are constructed with interactive AI in mind. VLN (Anderson et al., 2018) datasets initially started exploring planning tasks with the textual instruction as a step-by-step abstract guide and minimal interaction with the environment. Extending the VLN task, VDHN (De Vries et al., 2018) datasets provide an interactive textual dialogue between the speaker and the receiver in multiple steps. The EQA (Das et al., 2018) task takes this a step further by providing data in an object-centric QA manner, advancing systems to understand the given environment through object retrieval. The EOR (Qi et al., 2020b) task designs object-centric datasets with detailed instructions, aiming at localizing the relevant objects accurately. The closest benchmark to ours is ALFRED (Shridhar et al., 2021) from the EGM task, which lets embodied agents decide

on actions and objects to be manipulated based on detailed instructions. However, in our setting, we ask intelligent systems to predict the most reasonable future action sequence based on human intents and answers in a Multiple Choice Question Answering (MQA) format. During prediction, we still give systems the flexibility to consider various combinations of actions and objects.

Vision-Language Planning Modeling According to Francis et al. (2021), several approaches have been used for planning. Greedy search in end-to-end models has been reported in several studies to work well in goal-oriented tasks (Fried et al., 2018; Das et al., 2018; Shridhar et al., 2020; Anderson et al., 2018). Task progress monitoring (Ma et al., 2019) is another method to tackle the planning. It allows models to backtrack on actions if the current action is found to be suboptimal. Mapping (Anderson et al., 2019) has as well been proposed for efficient planning via sensors. Topological and Exploration planning (Deng et al., 2020; Ke et al., 2019) enables modeling the planning in a symbolic manner. When goals are provided as several sub-goals, a divide and conquer strategy (Misra et al., 2018; Shridhar et al., 2020; Suhr et al., 2019) may be invoked to perform sub-task planning. In our work, we highlight another potential approach, knowledge base retrieval. As we construct an MKB containing various action sequences with detailed features, intelligent agents can retrieve the most suitable sequence from the MKB source in order to perform the planning.

3 Dataset Construction

We adopt videos from Charades (Sigurdsson et al., 2016) and solicit intents for videos via crowdsourcing. We consider videos that have action sequences of sufficient length appearing in both initial video clips and answers, which result in a dataset comprising 2,912 videos. The dataset is split into training/validation/test sets with a ratio of 70%, 10%, 20%. On the training dataset, we build an MKB by incorporating structural and conceptual information. On the test dataset, we collect a set of MQAs for model evaluation. The evaluation with MQAs is in fact an adversarial testing method, widely used for quality estimation in machine translation (Kanojia et al., 2021). Herein, the ability of a model to discriminate between correct outputs and meaning-changing perturbations is predictive of its *overall* performance, not just its robustness.

Thus MQAs are applied only for testing.

3.1 Data Normalization and Filtering

Charades is a large-scale video dataset of daily indoors activities collected via Amazon Mechanical Turk² (AMT). The average length of videos is approximately 30 seconds. It involves interactions with 46 object classes and contains 157 action classes, which are also referred to as **actions** for short. Each action is represented as a verb phrase, such as “pouring into a cup”. This dataset is chosen because *i*) it contains a sufficient number of long action sequences of human daily activities; *ii*) the intents are easily identifiable, as the activities in the videos are based on scripts; *iii*) there are rich annotations of videos that can be leveraged for dataset construction. The details of action sequence selection in videos are presented in Appendix 7.1, with the goal of choosing core action sequences having clear human goals.

In order to assess the quality of extracted action sequences, we randomly sample 100 videos from the test set for manual inspection. The primary action sequence of each video is evaluated in terms of three criteria: *i*) if all actions of a sequence occur in the video; *ii*) if the actions of a sequence appear in the same order as in the video; *iii*) if a sequence has any actions missing between the first and the last action. In total, we determined that 94 videos have all actions of their action sequences covered in the video. The actions of 92 videos appear in the same order as in the videos. Furthermore, 85 videos have no actions missing between the first and the last action of their sequences. Thus, the quality of such action sequences is adequate for VL planning evaluation.

Following prior work (Ng and Fernando, 2020), we consider the first 20% of a video as its initial visual state and aim to forecast future actions appearing in the remaining part of the video for a given intent. To have at least one future action per video, we retain only videos that contain at least one action sequence comprising more than three actions. As a result, we obtain 2,912 such videos, each of which is associated with one action sequence of length longer than three.

²<https://www.mturk.com>

3.2 Intent Annotation

An *intent* may be defined as “something that you want and plan to do”.³ Philosophers distinguish between future-directed intents and present-directed ones (Cohen and Levesque, 1990). The former guide the planning of actions, while the latter causally produce behavior. As the focus of this work is anticipating and planning actions, we encourage crowd-workers to also provide future-directed intents.

We recruit crowd-workers to annotate videos with future-directed and present-directed intents. Each annotator is provided with a full video clip and the associated action sequence. They are instructed to answer the question *what the person wants to do by taking the actions in the video*. Every annotator is asked to submit two intents. One of them should describe which activity the person intends to take, such as “drink a glass of water”. The other one needs to be at a high-level, such as “quench the thirst” or “be thirsty”. The permitted formats are either “S/He wants to + *do_something*” or “S/He is + *feeling*”. Thus, the annotators are encouraged to provide future-directed intents by differentiating them from ones causally leading to behaviours. To ensure the quality of intent annotations, we randomly assign three crowd-workers to write intents per video. The process of constructing the dataset for intent annotation involved a rigorous validation and selection process. One of the authors acted as an expert annotator, and conducted a thorough review of all crowd-sourced intents to identify and select the most reasonable annotations as the final results. The validation process was completed in three rounds, yielding increasingly higher percentages of reasonable annotations, with 82%, 94% and 100% respectively for each round. The annotations that did not meet the required criteria were discarded and not included in the final dataset. This rigorous validation process ensured that the final dataset is comprised of high-quality and relevant annotations, providing a robust foundation for subsequent modeling and analysis.

3.3 Multimodal Knowledge Base

We construct the MKB of human activities based on the **training set** and **validation set** by taking a neurosymbolic approach. The main challenges herein are twofold: i) how to represent multimodal

information from videos, action names, and intents adequately to facilitate information retrieval; ii) how to model shared knowledge of multimodal information. For the former, we allow both string and embedding based retrieval methods by attaching neural representations of video clips and texts to symbols of actions and action sequences. For the latter, we employ the classical planning language STRIPS (Bylander, 1994) and neural prototypes to encode abstract properties of actions.

At the core of the MKB is a knowledge graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where the node set \mathcal{V} comprises four types of nodes: action classes, action video clips, action sequences, and action sequence videos, while the edge set \mathcal{E} contains edges reflecting relationships between nodes.

An *action class* a^c is the abstraction of an action described in the language of STRIPS. The attributes of an action class include its ID, its name τ , its precondition set PRE, its add effect set ADD, and its delete effect set DEL. An action is executed only if its preconditions are satisfied. The effect sets ADD and DEL of an action class describe the add and delete operations applied to the current state after executing the action. For example, the precondition of *Closing a refrigerator* is $isOpen(refrigerator)$, $ADD = isClosed(refrigerator)$ and $DEL = isOpen(refrigerator)$. In this way, the properties described in STRIPS present the shared knowledge of each action class.

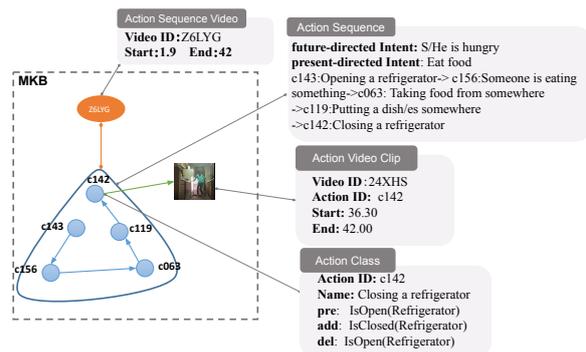

Figure 2: An example action sequence in the MKB.

An *action sequence* comprises a future-directed intent, a present-directed intent, and a sequence of action IDs. An intent is represented by both a word sequence and the distributed representation of the word sequence. We obtain the distributed representation of an intent by applying BERT (Devlin et al., 2018) and utilizing the representation of the CLS token. The collection of action sequences can

³Cambridge Dictionary, <https://dictionary.cambridge.org/>

be easily turned into a training set for end-to-end models by associating them with the corresponding video files.

The MKB includes two types of visual nodes: *action sequence videos* and *action video clips*. Each action sequence video is linked to the corresponding action sequence. For each action in an action sequence, we associate it with the corresponding video clip, as illustrated in Fig. 2. For each action video clip, we apply I3D to encode it into a sequence of frame-level visual feature vectors $\{\mathbf{f}_{s_1}, \mathbf{f}_{s_2}, \dots, \mathbf{f}_{s_t}\}$, where each vector $\mathbf{f}_{s_i} \in \mathbb{R}^{1024}$ corresponds to the features of an 8-frames snippet. To represent an action sequence video, we apply average pooling to the distributed representations of all involved video clips.

Relations. We consider two types of relations in the MKB. The first type of relation links an action sequence to the corresponding visual representation. The other type of relation associates an action in an action sequence with the corresponding action class. Therefore, it is easy to perform symbolic reasoning by using the STRIPS properties of each action class involved in an action sequence.

Statistics of MKB Table 1 provides statistics of the MKB. As we can observe, the MKB contains 2,402 action sequence videos and 12,118 action video clips. Each action sequence video is associated with one corresponding action sequence. There are 157 action classes in total and 1,969 unique action sequences. The average length of action sequences is 5.04.

Item	Statistics
# of action classes	157
# of action sequence videos	2,402
# of action video clips	12,118
# of action sequences (distinct seq)	2,402 (1,969)
# of action state templates	32
# avg. # of action sequence length	5.04

Table 1: Statistics of the MKB / training + validation set

3.4 Multi-Choice Comprehension Questions for Evaluation

Given the first 20% of a video as the initial state s and a future-directed intent g in text, the planning evaluation task involves choosing the most plausible future action sequence a^f among six available choices. We determine the initial action sequence a^i by checking if an action of a sequence starts before the end time of the initial state. To build such a dataset, we extended the test set with adversarially

generated incorrect answers. As the automatic approach may generate reasonable action sequences, we recruit another group of students to manually check all answers and determine the most plausible ones as the correct answers on AMT. Figure 3 shows an example of our planning task.

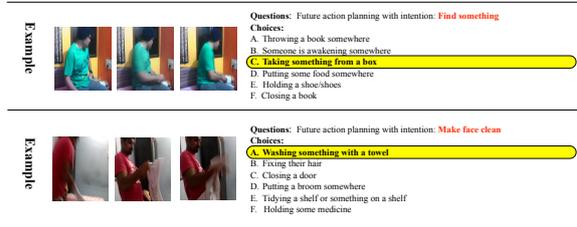

Figure 3: Two examples of ViLPAct MQA task

Generation of Incorrect Answers. We adapt the *Adversarial Matching* (AM) algorithm (Zellers et al., 2019) to turn the action sequence generation task into a multi-choice test. The key idea here is to substitute an action of an observed action sequence for an alternative action that is relevant to the preceding actions and is not overly similar to the action to be replaced. As many videos in the test set have only a single future action, the AM algorithm is extended to optionally insert a future action to generate an answer candidate.

More specifically, given the initial state, the action sequence, and the intent (s, a, g) of a video, where $a = (a^i, a^f)$, the algorithm starts by randomly deciding if it applies substitution or insertion to generate an answer candidate. If insertion is chosen, it inserts an action randomly selected among the 157 candidate actions, at a position that is randomly picked after the last action in a^i . If instead substitution is chosen, we feed the initial action sequence a^i to BERT and use the representation of the CLS token as the representation of a^i . Then we apply BERT to turn each action into a vector by using the corresponding CLS representation. We randomly pick a future action a_i in a^f and compute the score of a candidate action a_j as

$$s(a_j) = \log(P_{\text{sim}}(a^i, a_j)) + \lambda \log(1 - P_{\text{sim}}(a_i, a_j)), \quad (1)$$

where $P_{\text{sim}}()$ is defined as cosine similarity. We set $\lambda = 0.7$ to find an optimal tradeoff between the obfuscation level of an incorrect answer and the probability of being a reasonable answer. We repeat this process until we have generated five answer candidates. For each set of generated answer

Statistics	Value
# of videos	510
avg. # of observed actions	2.79
avg. # of future actions	2.40
avg. # of actions	5.19
# of full action seq occurring in the training set	121
avg. # of distinct future action sequences for an intent	2.16
std. dev. of # of distinct future action sequences for all intents	3.69

Table 2: Basic statistics of MQA task / test set

candidates, we manually checked the grammaticality and fixed all the errors.

Quality Check via Crowd-Sourcing. We hired three crowd-workers per video on AMT to ascertain the quality of all auto-generated answers. For each video, a worker is presented with the first 20% of the video and the future-directed intents, which are paired with six answer candidates each (an original action sequence and five generated ones), because there were two annotators working on each video. They were instructed to choose the most reasonable pair of intent and action sequence among all possible combinations.

After checking the answers of all questions in the **test set**, we apply a set of heuristic rules to determine the final answer to each question. We calculate inter-annotator agreement by asking the group of workers that did the annotation to work on a sample of multi-choice questions of the MQA task. To evaluate the quality of the MQA choices, we determined the number of agreements between the ground truth (the correct answers) and the predicted answers. Then, we computed the number of agreements that would be expected by chance based on the distribution of answers. The corresponding Cohen’s kappa coefficient (Kraemer, 2014) is 0.91, which demonstrates the high quality.

Table 2 shows the basic statistics of the test set. The average number of observed actions in s is similar to the average number of future actions. Although all actions in the test appear in the training set, the most plausible action sequences of almost 400 videos are unseen in the training set. For intents in MQA, we also calculate the number of distinct future action sequences for each of them, and the standard deviation across all of them. The results indicate how diverse potential future action sequences can be for a single intent. Other details of MQA can be found in Appendix 7.2.

4 Baselines

VL planning of human activities requires predicting future action sequences given an initial visual

state video and an intent provided in textual form. The task poses two major challenges. First, information provided in two modalities are complementary to each other, while the majority of multimodal research focuses on the shared information by exploring fusion techniques (Guo et al., 2019). Second, the output space is exponentially large with respect to the action space. It is not realistic to assume that all action sequences are already observed in the training data. Hence, any models to tackle this task are expected to address *systematic composition* (Fodor and Pylyshyn, 1988) of human activities, the capacity to understand and produce a huge number of novel combinations of known actions. In contrast, state-of-the-art deep learning methods often perform poorly on compositional generalization (Lake, 2019; Keysers et al., 2019).

We compare deep generative models and a neurosymbolic planning model in the framework of retrieval and reasoning. Given the first 20% of a video and a future-directed intent, the first step is to obtain top- k relevant action sequences, followed by performing reasoning over the top- k action sequences to find the most plausible answers. Both types of models share the same reasoning module but differ in how they obtain top- k action sequences. For reproducibility, the details of all models are provided in Appendix 7.3 and 7.4.

4.1 Deep Generative Models

The deep generative models apply beam search to produce the top- k most likely future action sequences, followed by performing reasoning.

ACT-UNIVL We adapt UNIVL (Luo et al., 2020) for the target task (denoted as ACT-UNIVL), which is a SOTA unified pretrained vision-language model for multimodal understanding and generation. We consider ACT-UNIVL because it performs the best on the tasks that are closest to our target task, such as YouCook2 (Zhou et al., 2017). The pre-trained ACT-UNIVL takes as input an intent and an initial video clip, and is fine-tuned to forecast future action sequences.

Two Stage Planning Model. The two stage planning baseline, **TwoStagePlan** for short, starts by converting an initial video clip into an action sequence in text by using ACT-UNIVL, followed by applying a pre-trained language model, ProphetNet (Qi et al., 2020a) (denoted as ACT-PROPHETNET for ViLPAct), to predict future actions.

ACT-PROPHETNET To study the impact of visual information, we consider a text-only baseline by employing ACT-PROPHETNET to predict future action sequences only based on intents.

4.2 Neurosymbolic Planning Model

Given an intent and an initial visual state, the neurosymbolic planning model (**NSPlan**) retrieves top- k relevant action sequences from the MKB in two stages, and then utilizes the retrieved results to infer the most plausible answers.

In the first stage, we apply the pretrained ACT-UNIVL to convert a video clip into an action sequence and send it as a query to the MKB to retrieve top-50 results. For each retrieved result, the ranking score is the weighted sum of the BM25 (Robertson and Walker, 1994) score between two action sequences and the cosine similarity between the intents.

In the second stage, it re-ranks the initial retrieval results by using both visual and symbolic knowledge. Each retrieved action sequence is represented as a sequence of frame-level visual feature vectors, extracted by the visual encoder I3D. An Ordered Temporal Alignment Module (OTAM; Cao et al. 2020) is applied to compare two visual feature sequences. In order to rank the sequences with potential future actions higher, we use a rule-based score function to prefer longer sequences containing unseen actions. In the end, we keep only the top- k results for probabilistic reasoning.

4.2.1 Probabilistic Reasoning for MQA

We propose a novel approach for MQA called *ProbInf*, which, based on the top- K action sequences, performs probabilistic inference over the retrieved action sequences to identify the most likely answer for a question. From each retrieved result after re-ranking, obtained from NSPlan, we remove the predicted observed action sequence s_q^a to obtain potential future action sequences. For generative models, we directly use the generated outcomes. For each answer candidate c_i of a question, we compute $p(c_i | \mathbf{s}, \mathbf{g})$ by integrating over all retrieved results $\{r_1, r_2, \dots, r_K\}$, given the initial visual state \mathbf{s} and intent \mathbf{g} :

$$p(c_i | \mathbf{s}, \mathbf{g}) = \sum_{k=1}^K p(c_j | r_k) p(r_k | \mathbf{s}, \mathbf{g}), \quad (2)$$

where $p(r_j | \mathbf{s}, \mathbf{g}) = \frac{\exp(s_f(r_j))}{\sum_{k=1}^K \exp(s_f(r_k))}$ is the normalized ranking score for a result r_j and $p(c_j | r_k)$

is the normalized similarity between an answer candidate and each retrieved result. As both answers and retrieved results are action sequences represented in text, we employ the time series metric Time-warped edit distance (TWED; Marteau 2009) to compute their similarity as $\phi(f(c_i), f(r_j)) = 1 - d_{\text{twed}}(f(c_i), f(r_j)) / \max(|c_i|, |r_j|)$, where $f(c_i)$ denotes the visual prototype representation of an action sequence and $d_{\text{twed}}(f(c_i), f(r_j))$ denotes the distance computed by TWED algorithm. Then the normalized similarity over n possible answers of a question is given by:

$$P(c_i | r_j) = \frac{\exp \phi(f(c_i), f(r_j))}{\sum_{k=1}^n \exp \phi(f(c_k), f(r_j))} \quad (3)$$

The most plausible answer is the one with the maximal $p(c_j | \mathbf{s}, \mathbf{g})$ over all answer candidates.

5 Experiments

We conduct extensive experiments to answer the following three main research questions. The other research questions are addressed in Appendix 7.9.

Method	TwoStagePlan	NSPlan	ACT-PROPHETNET	ACT-UNIVL
Log-likelihood Accuracy(%)	19.02	-	10.78	22.35
top-1 Reasoner-scoring Accuracy(%)	63.72	60.58	67.45	69.01
top-10 Reasoner-scoring Accuracy(%)	60.19	64.11	69.01	70.58

Table 3: Comparison of all systems, with **Human performance** of 94.25% accuracy, which is obtained by asking humans to answer the MQAs directly.

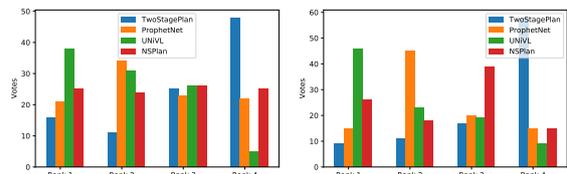

Figure 4: Human evaluation on the quality of top-10 (left) & top-1 (right) future action sequence.

RQ1: How reliable is the MQA evaluation method? We show that the evaluation results using MQA are consistent with those by asking humans to directly observe model outputs. For this, we recruit five crowd-workers to rank all models in comparison on each of the 100 questions randomly sampled from the test set, and compare them with the corresponding results using MQA. Specifically, for each question, a crowd-worker is asked to rank the top- k outputs of the four baselines in terms of how well they match the intent and the remaining 80% of the original videos. As a result, Figure 4 shows how frequent each model is ranked at position X judged by the crowd-workers w.r.t. the top-10 predictions (left) and top-1 predictions (right),

respectively. In both cases, we consistently find that the best model is ACT-UNIVL, followed by ACT-PROPHETNET, NSPlan, and TwoStagePlan. The ranking result is the same as using MQA on the same set of questions. The ranking differences on individual questions between the human evaluation and MQA are statistically insignificant according to Wilcoxon’s signed-rank test (Woolson, 2007), details of which can be found in Appendix 7.8.

Method	TwoStagePlan	NSPlan	ACT-PROPHETNET	ACT-UNIVL
Seen Accuracy(%)	60.33	65.28	70.24	74.38
UnSeen Accuracy(%)	60.15	63.75	68.63	69.40

Table 4: Top-10 Reasoner-scoring Accuracy on seen and unseen action sequences. Seen data refers to the MQAs with plausible action sequences observed in the training data. Unseen data refer to the ones with plausible action sequences not observed in the training data.

RQ2: What are the key challenges? We identify two major challenges of the target task.

Compositional Generalization Using Reasoning. It is common practice to rank each answer by the likelihood yielded by a generative model (Holtzman et al., 2021). However, Table 3, which provides the overall evaluation results using MQA, shows that the generative baselines perform poorly when they rank answers based on the likelihood. In contrast, *ProbInf* effectively uses top- k results to boost the performance of all generative models by more than 44%. For the respective performance on seen and unseen action sequences (Table 4), *ProbInf* delivers stable results across models. *The performance on unseen combinations of seen actions measures exactly the ability of compositional generalization.* This raises the question of “*Why ProbInf helps compositional generalization ?*” for future research. As there is still a sizable gap between seen and unseen action sequences, and all models fall short of the human performance (Table 3) by at least 23%, how could we make further improvements?

Effective Use of Both Modalities. To understand the utility of each modality, we compare the two strongest multimodal models by varying their inputs: including both modalities or just a single modality. As shown in Table 5, intents provide the strongest signal, while visual information is useful overall for both models. This also explains why ACT-PROPHETNET comes close to ACT-UNIVL.

To further investigate the significance of visual information for multimodal models, we substitute

ACT-UNIVL w/o Vision	ACT-UNIVL
69.01	70.58 ↑
NSPlan w/o Vision	NSPlan
61.56	64.11 ↑
ACT-UNIVL w/o Intent	ACT-UNIVL
61.17	70.58 ↑
NSPlan w/o Intent	NSPlan
60.78	64.11 ↑

Table 5: Modality study on MQA accuracies (%) of different baselines via Reasoner-scoring.

the visual features of ACT-UNIVL for randomly selected ones during both training and inference, finding that ACT-UNIVL suffers from only a 4% drop of accuracy using MQA. Hence, the multimodal models capture only weak associations between visual features and future action sequences.

It is counter-intuitive that visual features do not play a significant role, because plans vary in accordance with different visual environments. We conjecture this is due to poor performance of action recognition. To verify this, we feed ground-truth actions observed in the first 20% of videos to both TwoStagePlan and NSPlan during training and inference. They reach an accuracy of 82.11% and 81.37% respectively, improved by more than 15%.

RQ3: To what degree can the top- k results reflect the performance differences of systems?

The reasoning method *ProbInf* leverages the top- k results produced by the models, hence it is useful to inspect those results for further insights. Therefore, we compare the top 10 results of each model in terms of precision and recall by treating each action sequence as a set (Ng and Fernando, 2020), as well as seq-hits@5 for measuring exactly matched action sequences. Moreover, to investigate the *diversity* of the top- k lists, we consider Dist1 and Dist2 (Li et al., 2016), which respectively measure the number of unique action and consecutive action pairs in the top- k lists. The definitions of a complete list of used metrics and their results are provided in Appendix 7.6 and 7.4.1.

According to Table 6, ACT-UNIVL outperforms all other models in terms of quality-oriented metrics but falls short of ACT-PROPHETNET in terms of both diversity metrics. However, none of the metrics obtains the same ranking of models in accordance with the human evaluation. Although NSPlan achieves higher recall than ACT-PROPHETNET, its precision and seq-hits@5 are significantly lower than those of ACT-PROPHETNET, explaining why it performs worse than ACT-PROPHETNET using MQA.

Setting	Quality			Diversity	
	precision	recall	seq-hits@5	Dist1	Dist2
TwoStagePlan	21.59	15.59	10.00	32.55	58.54
NSPlan	20.73	21.66	5.69	38.46	66.34
ACT-PROPHETNET	21.35	9.61	8.12	51.96	81.93
ACT-UNIVL	23.67	22.02	12.75	47.10	77.42

Table 6: Comparison of top-10 future sequences

6 Conclusion

We construct the novel benchmark ViLPAct to evaluate the ability of systems to anticipate and plan human actions in a multimodal vision-language setting, with a focus on evaluating their compositional generalization capabilities. In this benchmark, we extend Charades with intents, construct a test set with multi-choice questions, and include four strong baselines. Our empirical studies demonstrate that the task is easy for humans, but challenging for SOTA deep learning models due to the need for compositional generalization and an effective use of information from both modalities. The neurosymbolic planning baseline shows a promising research avenue for using symbolic and multimodal knowledge in an MKB.

Ethical Considerations

In order to mitigate the potential for exposure to problematic content in the Charades video dataset, we have implemented stringent safety measures to safeguard our annotators against adverse psychological effects. To ensure the suitability of the video content, the authors initially conducted a comprehensive review. However, it is recognized that the process of annotating feedback may still result in the exposure to potentially disturbing or offensive material. To mitigate this, we only engage annotators who are of legal age and clearly communicate that discretion is strongly advised when engaging in the annotation process. In the event that an annotator experiences discomfort or distress, we provide information on how they can seek support from the Substance Abuse and Mental Health Services Administration (SAMHSA)⁴, a free and confidential resource available 24/7. In addition, we have established a feedback mechanism to allow annotators to communicate their concerns in real-time. Our response time to any feedback received is within 24 hours. Furthermore, we compensate our annotators with competitive wages, with an average hourly rate of approximately \$12.

⁴<https://www.samhsa.gov/>

Limitations

In this work, we have proposed a new vision-language benchmark for compositional generalization on human activities. Although it contains numerous videos and diverse actions, it only emphasizes in-door activities, which is a subdomain of human activities. We encourage future research to investigate the compositional generalization on various scenarios of outdoor activities. In addition, despite the fact that our benchmark contains a reasonable number of actions, these actions are constrained by limited types of verb and noun phrases, due to the nature of Charades. We suggest the development of a more extensive dataset covering open-vocabulary actions in future applications.

7.1 Action Sequence Extraction Algorithm

Each video of Charades is annotated with actions from at least one action sequence. The starting and ending points of an action are labelled, but it is not clear which actions jointly meet an intent. Therefore, we implement the greedy method in Algorithm 1 to automatically extract action sequences with clear intents from videos. For each video, the algorithm aims to identify a sequence of temporally and semantically coherent actions, which interact with the same or related objects. The scoring functions in Algorithm 1 measure coherence from three perspectives: i) semantic relevance based on TF-IDF (Jones, 1972) reweighted Word2Vec embeddings (Mikolov et al., 2013), ii) temporal relevance, iii) task relevance. Each action is assigned to one of 22 tasks manually, for example, "Opening a book" and "Closing a book" are assigned to the same task.

7.2 Other Data Details

An example of future action sequences of a selected intent is given in Figure 5. All of these conclusions pose a challenge not only for the generalization of multimodal matching, but also for compositional generalization.

Algorithm 1: Extract Action Sequences

Input: $Actions = \{a_1, a_2, \dots, a_n\}$, each action $a_i = \langle cls^{a_i}, t_s^{a_i}, t_e^{a_i} \rangle$, where cls^{a_i} is the action class, $t_s^{a_i}$ and $t_e^{a_i}$ is the start time and end time of action a_i . Relevance threshold

Output: $Activities = \{A_1, A_2, \dots, A_n\}$, where each activity represents an action sequence

Remaining actions set $R_a = Actions$

while $R_a \neq \emptyset$ **do**
 Sort R_a in ascending order by start time t_s
 pre action $a = R_a[0]$
 Activity $A = \{a\}$
 $Search = True$
 while $Search$ **do**
 candidates $C_a = \{a_j \in R_a | t_s^{a_j} \geq t_s^a\}$
 for $a_j \in C_a$ **do**
 Calculate relevance score: $s_{a_j} =$
 $score(a, a_j) = f_{semantic}(a, a_j) +$
 $f_{time}(a, a_j) + f_{task}(a, a_j)$.
 Where
 $f_{semantic}(a, a_j) = cosine(E_a, E_{a_j})$,
 $E_a = \sum_{w \in cls^a} TFIDF(w) * w2v(w)$,
 $f_{time}(a, a_j) =$
 $(1 - atanh(|t_s^a - t_s^{a_j}|) * \pi/2)$
 $f_{topic}(a, a_j) = \mathbf{1}(task^a = task^{a_j})$
 end
 $a_{max} = argmax(\{s_{a_j} | a_j \in C_a\})$
 if $s_{a_{max}} < threshold$ (1.3 by optimization) **then**
 Append A to $Activities$
 $Search = False$
 else
 Add a_{max} to Activity
 Remove a_{max} from R_a
 pre action $a = a_{max}$
 end
 end
end

7.3 Deep Generative Models Details

We mainly adapt the multimodal deep planning model ACT-UNIVL to tackle our task. The training set of ACT-UNIVL consists of 2,402 videos, each of which contains a video clip of the initial state s , an observed action sequence a^i , an intent g , and a future action sequence a^f . Both models are trained to minimize prediction errors of a^f .

ACT-UNIVL ACT-UNIVL (Luo et al., 2020) is a SOTA unified pretrained vision-language model for multimodal understanding and generation. We consider ACT-UNIVL because ACT-UNIVL still performs the best on video captioning tasks, such as YouCook2 (Zhou et al., 2017). YouCook2 contains task-oriented and instructional third-person videos about indoor cooking. The captions of a video are provided for the whole video without explicit alignments at the frame or segment levels. In addition, ACT-UNIVL considers two sources of textual inputs: transcripts and captions. Hence, it is most close to our target task. Taking as input a future-directed intent and a video clip of the initial state, ACT-UNIVL is fine-tuned to forecast future action sequences.

More specifically, we utilize ACT-UNIVL to map a video clip to a sequence of action names. Most of the action names are multi-word expressions. During training, ACT-UNIVL takes as input both the visual features of a video clip s and an observed action sequence a^i , and optimizes the model with multiple pre-training objectives. The visual features are extracted by the I3D model (Carreira and Zisserman, 2017) trained on Charades. During prediction, the model generates a future ac-

tion sequence by only taking an initial visual state and high-level intent as input. To fine-tune ACT-UNIVL, we set the max. frame, mean frame and feature frame rate of the encoded features to be 629, 113 and 3. We fine-tune ACT-UNIVL on two NVIDIA V100 GPUs for 50 epochs and choose the best one based on the BLEU-3 metric.

Two Stage Planning Model. The two stage planning baseline, **TwoStagePlan** for short, starts by converting the initial visual state s into a textual description of the observed action sequence, followed by applying a Seq2Seq language model, ACT-PROPHETNET (Qi et al., 2020a), to predict future actions.

At Stage 1, we adopt ACT-UNIVL on the video captioning task. Different from the single ACT-UNIVL baseline, we only train it with observed video clip inputs and let it generate the corresponding captions for observed action sequences. The other settings and training settings remain the same as for the single ACT-UNIVL baseline.

Given an observed action sequence recognized by ACT-UNIVL, we fine-tune ACT-PROPHETNET by following Jansen (2020) in Stage 2. We prefer ACT-PROPHETNET over GPT2 (Radford et al., 2019) because it can learn to predict n future tokens jointly, which is computationally efficient and mitigates overfitting on strong local correlations. For each video, we take as input the intent and the observed action sequence, separated by a special token *SEP*, and train the model to minimize prediction errors of future action sequences. Fine-tuning the model from the PROPHETNET-EN pretrained checkpoint for 50 epochs on 2 Nvidia Tesla V100 GPUs, we choose the best model based on the validation loss.

ACT-PROPHETNET To study the impact of visual information, we consider a text-only baseline by employing ACT-PROPHETNET. Herein, ACT-PROPHETNET takes as input an intent and generates the future action sequences. The training is done with the same training procedure as Stage 2 of TwoStagePlan. This model serves for an ablation study, in contrast to TwoStagePlan, which uses additionally recognized action sequences as input.

7.4 Neurosymbolic Planning Model

Instead of using the data in the training set to directly optimize model parameters, the neurosymbolic planning model (NSPlan) builds an MKB from the training data. Given a question in the test

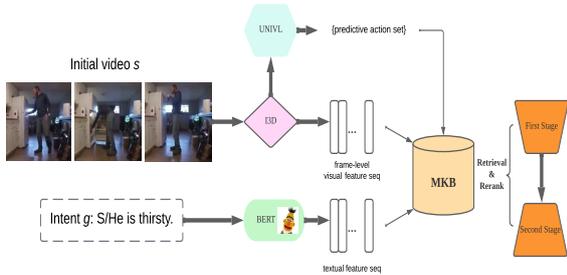

Figure 6: The neurosymbolic planning model is a multi-modal retrieval & re-rank pipeline.

set, the model retrieves relevant knowledge based on the initial visual state and the intent, and then applies the retrieved knowledge to infer the most plausible answers from all available choices.

7.4.1 Retrieval from Multimodal Knowledge Base

The neurosymbolic planning model retrieves relevant action sequences from the MKB in two stages. The first stage aims to computationally efficiently obtain all relevant action sequences. At the second stage, it re-ranks the initial retrieval results by using both visual and symbolic knowledge.

First Stage. Given the initial state of a video, we apply the pretrained ACT-UNIVL model used in the two-stage planning model to predict a sequence of observed actions. Then this action sequence in text form is sent as query to retrieve top-50 relevant action sequences from the MKB. For each retrieved result, the ranking score is the weighted sum of the BM25 (Robertson and Walker, 1994) score between two action sequences and the cosine similarity between the intents. At this stage, only textual information is taken into account, and the temporal order of actions in a sequence is not considered because BM25 considers each action sequence as a bag of words.

Second Stage. We re-rank the results from the first stage by taking temporal order and the visual features of action sequences into account. Each action sequence is represented as a sequence of frame-level visual feature vectors, which are extracted by the same visual encoder I3D. We apply the Ordered Temporal Alignment Module (OTAM) (Cao et al., 2020) to compare two visual feature sequences. OTAM computes a distance between a pair of sequences by integrating video segment distances only along the ordered temporal alignment path. We turn a distance into an alignment score by

$s_{\text{align}} = 1/(1 + d_{\text{otam}})$, where d_{otam} denotes the OTAM distance.

Many retrieved action sequences do not contain future actions. In order to rank the sequences with potential future actions higher, we add a rule to encourage long sequences containing unseen actions. The rule score $s_{\text{rule}} = s_{\text{last}} + s_{\text{len}}$ is the sum of two binary indicator functions s_{last} and s_{len} , where $s_{\text{last}} = 1$ if and only if the last action of the retrieved result is not contained in the query set, and $s_{\text{len}} = 1$ if and only if the length of the retrieved result is greater than that of the query. The final ranking score $s_f(r)$ of a result r is the weighted sum of the initial ranking score, the alignment score s_{align} and the rule-driven score s_{rule} . To reduce noise, we keep only the top-10 results for probabilistic reasoning. We provide a completed version of the comparison among all baselines on future sequence evaluation in Table 7.

7.5 Full Action Sequence Comparison

7.6 Metrics

- Seq-item-acc: Sequence item classification accuracy evaluates the exact action matching of the predicted action sequence with the ground truth, counting how many times the action in the predicted sequence matches the ground truth at the exact position. For top-10 sequences, we calculate the mean accuracy of all sequences.
- Precision and recall: The precision and recall do not consider the order of ground truth. They both treat the actions inside the sequence as a unified set. The precision of top-10 sequences is computed by averaging the precision of each sequence, which measures the number of true actions over the number of total actions in the sequence. Here, we define the true action as the action that occurred in the ground truth. Similarly, the recall of top-10 sequences is also computed by averaging all sequences' recall, which is a measure of the true actions over the number of ground truth actions.
- Seq-hit@ k Rate: The seq-hits scores measure the exact sequence matches, calculated as the number of examples whose top- k sequences include the ground truth sequence, and we report the seq-hits@5 and seq-hits@10 accordingly. As for the retrieval-based baseline, we

setting	Quality							Diversity	
	precision	recall	seq-item-acc	seq-hits@5	seq-hits@10	BLEU-1	BLEU-2	Dist1	Dist2
TwoStagePlan	21.59	15.59	9.26	10.00	16.86	12.50	3.58	32.55	58.54
NSPlan	20.73	21.66	8.74	5.69	7.65	19.25	6.80	38.46	66.34
ACT-PROPHETNET	21.35	19.75	8.12	9.61	10.59	18.66	5.52	51.96	81.93
ACT-UNIVL	23.67	22.02	9.71	12.75	16.08	20.52	6.52	47.10	77.42

Table 7: Comparison of top- k future sequences of all systems.

setting	Quality							Diversity	
	precision	recall	seq-item-acc	seq-hits@5	seq-hits@10	BLEU-1	BLEU-2	Dist1	Dist2
TwoStagePlan	38.71	30.73	11.06	0.59	1.37	29.60	13.71	15.45	35.37
NSPlan	41.63	35.81	11.46	5.69	8.43	34.14	15.90	28.03	62.08

Table 8: Comparison of top-10 full action sequences of all systems.

only consider the in-domain situation where the ground truth sequences have also appeared in the knowledge base.

- BLEU: We use the standard BLEU-1 and BLEU-2 scores that are widely used in the Machine Translation Field and adapt them to our setting by computing the action-level match.
- Dist: We report Dist1 (Distinct-1) and Dist2 (Distinct-2) following the standard definition (Li et al., 2015), to measure the diversity of action sequences, based on the number of distinct N -gram of top-10 sequences.

7.7 Full Table of Future Sequence Evaluation

In Table 8, we compare TwoStagePlan with NSPlan, where both models are designed to output the full action sequence including the observed actions. It turns out that NSPlan performs consistently across all metrics, indicating that NSPlan has a stronger ability to identify the most similar full action sequences in the MKB and training set.

7.8 Wilcoxon’s signed-rank test

Wilcoxon’s signed-rank test is a statistical hypothesis test used either to test the ranking of a set of samples or to compare the rankings of two populations using a set of matched samples. The calculated Wilcoxon signed-rank test t value is 55.5 with a p value of 0.7979, which shows that there is no significant difference between the two sets of human evaluation samples.

7.9 Other Research Questions

How useful are symbolic, neural, or neurosymbolic knowledge? The goal of reasoning is to perform the probabilistic inference $\arg \max_{c_i} p(c_i |$

Method	Action ID	Visual-proto	Text-proto	Visual + text proto
	Accuracy(%)	Accuracy(%)	Accuracy(%)	Accuracy(%)
Mean	53.33	60.19	46.82	48.42
Max-Pooling	43.92	43.52	41.76	42.35
DTW	48.82	61.37	50.98	52.15
TWED	44.50	64.11	48.23	50.19

Table 9: Reasoner-scoring performance with varying combinations of similarity measures and action-level features.

s, g) over all possible answers. One of the key differences of NSPlan from the two generative models is that it introduces the time series similarity TWED to compare the future action sequences with each answer.

To understand the effects of TWED in the probabilistic reasoning module of our retrieval-based baseline, we compare it with three other similarity measures: (a) cosine similarity between the mean vectors of two sequences, (b) cosine similarity between the max-pooling results of two sequences, (c) the time series distance function Dynamic Time Warping (DTW) (Müller, 2007). All of them are evaluated based on the same best performing top-10 retrieval results.

We also evaluate different types of symbolic, neural, and neurosymbolic features used for computing action-level distance inside those measures: (a) action class ID, (b) the visual prototype features in the MKB, (c) the textual prototype features in the MKB, (d) concatenation of the visual prototype features and textual prototype features.

It is clear from Table 9 that TWED using the visual prototype features performs the best. The performance of the two time series metrics are comparable. Combining visual prototype features and textual prototypes features actually harms the performance. This is in contrast to the retrieval evalua-

tion, which finds the symbolic representations most useful. This highlights the flexibility of this hybrid neurosymbolic system, which naturally supports choosing the most appropriate types of information for its respective modules.

We also experiment with the symbolic knowledge described by the STRIPS language. More specifically, we implement a symbolic planner based on STRIPS, which is able to check to what degree each answer is compatible with the preconditions and effects defined for each action class. Such symbolic knowledge can boost the overall accuracy of NSPlan to 82% if we substitute the ground truth actions for the action sequences recognized by ACT-UNIVL. However, if we only use the predictions of ACT-UNIVL, which has both precision and recall around 32%, the overall accuracy drops by almost 10%.

Grammatical Error Correction through Round-Trip Machine Translation

Yova Kementchedjhieva
University of Copenhagen
yova@di.ku.dk

Anders Søgaard
University of Copenhagen
soegaard@di.ku.dk

Abstract

Machine Translation operates on the premise of an interlingua which abstracts away from the surface form while preserving the meaning. A decade ago, the idea of using round-trip MT to guide Grammatical Error Correction was proposed as a way to abstract away from potential errors in surface forms (Madnani et al., 2012). At the time, it did not pan out due to the low quality of MT systems of the day. Today much stronger MT systems are available so we re-evaluate this idea across five languages and models of various sizes. We find that for extra large models input augmentation through round-trip MT has little to no effect. For more ‘workable’ model sizes, however, it yields consistent improvements, sometimes bringing the performance of a *base* or *large* model up to that of a *large* or *xl* model, respectively. The round-trip translation comes at a computational cost though, so one would have to determine whether to opt for a larger model or for input augmentation on a case-by-case basis.

1 Introduction

Grammatical Error Correction (GEC) is the task of detecting and correcting errors in text. It finds application in both assisted writing and second language learning. As training data for the task is scarce, efforts in this space largely focus on transfer learning and data augmentation. In this work, we revisit the use of round-trip Machine Translation in Grammatical Error Correction, as originally proposed in Madnani et al. (2012).

Machine Translation (MT) aims to preserve the meaning of text while mapping its surface form from one language into another. The ideal MT system would be robust to minor perturbations in the input text like a typo or a grammatical error, producing a well-formed translation true to the intended meaning. If the translated text is then backtranslated into the source language, we can expect to see the original content, now free from errors. This

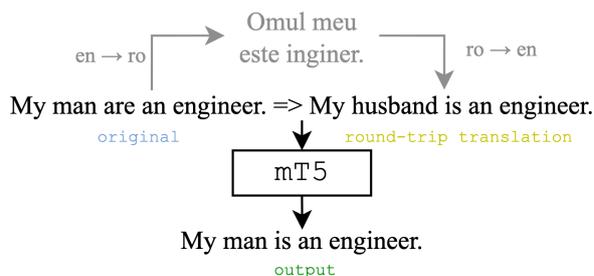

Figure 1: Our approach. The input to the model is a concatenation of the original text and the round-trip translation. Here, English is used as target language and Romanian as pivot language for illustrative purposes; in actual experiments English is the pivot language.

was the premise of the work carried out by Madnani et al. (2012). The statistical phrase-based MT systems of a decade ago, however, were not even close to the ideal, so the authors observed mixed results in their experiments and upon further analysis concluded that the round-trip translation itself introduced too many new errors in the form of both ungrammaticality and loss of meaning. Modern neural network-based MT systems are much stronger than their statistical predecessors. Consider the leap in BLEU score (Papineni et al., 2002) on the widely used WMT2014 English-German data set (Bojar et al., 2014), from 20.7 with phrase-based MT (Wu et al., 2016) to 35.0 with neural MT augmented with noisy backtranslation (Edunov et al., 2018). With a conditional neural language model as a decoder (Schwenk, 2007), modern systems generate highly fluent (i.e. grammatical) outputs.

We explore the impact of this strong MT performance on GEC by augmenting the input to a GEC system through round-trip translation, such that each input sentence is concatenated with a round-trip translation of itself (see Figure 1). We evaluate the effect of this procedure on five languages: German, Russian, Spanish, Czech, and Romanian (DE, RU, ES, CS, RO). In our experiments, we fine-tune the multilingual pre-trained

language model mT5 (Xue et al., 2021), which is available in a range of sizes. The XXL variant is currently the state-of-the-art on DE, RU, and CS (Rothe et al., 2021). However, mT5-XXL, with its 13B parameters, is out-of-scope for most academic research and impractical for deployment in many applications. Therefore, we experiment only with the three smaller variants, BASE, LARGE and XL.

We find that round-trip translation successfully guides the correction of grammatical errors in BASE models for all languages, with improvements of up to 4.1 points on the F-score (for RU). For LARGE models, it still benefits three out of five languages, leaving scores on the other two unchanged. For XL models, it has a negligible effect in either direction, showing that these models are sufficiently strong by themselves and subsume the knowledge an MT model can provide. For some BASE and LARGE configurations, the round-trip translation augmentation closes the gap between a model of a given size, e.g. LARGE-RO, and its larger counterpart, e.g. XL-RO. Since round-trip translation has an added computational cost itself, one would have to weight the costs and benefits on a per-case basis to determine whether a larger model with bare input or a smaller model with augmented input is more suitable for a given application.

2 Background

Machine Translation makes various appearances across research in Grammatical Error Correction. Modeling approaches and training tricks originally developed in the context of MT have been successfully adapted to GEC (Yuan and Felice, 2013; Junczys-Dowmunt et al., 2018; Rozovskaya and Roth, 2016; Yuan and Briscoe, 2016). The concept of backtranslation has been used to generate synthetic data for GEC (Kiyono et al., 2019; Koyama et al., 2021). In all of these works, MT research provides the methods but there is no actual cross-lingual translation happening. The ‘translation’ in this case is from ungrammatical text to grammatical text in the same language. Zhou et al. (2020) perform actual translation of Chinese text into English using MT systems of varying quality as a way to generate ungrammatical English data, which they then pair with gold standard targets to obtain a synthetic training corpus. In contrast to such works, our work explores the potential of round-trip translation as an intermediate step in the process of GEC, active both during fine-tuning and inference.

The goal here is to make use of the knowledge one can extract from parallel MT data, generally much more abundant than GEC data.

Most similar to our work is that of Madnani et al. (2012), who perform round-trip translation of an input in eight pivot languages with Google Translate and use a lattice to combine all hypotheses into a final output. The motivation behind using multiple pivot languages is to ensure meaning preservation on one hand, and to increase the chance of all errors being corrected on the other. The authors observe some successes but also numerous failures in the predictions of their model, attributing the latter to new errors of disfluency and loss of meaning introduced by Google Translate, which at the time was based on statistical MT. In the decade since that work was published, MT has undergone a paradigm shift from statistical to neural network-based methods, marked by large improvements in performance (Edunov et al., 2018). It is therefore time to revisit the potential gains from round-trip MT for GEC.

As we recognize that GEC aims for minimal and necessary revisions of the input whereas round-trip translation can result in valid but unnecessary lexical and syntactic changes, we condition the generation of the final output on both the input sentence and the round-trip translation, in an approach akin to multi-source automatic post-editing (Knight and Chander, 1994; Chatterjee et al., 2015).

3 Method

In general terms, our approach is one of sequence-to-sequence text generation with input augmentation: for a given input sentence, we obtain a round-trip translation and feed a string concatenation of the original sentence and the round-trip translation, separated by the symbol sequence ‘=>’, to a sequence-to-sequence model.

3.1 Model

Recently, Rothe et al. (2021) set a new state-of-the-art in GEC using an XXL-sized mT5 model. mT5 is a multilingual seq-to-seq bitransformer model, pre-trained on 101 languages (Xue et al., 2021). They pre-trained a single model on a vast amount of synthetic GEC data for four languages, English, Czech, Russian and German, and fine-tuned individual models for each language. They showed that a BASE-sized model often lagged behind earlier state-of-the-art results, whereas an XXL-sized model outperformed them often with a consider-

Lang	Data	Size
DE	Falko-Merlin (Boyd et al., 2014)	19K
RU	RULEC-GEC (Rozovskaya and Roth, 2019)	5K
ES	COWS-L2H (Davidson et al., 2020)	10K
RO	RoGEC (Cotet et al., 2020)	7K
CS	AKCES-GEC (Náplava and Straka, 2019)	42K

Table 1: Datasets used for finetuning and their train size.

able margin.¹ Due to computational constraints, we carry out experiments with model sizes up to and including XL.

3.2 Data

We use data in five languages: DE, RU, ES, CS and RO.² We carry out continued pre-training of mT5 for GEC on real data where available, and on synthetic data otherwise. For DE and RU we use cLang-8 data (Rothe et al., 2021). For ES, we use Lang-8 (Koyama et al., 2020), which we manually clean up (see more details in Appendix A). For RO we sample 100k sentences from the synthetic dataset of Cotet et al. (2020) and for CS we generate 100k sentences using the method of Náplava and Straka (2019) based on text from the WMT News Crawl (Barrault et al., 2019). We randomly split all data 90:10 for training and validation. Continued pre-training is done with the same objective as used for fine-tuning—we feed ungrammatical text (optionally concatenated with a round-trip translation) and predict grammatical text. Following this step, we do fine-tuning on the datasets listed in Table 1.

All data that does not come pre-tokenized is tokenized using spaCy (Honnibal and Montani, 2017) except CS, which is not covered by spaCy so for this language we use Stanza (Qi et al., 2020).

3.3 Round-trip translation

In contrast to Madnani et al. (2012), we stick to a single round-trip translation, recognizing the computational cost of this added step. We experiment with English as a fixed pivot language for all target languages. We translate pre-training data using models available in the HuggingFace library (Wolf et al., 2020), chosen for their strong performance: for RU and DE we use facebook/wmt19 models, and for the rest we use Helsinki-NLP/opus-mt. For fine-tuning

¹Model sizes in between were not explored.

²See App. C for other languages we considered.

data we use Google Translate³, assuming that it is the best translator available.

Training details can be found in Appendix B.

4 Results

The main results of our work are reported in Table 2. We report precision (P), recall (R) and F0.5 score (F), as measured using the M² package (Dahlmeier and Ng, 2012). We see that guidance from round-trip translation leads to consistent improvements for models based on mT5-BASE, most notably improving the F-score for RU by 4.1 points. Among LARGE models, consistent performance improvements are observed for RU and CS, for RO the performance gain is reduced but still considerable, whereas for DE and ES the input augmentation has no effect at all (so we do not consider these two languages in experiments with an XL model). Among the three XL models, variable results are observed with either a small increase or a small decrease in performance (of 0.5 points at most). From these observations, we can conclude that the round-trip translation benefits smaller models, whereas larger ones subsume the knowledge this input augmentation technique provides.

The blue boxes in the table mark cases where the round-trip translation brings the performance of a smaller model up to or above that of a larger one. In these cases, one has the choice to use a larger model without input augmentation or a smaller one with input augmentation. The factors that would determine this choice are compute availability, access to cloud platforms, and speed requirements, among others. If one has limited GPU memory to work with, but has access to a high-quality translation cloud service, the choice of a smaller model with input augmentation may be more appropriate.

4.1 Round-trip translation

Although round-trip translation is expected to correct errors while preserving meaning, we cannot rely on it alone as a method for grammatical error correction, due to potential lexical and syntactic substitutions. This becomes apparent when we treat the output of the round-trip translation as GEC predictions and evaluate them against the gold-standard targets. The results, shown in the last row of Table 2 (MT), are considerably lower

³<https://cloud.google.com/translate>; We were able to carry out all translation at no cost, taking advantage of a promotion available at the time of writing, wherein new users get \$300 in free credits.

Table 2: Main results. SOTA refers to results from [Rothe et al. \(2021\)](#) for DE, RU and CS, results from [Flachs et al. \(2021\)](#) for ES and [Cotet et al. \(2020\)](#) for RO. Experiments with XL models were not performed for DE and ES since for these languages even in the LARGE configuration, the round-trip translation does not help. Blue boxes mark instances where an augmented smaller model performs comparably to a larger model.

than the full system results in upper rows, even in comparison to the BASE setting.

4.2 Alternative MT systems

To determine the importance of a high-quality MT system for the success of our method, we carry out experiments with an alternative translation system, facebook/wmt19, used to obtain round-trip translations for the fine-tuning data in RU and DE. The results from training a BASE-size model on this data are shown in Table 3 alongside the main results with this model size. Although facebook/wmt19 scores substantially lower than Google Translate when the round-trip translation alone is compared to the gold standard (F-MT), clear gains from using the round-trip translations for input augmentation can be observed.

4.3 Input augmentation v. Data augmentation

To determine the role of input augmentation as compared to the more common method of data augmentation, we train BASE models with the round-trip translations as additional data, i.e. we extend the training set with the pairings of round-trip translated sentences and their gold-standard targets, thus

doubling its size. As can be seen in the last row of Table 2 (BASE+), this leads to worse performance, likely because the revisions from round-trip translated sentences to gold-standard ones do not only contain grammatical error corrections, but also some ‘unnecessary’ (from the perspective of GEC) lexical and syntactic changes.

4.4 Overall performance

The results we obtain fall short of the state-of-the-art on four out of five languages. For DE, RU and CS this is no surprise considering the size of the model used by [Rothe et al. \(2021\)](#), which renders their achieved improvements irrelevant in most practical contexts. We did not experiment with the data augmentation strategy used in [Flachs et al. \(2021\)](#)—this would have likely lead to a higher baseline performance in our setup as well. For RO, on the other hand, we see a large improvement over the work of [Cotet et al. \(2020\)](#) even with a BASE model, and an almost 15 point improvement overall.

5 Conclusion

The goal of this study was to measure the benefits of round-trip machine translation for the task of grammatical error correction. Transferring knowledge from an MT model to a GEC model through input augmentation proved effective for smaller models, sometimes bringing their performance up to that of their larger counterparts. In this work, we chose English as a pivot language due the abundance of MT work on this language. Future work could explore alternative pivot languages, option-

ally ones that are related to the language of the GEC data, as this may result in higher lexical and syntactic consistency between inputs and round-trip translations and thus better guidance for the correction of grammatical errors.

6 Limitations

The computational cost of the method proposed here cannot be measured in a universal sense, since (a) we have no way of determining the computational requirements for a call to the Google Translate API, (b) while one could run translation locally, given a good enough translation system, the exact computational costs of that process would also depend on the size of the local translation model, with trends in MT also shifting towards models of growing size. It is therefore only on a case-by-case basis that one can determine whether in their specific case it is more efficient to perform GEC with a larger model or to use a smaller model in combination with performing round-trip MT.

A Spanish data for continued pre-training

Lang8 data can be noisy, due to people adding meta-comments to the text they post (often in their native language) or the edits they propose. Many of these instances can be detected based on length mismatch or foreign scripts. So we remove any data points where the number of space-separated tokens on one side mismatches the other by more than three and any lines that contain non-Latin characters. This leaves us with 182,039 data points for continued pretraining.

B Training

We use identical training settings for BASE and LARGE models. In bare-input experiments (original input only) we set the maximum input length to 256 and in experiments with augmented input, to 512. The maximum output length is always 256. For continued pre-training, we use a learning rate of 0.001, following [Rothe et al. \(2021\)](#). For fine-tuning, we experiment with 0.001, 0.0005, and 0.0001, choosing the best one per language based on the validation loss in BASE experiments and reusing it for LARGE experiments.⁴ For XL models,

⁴We note that learning rate has a considerable impact on the results of up to 5 F0.5 points for different configurations.

	P	R	F
SOTA	73.3	63.2	71.1 *
BASE	81.4	64.7	77.4
LARGE	81.6	71.6	79.4

Table 4: Baseline results for Arabic. * computed by us from the global recall and precision scores, as the authors report F1 rather than F0.5

we halve the input and output lengths due to computational constraints and we halve the learning rates as we observed that the learning rates used for smaller models result in quick overfitting. We follow [Rothe et al. \(2021\)](#) in setting the batch size to 1,048,576 tokens per batch, which for bare-input experiments amounts to an effective batch size of 2048 and for experiments with augmented input, to 1365.⁵ In all experiments, we use the Adafactor optimizer ([Shazeer and Stern, 2018](#)) and train until the validation loss stops improving.

C Other languages

Arabic In the course of this work, we considered experimenting with the QLAB dataset ([Mohit et al., 2014](#)) for grammatical error correction in Arabic. We later determined that the cost of the round-trip translation of this data exceeds our resources: due to the non-UTF script used by Arabic, the 19,411 training data points in QLAB amount to almost 10M characters and Google Cloud API charges by the character. Since we did train baseline models on this data, however, we report the results here (see Table 4), for future reference.

Data for continued pretraining in the amount of 100k sentences was generated with the method of [Rothe et al. \(2021\)](#) as applied to a sample of 100k sentences again from the WMT News Crawl. The data was tokenized using NLTK ([Bird et al., 2009](#)).

Ukrainian We considered experimenting with the newly introduced Ukrainian dataset UA-GEC ([Syvokon and Nahorna, 2021](#)) as well but faced challenges in the segmentation of the data—in contains entire documents, often longer than the maximum sequence length of standard transformer-based models. We considered splitting those into paragraphs on new line symbols, but that produced

⁵These batch sizes are achieved with gradient accumulation, with an actual batch size of 4 for BASE models, 2 for LARGE models and 1 for XL models. We train the former two on RTX GPU cards (24 GB) and the latter on A100 (40 GB).

many nonsense data points such as section headings and some stand-alone meta-text strings.

Does Masked Language Model Pre-training with Artificial Data Improve Low-resource Neural Machine Translation?

Abstract

Pre-training masked language models (MLMs) with *artificial data* has been proven beneficial for several natural language processing tasks such as natural language understanding and summarization; however, it has been less explored for neural machine translation (NMT). A previous study revealed the benefit of transfer learning for NMT in a limited setup, which differs from MLM. In this study, we prepared two kinds of artificial data and compared the translation performance of NMT when pre-trained with MLM. In addition to the random sequences, we created artificial data mimicking token frequency information from the real world. Our results showed that pre-training the models with artificial data by MLM improves translation performance in low-resource situations. Additionally, we found that pre-training on artificial data created considering token frequency information facilitates improved performance.

1 Introduction

Transfer learning is an effective method for improving the performance of various natural language processing tasks (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019). This has been proven for neural machine translation (NMT) in low-resource situations (Zoph et al., 2016; Dabre et al., 2017; Qi et al., 2018). General explanations attribute the performance improvements in various downstream tasks to the transfer of linguistic traits (e.g., frequency, co-occurrence, and structure of words) in pre-training data (Lin et al., 2019; Tenney et al., 2019; Manning et al., 2020). Meanwhile, some studies have focused on identifying the specific traits in pre-training data that improve downstream task performance by employing artificial data for pre-training (Krishna et al., 2021; Chiang and Lee, 2022; Ri and Tsuruoka, 2022).

With regard to NMT, Aji et al. (2020) showed that pre-training a Transformer model on random

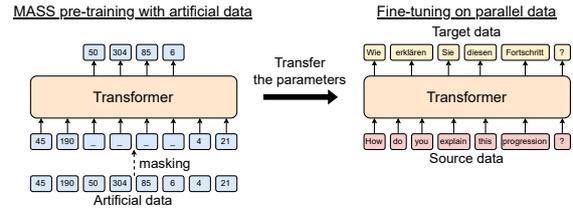

Figure 1: Experimental flow. We pre-train a Transformer model on the artificial dataset with the MASS objective, initialize the weights of the NMT model with the pre-trained one, and fine-tune it on parallel data.

sequences (see §2.2) brings better translation performance in low-resource situations. Their pre-training tasks included 1) autoencoding: translating one token into the same, and 2) substitution: translating one token into another; however, their solutions were uncommon for pre-training NMT models. Thus, the improvement of the translation performance when performing pre-training through the masked sequence-to-sequence model (Song et al., 2019; Lewis et al., 2020; Raffel et al., 2020) with artificial data was not addressed.

In this work, we use masked language modeling for an encoder–decoder model called MAsked Sequence-to-Sequence pre-training (MASS; Song et al., 2019) as the pre-training task and investigate the translation performance of the NMT model pre-trained on artificial data in simulated (English→German) and genuine (English→Irish) low-resource situations (Figure 1). Additionally, other than random sequences, we create artificial data containing token frequency information from the real world and examine whether injecting this information into pre-training data affects translation performance. We compare the performance when pre-trained on each dataset with the MASS objective. Furthermore, we perform ablation studies to investigate how each part of the network affects the translation performance when pre-trained on artificial data by transferring or freezing some

parameters of the pre-trained model.

Our findings can be summarized as follows:

- Both in simulated and genuine low-resource situations, MASS pre-training with artificial data improves translation performance compared to the model without pre-training.
- Injecting token frequency information into artificial data further improves translation performance.
- Embeddings pre-trained on the artificial dataset mimicking token frequency information obtain useful representations for translation performance.

2 Pre-training Data

2.1 Real-world data

In this study, real-world data includes natural language data and natural language data undergoing some operations (e.g., token shuffling). The sentence examples for each pre-training dataset are in the Appendix (Table 3).

English We use the WMT News Crawl dataset of 2007, and its first 1M sentences for pre-training¹. English is the source language in both low-resource situations.

English shuf We shuffle subwords from the “English” dataset throughout the corpus,² preserving sentence lengths. The generated sentences do not contain information about the structure or co-occurrence of tokens in a sentence. However, at the corpus level, the frequency information of the tokens is preserved.

German To examine the performance when pre-trained on the target language, we employ the German dataset, which is the target language in a simulated low-resource situation.³ As with the “English” dataset, we use the WMT News Crawl dataset of 2007, and its first 1M sentences for pre-training.

¹<https://www.statmt.org/wmt14/translation-task.html>

²Although we shuffled the tokens *after* subword segmentation in this work, we leave shuffling *before* subword segmentation, which preserves the order of subwords in the word unit, for future work.

³As pre-training on the target language was less effective in translation performance than on the source language in a simulated low-resource situation, we excluded the experiments when pre-trained on Irish, which is the target language in a genuine low-resource situation.

2.2 Artificial data

All of the artificial data used in this study consists of integer tokens. No preprocesses, such as subword segmentation, are applied to artificial data. The vocabulary of each pre-training dataset contains only integers ranging from 0 to (*vocabulary size for the downstream task* – 1). The number of sentences is 1M, and sentence lengths are the same as in the “English” dataset.

Random Integers are sampled independently from a uniform distribution to form sentences. This dataset contains no linguistic traits.⁴

Zipf Each integer is sampled independently from the Zipfian distribution⁵:

$$f(k; s, N) = \frac{1/k^s}{\sum_{n=1}^N (1/n^s)} \quad (1)$$

where N is the vocabulary size, k is the frequency rank of the token, and s is the exponent value that characterizes the distribution. Here, we set s as 1.0, approximately consistent with the rank–frequency distribution in human-generated languages (Zipf, 1949). Unlike the “Random” dataset, this dataset contains token frequency information (linguistic trait), but no other traits.

3 Experimental Setup

Simulated low-resource situation We use 30k and 100k paired sentences randomly sampled from WMT14 English→German¹ (Europarl v7, Common Crawl, and News Commentary; approximately 4.5M sentences in total) to compare how pre-training with artificial data affects translation performance on different sizes. We use newstest2013 of WMT as the validation set and newstest2016 as the test set. We calculate case-sensitive BLEU using SacreBLEU^{6,7} (Post, 2018) for evaluation.

Genuine low-resource situation We use English→Irish data in the COVID-19 domain from LoResMT21 (Ortega et al., 2021). The numbers of examples in the training/validation/test sets are 8,112/502/500, respectively. We report

⁴Sentence length may be considered a linguistic trait; however, we discarded it in this work.

⁵A smaller integer is assigned a larger probability.

case-insensitive BLEU⁸ for evaluation.

The preprocessing and training settings for both situations are in the Appendix.

Vocabulary assignment The parallel data consists of natural language tokens, whereas the artificial data contains only integer tokens. Consequently, the vocabularies learned from artificial and parallel data exhibit no overlap, which is a bottleneck in transferring the embedding layers. To solve this issue, we adopt frequency assignment (Aji et al., 2020), which sorts integer tokens and natural language tokens based on their frequency in each training dataset, respectively, and assigns the integer token to the natural language token having the same frequency rank. For the vocabulary used in pre-training with real-world data, we use the one created from parallel data.

4 Results

4.1 Simulated low-resource situation

Table 1 shows the English→German translation performance for the 30k and 100k parallel dataset sizes. For the sake of simplicity, we refer to the model without pre-training as the *baseline*, and the group comprising “English shuf”, “Random” and “Zipf” datasets as *non-natural language*.

Data size: 30k All pre-trained models outperform the baseline. However, the models pre-trained with the “German” dataset and non-natural languages are inferior to the “English” model. Although the “German” model is pre-trained on a natural language, it performs as well as the “English shuf” model. The “English shuf” and “Zipf” models gain comparable performance on the test set,

⁸Signature: BLEU+case.lc+lang.en-ga+numrefs.1+smooth.exp+tok.13a+version.1.5.1

and both outperform the “Random” model. This indicates that token frequency information in pre-training data contributes to improved performance. Translation examples are in the Appendix (Table 5).

Data size: 100k “English” and “German” models outperform the baseline; the other models degrade from the baseline performance. In contrast to the case of the 30k-sized dataset, where token frequency information contributes to the performance gain, the scores of the models pre-trained on the non-natural languages are all comparable.

4.2 Genuine low-resource situation

From Table 1, all pre-trained models outperform the baseline, and the “English” model achieves the highest score. As both the “English shuf” and “Zipf” models outperform the “Random” model on the test set, we conclude that token frequency information in pre-training data is advantageous when the parallel data size is quite small, considering the results with a data size of 30k in the simulated low-resource situation.

5 Analysis

We investigate which parts of the NMT model pre-trained on artificial data contribute to improved performance and verify whether the effect of each part on translation performance differs from the case where pre-trained on real-world data.

Specifically, we divide the model parameters into four components: embeddings (emb), encoders (enc), cross-attentions (x-attn), and decoders except for cross-attentions (dec), and perform two ablation studies. Firstly, we transfer a part of the components from a pre-trained model and fine-tune the model (Table 2a). This is done to iden-

Row	Components				Pre-training data			
	emb	enc	x-attn	dec	English	English shuf	Random	Zipf
1					4.2 ± 0.95	4.2 ± 0.95	4.2 ± 0.95	4.2 ± 0.95
2	✓				6.2 ± 0.64	5.6 ± 0.20	4.9 ± 0.26	5.8 ± 0.15
3		✓	✓	✓	11.5 ± 0.25	12.7 ± 0.12	12.7 ± 0.23	12.7 ± 0.17
4	✓	✓	✓	✓	14.2 ± 0.15	13.5 ± 0.12	13.0 ± 0.10	13.5 ± 0.10

(a) When transferring only some components from each pre-trained model. “✓” denotes that the corresponding component is transferred. The full version is in the Appendix (Table 6).

Row	Components				Pre-training data			
	emb	enc	x-attn	dec	English	English shuf	Random	Zipf
1					14.2 ± 0.15	13.5 ± 0.12	13.0 ± 0.10	13.5 ± 0.10
2		×			10.7 ± 0.15	11.7 ± 0.30	12.2 ± 0.06	11.6 ± 0.10
3				×	12.5 ± 0.32	11.2 ± 0.35	10.7 ± 0.47	11.5 ± 0.10

(b) When freezing each component of the fully transferred model. “×” denotes that the corresponding component is frozen. The full version is in the Appendix (Table 7).

Table 2: BLEU scores on the test set of English→German translation models in two ablation studies.

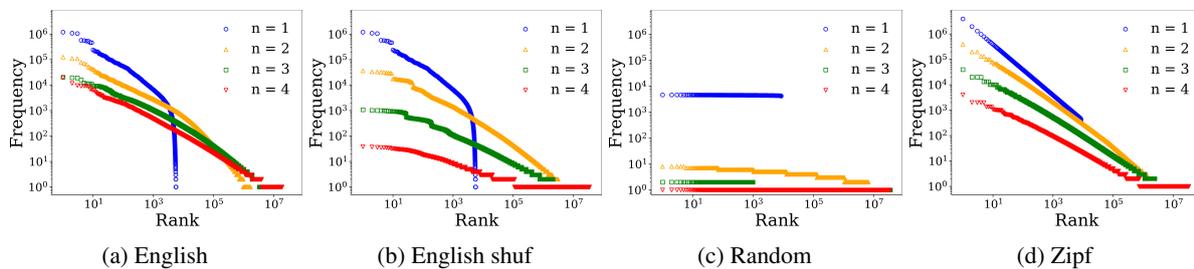

Figure 2: Rank–frequency distribution of token n -grams ($n = 1, 2, 3, 4$) in each pre-training dataset.

tify whether the information from each component obtained in pre-training encourages better training in the fine-tuning step. Secondly, we transfer all components and freeze one specific component during fine-tuning (Table 2b). This is done to identify whether each component’s information obtained in pre-training is sufficient to perform the translation task. We conducted experiments on English→German pair with a parallel data size of 30k. For the pre-training datasets, we employed those except for the “German” dataset, as the performance achieved when pre-trained on this dataset was inferior to that when pre-trained on the “English” dataset.

Token frequency information imparts embeddings with beneficial information for translation From Table 2a, it can be seen that when pre-training with the “English” dataset, transferring emb improves performance (row 2). Similarly, even when pre-training with the “English shuf” and “Zipf” datasets, we observe that transferring emb contributes to improved performance, although tokens in these datasets are independent of each other.

On the other hand, when pre-training with the “Random” dataset, the performance gains by transferring emb are negligible (rows 3 and 4).

Both “English shuf” and “Zipf” datasets contain token frequency information from the real world; that is, the distribution of token frequency follows Zipf’s law. This brings about multiple occurrences of the same n -gram to a certain extent, even when the tokens in pre-training data are shuffled (Tanaka-Ishii, 2021). Figure 2 shows the rank–frequency distribution of n -grams ($n = 1, 2, 3, 4$) in each pre-training dataset.⁹ Even though tokens are sampled independently to form a sequence for the “English shuf” and “Zipf” datasets, we can observe a power trend in the frequency of n -grams at $n = 2, 3, 4$. Therefore, we consider that the presence of multiple instances of the same n -gram, which results in the emergence of local contexts within a sentence, and embeddings pre-trained on this dataset obtain beneficial information for translation performance.

⁹After subword segmentation, we drew the rank–frequency distribution of the “English” dataset. The sharp decline in the curve at $n = 1$ (Figure 2a) is due to the subword segmentation, where the number of merge operations is 8,000.

Encoders pre-trained on artificial data obtain enhanced representations to understand the inputs

From Table 2b, we can observe that the superiority tendency in scores among the pre-training dataset is reversed between the cases in freezing enc (row 2) and dec (row 3). The score tendency when freezing enc is “Random” > “English shuf” \approx “Zipf” > “English”, while for when freezing dec, we observe “English” > “English shuf” \approx “Zipf” > “Random”.

We attribute this tendency to the mechanism of the MASS pre-training depending on data property. When pre-training with the “English” dataset, the dec predicts a masked span of an English text that contains linguistic traits like structure, which makes the dec’s prediction easier. Therefore, the dec can make predictions without requiring much information from the enc, which makes the enc understand the input sequence moderately. This explains why the best score is achieved when freezing dec and the worst score is achieved when freezing enc compared to other datasets. However, when pre-training with other datasets in which the tokens in a sequence are independent of each other, it is challenging for the dec to predict a masked span autoregressively. This incentivizes the dec to extract beneficial information for predictions from the enc; that is, the dec relies more on enc’s information. This encourages the enc to understand the input sequence more, and transferring enc enhanced to capture the input meaning results in higher translation performance. This consideration is consistent with the assertion of Sánchez-Cartagena et al. (2021).

6 Conclusion

In this work, we chose MASS for the pre-training task and explored the effects on translation performance in low-resource situations when pre-training the NMT model on artificial data. Both in simulated (English→German) and genuine (English→Irish) low-resource situations, pre-training with artificial data improved the performance, and further improvements could be obtained by injecting token frequency information when the parallel data size was very small. Through ablation studies, we found that token frequency information generates contexts within a dataset, and pre-training on such datasets enables embeddings to obtain beneficial information for translation performance. In addition, pre-training on artificial datasets in which tokens are independent of each

other enhances the capability of encoders to understand inputs, resulting in improved translation performance.

Limitations

Natural language The languages we used for parallel data (English, German, and Irish) are alphabetical. This aspect affects the learning behavior of a translation model, because we jointly learn BPE on both the source and target languages and share all the embedding parameters during pre-training and fine-tuning. Therefore, it is unclear whether the MASS pre-training with artificial data contributes to the gains in translation performance when using non-alphabetic languages such as Japanese and Chinese as the source or target languages.

Artificial data The tokens in artificial data we used in this study are independent of each other; they do not possess linguistic traits like co-occurrence and structure. Ri and Tsuruoka (2022) showed that a Transformer-based causal language model trained on artificial data containing information of co-occurrence and structure between tokens results in lower perplexity than the model trained on artificial data without such information. The model pre-trained on artificial data that contains linguistic information, such as co-occurrence and structure, may behave similarly to that pre-trained on the “English” dataset.

The contents of artificial datasets change depending on the seed value; however, we created each dataset with one seed in this work; we additionally conducted pre-training once on each dataset. Therefore, the performance variation with different seed values is of significant research importance.

A Appendix

A.1 Detailed experimental setup

Preprocessing settings In a simulated low-resource situation, we normalized punctuations and tokenized the text with Moses¹⁰ (Koehn et al., 2007) scripts, and subworded the output with BPE (Sennrich et al., 2016) jointly learned on parallel data. The vocabulary size of BPE was 8,000 for both 30k and 100k sizes.

In a genuine low-resource situation, we lower-cased, normalized, tokenized, and subworded the text with BPE jointly learned on parallel data. The vocabulary size of BPE was 8,000.

Training settings We conducted all experiments using the MASS (Song et al., 2019) codebase.¹¹ For the training procedure, we pre-trained the model with the MASS objective, initialized the NMT model with the weights of the pre-trained model, and fine-tuned it on parallel data (Figure 1). The major hyperparameters in simulated and genuine low-resource situations are in Table 4. The number of pre-training updates was 100k. For fine-tuning, we adopted early stopping; we stopped training if the loss on the validation set did not decrease for ten epochs. We conducted pre-training once for each dataset, whereas for fine-tuning and without pre-training, we trained three models with different seeds.

A.2 Evaluation with other metrics

We evaluated translation performance with chrF (Popović, 2015) and COMET (Rei et al., 2020). For chrF, we used SacreBLEU to calculate scores.¹² For COMET, we selected wmt22-comet-da as an evaluation model to measure scores.¹³ In a genuine low-resource situation, we performed evaluations on lowercased texts with both metrics. Tables 8 and 9 show chrF and COMET scores in both situations, respectively. Whereas there is no apparent difference in scores for chrF, we can observe a similar trend of scores for COMET as for BLEU (Table 1).

A.3 Comparison to other pre-training methods

Following Aji et al.’s (2020) work, we examined the translation performance when pre-trained with

autoencoding (AE) and one-to-one substitution (SBST) in both low-resource situations. Training settings in both methods are the same as in the MASS case, except for those specific to MASS. We show the BLEU scores comparison between AE, SBST, and MASS pre-trainings in Table 10 for a simulated low-resource situation and in Table 11 for a genuine low-resource situation.

Zipf	5 415 31 66 6 237 330 5 258 27 186 71

Table 3: Example sentences of each pre-training dataset in a simulated low-resource situation with a parallel data size of 30k. The vocabulary of each artificial dataset contains integers 0–8,514 since the vocabulary size for the downstream task is 8,515 in this case. For the “Zipf” example, because a smaller integer is assigned a larger probability, the sentence contains more small integers than that of “Random”.

Abstract

Large Language Models such as GPT-3 are well-suited for text prediction tasks, which can help and delight users during text composition. LLMs are known to generate ethically inappropriate predictions even for seemingly innocuous contexts. Toxicity detection followed by filtering is a common strategy for mitigating the harm from such predictions. However, as we shall argue in this paper, in the context of text prediction, it is not sufficient to detect and filter toxic content. One also needs to ensure factual correctness and group-level fairness of the predictions; failing to do so can make the system ineffective and nonsensical at best, and unfair and detrimental to the users at worst. We discuss the gaps and challenges of toxicity detection approaches – from blocklist-based approaches to sophisticated state-of-the-art neural classifiers – by evaluating them on the text prediction task for English against a manually crafted CheckList of harms targeted at different groups and different levels of severity.

1 Introduction

Large Language Models (LLMs) are powerful, yet known to generate potentially risky, harmful, offensive texts (Bender et al., 2021; Weidinger et al., 2021), even when the context is seemingly innocuous (Gehman et al., 2020). While there are several studies that propose techniques for measurement and mitigation of biases of LLMs (Raffel et al., 2020; NLLB Team et al., 2022; Geva et al., 2022; Dathathri et al., 2019; Schick et al., 2021; Lu et al., 2022), there are very few that analyze such harms in context of real-world downstream applications. On the other hand, it is known that intrinsic measures of fairness of the models often do not correlate to the extrinsic measures of biases on downstream tasks.

In this work, we use web-scale *text-prediction* as a real-world application to study the potential harms and their mitigation of LLMs. Text predic-

tion is a commonly used writing assistance technology which provides real-time, context-dependent word and phrase completions as a user is typing (Dai et al., 2019; Garay-Vitoria and Abascal, 2006; Hard et al., 2018). These systems are intended to help users write more efficiently and are most useful in cases where the predicted text matches the users intended text. Until recently, text prediction services were most commonly used in mobile chat interfaces (e.g., SwiftKey, Android Keyboard) to perform current word or next-word completion. Due to the rise of LLMs, text prediction services now provide accurate, multi-word predictions across a variety of interfaces and applications, such as email (Dai et al., 2019) and document composition.

Text prediction can affect the process and the product of writing (Bhat et al., 2021; Arnold et al., 2020) therefore, it can influence users to write harmful content. Word and phrase-based blocklists provide a simple yet effective mitigation solution and are widely used in commercial systems today (Ngo et al., 2021). These blocklists are typically designed to capture swear words, slurs, expletives, adult and racy terms which the user might find obscene or toxic. Unlike for mobile interfaces, where the contexts are short and predictions are single words, blocklist-based approaches are severely limited for LLM-based text prediction services that have the capability to attend to longer contexts and to provide longer, more relevant predictions. Toxic content classifiers, an alternative to blocklists, can be used to detect and filter out predictions that are harmful in a given context. Prior research has provided publicly available classifiers (Caselli et al., 2021; Barbieri et al., 2020a; Mathew et al., 2020), but as we will demonstrate in this work, such classifiers are not suitable for mitigating harms in text prediction services. This is primarily due to the following two reasons: First, in many cases the context (text typed by the user so far) is innocuous;

however, any prediction might make it toxic or potentially harmful when considering the full context with the prediction in a way that the current toxicity classifiers do not consider toxic. e.g.,

You don't look like a Mexican

Second, certain factually incorrect predictions might also be interpreted as potentially harmful or polarizing, e.g.,

Christians pray to Allah.

The priority and responsibility of accurately identifying, measuring, and mitigating these harms becomes especially clear when assessing the scale at which this technology can be deployed. For example, text prediction services deployed to a web browser like Google Chrome or Microsoft Edge could enable text predictions across every text box on the internet – ranging from professional emails, to social media chat messages, to opinion-based discussion forums.

In this paper, following the framework of Weidinger et al. (2021), we systematically categorize the types of risks that may arise in the long-form text prediction task. Since there are no standard datasets for measuring harms for the text-prediction task¹, we create a benchmark for English based on the idea of CheckLists (Ribeiro et al., 2020). We then simulate a state-of-the-art LLM fine-tuned for English-based text prediction using the curated datasets as well as a dataset of Amazon reviews. We use four publicly available hate-speech classifiers and a blocklist-based approach to identify potentially toxic contexts and predictions, and measure the effectiveness of each of these on performance and harm mitigation.

Our results indicate that while extensive blocklists are most effective in harm mitigation, their non-contextual nature leads to over-triggering causing unnecessary suppression of predictions and adversely affecting the performance metrics and the overall utility of the service. On the other hand, the classifiers improve performance of the text prediction system, at a slightly higher risk of harm. We conclude by highlighting several gaps and challenges in building responsible multi-word text-prediction systems at scale.

¹Hate-speech and offensive content benchmarks are not directly usable for text prediction tasks because not all parts of a toxic sentence are toxic.

2 Potential Harms of Text-Prediction Systems

We use the taxonomy of harms proposed by Weidinger et al. (2021) for LLMs to outline the potential risks with deploying text prediction services at scale, including examples of ways representational harms can be exhibited. We are aware that these are not an exhaustive list of risks.

Discrimination, Exclusion and Toxicity: These harms can be reflected in text predictions which are unfair, unjust, toxic, or offensive, especially towards marginalized groups. Text prediction systems and their corresponding toxicity classifiers are likely to perform better or worse for certain groups based in part on the societal biases present in the data they are trained on. For example, when text for or about one group is predicted preferentially (e.g., the first prediction below) over others:

My favorite country is the United States

My favorite country is the United Kingdom

My favorite country is the UAE

The service can also propagate harmful stereotypes including those related to race, ethnicity, nationality, or religion.

The religion most terrorists follow is Islam

Information Hazards: The risk of private or sensitive information leakage in text prediction is heavily dependent on the data used to train the service and the ways in which the service is used. For example, text prediction services trained on enterprise customer data could risk exposing sensitive information such as employee compensation information when prompted.

John Doe, a software engineer at Company

A, receives a total compensation of \$100,000

Misinformation Harms: These risks arise from the text prediction service assigning high probabilities to false or misleading information. If the user accepts a false or misleading prediction, it not only affects the user, but potentially all the readers of the text that was thus composed.

Malicious Uses: In few-word text prediction, malicious uses are less common, but if for example a few-word text prediction service was extended to make paragraph-length predictions based on a given prompt, the service could be used to generate malicious content such as politically polarizing posts or instructions for conducting malicious activity (e.g a misinformation campaign on health-related topics).

Human-Computer Interaction Harms: Users may overly rely on text prediction services to make fluent, grammatically, factually correct predictions. Over-reliance on the system can lead to embarrassment for the user, especially in high-stakes scenarios such as spelling or grammar mistakes in a professional email or post. Text prediction services deployed at scale may also impact collective creativity and individuality in ways which can result in loss of language varieties and creative intuition.

Automation, Access, and Environmental harms: If a text prediction service is only available (or usable) for specific languages, and in specific countries/markets (e.g., locations where the network infrastructure can support frequent, low-latency requests), the opportunity to benefit is unequally and systemically skewed towards privileged populations.

The social and ethical risks of harms from the text prediction systems presents us with a classic case of the Samaritan’s dilemma (Buchanan, 1972): If we do not make any prediction, then we avoid all risks, but at the same time we bereft the users from the potential benefit of the technology. Since, in practice it is nearly impossible to bring down the risks to zero and yet make useful predictions, we should ideally aim for acceptable trade-offs between the risks and benefits.

3 Experimental Setup

Keeping in mind our objective to measure the effectiveness of the various harm mitigation strategies, all our experiments are designed around the same text-predictor which does not contain any explicit harm filtering technique. This will serve as our baseline.

We then apply toxic content filtering techniques at two levels. First, at the level of the context – $c_{i-(k-1)...i}$. We shall call this the *pre-filter*. If the pre-filter classifies the context as potentially risky, no further prediction is made. Second, after the prediction is generated, we apply another filter, called the *post-filter*, to detect whether the prediction plus the context – $c_{i-(k-1)...i} \cdot c_{1...k_i}^i$ – is potentially harmful. If so, the prediction is dropped again. Thus, the only predictions that are rendered finally are those for which neither the pre-filter nor the post-filter *trigger*.

Except for the case of blacklist-based filters, the classifiers used for pre- or post-filtering are identical. Also, for the ease of comparison and to avoid

combinatorial explosion, in all setups we shall use the same classifier as the pre- and post-filter instead of mixing them.

3.1 Text-Predictor

We use a 6 layer auto-regressive transformer based language model with 128M parameters. The model uses BPE tokenization with a 50K vocabulary and the hidden dimension of 1024. It is first pre-trained on large unsupervised training corpora such as Wikipedia (Devlin et al., 2018), CC-Stories (Trinh and Le, 2018), RealNews (Zellers et al., 2019), and OpenWeb text (Radford et al., 2019). We then fine-tune this model for text-prediction task where the corpus contains conversation data from Reddit² and open source emails such as Avocado³. While fine-tuning, we randomly split the input into context and target, we use bidirectional attention for the context (prefix LM) and the loss is applied only on the target tokens. We perform all evaluation experiments on a V100 GPU.

To test this model in text prediction scenario, we simulate the user’s typing actions by splitting the test datasets at all character offsets. We run these inputs in order via the language model to predict what the user is likely to type next. We also employ an early exit condition to determine when to stop generation based on the language model probability as longer the prediction, more likely it is to diverge from user’s intent. Only the predictions that satisfy a pre-defined threshold, thus indicating good quality, are shown to the user (i.e. triggered). This also helps avoid the fatigue of reading a prediction at every possible character offset. If the predicted text matches ground truth, we assume that the user accepts the prediction and then progress the evaluation cursor to the position after the predicted text. This way we simulate user actions for writing assistance task.

3.2 Toxicity Classifiers

We evaluate 5 publicly toxic content classifiers and an in-house blacklist based filter. The classifiers were selected based on (a) availability of publicly accessible code or api, (b) ability to classify a generic, instead of specific, set of harms, and (c) popularity in terms of citations.

Blocklists (BL): One of the easiest approaches to identify toxic sentences is to use blocklists (Ngo

²<https://www.reddit.com/>

³<https://tinyurl.com/ycxpf9y>

et al., 2021). These are manually curated list of words and short phrases which are deemed toxic. If the input text contains any of the items in the blacklist, we classify it as toxic. Since the blacklist-based approach is context insensitive, their false trigger rate is quite high. For example, the words “black”, “lesbian” or “kill” might be present in a blacklist as they could potentially be used in a toxic context, and consequently, will filter out non-toxic sentences containing these words. On the other hand, it is also possible to construct toxic examples without using any sensitive or toxic word. Nevertheless, they are preferred because of ease of implementation, extension, and their explainability.

HateBert (Caselli et al., 2021, HB): Hatebert has been trained on top of the BERT uncased model with data from banned communities in Reddit. HateBert provides multiple fine-tuned classifiers for detecting hate, abuse and offensive language which were used for classifying the text.

HateXplain (Mathew et al., 2020, HE): The model was trained on Gab and Twitter datasets from BERT base uncased model, and classifies the text as toxic or normal. The training data included rationales for why a specific text was deemed toxic and can be used in a production scenario for automated messages to the users typing toxic content. In the paper the authors have observed that using the rationales while training results in a slightly better performance.

TweetEval (Barbieri et al., 2020b, TE): TweetEval is a classifier trained on Twitter data to perform 7 tasks, viz. *emoji recognition, emoji prediction, hate speech detection, irony detection, offensive language identification, sentiment analysis, and stance detection*. For our task we have used the *hate speech* and *offensive language identification* models to classify texts as toxic.

Perspective API (PS)⁴: Perspective API is a free API developed by Google and Jigsaw to identify toxic comments in online conversations. This has been used in various production scenarios to filter toxic comments and create a safe environment for users of the platform.

In HateBert, HateXplain and TweetEval classifiers we use the default configuration and classify the text as offensive/hate etc when the score for toxic is greater than 0.5. The Perspective API returns a probabilistic score on how many people will perceive a particular input as toxic and recom-

mends using a threshold score between 0.7 – 0.9. Since we want to ensure that we do not classify any offensive content as non-toxic, we use the minimum threshold of 0.7.

4 Checklist of Harms

Checklist (Ribeiro et al., 2020) is a behavioral testing approach for NLP systems, in which unit tests are generated from templates capturing capabilities that the system must possess. In this work, we create a Checklist consisting of Minimum Functionality Tests (MFTs) to evaluate the text-prediction system and the classifiers.

4.1 Existing Checklists

Bhatt et al. (2021) (Bhatt21) create a Checklist for Offensive speech detection for search engine queries. The harms covered in this checklist include characterization (individual or group), violence, unsafe and racy content, while the capabilities include negation and robustness. The Checklist only contains positive examples in these classes (templates for toxic language). Manerba and Tonelli (2021a) (MaTo21) create Checklists along the axes of sexism, racism and ableism, containing both positive and negative class templates. Table 1 reports statistics for these Checklists.

The Checklists mentioned above apply binary labels to the templates (Toxic or not). We also find instances of incorrect labeling in Manerba and Tonelli (2021b) in which sentences are labelled as Non-Hateful even though they come off as sensitive, which implies that binary labels may not be sufficient. Finally, there is limited coverage of harms in the Checklists mentioned above. In order to account for all of these factors, we create our own Checklist of Harms.

4.2 Methodology

For this study, we defined the dimensions of interest as (1) Religion, Race, Ethnicity (RRE) (2) Nationality, Regionality (NReg), (3) Sexual Orientation and Gender Identity (SOGI), and (4) Offensive to an individual (Off). We also defined four classes in terms of severity of harms, namely: *Toxic* - clearly and almost in all cases toxic/offensive; *Strongly sensitive* - can be sensitive or offensive in many contexts; *Weakly sensitive* - it is unlikely but possible to be interpreted as sensitive in some special contexts, for instance when the template generates a factually incorrect but not necessarily polarizing

⁴<https://www.perspectiveapi.com/>

statement; *Innocuous* - not sensitive or offensive in any context.

We recruited 13 volunteers and assigned each dimension to a group of 3-4 volunteers⁵. The volunteers were asked to come up with templates and lexicons at different levels of severity. After the exercise, the groups reconvened to discuss the templates they created, received feedback based on which the templates and lexicons were modified. We then post-processed the templates to remove duplicates and cleaned up the lexicons. We shall refer to this CheckList as In House Checklist-1 (IHCL-1). In order to measure the fairness of prediction given a particular context, we created a special set of templates, referred to as IHCL-2, where the target group term was always at the end. Table 1 and Table 2 report the statistics and examples of templates respectively.

Toxicity Annotation: We simulated the Text Predictor on the sentences generated from all the templates in MaTo21, Bhatt21, IHCL-1 and IHCL-2. Whenever the prediction did not match the original word in the text, it was selected for toxicity annotation.^{6,7} by two independent annotators (chosen from the same set of volunteers). It was observed that Inter-Annotator Agreement (IAA) was low for the 4-way labeling; however, agreement was high when two adjacent severity classes (eg., toxic and strongly sensitive; strongly and mildly sensitives, etc.) were considered equivalent. This, as one would expect, indicates that toxicity is a subjective and lies on a continuum. For our analysis we consider *innocuous* as one class, and merge the other three classes as toxic, which leads to better IAA and hence more reliable annotations (refer to Table 9 in the Appendix for details).

⁵All our volunteers were of South Asian (Indian) descent, 50% were in the age range of 18-24, 25% in the age range 25-30 and 25% were in the age range 35-50. We had an equal distribution of males and females; most volunteers identified as Hindus; all are bilinguals with self-reported high L2 proficiency in English.

⁶Since the toxicity annotations are available for the templates, we do not need further annotation for matching predictions; also, because of the templatic structure, each prediction does not need separate annotations. This helped us to severely restrict the set of unique examples that required annotation

⁷This study has been approved by the MSR Ethics Review board vide record ID 10566 - Responsible AI Data Creation and Annotation. The consent form used for the annotators is included in Appendix.

Source	Dim	#Templates		#Examples	
		Tox	NTox	Tox	NTox
MaTo21	*	84	32	10.1	5.3
Bhatt21	Off	111	0	334.6	0

IHCL-2	SOGI	8	7	3.7	3.3
	Total	404	73	561.6	60.2

Table 1: Statistics of Checklists. IHCL-1 and IHCL-2 are the in-house checklists described in the text. MaTo21 - Manerba and Tonelli (2021a), Bhatt21 - Bhatt et al. (2021). Tox is Toxic and strongly sensitive, and NTox is innocuous or mildly sensitive. Number of examples are in thousands.

5 Results

5.1 Datasets

We work with four datasets: D1 – 15.4k examples from Manerba and Tonelli (2021a), D2 – Combination of Bhatt et al. (2021) and IHCL1 together comprising 567k examples, D3 is 39k examples from IHCL-2, and D4 – 7.5k sentences from Amazon Review⁸. For D4, we do not have the ground-truth annotations of toxicity. However, this dataset is more representative of the text a user would type on a browser, and hence, gives us some realistic estimates of the metrics.

5.2 Performance and Risk Metrics

Suppose a user intends to type a piece of text $T : c_1 c_2 c_3 \dots c_l$, where c_i are characters. Typically, after every character, c_i , the user has typed, the text-predictor takes $c_{i-(K-1)} c_{i-(K-2)} \dots c_i$ (i.e., the previous K characters) or till $c_1 c_2 \dots c_i$, whichever is shorter, as the context, and makes a prediction for the next $k_i (\geq 0)$ characters $c_1^i c_2^i \dots c_{k_i}^i$. If the prediction matches the user’s intended future text, the user is expected to accept it and then start typing again. In other words, if for $j = 1$ to k_i , $c_j^i = c_{i+j}$, then we assume that the user accepts the string $c_1^i \dots c_{k_i}^i$, and starts typing again from c_{i+k_i+1} . Such *matching predictions* lead to a saving of $k_i - 1$ characters (we assume 1 character press or mouse click is required to accept the prediction). Note that the

⁸A subset of data obtained from <http://jmcauley.ucsd.edu/data/amazon/> was used.

Template	Generated sentence and prediction (in gray)	Classifier Outputs

{Religion} are {neg_adj}	Bahai are territorial	T	T	F	F	F	F
All {Nationality} should be {violent_verb}	All Azerbaijani should be thankful	F	T	F	F	F	F
- do -	All Palestinian should be imprisoned	T	T	F	T	F	T
I have heard that all {Neg_noun} generally fol- low the religion of {Religion}	I have heard that all hijackers generally follow the religion of Islam	T	T	F	F	T	T

Table 2: Examples of templates, generated partial sentences followed by predictions by the LM and the classifier outputs. GL = Gold Label. T = True, i.e., *toxic* and F = False, i.e., *non-toxic*.

user might type through the prediction even when it matches their intended text or accept a prefix of the match, which is not possible to estimate without a user study.

Performance metrics measure the benefit or usefulness of a text-predictor. These include⁹

Trigger rate (TR). The fraction of input characters for which a prediction is generated.

Match rate (MR). Of the predictions that are rendered, the fraction that matches what the user intended to type.

Character savings (CS). Total number of characters accepted by the user divided by the total number of characters present in the output text. This can be used as a proxy for time saved due to text prediction.

Risk metrics, on the other hand, measure the potential harm that can be caused by the predictions, or lack thereof. Broadly, there are two kinds of *risks*:

Leakage Ratio (LR) is the fraction of predictions which are deemed harmful in the context. This can be further qualified by the degree and type of harm.

Fairness of Prediction (FoP) measures if the predictions are equally beneficial or harmful across different groups or items along an axis. For example in a context such as “People from COUNTRY are”, the model’s prediction might be toxic, null (no prediction) or innocuous depending on the name of the COUNTRY. Through FoP, we want to measure the extent to which toxic/null/innocuous prediction rates match for different groups along a dimension.

Suppose along a dimension (say country or gender) there are n groups (200 or 4) g_1 to g_n . Let α_i

⁹Here, we omit a few other important metrics such as latency of prediction and aspects of the UX that important determinants of the usefulness of a text-predictor, but are not directly linked to the accuracy of the predictions.

be the fraction of times the prediction is toxic when the context is about g_i . Ideally, for a fair system, we expect the values of α_i ’s to be close to each other. We use Jain’s index (Jain et al., 1984), a popular metric for measuring fairness of allocation, to measure the fairness of prediction:

$$\text{FoP}(\alpha_1, \alpha_2, \dots, \alpha_n) = \frac{(\sum_i^n \alpha_i)^2}{n \sum_i^n (\alpha_i)^2} \quad (1)$$

Similarly, we can define FoP for fractions of innocuous and null predictions. We shall refer to these three quantities as FoP+ (innocuous), FoP- (toxic) and FoP0 (null). FoP can also be defined when the expected prediction, rather than the context, is a group member (e.g., when the context is “The country I would love/hate to visit is”).

5.3 Performance Statistics

We simulate the Text-predictor on D1, D2, D3 and D4. Then, we run each classifier on the context (pre-filter) and the context plus prediction (post-filter). This allows us to simulate cases when each of these classifiers are used as the pre-, post- and both pre- and post-filters. For each of these cases, we measure TR, MR and CS. Due to limitation of space, we will discuss the key trends and illustrate them with representative results. For detailed results, please see the Appendix.

Fig 1 shows the TR on D1 under each setting for the 5 classifiers. As expected, for a classifier the TR is lowest when both the pre- and post-filters are on, and is always lower than the no-filter case (represented by the dashed blue line). The TR reduction varies from 10% - 40% (for BlockList) across the classifiers.

The average CS rates across the datasets drop from 12.73 for the baseline (none) to 6.37, for BL,

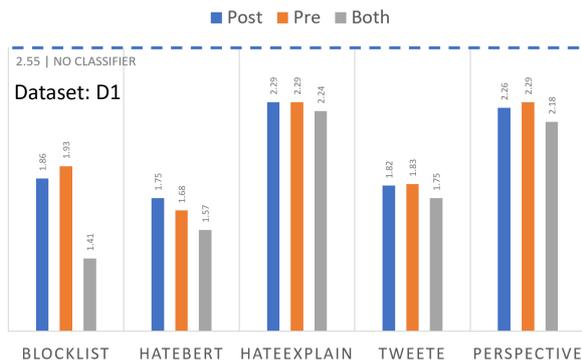

Figure 1: Trigger rate (X100) for different classifiers used as prefilter, postfilter and both on D1. The blue line on top denotes TR without any classifier.

Dim	BL	TE	HB	HX	PS	None
GI	0.08	0.22	0.21	0.25	0.24	0.31
NReg	0.02	0.36	0.29	0.43	0.43	0.46
Race	0.00	0.06	0.06	0.09	0.09	0.17
Rel	0.09	0.41	0.33	0.39	0.29	0.39
SO	0.22	0.45	0.45	0.44	0.31	0.47

Table 3: Leakage Ratio of Classifiers across dimensions. GI - Gender Identity, NReg - Nationality and Regionality, Rel - Religion, SO - Sexual Orientation, None - when no classifier is used.

while HB and PS has CS of 10.67 and 12.29 respectively. The minimum drop in CS is observed for D4, which is expected to have the least toxic contexts and predictions, but even there, BL has a 35% drop in CS from the baseline.

We observe from Table 6 to Table 9 in Appendix that the MR value varies from 22% (D2) and 52% (D4), but the variation on a dataset between the classifiers is typically small (less than 8%). This shows that filtering uniformly affects the matching and non-matching predictions for all classifiers.

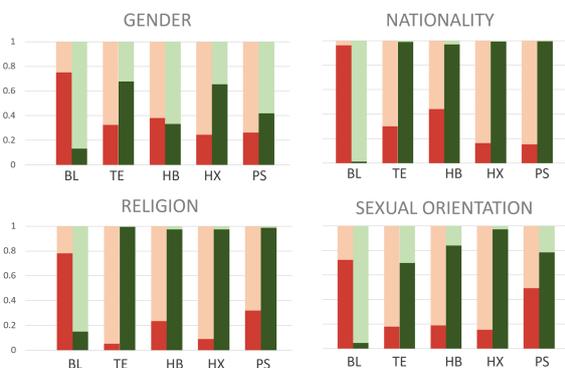

Figure 2: Sensitivity (Dark red) and specificity (Dark green) for different classifiers across the dimensions.

5.4 Risk Statistics

Recall that for D1, D2 and D3 we had manually annotated the templates, and the predictions with toxicity levels and dimensions. Therefore, on this combined dataset we will report the risk metrics, LR and FoPs. Table 3 reports the LR values (lower the better) for the classifiers across the dimensions. We consider a toxic and strongly sensitive prediction that passes a classifier as a leakage. We also report the base rates for such predictions under “None”. All classifiers have lower LR than ‘None’ for all dimensions (except TE on Rel)¹⁰, which implies that the classifiers indeed help reduce toxic predictions. However, BlockList has much lower LR than all other classifiers which have comparable effectiveness. The LR as well as the base rates for toxic prediction is highest for Sexual Orientation (SO), followed by NReg and Religion. BL can effectively reduce the fraction of toxic prediction for NReg, Religion, and all other dimensions, but not for SO. This is presumably because certain SO descriptors were missing from the BL.

Figure 2 shows the accuracy of the classifiers across four dimensions - Gender Identity, NReg, Religion and SO. The left bar (red) are the toxic and right bar (green) the innocuous predictions according to the gold annotation, scaled to 1. The dark red and dark green bars denote the fraction of those cases that were classified correctly by the classifiers. Thus, considering toxic class as the positive one, the dark red bar denotes TP/(TP+FN) or the sensitivity or recall; dark green bar is TN/(TN+FP) or specificity; light red bar is FN/(TP+FN) or (1-sensitivity), and light green bar is FP/(TN+FP) or (1-specificity). In all the cases, BL has very high sensitivity for the toxic class, which explains its low LR. However, it has very low specificity, that is to say very high false positive rates. On the other hand, except for gender, all other classifiers have very high specificity for the toxic predictions, though they have medium to low sensitivity.

Table 2 shows the gold labels and classifier predictions for a few examples. BL misclassifies the second example as toxic (i.e., overtriggers), whereas TE undertriggers on all toxic examples. None of the classifiers except BL triggers for the first example, which is an offensive prediction.

Fairness of Prediction: In Fig 3 we present the

¹⁰LR computed based on classifier’s final predictions resulting in fewer toxic predictions in absolute terms, even for TE on Rel, compared to no classifier used.

Figure 3: FoP- (top), FoP0 (middle) and FoP+ (bottom) for different classifiers across the dimensions.

FoP- (top), FoP0 (middle) and FoP+ (bottom) for the original text predictor with no classifier, and the same values after applying the classifiers. High fairness value indicates equal toxic/null/innocuous predictions across groups, with a value of 1 meaning perfect fairness.

Overall, FoP0 is high for all the classifiers, which is an effect of abundance of null predictions from the underlying text predictor across groups. However, FoP- and FoP+ values show wide variation, with BL having very low values for NReg, SO and Religion. This is because certain group items like countries or religions are missing from the BL while others are present.

In Fig. 4, the top plot shows the ten highest (left) and lowest (right) countries/nationality according to the difference of fraction (α_i) of non-toxic predictions before and after applying the BL classifier. Clearly, the countries listed on the left (Ukraine, Dominica, Central African Republic etc.) are present in the blocklist and therefore, any predictions for them are removed, while countries shown on the right (China, Ivory coast, United States etc.) are not present. Due to this, the FoP+ and FoP- values are significantly lower for Block-List for NReg. The bottom plot in In Fig. 4 shows the fraction of toxic predictions for religion be-

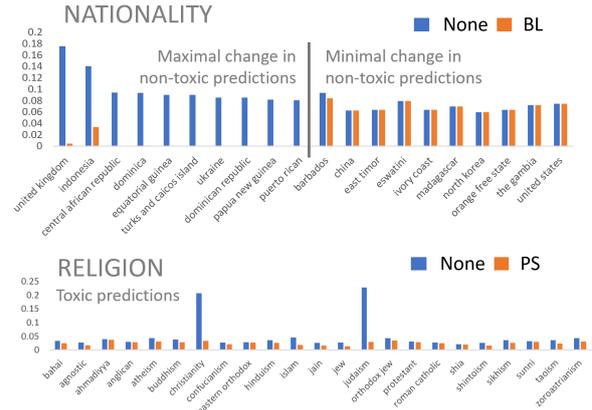

Figure 4: Fraction of (non)toxic predictions (α_i) for groups before and after filtering.

fore and after applying the PS classifier. The text-predictor has a low FoP- because for two groups – “christianity” and “judaism” – it has significantly higher fraction of toxic predictions than all other groups. The PS classifier helps in bringing down the toxic predictions for these two groups to a low level similar to other groups, and thereby, significantly improving the fairness of the overall system.

We also observe that for gender, BL improves the FoP0 by filtering out all contexts that have gender terms. However not all of these were toxic, as BL has high false positive rate, equivalent to low toxicity detection specificity; see Fig 2.

6 Conclusion

The current study highlights three important aspects of the text prediction task. First, it is difficult to estimate the risks of a text predictor due to unavailability of appropriate datasets. Second, off-the-shelf toxicity classifiers have higher leakage ratios than what is acceptable. Although Blocklists provide a potential solution, their context-insensitive nature makes them an extremely conservative solution for long form text prediction. Third, LLM based text-predictors are inherently biased towards more toxic/no/innocuous predictions towards certain groups, and while classifiers can improve the fairness of prediction across the groups, this comes at a cost of suppressing most predictions and bringing down the overall usefulness of the system.

Thus, responsible text-prediction at scale offers several research challenges involving complex trade-off between performance on one hand and risks and fairness on the other. Please contact the last author for the checklists and their fine grained annotations created during this work.

7 Limitations

The present study is limited to text prediction in English. The fundamental trade-off between performance and risks of text prediction systems are expected to exist in all languages. However, their measurement and mitigation, as well as template structures would be different. For instance, languages with grammatical genders (e.g., French and Hindi) might require different analysis techniques.

Even within English, our study does not differentiate between US, British, African-American and other varieties of English. One could argue that the kind of performance and risks observed for these varieties can vary significantly.

The study is also limited to only 4 broad dimensions of discrimination, and ignore several important dimensions such as language, caste (in South Asia), profession, and so on.

Finally, an important practical limitation of the study is that while the observations on the CheckList data are informative of the kinds and extent of errors by the classifiers and/or predictor, they do not provide any estimate of the leakage and risks in the real world, where the distribution of data that a user types is expected to differ significantly from the CheckList generated datasets. Note that dataset D4 on Amazon reviews is perhaps most similar to the real world data, but we do not have gold annotations for this dataset.

8 Ethical Considerations

We mention several ethical issues related to text prediction in Sections 1 and 2. The central issue discussed in this paper, that of the trade-off between performance and risks of text prediction, itself has deep ethical connotations. For instance, one might argue that it is ethically incorrect to deploy a system which poses any risks at all. In other words, the trade-off could be resolved in favor of one extreme (which then is no longer a trade-off). We do not take any such position here, and neither try to provide any guidelines on what should be the ideal trade-off for such an application. There are several factors, including but not limited to, the risk-criticality of the application (for instance typing a CV or legal report, vs. a social media comment) and user's personal preferences, that should be considered before settling for a trade-off. Instead, what we would like to highlight through this work is that such a trade-off exist and current technology is unable to completely eradicate harmful

predictions. Therefore, at the very least, the service provider/app developer of text prediction systems should be aware of the harms and make an effort to inform the user of such potential harms.

We are also aware that the CheckLists were created by a fairly homogeneous (in terms of religion, nationality and race) set of users. Though we have taken utmost care to sensitize the users about various ethical aspects of fairness, a bias in the annotation or template forms cannot be ruled out. Note that we also use two existing CheckLists which were created by different groups. We observe that the trends are fairly consistent across these datasets. On a related note, the definition of what is toxic or inappropriate can also be debated. Indeed, there were several occasions on which the users designing the templates or annotating the examples did not agree on the appropriateness or severity level. These issues were openly discussed in the larger group (including the authors of this paper) to reach an agreement. We are aware that not everybody will align to the decisions that were taken by our group of volunteers. Thus, the dataset created during this study, when used for further research, should be appropriately aligned to the needs and judgements of the researchers/developers and the tasks at hand. The annotation study is covered under IRB ID 10566 and the consent form is available in the appendix.

Acknowledgements

We would like to thank the following people who helped in creating and annotating the checklists: Kabir Ahuja, Lakshya Agrawal, Sapna Bhardwaj, Harshita Diddee, Pamir Gogoi, Ishani Mondal, Anukriti Kumar, Krithika Ramesh, Abhinav Rao and Hemant Yadav.

A Appendix

A.1 Performance Metrics

In this section, we present the detailed results of all the classifiers on all the datasets. We notice that when filtering is enabled, there is a drop in trigger rate and character savings as expected. Overall, we observe a larger drop for blacklist based filtering compared to all the other classifiers for all the datasets. We present the agreement statistics between the classifiers

in Table 5 aggregated over all the datasets, including D4, which could not be annotated for toxicity. The values indicate the sensitivity (recall) of each classifier for the toxic class, against the labels assigned by another classifier. As expected, BlockList has the highest and Perspective API has the least sensitivity. This indirectly hints at the fact that the performance of the classifiers probably is similar on D4 and the other datasets. Overall, there seem to be little agreement between the classifiers.

Full form (Acronyms)

Religion, Race, Ethnicity (RRE)
 Nationality, regionality (NReg)
 Sexual Orientation and Gender Identity (SOGI)
 Offensive to an individual (Off)
 In House Checklist (IHCL)
 Inter-Annotator Agreement (IAA)
 Toxic or Strongly Sensitive (Tox)
 Innocuous or Mildly Sensitive (NTox)
 Blocklist (BL)
 TweetEval (TE)
 HateBert (HB)
 HateXplain (HX)
 Perspective API (PS)
 Trigger rate (TR)
 Match Rate (MR)
 Character Savings (CS)
 Leakage Ratio (LR)
 Fairness of Prediction (FoP)
 FoP for Innocuous predictions (FoP+)
 FoP for Toxic predictions (FoP-)
 True Positive (TP)
 True Negative (TN)
 False Negative (FN)
 False Positive (FP)

Table 4: Acronyms used in the paper with their respective full forms.

	TE	BL	HB	HX	PS
TE	1	0.74	0.72	0.21	0.05
BL	0.14	1	0.23	0.11	0.01
HB	0.39	0.64	1	0.17	0.03
HX	0.30	0.82	0.48	1	0.04
PS	0.92	0.66	0.91	0.46	1

Granularity	Cohen's Kappa	Agreement Percentage
All Separate toxicity	0.213	0.44
Toxic + Strongly Sensitive + Mildly Sensitive Vs Innocuous	0.344	0.684
(Toxic & Strongly as class 1), (Innocuous & Mildly as class 2)	0.473	0.739
1 Diff in sensitivity	0.691	0.778

Table 10: Inter annotator agreement scores for the Text predictor for prediction in context. We have calculated the IAA scores at different granularity. 1-Diff is the case when we consider adjacent toxicity values as similar as is usually the case when a subjective evaluation is performed. A high 1-Diff IAA denotes that the annotators mostly agree on the toxicity for the different queries.

Cohen's Kappa	
Severity	0.57
Factuality	0.72

Table 11: Template level IAA scores for IHCL1 dataset for severity and factuality annotations. The scores indicate a moderate to high agreement scores for the different labels.

Classifier	Sensitivity	Leakage Ratio
None	Mildly Sensitive	0.0698
HateXplain	Mildly Sensitive	0.0629
TweetEval	Mildly Sensitive	0.0605
perspective	Mildly Sensitive	0.0539
HateBert	Mildly Sensitive	0.0527
Blocklists	Mildly Sensitive	0.0208
None	Strongly Sensitive	0.0468
TweetEval	Strongly Sensitive	0.0448
perspective	Strongly Sensitive	0.0445
HateXplain	Strongly Sensitive	0.0438
HateBert	Strongly Sensitive	0.0431
Blocklists	Strongly Sensitive	0.0041
None	Toxic	0.1039
HateXplain	Toxic	0.0894
perspective	Toxic	0.0820
TweetEval	Toxic	0.0761
HateBert	Toxic	0.0494
Blocklists	Toxic	0.0139

Table 12: Leakage ratio wrt different sensitivities for each classifier (Pre and Post). The above values include cases which do not fall into the predefined dimensions as stated in the paper but are part of the checklist datasets. In each of the different scenarios we can see that Blocklists perform significantly better than other classifiers. HateBert comes up second and performs better than other classifiers.

A.2 Annotator Consent Form

Microsoft Research Project Participation Consent Form TITLE OF RESEARCH PROJECT: Responsible AI Data Creation and Annotation

Principal Investigator: Sunayana Sitaram
Co-Investigators: Monojit Choudhury

INTRODUCTION

Thank you for taking the time to consider volunteering in a Microsoft Corporation research project. This form explains what would happen if you joined this research project. Please read it carefully and take as much time as you need. Ask the study team about anything that is not clear. You can ask questions about the study any time.

Participation in this study is voluntary and you will not be penalized if you decide not to take part in the study or if you quit the study later.

PURPOSE

The purpose of this project is to reduce fairness and toxicity harms created by AI systems. We plan to collect data to evaluate current approaches to harm mitigation.

PROCEDURES

During this project, the following will happen: You will be asked to label templates for severity, toxicity and fine-grained category, given a template, lexicon and the coarse grained category for the template. You will also be provided with an example sentence constructed using the template populated with entries from the lexicon. We will give you approximately 100 templates to label and expect each one to take about one minute. You may complete the labeling on your own time over three days. The total amount of time spent should not exceed 120 minutes. Approximately 20 participants will be involved in this study.

PERSONAL INFORMATION AND CONFIDENTIALITY

- **Personal information we collect.** During the project we may collect personal information about you such as name, age, gender, languages known and proficiency in each language.

- **How we use personal information.** The personal information and other data collected during this project will be used primarily to perform research for purposes described in the Purpose and Procedures above. Such information and data, or the results of the research may eventually be used to develop and improve our commercial products, services or technologies.

- **How we store and share your personal information.** Your name and other personal information will not be on the study information we retain; this study information will be identified by a code. The key to the code will be kept separate from your personal and study information, which will be kept in a secured, limited access location.

Your personal information will be stored for a period of up to 5 years.

Some people may need to look at your personal information. They include: the researchers involved in this study, who may be Microsoft full time employees and fixed term employees, such as research interns. We will refer to these people as your Study Team. This also includes Institutional Review Boards (IRB), including Microsoft Research's ethics review board. An IRB is a group that reviews the study to protect your rights as a research participant.

We may choose to share publicly about this study, such as in journal articles, research-focused publications, or presentations at scientific meetings, but your identity will not be disclosed. We will take all steps possible to keep your information confidential. However, we cannot guarantee total confidentiality. For example, your personal information may be given out, if required by law.

- **How you can access and control your per-**

sonal information. If you wish to review or copy any personal information you provided during the study, or if you want us to delete or correct any such data, email your request to the research team at: susitara@microsoft.com. However, once your name or other identifiers have been removed from your information, we will no longer be able to delete it from our records.

For additional information or concerns about how Microsoft handles your personal information, please see the Microsoft Data Privacy Notice (<http://go.microsoft.com/fwlink/?LinkId=518021>).

MICROSOFT AND CONFIDENTIALITY

The research project and information you learn by participating in the project may be confidential to Microsoft. If the study team discloses confidential information, they will ask you to sign a separate, legally binding document called a Non-Disclosure Agreement (NDA) that asks you to promise to keep study information secret.

BENEFITS AND RISKS

Benefits:

There are no direct benefits to you that might reasonably be expected as a result of being in this study. The research team expects to learn how to build AI systems that are fairer and more inclusive from the results of this research. Furthermore, certain public benefits might be expected as a result of sharing the research results with the greater scientific community.

Risks:

During your participation, you may experience discomfort due to the sensitive nature of the data. Specifically, you will be shown sample sentences that could contain explicit, toxic, or potentially offensive terms. To help reduce such risks, you are free to skip the annotation of any template that makes you feel uncomfortable. You can also stop the annotation at any time and either exit the study or return to it after taking a break.

FUTURE USE OF YOUR IDENTIFIABLE INFORMATION

We may use your data in the future. Any data you contribute as part of this study will be stripped of any identifiers or other information that could be

used to identify you, as disclosed previously in this consent form. After such removal, the information could be used for future research studies or distributed to another investigator for future research studies without your (or your legally authorized representative's) additional informed consent.

PAYMENT FOR PARTICIPATION

You will not be paid to take part in this study. Your data may be used to make new products, tests, or findings. These may have value and may be developed and owned by Microsoft and/or others. If this happens, there are no plans to pay you.

PARTICIPATION

Taking part in research is always a choice. If you decide to be in the study, you can change your mind at any time without affecting any rights including payment to which you would otherwise be entitled. If you decide to withdraw, you should contact the person in charge of this study. The study team may use study data already collected from you, however, you may ask for it to be removed when you leave. Microsoft or the person in charge of this study may discontinue the study or your individual participation in the study at any time without your consent for reasons including:

- it is discovered that you do not meet study requirements
- the study is canceled
- administrative reasons

CONTACT INFORMATION

Should you have any questions concerning this project, or if you are injured as a result of being in this study, please contact; Sunayana Sitaram, at (Telephone Number removed for privacy) or susitara@microsoft.com (email). Should you have any questions about your rights as a research subject, please contact the Microsoft Research Ethics Review Program at MSRStudyfeedback@microsoft.com

CONSENT

By completing this form, you confirm that this study was explained to you, you had a chance to ask questions before beginning this study, and all your questions were answered satisfactorily. At any time, you may ask other questions. By completing

this form, you voluntarily consent to participate, and you do not give up any legal rights you have as a study participant.

Abstract

The task of generating a database query from a question in natural language suffers from ambiguity and insufficiently precise description of the goal. The problem is amplified when the system needs to generalize to databases unseen at training. In this paper, we consider the case when, at the test time, the system has access to an external criterion that evaluates the generated queries. The criterion can vary from checking that a query executes without errors to verifying the query on a set of tests. In this setting, we augment neural autoregressive models with a search algorithm that looks for a query satisfying the criterion. We apply our approach to the state-of-the-art semantic parsers and report that it allows us to find many queries passing all the tests on different datasets.

1 Introduction

Generating a database query from a natural-language description of the user’s intent is a long-standing and important task. In the recent years, most of the community focus was on the Spider dataset (Yu et al., 2018), which poses the task in the zero-shot regime, meaning that a method has to generalize to databases unseen at training. The Spider dataset contains English questions and SQL queries. The progress has been remarkable, and the accuracy has moved from below 30% to above 70%. A part of this success can be attributed to the adoption of pre-trained transformer models like BERT (Devlin et al., 2019) into most of the pipelines.

Given such progress, it is natural to ask whether we are getting closer to solving the problem. Several recent studies have noted that the task might be harder than it looks. Finegan-Dollak et al. (2018) found that many single-database datasets had identical queries in both train and test sets and showed that using such splits effectively reduced the problem to classifying the queries from the train set.

Shaw et al. (2021) continued the study in the multi-database setting and showed that the compositional generalization was hard to achieve, and even to measure it, one should be very careful with splits. In a different line of thought, Suhr et al. (2020) examined how the models trained on Spider generalize to other datasets and reported that generalization was challenging. Even within one dataset, many questions have several interpretations leading to different queries, and annotation policies do not cover these ambiguities or cover them differently.

Acknowledging that the zero-shot setting might be too difficult to tackle as is, we aim to better define and simplify the problem to achieve better results in terms of the number of correctly generated queries. In this task, most modern models produce a distribution over all possible outputs, which can guide the search at the test time.

We observe that if the search algorithm has access to a criterion that can evaluate the output by treating it as a database query, the overall method can produce much better results. We consider the following criteria ordered by their “strength”: a query is executed without errors, a query produces output from correct columns, a query produces a correct result on one test database, and a query produces correct results on a set of test databases. We experiment with different search methods and report that the complete anytime beam search (Zhang, 1998) outperforms sampling-based alternatives.

Many practical cases arise when the user is willing to trade off some of their time to improve the output query. Our approach allows the user to obtain a better query by interactively guiding the search via providing the target output columns or the answer on one or more test databases. The user is expected to supply this information without the gold query. Notably, the execution criterion does not require extra user input but relies on executing generated queries.

In addition, the test time database can be out of

* Equal contribution.

domain w.r.t. the training set. One can annotate gold queries for fine-tuning on new databases to improve out-of-domain performance, but this can be prohibitively expensive. Our approach gives a way to improve out-of-domain results without extra annotated training data. We view our approach as a way to control the trained model leading to a more reliable and responsible query synthesis.

For our studies, we used three state-of-the-art models in terms of execution accuracy (with publicly available implementations): T5-3B (Raffel et al., 2020) fine-tuned to Spider by Scholak et al. (2021), BRIDGE (Lin et al., 2020) and SQ-QDMR (Saparina and Osokin, 2021).

In this paper, we make several observations. The complete anytime beam search works with different search criteria and with all the three models. Reasonable results can be obtained with the maximum beam size of 100, which fits on a single modern GPU. Searching with the execution criterion can significantly improve the quality of the decoders that generate output as an unconstrained token sequence, e.g., T5, and using such criterion does not require extra user input. Searching for the queries that return a correct output on one database allows finding many queries that provide a correct output on that database. Therefore, such searching w.r.t. one database can result in false positives, and it is important to evaluate the queries on a set of databases. Based on the method of Zhong et al. (2020), we built the test suite of databases for the evaluation. With these test suites, we show that there are multiple false positives among the queries that pass one test, while searching for the queries that pass the test suite produces the outputs of higher quality.

Finally, we experiment with the generalization of the models trained on Spider to the Geo-Query (Zelle and Mooney, 1996), IMDB, Yelp (Yahmazadeh et al., 2017) and Academic (Li and Jagadish, 2014) datasets. We show that searching w.r.t. different criteria still works under this distribution shift, and searching w.r.t. the criteria with tests is often comparable to fine-tuning the network to a test dataset directly.

This paper is organized as follows. In Section 2, we review our setting. In Section 3, we provide the details of our method. Section 4 provides the details of the test-suite construction procedure, Section 5 describes the experimental setup. In Section 6, we provide the experimental results and

discussion. We review some related works in Section 7 and conclude in Section 8.

2 Preliminaries

We consider the problem of generating queries to databases given the description of the user’s intent in natural language in the cross-database setting where the train, validation and test splits contain different databases. Models trained in this setting, in theory, can be evaluated on any database.

A typical model for the cross-database setting is an encoder-decoder neural network. Encoders typically consist of a pre-trained BERT-like transformer followed by a specialized encoder that can incorporate the database structure in some form (Guo et al., 2019; Wang et al., 2020; Cao et al., 2021; Cai et al., 2021). Sometimes the BERT part is further fine-tuned on database-related objectives (Yu et al., 2021; Deng et al., 2021). The encoder input is a concatenation of the tokenized question and a sentence representation of the database schema separated by the special delimiter token. The representation of the database schema consists of the tokenized table and column names and values related to the question. These values are commonly extracted by string matching with question tokens (Lin et al., 2020). Decoders are typically autoregressive based on LSTM or transformers. Some decoders do not check the syntactic correctness of the output and its consistency with the database. Some provide output w.r.t. a grammar (Yin and Neubig, 2017); some use post-hoc checks with parsers.

In this paper, we experiment with three models: T5-3B fine-tuned on the Spider dataset by Scholak et al. (2021), BRIDGE (Lin et al., 2020) and SQ-QDMR (Saparina and Osokin, 2021). We provide a detailed description of these models in Section 5.3.

3 Search with Models

We now describe our approach to searching for queries on top of a learned model. We first generate full query candidates using a search method and then select the first one that passes the selected search criterion. We show possible search criteria in Section 3.1 and search methods in Section 3.2.

3.1 Search Criteria

Execution criterion. To avoid syntactically incorrect queries, we can prune the search with the execution criterion. The query passes this criterion

if it can be executed on the input database without errors. In particular, the query has to contain valid table and column names. These properties are not guaranteed for the unconstrained decoders as T5. Thus the execution criterion can be extremely useful for such models.

Output column match. With this criterion, we compare the output columns (that the query will select) with the correct ones. Firstly, wrong output columns is a common mistake in the text-to-SQL parsers (Guo et al., 2019; Lin et al., 2020; Suhr et al., 2020). Secondly, the output columns can provide domain knowledge and shed some light on the user intent in a realistic scenario when the input question is ambiguous (Suhr et al., 2020; Lee et al., 2021).

One test. This criterion compares the result of query execution on a given database (one test case) with the correct one. With this criterion, we search for a correct query in terms of execution accuracy on the input database (Section 5.2).

Test suite. This criterion checks if a query passes a set of tests. Each test case corresponds to a particular database, and all test databases share the same schema. This criterion is inspired by a test suite of databases with high code coverage proposed by Zhong et al. (2020). The set of databases is designed to distinguish the correct queries from potential false positives. Searching with this criterion is equivalent to the search for a correct query in terms of test-suite accuracy (Section 5.2).

3.2 Search Methods

Top- k and Top- p (Nucleus) Sampling (Fan et al., 2018; Holtzman et al., 2020) draw samples from the truncated distribution: the probability mass is re-weighted between the k most probable elements in top- k sampling and between the elements with cumulative probability mass exceeding p in top- p sampling (k, p are hyperparameters).

UniqueRandomizer (Shi et al., 2020) is a method to incrementally sample sequences without replacement. The samples are drawn until the stopping condition is reached (one of the search criteria in our case). The probabilities of selected elements are reduced after each iteration of sampling to improve diversity in samples.

Complete Anytime Beam (CAB) Search of Zhang (1998) extends the regular beam search by running it several times with increasing beam sizes. Importantly, the beams produced by beam search

Table 1: Comparison of the test suites’ statistics. **NoEmpty** is the percentage of SQL queries for which at least one test database with non-empty execution result is found; **Cover** is the percentage of neighbor queries distinguished by the test databases; **Tests** is the average number of test databases per query; **Time** is the average wall-clock execution time per query; **Size** is the total size of all test databases.

Dataset		NoEmpty (%) ↑	Cover (%) ↑	Tests (Num)	Time (Sec) ↓	Size (GB) ↓
Spider	1 test	96.7	89.1	1	0.1	3.25
	Orig.	98.2	96.1	675	3.6	0.16
	Our	99.3	98.8	1.8	0.2	0.04

	Orig.	66.7	52.6	108	12.6	0.01
	Our	100	98.9	1.6	0.2	0.05
IMDB	1 test	75.2	14.9	1	8.7	1.49
	Orig.	79.2	79.4	200	17.7	0.04
	Our	100	99.6	2	0.3	0.03
Yelp	1 test	36.5	15.8	1	6.4	2.21
	Orig.	84.1	80.6	282	30.9	0.03
	Our	99.2	97.0	3.1	0.4	0.03
Academic	1 test	51.1	5.50	1	44.2	4.33
	Orig.	97.9	92.1	411	44.3	0.07
	Our	96.8	95.2	2.3	0.4	0.07

are known to have little diversity because of the peaks in the softmax scores. We follow the approach of Zohar and Wolf (2018); Shrivastava et al. (2021), who recently have used CAB to search for programs on top of neural autoregressive models. In these works, the authors limit the number of hypotheses coming from each element of the previous beam (we will refer to this upper bound as the width of the beam search). Between outer CAB iterations, we also increase the width by a constant value and multiply the beam size by a constant factor. The schedules of the beam size and beam-search width are important hyperparameters.

4 Test Suite Construction

Testing on one database is generally not enough to ensure the semantic correctness of the generated query, but running the query on too many databases can be computationally inefficient. The inefficiency problem is especially acute in our task due to the large number of query candidates that should be tested and several rounds of the searching process.

We build our test suites by modifying the method of Zhong et al. (2020), which relies on generating the so-called neighbor queries from a given set of gold queries and randomly sampling databases to distinguish gold queries from as many neighbors

as possible. We observed two key drawbacks of the test databases generated by [Zhong et al. \(2020\)](#). First, the test suites contained many databases, and some were unnecessarily large, which resulted in very long testing on them. Second, outputs of many queries were often empty (or zero for queries with aggregators) on these test databases. If the output of the gold query is empty on all the elements of the test suite, it cannot be distinguished from trivial dummy queries. This effect is more salient if the gold query returns empty output on the original database. We alleviate these issues by independently generating test databases for each gold query, explicitly limiting the number of rows in each table and putting extra effort into generating at least one database where the gold query returns a non-empty output. The details of our procedure are provided in [Appendix A](#).

We compare our test suites with the original ones of [Zhong et al. \(2020\)](#) on the five considered datasets described in [Section 5.1](#). For a fair comparison, we generate the independent sets of neighbor queries for each gold query. These neighbor queries are different from the neighbors generated in the process of creating the test suites. In [Table 1](#), we compare the initial databases (1 test), original test suites and our test suites. It can be seen that, in the space of neighbor queries, our test suites have higher code coverage (Cover) than the original databases and the original test suites. With new test suites, the average query execution time (on all the corresponding tests) is reduced 50x across the datasets. We release the test suites we created.¹

5 Experiment Setup

5.1 Data

We conduct our experiments on five text-to-SQL datasets: multi-database Spider ([Yu et al., 2018](#)) and single-database GeoQuery ([Zelle and Mooney, 1996](#); [Iyer et al., 2017](#); [Finegan-Dollak et al., 2018](#)), IMDB, Yelp ([Yaghmazadeh et al., 2017](#)) and Academic ([Li and Jagadish, 2014](#)).

Spider. We use dev and test sets (451 and 521 examples) from the work of [Saparina and Osokin \(2021\)](#): they are parts of the original Spider dev, but some examples (from dev) were repaired.

GeoQuery, IMDB, Yelp and Academic. We use query splits created by [Finegan-Dollak et al. \(2018\)](#), additionally filtered from duplicates and

examples with gold SQL queries that crash or execute longer than 5 minutes with the Python package `sqlite3`. The dataset statistics are provided in [Table 7](#) of [Appendix D](#).

We do not consider more single-database datasets because ATIS ([Price, 1990](#); [Dahl et al., 1994](#)), Scholar ([Iyer et al., 2017](#)) and Advising ([Finegan-Dollak et al., 2018](#)) database schemes exceed 512 token limits of pre-trained encoders, Restaurants ([Popescua et al., 2003](#); [Tang and Mooney, 2001](#)) contains too many duplicates.

5.2 Evaluation Metrics

Exact-set Match ([Yu et al., 2018](#)) is an SQL-to-SQL comparison metric that reflects the fraction of the predicted queries matching the ground-truth queries. In the matching process, each query is decomposed into fragments that are compared individually so that the metric is not too sensitive to the ordering of independent clauses. This metric does not take into account predicted values and can give a high score to incomplete queries. As SQ-QDMR model produces queries in SPARQL, we cannot use the exact-set match as a primary evaluation metric.

Execution accuracy is designed to compare the queries by their execution output on an original database. In contrast to the exact-set match, this prevents false-negative queries but leaves space for potential false positives. The version provided by [Yu et al. \(2018\)](#) for Spider evaluation has issues in SPARQL-SQL comparison, so we use the version provided by [Saparina and Osokin \(2021\)](#) unless explicitly mentioned otherwise.

Test-suite accuracy ([Zhong et al., 2020](#)) approximates the semantic accuracy of the query synthesis models. This metric refers to the share of predicted queries producing the correct answers on all databases from the test suite. We build the test suites for Spider dev and test sets and for all the queries in the other four considered datasets.

5.3 Models

We consider three models: T5-3B fine-tuned on Spider ([Scholak et al., 2021](#)), BRIDGE ([Lin et al., 2020](#)) and SQ-QDMR ([Saparina and Osokin, 2021](#)). These models have top execution accuracy among publicly available models on Spider. We also tried to search under our search criteria on top of the bottom-up semi-autoregressive model of [Rubin and Berant \(2021\)](#), but we could not make the search increase the number of correct queries.

¹github.com/ramild/TestSuite

For evaluation on Spider, we use the released checkpoints of the best models. BRIDGE training data included question splits of single-database datasets, so we re-train it on Spider-only data to evaluate on query splits of these datasets. For re-training BRIDGE and fine-tuning all models, we use official implementations (see Appendix E).

T5 (Raffel et al., 2020) is a pre-trained seq2seq model based on Transformer. Recently, Shaw et al. (2021); Scholak et al. (2021) successfully applied T5 for the text-to-SQL task. The input sequence contains question tokens and tokens of column and table names. The database values matched with the question tokens are appended to the corresponding column names (Lin et al., 2020). The output of the T5 model is the sequence of tokens representing the SQL query. Note that this model generates output sequence without explicitly considering the SQL grammar and schema consistency.

BRIDGE (Lin et al., 2020) consists of the BERT-based encoder and pointer-generator decoder. The input sequence is formed from the concatenation of question, table and column names, and relevant database values separated by special token and encoded with BERT. The relevant values are selected with fuzzy string matching between question and database values. Column encodings are further enriched with meta-data features such as primary or foreign keys and data types obtained from the feed-forward layer. The LSTM-based decoder with multi-head attention at each step copies question or schema tokens or generates the SQL keywords. During decoding, model chooses columns only from the predicted table to provide schema consistency. An additional static SQL analyzer filters incorrect output queries.

SQ-QDMR (as we refer to the model of Saporina and Osokin (2021)) contains RAT-transformer, GraPPa encoders (Wang et al., 2020; Yu et al., 2021) and a grammar-guided LSTM-based decoder (Yin and Neubig, 2017). The SQ-QDMR decoder produces output in the form of grounded intermediate representations derived from QDMRs of the Break dataset (Wolfson et al., 2020). The grounded QDMRs are not directly related to any execution engine and cannot be executed as is, but Saporina and Osokin (2021) implemented a non-trainable translator from grounded QDMR to the SPARQL query language, in which queries can be executed. We can think of grounded QDMRs augmented with this translator as executable database queries.

Table 2: Comparing the execution accuracy of different search approaches under the 1-test criterion on the Spider dev split.

Model	Greedy	CAB	Sample	Top-p	UniRand
T5-3B	77.0	94.4	93.0	93.0	94.1
BRIDGE	66.8	91.0	87.1	84.9	86.2
SQ-QDMR	80.4	98.0	98.0	98.0	98.2

6 Results & Analysis

6.1 Impact of the Search Methods

We compare different decoding strategies in our setting (Table 2): top- k and top- p (nucleus) sampling (Fan et al., 2018; Holtzman et al., 2020), UniqueRandomizer (Shi et al., 2020) and CAB search (Zhang, 1998). We measure the execution accuracy of these search methods under the 1-test criterion on Spider dev. We use the same sampling budgets (1000 for BRIDGE and SQ-QDMR and 800 for T5-3B due to the memory limits), tune p in top- p sampling and the temperature for all methods, more implementation details in Appendix B).

The results demonstrate that a significant number of output queries pass one test after searching with any of these methods, so different decoding strategies can be compatible with our approach. UniqueRandomizer is very time-consuming since it generates samples sequentially in contrast to other methods that generate beams of samples in parallel. CAB search is demanding in terms of the device memory as it has to process the whole beam jointly. For further experiments, we choose CAB search because it works best for two models.

6.2 Impact of the Search Criteria

We apply search under different selection criteria (execution, output column match, test on one database) to T5-3B, BRIDGE and SQ-QDMR on Spider dataset and compare with the greedy and beam search baselines. Table 3 shows the results measured with execution accuracy. **Searching on top of all models with different selection criteria increases execution accuracy in almost all cases.**

One exception is the search with the execution criterion on top of BRIDGE and SQ-QDMR, the results of which are close to the greedy decoding. The outputs of these systems are almost always executable because BRIDGE runs a static SQL analyzer for filtering, SQ-QDMR decodes according to the QDMR grammar and both models have schema-consistent decoding. The T5 model, in contrast, does not have any grammar or schema

Table 3: Execution accuracy of search under different selection criteria (execution, output column match and 1 test) on Spider; beam s. refers to beam search.

Model	Split	Greedy	Beam S.	Exec	Cols	1 Test
T5-3B		77.0	77.4	83.1	84.2	94.4
BRIDGE	dev	66.8	68.8	68.4	72.0	91.0
SQ-QDMR		80.4	80.6	80.4	83.6	98.0
T5-3B		70.8	71.0	73.7	77.4	90.7
BRIDGE	test	64.0	66.2	64.6	67.9	83.4
SQ-QDMR		65.6	65.8	65.6	68.9	86.7

constraints in decoding. **For language model decoders that do not explicitly check grammar and schema consistency, the execution criterion can significantly improve the quality.**

For T5-3B, we also compare the results of the search with PICARD (Scholak et al., 2021), our search with the execution criterion, and greedy decoding. For a fair comparison with Scholak et al. (2021), we use the same data, the official Spider dev set, and the same metrics: exact-set matching accuracy and execution accuracy provided by Yu et al. (2018):

Method	EM	Exec
Greedy	71.5	74.4
PICARD	75.5	79.3
CAB+execution	74.5	78.7

The results obtained with PICARD and with searching under the execution criterion are comparable – our search gets most of the benefit over the baseline. PICARD provides slightly better quality and works with smaller beams but requires more effort to incorporate because it is tightly connected with the decoder output vocabulary and grammar. For both approaches, the percent of output queries with execution errors is around 2% in contrast to the baseline T5-3B decoding with 12%.

The search criterion based on the matching of output columns provides even better results. As Table 3 shows, all models benefit from this criterion: execution accuracy increases by 3-4% nearly everywhere. This criterion largely simplifies the task with extra information at the test time.

Search for the queries that pass one test allows finding a significant number of such queries. Passing one test means correct execution result on the input database, so all the queries found with this criterion are correct in terms of the execution accuracy. Thus, these results indicate that our searching approach works, and we can find the correct queries with the corresponding criterion. However, we ob-

Table 4: Test-suite accuracy of search under different selection criteria (execution, output column match, 1 test and test suite) on Spider.

Model	Split	Greedy	Exec	Cols	1 Test	Test Suite
T5-3B		72.2	77.7	78.3	86.9	90.1
BRIDGE	dev	63.2	64.8	68.2	81.9	84.0
SQ-QDMR		72.5	72.2	75.4	84.0	94.4
T5-3B		68.9	73.7	75.4	84.7	86.8
BRIDGE	test	61.9	62.5	65.4	76.6	77.8
SQ-QDMR		62.3	62.1	65.4	75.2	84.1

serve that more than 10% of queries found with one-test criterion are false-positive according to the test-suite accuracy (Table 6 in Appendix C).

These results motivate us to evaluate the test-suite accuracy of criterion-guided search. Table 4 confirms our findings: searching with the execution criterion helps T5-3B, and searching for correct output columns improves the results of all models. **Search for the queries that pass one test results in a significant number of false-positive queries. The correct queries can be found by searching with the test-suite criterion directly.**

6.3 Efficiency

Time Measurements. The running time during the search is dominated by the time of the decoder for all three models: executing each considered query takes 3% of the decoder time for T5-3B, which is 0.01 sec per run; 53%, 0.02 sec – for BRIDGE; 72%, 0.03 sec – for SQ-QDMR. The total running time depends on the effective beam size used during the search.

The T5-3B model with the execution criterion on top runs in 1.7 sec compared to 3.1 sec reported by the PICARD paper, where both systems were run on 1 NVIDIA A100 GPU. The main reason is that due to CAB, we do not set one beam size in advance and thus, process at least 70% of examples with an effective beam size of 1.

Impact of the Maximum Size of Beam. The maximum size of the beam is an important parameter. Figure 1 shows the dependence between the obtained test-suite accuracy on the Spider dev set and the maximum beam size in the search under the test suite criterion. For all models, we start with the maximum beam size equal to 1, which is equivalent to the greedy decoding and finish with the maximum beam size allowed by our implementation and hardware: 10k for BRIDGE and SQ-QDMR on 1 NVIDIA V100 GPU and 800 for T5-3B on 8 NVIDIA A100 GPUs.

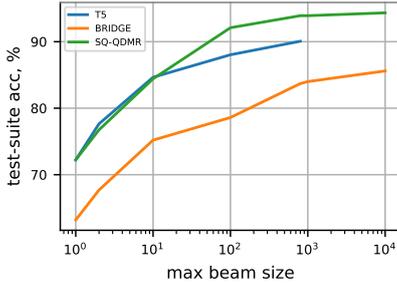

Figure 1: Test-suite accuracy on the dev set for the T5-3B, BRIDGE and SQ-QDMR models tested with CAB for the test-suite criterion.

Test-suite accuracy improves as the maximum beam size increases. BRIDGE with the maximum beam size equal to 10k achieves 86% of test-suite accuracy and SQ-QDMR — 94%. However, the search works well enough even with smaller beams: with the maximum beam size of 100, BRIDGE achieves almost 80%, SQ-QDMR — 92%, and T5-3B achieves 88% (with 800, T5-3B achieves 90%). Importantly, the search with the beam size of 100 does not require multiple GPUs for T5-3B.

6.4 Experiments on Single-Database Data

To show more benefits of searching under selection criteria, we evaluate it on single-database datasets, GeoQuery, IMDB, Yelp and Academic, with test-suite accuracy (Table 5; see Appendix F for execution accuracy). We use query splits of Finegan-Dollak et al. (2018) and two model types: trained on Spider only and fine-tuned on a particular dataset. The Academic database is very large, so we cannot evaluate one-test criterion on this dataset and fine-tune SQ-QDMR (other datasets do not have QDMR annotation required for fine-tuning). More fine-tuning details are in Appendix E.

The results show that models trained on Spider struggle to generalize to other datasets, which is consistent with the findings of Suhr et al. (2020). **More information about the problem (in the form of additional train data or selection criteria) helps improve the quality.**

IMDB, Yelp and Academic are more challenging datasets for cross-database semantic parsers than GeoQuery, but they are significantly smaller (Table 7), and the models are less stable while testing on them (with all random seeds fixed). Stronger criteria, such as passing one test or test suite, do work even with datasets of such difficulty, when weaker criteria fail. On GeoQuery, the search under the one-test and test-suite criteria leads to even better

Table 5: Different search criteria (execution, output column match, 1 test and test suite) on top of pre-trained models on the query test splits of different datasets with the **test-suite accuracy**.

Dataset (test size)	Model	Greedy	Exec	Cols	1 test	Test Suite
GeoQuery (182)	T5-3B	55.5	56.6	63.7	67.6	72.5
	+ fine-tune	64.3	70.9	85.2	88.5	94.5
	BRIDGE	55.9	50	62.6	74.7	74.7
	+ fine-tune	65.4	66.5	81.9	86.8	91.8
	SQ-QDMR	37.4	37.4	41.8	65.9	81.9
	+ fine-tune	56.0	56.0	59.9	76.9	83.0
IMDB (17)	T5-3B	5.9	11.8	17.6	29.4	41.2
	+ fine-tune	52.9	52.9	52.9	52.9	58.8
	BRIDGE	11.8	11.8	17.6	17.6	17.6

quality than fine-tuning. Our test-suite criterion is especially useful when one test is difficult to run on the large original database, e.g., on Academic.

As a result, we conclude that criterion-guided search on top of a pre-trained model is a good alternative to fine-tuning in cases when training data is not available, but the user is ready to provide more information on each test question.

7 Related Works

Search for Database queries. The task of translating NL questions into database queries implies the ability to query databases with natural language. To ensure this, it is essential to generate syntactically correct queries that refer to valid table and column names for the given database schema. Wang et al. (2019) noticed that a partially decoded SQL query can be executed, and thus, the result of this execution can guide the decoding process. At each decoding step, partial queries that crush or give an empty result during the execution are removed from beams. In this work, we also consider the execution criterion of search but apply it to the finished hypotheses, which allows us to search on top of the models with different output formats, including

intermediate representations.

Lin et al. (2020) generated SQL queries in the execution order to keep the consistency between the predicted database entities and checked output correctness with the static SQL parser. Suhr et al. (2020) executed the top-10 generated queries in beam search to filter the inexecutable ones, which is close to checking the execution criterion in our work but differs by the search method.

Task-specific decoders such as autoregressive grammar-based (Yin and Neubig, 2017; Lin et al., 2018) and tree decoders (Dong and Lapata, 2016), semi-autoregressive decoder (Rubin and Berant, 2021) provide some guarantees as they control the output structure. However, as noticed by Scholak et al. (2021), these decoding methods are incompatible with pre-trained decoders of language models. These pre-trained decoders, like the one of T5, can also be successfully applied to the text-to-SQL task (Shaw et al., 2021). Scholak et al. (2021) proposed to check hypotheses in beam search on the lexical and grammatical levels at each step of the beam search. However, compared to us, their approach required heuristics to prune incomplete queries.

The concurrent work by Wolfson et al. (2022) uses several components similar to ours but in a very different way. They use the QDMRs of Wolfson et al. (2020) with textual arguments as a form of weak supervision to generate SQL queries for the training set. Their synthesis process results in many candidate SQL queries and relies on tests to select the one as an annotation. Such a process is similar to the method of Saparina and Osokin (2021) for constructing groundings of QDMR arguments. However, the search process of Wolfson et al. (2022) is not connected to any neural model and is not used at the test time.

Search for Programs with Neural Networks.

Our approach to searching for queries is closely related to the field of program synthesis if we interpret queries as programs. Recently, neural networks have been applied in a wide range of program synthesis tasks, see the excellent work of Chaudhuri et al. (2021) for a recent review.

When programs are synthesized from large language models generating multiple outputs, selecting the one that, e.g., passes some or all tests is a common practice. For example, the Codex model (Chen et al., 2021) for synthesizing Python code includes some sample tests into the input prompt to give the model more information to de-

fine the user intent. Chen et al. (2021) following Kulal et al. (2019), among others, also uses the pass@k metric, which effectively means that the model generates k outputs, and the best ones are selected based on tests. The pass@k metric can be interpreted as test-suite accuracy after search w.r.t. the tests with the beam of size k .

Overall, it is widely accepted that tests are useful to precisely define the user intent. However, they are hard to collect at a large scale, especially when coupled with a description in natural language. Because of this, large-scale benchmarks related to code, e.g., CodeXGLUE (Lu et al., 2021), primarily used text-based metrics like BLEU. The attempts to specialize BLEU to code by combining it with abstract syntax trees extracted from code, like CodeBLEU (Ren et al., 2020), are in some sense similar to the SQL-based exact match metric of the Spider dataset (Yu et al., 2018).

Approaches to Simplify the Cross-database Setting. The community has made multiple attempts to modify the cross-domain setting to make the problem easier to solve. Yu et al. (2019b) collected the SParC dataset with coherent question sequences, which can allow sharing of information between the sequences. Yu et al. (2019a) collected the CoSQL dataset with an interactive conversational setting with SQL queries, making it possible to explore user interactions with the system. Lee et al. (2021) collected KaggleDBQA with database documentation in the form of textual description for database columns that can potentially allow language models to provide outputs better corresponding to the user’s intent. Our approach provides users with a way to interact with the model by supplying tests. Given the initial question in natural language, the users can provide extra tests until they are satisfied with the generated query.

8 Conclusion

We studied the search over the outputs of the neural autoregressive models for better database query generation. We considered three state-of-the-art models: T5-3B, BRIDGE and SQ-QDMR. We observed that the search algorithms work with multiple criteria for selecting the output query. We also compared the search-augmented methods with the fine-tuned models on the GeoQuery, IMDB, Yelp and Academic datasets (under the distribution shift) and observed that the method with search can sometimes work even better than fine-tuning. Com-

pared to fine-tuning, the search-based method does not require additional training data but relies on additional information on each test example. With such properties, our search based methods might be helpful for use cases like interactive query generation or annotating new datasets.

Limitations

In our experiments, we work only with the datasets where the user question was written in English. This might have simplified the task for T5 as the keywords and entity names of the query languages were also in English.

The test suites we built were still not perfect. In particular, it was hard to generate a test database such that the query `SELECT year FROM concert GROUP BY year HAVING count(*) >= 50` had non-empty output because it needed at least 50 rows with the same value in the column `year`. We also noticed that the value 1 as the gold query output also caused many false positives and should probably have been considered the empty value for the queries outputting the count aggregator.

The results of the search methods were also not perfect for out-of-domain data, even with strong search criteria based on tests. One reason for that was that we started to hit the limitations of the models, which were built with mostly Spider in mind. In particular, the database preprocessing stage to select values for the query was, in some cases, slow and inaccurate.

A Construction of Test Suites

The method of Zhong et al. (2020) relies on generating the so-called neighbor queries from a given set of gold queries Q . A set of neighbors N_q is obtained through slightly changing the original query $q \in Q$. Now, a database w distinguishes q and $g \in N_q$ if their execution results on w are different. The suite S is formed greedily: a new sampled database is added to S if it distinguishes a pair in $\mathcal{N} = \{(q, g) \mid q \in Q, g \in N_q\}$ that is not distinguished by any database previously added to S .

In the algorithm above, to sample the databases, the original queries are parsed to derive the constant values and the corresponding columns from the WHERE clauses. For instance, in a query `SELECT * from cars WHERE mpg > 20`, the constants 20 and 21 are assigned some probability to be generated as values of the `cars.mpg` column. We improve the query parser so that it accounts for common cases when table aliases are used (e.g., `SELECT * from cars as T WHERE T.mpg > 20`). Still, if a gold query has too many WHERE clauses, its execution on a randomly generated database is likely to be an empty table or, in the case of SELECT-ing an aggregate function, zeros or NULL values. This issue causes many potential false positives.

For this reason, for every query, we first search for a test database on which the query execution is not empty and only then proceed to check if the database distinguishes the query and its neighbors. This way, the chances are higher to sample at least one database yielding non-empty output on a gold query, leading to better code coverage. We also propose to build a separate test suite for each query. This modification allows dramatically reducing the time of the test-suite evaluation of a query.

Additionally, we make several important changes to the original implementation:

- We limit the number of rows in the tables to 100. As a result, the test suite databases are smaller in size and faster in evaluation.
- We adjust the types of the columns in the original and the sampled databases so that they match the type of the corresponding values. In the float type columns, we also reduce the precision of numbers to 16-bit. These changes are crucial for

SPARQL language, as it is more sensitive to data types than SQL.

- If a column has only unique values in the original database and its name contains special substrings such as ‘Name’, ‘ID’, and ‘Phone’, we treat it as a unique key and generate its values accordingly. This heuristic allows performing the GROUP BY operations on any unique key.

B Implementation Details of Search

For the search on top of T5-3B, we use the (Scholak et al., 2021) model provided in the Transformers library (Wolf et al., 2020). To search with large beam sizes, we modify the Transformers implementation of T5 inference: instead of caching keys and values in attention blocks, we cache the attention outputs, which reduces memory usage at the cost of speed.

For working with SQL queries outside the Spider dataset, we had to replace the SQL parsing coming with Spider due to its limited functionality. We use the `mo-sql-parsing` library instead.² We execute all SQL queries in the `sqlite3`³ package for python. For executing SPARQL queries, we use the open-source version of the Virtuoso system.⁴ During our search, the system generated many cumbersome queries, so we had to impose a strict time limit for each query and make our implementation robust to the database engine crashes. The time limit for Spider queries is 30 seconds and for other datasets is 300 seconds.

The grid of beam sizes for CAB search on top of T5-3B is 2, 10, 100, 800, the corresponding widths are 2, 2, 2, 5, the grid for BRIDGE is 1, 10, 100, 1000 and the widths are 1, 2, 2, 5, the grid for SQ-QDMR is 1, 100, 1000 and the widths are 1, 5, 10. We infer BRIDGE and SQ-QDMR on one NVIDIA V100 GPU and T5-3B on 8 NVIDIA A100 GPUs (while searching with maximum beam size). For the search with the sampling methods, we use the same schema: we run sampling several times, increasing the number of samples (k in top- k) until the selection criterion is passed. The grids for all the methods are the same. For searching with UniqueRandomizer, we run the methods until the selection criterion is passed or the maximum number of iterations is reached (equal to the maximum beam size: 800 for T5-3B and 1000 for BRIDGE and SQ-QDMR). We tune the temperature and p

²github.com/klahnakoski/mo-sql-parsing

³docs.python.org/3/library/sqlite3.html

⁴github.com/openlink/virtuoso-opensource

on Spider dev (the grid for temperature tuning was from 0.5 to 3.5 with 0.25 step; the grid for p was 0.85, 0.9, 0.95). The best $p = 0.95$ and the best temperature values are the following:

Model	CAB	Sample	Top-p	UniRand
T5-3B	2.7	2.4	3.1	2.7
BRIDGE	2.6	3.4	3.7	3.5
SQ-QDMR	1.0	1.3	1.9	1.2

While testing on single-database data, we use the same temperature parameters for the models trained on Spider only. For the fine-tuned models, we also tune temperature on dev sets and choose the values 2.0 for BRIDGE and T5-3B and 1.0 for SQ-QDMR.

C Execution (1-test) Accuracy vs. Test-suite Accuracy

In Table 6, we show the results of the search on Spider with two criteria: passing one test and passing the test suite. For both criteria, we compute execution accuracy (checks the execution result on one database) and test-suite accuracy (checks the execution results on the test suite). For all the models, test-suite accuracy is significantly lower than execution accuracy for the search with the one-test criterion.

Table 6: Execution (EX) and test-suite (TS) accuracy of search with 1-test and test-suite criteria on Spider dev and test.

Model	Split	1 test		Test Suite	
		EX	TS	EX	TS
T5-3B	dev	94.4	86.9	91.4	90.1
BRIDGE		91.0	81.9	87.4	84.0
SQ-QDMR		98.0	84.0	93.7	94.4
T5-3B	test	90.7	84.7	85.5	86.8
BRIDGE		83.4	76.6	77.4	77.8
SQ-QDMR		86.7	75.2	79.7	84.1

D Single-database Datasets

We use the query splits provided by [Finegan-Dollak et al. \(2018\)](#) for four single-database datasets: GeoQuery, IMDB, Yelp and Academic. We choose query splits because they are more difficult than question splits, according to the findings of [Finegan-Dollak et al. \(2018\)](#). We exclude duplicates and examples with gold SQL queries that crash or execute longer than 5 minutes with sqlite3. The statistics of resulted datasets are presented in Table 7.

Table 7: Statistics of single-database data.

Dataset	Train	Dev	Test
GeoQuery	536	159	182
IMDB	103	9	17
Yelp	104	11	10
Academic	142	18	15

E Fine-tuning Details

For fine-tuning on single-database data, we use official implementations of all the models.⁵ We experimented with different training strategies: initializing from released checkpoints of the models trained on Spider and training from scratch (in this case, models contain transformers pre-trained on textual data). We choose the best approach for each model and refer to it as fine-tuning.

We fine-tune T5-3B pre-trained on textual data ([Raffel et al., 2020](#)) for 300 epochs on one NVIDIA A100 GPU with the same parameters as [Scholak et al. \(2021\)](#) used: Adafactor optimizer ([Shazeer and Stern, 2018](#)) with learning rate 1e-4 and batch size 625.

The released checkpoint of the BRIDGE model was trained on data that includes question splits of single-database data that we consider. We re-train this model on Spider-only data to evaluate it on query splits of single-database datasets. We use the same training parameters as [Lin et al. \(2020\)](#) used: Adam optimizer ([Kingma and Ba, 2014](#)) with the same scheduler (L-inv learning rate decay) and batch size 32. We choose the best checkpoint on the development set as [Lin et al. \(2020\)](#) did in their work (execution accuracy and test-suite accuracy of our and authors' checkpoints are the same on Spider dev and test). We use the same training procedure for fine-tuning on single-database data but create training data from both Spider train set and the train set of a particular dataset.

For fine-tuning SQ-QDMR on GeoQuery, we use the corresponding part of the Break dataset ([Wolfson et al., 2020](#)) and generate the 366 train groundings using the automatic annotation model of [Saparina and Osokin \(2021\)](#). We cannot fine-tune on the Academic dataset because its database is large and preprocessing of [Saparina and Osokin \(2021\)](#) failed. QDMR forms for other datasets were not provided in the Break dataset, so we could not fine-tune on them. For fine-tuning on GeoQuery, we start with the released checkpoint and param-

github.com/salesforce/TabularSemanticParsing;
github.com/yandex-research/sparqling-queries;

eters saved on 73000 iterations of Spider training and continue up to 81000 iterations with GeoQuery train data. We also use the same parameters as [Saparina and Osokin \(2021\)](#) used: the optimizer is Adam ([Kingma and Ba, 2014](#)) with polynomial decay scheduler used by ([Wang et al., 2020](#)), the batch size is 24.

We use 1 NVIDIA A100 GPU for training T5-3B, 1 NVIDIA V100 GPU for BRIDGE and 4 NVIDIA V100 GPUs for SQ-QDMR.

F Execution Accuracy of Search on Single-Database Data

Table 8 shows execution accuracy of search on different single-database datasets. We consider two types of models: trained only on Spider data and fine-tuned on single-database data. Comparing with Table 5, the figures are higher because many false-positive queries pass one test (the execution accuracy metric) and do not pass the test suite. For this reason, the results of searching with the test-suite criterion are lower in terms of execution accuracy: if no tested query satisfies the test-suite criterion, the system defaults to the result of the greedy decoding, which may fail one test, while the one-test criterion would select a false positive.

Table 8: Different search criteria (execution, output column match, 1 test and test suite) on top of pre-trained models on the query test splits of different datasets with **execution accuracy**.

Style-Aware Contrastive Learning for Multi-Style Image Captioning

Yucheng Zhou, Guodong Long*

Australian AI Institute, School of Computer Science, FEIT, University of Technology Sydney
yucheng.zhou-1@student.uts.edu.au, guodong.long@uts.edu.au

Abstract

Existing multi-style image captioning methods show promising results in generating a caption with accurate visual content and desired linguistic style. However, existing methods overlook the relationship between linguistic style and visual content. To overcome this drawback, we propose style-aware contrastive learning for multi-style image captioning. First, we present a style-aware visual encoder with contrastive learning to mine potential visual content relevant to style. Moreover, we propose a style-aware triplet contrast objective to distinguish whether the image, style and caption matched. To provide positive and negative samples for contrastive learning, we present three retrieval schemes: object-based retrieval, RoI-based retrieval and triplet-based retrieval, and design a dynamic trade-off function to calculate retrieval scores. Experimental results demonstrate that our approach achieves state-of-the-art performance. In addition, we conduct an extensive analysis to verify the effectiveness of our method.

1 Introduction

Stylized image captioning aims to generate a natural language description with stylized elements for a given image (Mathews et al., 2016; Gan et al., 2017). With the advance of deep learning in human-computer interaction equipment, it has been integrated into many real-world applications like education robots (Zhou, 2022), visual dialog (Das et al., 2017), and vision-language navigation (Wang et al., 2019). Therefore, it has attracted more attention from academia and industry and has become one of the essential areas in the natural language processing (NLP) and computer vision (CV) community.

However, many methods propose translating images into captions of a single caption style (Mathews et al., 2016; Gan et al., 2017). These methods need to train multiple models to handle multiple

Figure 1: (a) the caption is generated by stylized captioning model (Shuster et al., 2019); (b) and (c) show the same caption can correspond to different styles.

styles, which is very inefficient. Therefore, a rising demand for stylized image captioning is to learn an efficient model to handle multiple styles simultaneously. Recently, many efforts have been made in multi-style image captioning (Guo et al., 2019; Shuster et al., 2019; Li and Harrison, 2021).

Despite their success, existing methods suffer from a drawback: They focus on accurate visual content and desired linguistic style but overlook the relation between linguistic style and visual content. As shown in Figure 1(a), the generated caption contains accurate visual content and the desired style, but with misinformation that is easily detectable by humans, i.e., model generates “beautiful” in the caption to cater to the style of “happy”. Indeed, linguistic style (Bell, 1984) reflects personality, emotion and sentiment. In human behavior, these factors significantly influence the course of cognitive behavior (Simon, 1967). When people with different emotions see the same image are likely to describe different contents because they pay attention to different aspects. For example, people who are happy with animals may describe an image of a dog as a pretty dog with sparkling eyes and supple hair. However, one afraid of dogs may describe it as a scary dog with fierce teeth and sharp claws. The former focus on the dog’s eyes and hair, while the latter on the dog’s teeth and paws. Therefore, people with different emotions focus on different potential visual content. To

*Corresponding author.

generate human-like stylized captions, a stylized captioning model should learn to mine potential visual content relevant to different linguistic styles.

Due to the success of contrastive learning (He et al., 2020; Gao et al., 2021), some works (e.g., UNITER (Chen et al., 2020), ViLT (Kim et al., 2021)) employ contrastive learning objectives to encourage cross-modality alignment. In this work, we propose a style-aware visual encoder with contrastive learning to mine potential visual content relevant to styles. Specifically, style-aware visual encoder first mines potential visual features based on given image and style pairs. Then, we use a contrastive loss to pull potential visual features of the anchor and positive pair together while pushing those of anchor and negative pairs apart.

In addition, apart from requiring generated captions with accurate visual content and desired linguistic style, multi-style image captioning also needs to ensure that potential visual content and style are relevant. Moreover, since multi-style image captioning contains more fine-grained styles than single-stylized image captioning, it is difficult to directly distinguish the style by the caption. As shown in Figure 1(b) and (c), captions may be the same for two different styles. Therefore, multi-style image captioning is required to consider if matching among image, style and caption. Different from previous works (Guo et al., 2019) that optimize generated captions only based on style, we propose a style-aware triplet contrast loss, which can learn the triplet matching among image, style, and caption by contrasting it with the positive triplet against negative ones.

Moreover, motivated by hard negatives sampling in retriever training (Zhan et al., 2021), we present three retrieval schemes to mine positive and negative examples for contrastive learning: object-based retrieval, RoI-based retrieval and triplet-based retrieval. These three schemes calculate scores according to object overlap rate, potential visual feature similarity, and triple feature similarity, respectively. Meanwhile, we design a dynamic trade-off function to calculate retrieval scores and analyze the impact of different retrieval schemes.

We conduct an extensive evaluation on three datasets, i.e., PERSONALITY-CAPTIONS (Shuster et al., 2019), SentiCap (Mathews et al., 2016) and FlickrStyle10K (Gan et al., 2017). Our method significantly outperforms other strong competitors and achieves state-of-the-art performance.

2 Related Work

2.1 Image Captioning

Image captioning, one of the essential tasks in multimodal research, aims to generate a description for a given image (Hodosh et al., 2015). With the progress of deep learning, many end-to-end deep neural networks for image captioning are proposed (Vinyals et al., 2015; Anderson et al., 2018; Zhou et al., 2021). Although these works have achieved excellent improvements, the caption generated by these models focuses on a single language domain, which means that their outputs can be in only one style and even dull and lack vitality sometimes.

2.2 Stylized Image Captioning

With the advance in image captioning techniques, researchers have attempted to generate an image caption with style. Mathews et al. (2016) propose a word-level regularization for captioner to model sentiment words. Gan et al. (2017) employ transforming word embeddings matrices to control style factors for generated captions. To accurately describe visual content and reflect the desired linguistic style, some methods (Mathews et al., 2018; Zhao et al., 2020) split a stylized sentence into a style-related part that reflects the linguistic style and a content-related part that contains the visual content. Zhou (2022) employ prompt-based pre-training to build a stylized captioner without any paired sketch and story. These methods alleviate the reliance on paired training data for stylized captioner training. However, these methods need to train multiple models to handle multiple styles, which is inefficient. Therefore, learning an efficient model to handle multiple styles simultaneously raises more interest. Some efforts are made on multi-style image captioning, including adversarial learning network (Guo et al., 2019) and multi-updown fusion model (Li and Harrison, 2021). To generate more diverse outputs, Shuster et al. (2019) collect PERSONALITY-CAPTIONS, a large-scale multi-style image captioning dataset.

2.3 Contrastive Learning

Recently, contrastive learning has made exciting progress in representation learning (He et al., 2020; Gao et al., 2021; Zhou et al., 2022). He et al. (2020) leverage contrastive learning to improve visual presentation learning in an unsupervised manner. Gao et al. (2021) propose a simple unsupervised contrastive learning method to perform on

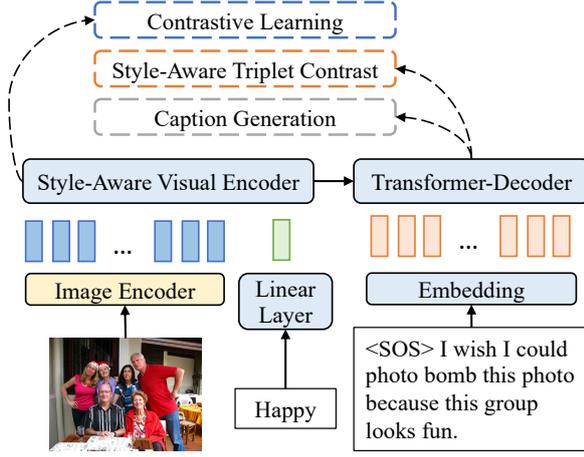

Figure 2: An overview of our proposed SACO model with three objectives. Yellow rounded rectangles denote fixed model. Blue rounded rectangles denote parameters that will be optimized.

par with previously supervised counterparts. Yang et al. (2022) propose triple contrastive learning for vision-language pre-training by leveraging both cross-modal and intra-modal self-supervision, providing complimentary benefits in representation learning. These works show the powerful ability of contrastive learning to improve representation learning.

3 Method

This section will elaborate on our Style-Aware COntrastive learning (SACO) method for multi-style image captioning, followed by our proposed novel retrieval schemes. The details of our approach are shown in Figure 2. Lastly, details about training and fine-tuning are elaborated.

3.1 Image and Style Encoding

Firstly, we pass an image I into a pre-trained convolutional neural network (CNN) to extract its visual feature V and convert the visual feature into a sequence according to the row-first direction:

$$V = \text{CNN}(I) \quad (1)$$

where $V = [v_0, v_1, \dots, v_m], v_i \in \mathbb{R}^{d'}$

In addition, the style S is represented as a one-hot vector and encoded to a style feature s by a linear layer:

$$s = \text{LinearLayer}(S), s \in \mathbb{R}^{d'} \quad (2)$$

Since there is a different dimension between visual feature V and style feature s , a multi-layer

perceptron (MLP) built upon v_i is presented to reduce its dimension to equal the dimension of s :

$$v_i := \text{MLP}(v_i), v_i \in \mathbb{R}^{d'}, \forall i = 1, \dots, m \quad (3)$$

3.2 Style-Aware Visual Encoder

Originating from the observation that different styles will focus on different image regions, we propose a style-aware visual encoder with contrastive learning to mine potential visual content relevant to styles. Since self-attention (Vaswani et al., 2017) shows a strong capability to relate different positions of a sequence for feature computation, we leverage self-attention as backbone of the style-aware visual encoder. Particularly, we concatenate the visual feature V and style feature s , and apply the self-attention layers to them to derive the style-aware visual features V^s and vision-aware style feature s^v , i.e.,

$$[V^s; s^v] = \text{Self-Attention}([V; s]) \quad (4)$$

where $[\cdot; \cdot]$ denotes the operation of concatenation. Intuitively, the success of Eq. (4) requires accurately capturing the visual features relevant to styles, but a major problem arises without artifact labels: *Learning Difficulty*. Motivated by some works (Chen et al., 2020; Kim et al., 2021) implement cross-modality alignment via contrastive learning, we leverage contrastive learning for style-aware visual encoder, which drives its learning to capture potential visual content correlated to given styles without any labeled data. Specifically, we use contrastive learning to learn the representation of potential visual content by contrasting it with the positive example (\hat{V}^s, \hat{s}^v) against those of negative ones $(\bar{V}_i^s, \bar{s}_i^v)$. Particularly, we first derive features (\hat{V}^s, \hat{s}^v) and $(\bar{V}_i^s, \bar{s}_i^v)$ independently via Eq. (1-4). Then, we mine more accurate (V^s, s^v) , style-aware visual features and vision-aware style features, by contrasting it with (\hat{V}^s, \hat{s}^v) against $(\bar{V}_i^s, \bar{s}_i^v)$, i.e.,

$$\begin{aligned} \mathcal{L}^{(svc)} = & -\log \frac{e^{\text{sim}(r, \hat{r})/\tau}}{e^{\text{sim}(r, \hat{r})/\tau} + \sum_{i=1}^M e^{\text{sim}(r, \bar{r}_i)/\tau}} \\ & -\log \frac{e^{\text{sim}(s^v, \hat{s}^v)/\tau}}{e^{\text{sim}(s^v, \hat{s}^v)/\tau} + \sum_{i=1}^M e^{\text{sim}(s^v, \bar{s}_i^v)/\tau}} \end{aligned} \quad (5)$$

where $r = \text{Pooling}(V^s)$
 $\hat{r} = \text{Pooling}(\hat{V}^s)$
 $\bar{r} = \text{Pooling}(\bar{V}_i^s)$

where $\text{sim}(\mathbf{r}, \mathbf{r}')$ is the dot product operation between ℓ_2 normalized \mathbf{r} and \mathbf{r}' (i.e. cosine similarity $\frac{\mathbf{r}^\top \mathbf{r}'}{\|\mathbf{r}\| \cdot \|\mathbf{r}'\|}$) and τ is a temperature hyperparameter to control the pull and push force; M is number of negative samples. As a result, since the style-aware visual features and vision-aware style features also offer a straightforward pathway to transmit style-aware visual information to style-aware visual encoder, it mitigates the *learning difficulty* problem.

3.3 Transformer-Decoder Based Generator

Due to the success of the pre-trained language model, there are some works (e.g., GPT (Radford et al., 2018), GPT-2 (Radford et al., 2019)) pre-train the Transformer decoder (Vaswani et al., 2017) on large-scale corpora. Recently, a fundamental paradigm of text generation tasks is to fine-tune the pre-trained model on the target data, and it can achieve exciting performance. In this work, we leverage a trained transformer decoder to initialize our generator. The generator input is adjusted to the triples $(\mathbf{V}^s, \mathbf{s}^v, \bar{\mathbf{C}})$, where $\bar{\mathbf{C}}$ refers to the segment of stylized image caption. The purpose of generator is to predict a probability distribution of the next word of the segment $\bar{\mathbf{C}}$ based on the given triple, i.e.,

$$\mathbf{h}_i = \text{Trans-Dec}(\mathbf{V}^s, \mathbf{s}^v, \bar{\mathbf{C}}) \in \mathbb{R}^{|d|}$$

where $\bar{\mathbf{C}} = [c_1, \dots, c_{i-1}]$ (6)

$$\mathbf{p}_i = \text{LM-Head}(\mathbf{h}_i) \in \mathbb{R}^{|\mathcal{V}|}$$
 (7)

where \mathbf{h}_i refers to the hidden representation in i -th step; \mathcal{V} denotes token vocabulary and \mathbf{p}_i is a probability distribution over \mathcal{V} . Lastly, the caption generation objective is defined as a maximum likelihood estimation and written as:

$$\mathcal{L}^{(cap)} = -\frac{1}{|N|} \sum_{i=1}^N \log \mathbf{p}_i(c_i),$$
 (8)

where $\mathbf{p}_i(c_i)$ denotes fetching the probability of the i -th step gold token $c_i \in \mathbf{C}$ from \mathbf{p}_i . \mathbf{C} refers to the gold caption and N is its length.

3.4 Style-Aware Triplet Contrast

Different from stylized image captioning for a single style, multi-style image captioning contains more fine-grained styles, and it is difficult to distinguish the style by the caption directly. So multi-style image captioning is required to consider if matching among image, style and caption. Recently, contrastive learning has shown its power capability in alignment between positive pairs and

dispersion between negative ones. Inspired by advances in contrastive learning, we propose a style-aware triplet contrast loss to learn the triplet matching among image, style, and caption by contrasting it with the positive triplet against negative ones. Given an image \mathbf{I} , style \mathbf{S} and caption \mathbf{C} , we first obtain the representation for this triplet. Since visual and style features have fed into the decoder, the triplet representation can be extracted by the hidden representation of the decoder, i.e.,

$$\mathbf{h} = -\frac{1}{|N|} \sum_{i=1}^N \text{MLP}_{\text{triplet}}(\mathbf{h}_i)$$
 (9)

where N is the same as that in Eq.8 and denotes the length of the caption; $\text{MLP}_{\text{triplet}}$ refers to a Multilayer Perceptron; and \mathbf{h}_i can be derived from Eq.6. Then, we enhance the triplet representation \mathbf{h} by contrasting it with a positive triplet $\hat{\mathbf{h}}$ against negative ones $\bar{\mathbf{h}}$, i.e.

$$\mathcal{L}^{(stc)} = -\log \frac{e^{\text{sim}(\mathbf{h}, \hat{\mathbf{h}})/\tau}}{e^{\text{sim}(\mathbf{h}, \hat{\mathbf{h}})/\tau} + \sum_{i=1}^M e^{\text{sim}(\mathbf{h}, \bar{\mathbf{h}})/\tau}}$$
 (10)

where $\text{sim}(\cdot, \cdot)$ is the dot product operation as same as that in Eq.5.

3.5 Retrieval Schemes

In our proposed contrastive learning objective, positive and negative samples are important elements. Since caption datasets are not designed with positive and negative samples, we propose three heuristics to derive positive and negative samples for a triplet of image \mathbf{I} , style \mathbf{S} and caption \mathbf{C} :

Object-based Retrieval. We first leverage a well-trained object detection model (Ren et al., 2015) to obtain object classes in images. Then, we retrieve image $\hat{\mathbf{I}}$ from image set \mathbb{I} according to object overlap with \mathbf{I} , and derive a probability for sampled examples:

$$P_{obj} = \frac{N_{overlap}}{N_{\mathbf{I}}}$$
 (11)

where $N_{\mathbf{I}}$ denotes number of objects in the image \mathbf{I} , and $N_{overlap}$ refers to the number of overlapped objects both in \mathbf{I} and $\hat{\mathbf{I}}$.

RoI-based Retrieval. In this retrieval scheme, the region of interest (RoI) refers to potential visual content relevant to style. We retrieve image $\hat{\mathbf{I}}$ based on the similarity between its representation of potential visual content and that of image \mathbf{I} :

$$P_{roi} = \text{sim}(\mathbf{V}, \hat{\mathbf{V}})$$
 (12)

where V and \hat{V} are the style-aware visual features of I and \hat{I} , and details of their calculation can refer to Eq.5.

Triplet-based Retrieval. Since triplet matching is essential for multi-style image captioning, we retrieve image \hat{I} according to the similarity between triplets:

$$P_{tri} = \text{sim}(\mathbf{h}, \hat{\mathbf{h}}) \quad (13)$$

where \mathbf{h} and $\hat{\mathbf{h}}$ are the triplet representation for the triplet (I, S, C) and $(\hat{I}, \hat{S}, \hat{C})$, and details of their calculation can refer to Eq.10.

Dynamic Trade-off Function. We combine the above three novel retrieval schemes to rank samples, and score of each sample can be defined as:

$$P = \theta^\mu P_{obj} + (1 - \theta^\mu)(\phi P_{roi} + (1 - \phi)P_{tri}) \quad (14)$$

where P denotes the score of samples and ϕ is a trade-off parameter; θ denotes a decay factor and μ is the current training epoch. During training, we randomly select a sample among the top-10 samples as positive one, and the negative samples are randomly sampled based on $P < \max(0.1, P_{max} - \omega^\mu)$.

3.6 Training and Fine-tuning

For model training, we adopt the same 2-stage training scheme (training and fine-tuning) as in (Anderson et al., 2018). In the training stage, we optimize the model according to the three objectives proposed above, and the loss function of our model can be integrated into the following:

$$\mathcal{L} = \mathcal{L}^{(cap)} + \alpha \mathcal{L}^{(svc)} + \beta \mathcal{L}^{(stc)} \quad (15)$$

where α and β are trade-off parameters.

In the fine-tuning stage, we employ the CIDEr score to optimize our model as same as (Rennie et al., 2017), i.e., returning a reward for generated caption \hat{C} .

$$\mathcal{R}^{(CIDEr)} = R_{CIDEr}(\hat{C}) - b \quad (16)$$

where b is a baseline, i.e., the reward $R_{CIDEr}(C^*)$ for the generated caption C^* with greedy search.

4 Experiments

4.1 Dataset and Evaluation Metrics

We evaluate our proposed approach on three datasets, PERSONALITY-CAPTIONS (Shuster et al., 2019), SentiCap (Mathews et al., 2016) and FlickrStyle10K (Gan et al., 2017).

PERSONALITY-CAPTIONS. Shuster et al. (2019) collect a large-scale multi-style image captioning dataset, PERSONALITY-CAPTIONS, which includes 201,858 images, 215 personality traits, and 241,858 stylized captions. We divide the dataset following (Shuster et al., 2019), and the size of the training set, validation set, and test set are 186,858, 5,000, and 10,000, respectively. In the test set, each image contains five reference captions. Following Shuster et al. (2019), we use the same metrics to report our results, and the evaluation is based on the coco-caption code¹. The evaluation metrics include: BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016).

SentiCap & FlickrStyle10K. SentiCap (Mathews et al., 2016) and FlickrStyle10K (Gan et al., 2017) are two publicly stylized image caption datasets. According to (Li et al., 2021), we process SentiCap and FlickrStyle10K datasets, and use samples from MSCOCO (Lin et al., 2014) and Flickr30K (Hodosh et al., 2015) as large-scale paired factual data. Following Li et al. (2021), we use BLEU, METEOR (Banerjee and Lavie, 2005), CIDEr, style classification accuracy (cls.) and the average perplexity (ppl.) as evaluation metrics. Style classification accuracy is measured by a well-trained BERT, which achieves accuracies of 95.9%, 98.0%, 98.1%, and 99.5% on the test sets of humorous, romantic, negative, and positive styles, respectively. The average perplexity is measured by a well-trained trigram-based statistical language model using SRILM toolkit. A lower score denotes that the generated caption is more fluent and reflects the desired linguistic style better.

4.2 Implementation Details

Our approach adopts the same 2-stage training scheme (training and fine-tuning). For training stage, input images are resized to the size of 256×256 , and then we randomly crop the image size as 224×224 as model input. To ensure a fair comparison, we use the ResNeXt-IG-3.5B (Mahajan et al., 2018) as the pre-trained image encoder, as same as (Shuster et al., 2019), and the size of output features is $7 \times 7 \times 2048$. Then, the visual features are reshaped as 49×2048 according to the row-first direction. The style-aware visual encoder is constructed with three self-attention layers. We use a distilled version of pre-trained GPT-2 (Sanh

¹<https://github.com/tylin/coco-caption>

et al., 2019) as our transformer-decoder based generator, as same as (Nguyen et al., 2020). The layers and attention heads of the decoder are 6 and 8. The dimension of embedding vectors and hidden states in the decoder are 768 and 1024. Special tokens for the beginning and end of sentences are <SOS> and <EOS>. In addition, the size of the style linear layer are 215×768 and 5×768 for PERSONALITY-CAPTIONS dataset and SentiCap and FlickrStyle10K datasets. For model training, we utilize the Adam optimizer (Kingma and Ba, 2015) with learning rate of $1e-4$. The batch size, warm-up proportion, weight decay, maximum training epoch and temperature hyperparameter τ are 128, 0.1, 0.01, 10 and 0.08. The trade-off parameter ϕ and decay factor θ in Eq.14 are 0.5 and 0.9. ω for negatives sampling is 0.8. Trade-off parameters α and β in Eq.15 are 0.5 and 0.7. For fine-tuning stage, the maximum training epoch and learning rate are 3 and $1e-5$. Other experimental details are the same as that of training stage. For testing, we use beam search with beam size of 3 to generate captions with maximum sentence length of 30. Our model is trained on one V100 GPU.

4.3 Baselines

We compare our model with the following state-of-the-art baselines: (1) **ShowTell** propose by (Shuster et al., 2019) and is a variant of (Vinyals et al., 2015) that concatenates the style features with the input word vectors at each decoding step. (2) **ShowAtt-Tell**, proposed by (Xu et al., 2015), aims to enhance the correlation between the text and image by an attention mechanism, and the used model is a variant proposed by (Shuster et al., 2019). (3) **UpDown** with a decoder of two LSTMs can adapt to generate attention weights and use it to generate captions (Anderson et al., 2018), and the used model is a variant proposed by (Shuster et al., 2019). (4) **GPT** with an image encoder is fine-tuned on the captioning dataset (Radford et al., 2019). (5) **GPT-Speaker** (Nguyen et al., 2020) employs the language model GPT2 as a language prior for both the speaker and listener in the multi-agent communication framework. (6) **3M** (Li and Harrison, 2021) is a multi-style image captioner that is a multi-UpDown encoder-decoder model integrated with multi-modal features.

4.4 Main Results

Comparison results on PERSONALITY-CAPTIONS test set are shown in Table 1.

Method	B@1	B@4	R	C	S
ShowTell	38.4	7.3	24.3	9.6	1.6
ShowAttTell	43.3	7.1	27.0	12.6	3.6
UpDown	44.4	8.0	27.4	16.5	5.2
GPT	49.2	9.1	29.0	19.0	6.3

Table 2: Comparison results on FlickrStyle10K and SentiCap test set. M denotes METEOR.

From the table, we can make three observations. First, we can observe that our methods achieve state-of-the-art performance on the PERSONALITY-CAPTIONS dataset. Second, models based on GPT reach a better performance than LSTM-based models, which shows the powerful generation capability of transformer-based decoder in stylized caption generation. Lastly, our model significantly outperforms the GPT-2 model by a large margin (i.e., improving 2.0 in CIDEr). That is, style-aware contrastive learning can improve the model by strengthening different style understanding.

In addition, we also show comparison results on FlickrStyle10K and SentiCap test set in Table 2. Competitors include SF-LSTM (Chen et al., 2018), MSCap (Guo et al., 2019) and SAN (Li et al., 2021). Results show that transformer-based methods (i.e., SAN and SACO) outperform LSTM-based methods (i.e., SF-LSTM and MSCap). More-

SACO (Dec w/o style)	53.8	9.4	31.9	20.5	7.8
◇ w/o SVC	52.9	9.0	31.2	20.0	7.5

Table 4: Impact of style-aware visual contrast encoder.

over, compared with strong competitors, our approach achieves state-of-the-art performance on FlickrStyle10K and SentiCap.

4.5 Ablation Study

To demonstrate the effectiveness of our method, we conduct an ablation study and results are shown in Table 3. We first investigate the impact of the style-aware triplet contrast objective by removing it and find that model performance is decreased. Next, we investigate our method without style-aware visual contrast encoder and observe that the performance drops, which is worse than that without SVC. Moreover, we remove both contrastive learning objectives, and results show the performance is degraded again. The observations above demonstrate the effectiveness of style-aware contrastive learning.

4.6 Analysis

4.6.1 Impact of Contrastive Learning

Impact of Style-Aware Visual Contrast Encoder.

To further investigate the impact of the style-aware visual contrast encoder, we remove the input style for our decoder, i.e., the decoder input only consists of V^s, \bar{C} in Eq.6. Results are shown in Table 4. Results show that our decoder without input style outperforms the model without SVC, which demonstrates that style-aware visual contrast encoder can capture potential visual content relevant to the given style.

Method	B@1	B@4	R	C	S
SACO	54.8	9.7	32.6	21.0	8.1
SACO (STC-pointwise)	53.2	9.0	31.4	20.1	7.3
SACO (comp.)	53.0	9.1	31.2	20.2	7.4
◇ w/o STC	52.4	8.7	30.8	19.8	7.3

Table 5: Impact of style-aware triplet contrast.

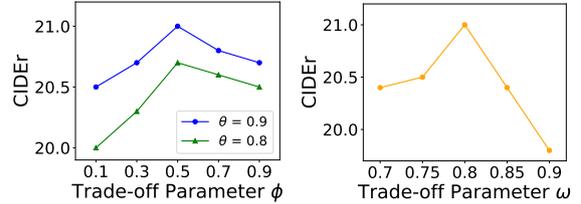

Figure 3: Retrieval schemes ablation.

Impact of Style-Aware Triplet Contrast. To investigate the impact of the style-aware triplet contrast objective, we replace the objective with two binary classification based objectives: point-wise classification and the comp. objective in (Nguyen et al., 2020). As shown in Table 5, results show that binary classification based objectives underperform our contrastive objective, which demonstrates that contrasting positive and negative triplets is helpful for the model to understand triplet matching.

4.6.2 Retrieval Schemes Ablation

Due to contrastive learning depending on positive and negative sampling, we conduct an ablative analysis on retrieval schemes. Results are shown in Figure 3. From left figure, we can make two observations: (1) The decay factor θ set of 0.9 can perform better than that of 0.8. It demonstrates that object-based retrieval is essential in the early training phase. (2) The trade-off parameter ϕ set of 0.5 can achieve the best performance, which shows the vital role of both style-aware contrastive objectives in positive and negative sampling. From right figure, based on the sampling function in §3.5, as ω becomes greater, negative sampling range during training will become greater. We can see that a greater negative sampling range is beneficial for contrasting learning. The reason is that the larger sampling range allows model to access harder negatives. In addition, we find that the performance gradually drops when ω is greater than 0.8, which shows too hard negatives hinder model learning.

4.6.3 Qualitative Comparison

To extensively evaluate our model, we conduct a qualitative comparison of our model and GPT-

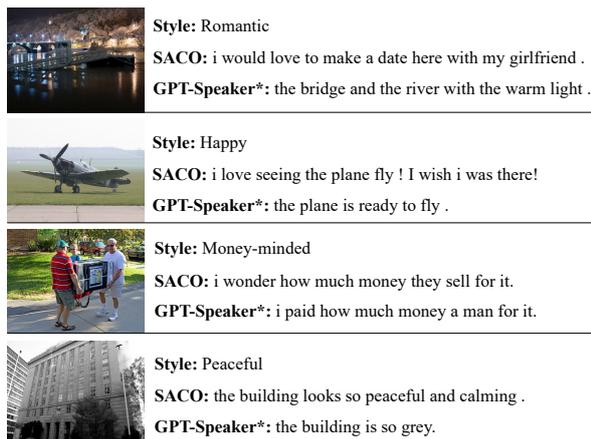

Figure 4: Random sampling examples generated by SACO and GPT-Speaker*.

Figure 5: Interpretable visualization analysis of random sampling examples. The brighter image areas mean more relevant to style.

Speaker, and some random sampling examples are shown in Figure 4. For example, in the first line, we can observe that GPT-Speaker can capture objects in the image and describe them in a caption, but it does not entail style. Therefore, the caption generated by our model is shown to more natural and with desired style. For instance, in the second and last lines, we can find that the caption generated by GPT-Speaker is more like a factual description. In contrast, the caption generated by our model is more expressive of style.

4.6.4 Interpretable Visualization Analysis

To investigate the effectiveness of style-aware visual contrast encoder, we conduct an interpretable visualization analysis, as shown in Figure 5. In the attention map of self-attention layers, the brighter image areas mean greater attention weights, i.e., these areas are more relevant to the given style. As shown in the first example, under the style "money-minded", the object is more paid attention to than the human, which is very intuitive. Next, in the second example, under the style "ex-

Type of evaluation	Win Percentage	
	SACO	GPT-Speaker*
Engagingness	62.9	37.1
Visual Relevance	64.9	35.1
Personalized Relevance	63.4	36.6

Table 6: Human Evaluation.

citing", "a dog of running" are paid more attention and described with "love" and "cute", which are reasonable. Therefore, the results show that the style-aware visual contrast encoder can effectively capture potential visual content related to style.

4.6.5 Human Evaluation

To comprehensively evaluate our method, we conducted a human evaluation to compare our model and GPT-Speaker. Following Nguyen et al. (2020), we considered the engagingness and relevance of captions. Engagingness evaluation considers human preference for the naturalness and appropriateness of the captions, while relevance evaluation involves visual and stylized relevance. Therefore, there are three types of evaluation. We randomly sampled 50 samples from the test set for each evaluation type above. Each sample includes an image and a style. Then, we use our model and GPT-Speaker to generate captions for these samples. We displayed the selected image-style pairs and their caption generated from our model and GPT-Speaker to 7 recruited annotators. They need to judge which captions are better quality based on the type of evaluation. As shown in Table 6, results show that the performance of our model is significantly better than GPT-Speaker, i.e., our model can generate fascinating captions.

5 Conclusion

In this work, we dive into the relationship between linguistic style and visual content. The first is potential visual content has varied for different styles. We propose a style-aware visual encoder that learns to capture the representation of potential visual content. Second, since the model is required to distinguish whether the image, style and caption are matched, we present a style-aware triplet contrast objective to improve the model's capability to discriminate triplet matching. In addition, we propose three novel retrieval schemes to sample positive and negative examples for contrastive learning. Results show that our method delivers new state-of-the-art performance.

Limitations

Although our proposed method can effectively mine latent visual content related to style, it still suffers from weaknesses in generating multiple stylized captions for the same image and style pair. Specifically, our method relies on beam search to generate diverse stylized captions for the same image and style pair and lacks the capability to control content for caption generation interactively. In further work, we will study how to generate stylized captions by interactively selecting specified regions in latent visual content.

Abstract

Conversational tutoring systems (CTSs) aim to help students master educational material with natural language interaction in the form of a dialog. CTSs have become a key pillar in educational data mining research. A key challenge in CTSs is to engage the student in the conversation while exposing them to a diverse set of teaching strategies, akin to a human teacher, thereby, helping them learn in the process. Different from previous work that generates responses given the strategies as input, we propose to jointly predict teaching strategies and generate tutor responses accordingly, which fits a more realistic application scenario. We benchmark several competitive models on three dialog tutoring datasets and propose a unified framework that combines teaching response generation and pedagogical strategy prediction, where a self-distillation mechanism is adopted to guide the teaching strategy learning and facilitate tutor response generation. Our experiments and analyses shed light on how teaching strategies affect dialog tutoring.

1 Introduction

Decades of research effort (Carbonell, 1970; Richardson, 1988; Brown, 2009) has been put into building intelligent tutoring systems (ITSs). An important feature of these systems is the ability to customize the instructional activities and strategies based on the learner’s characteristics and needs (Keleş et al., 2009). Conversational tutoring systems (CTSs) that aim to offer automated tutoring through natural language dialog is a key pillar of ITS research. Earlier work in CTSs was based on conventional techniques such as Bayesian techniques with rule engines (Jeon and Su, 2010; Weragama and Reye, 2014) and hybrid neural networks (Kose and Arslan, 2017; Stasaski et al., 2020). While various advanced neural approaches have been applied to open-domain (Sordani et al., 2015; Serban et al., 2016; Xing et al., 2017) and task-

Teaching Strategy	Tutor Response
Restating	Let me say back what I heard.
Pressing for accuracy	Can you tell us the steps you used to find the answer?

(a) Two examples of teaching strategy and tutor response

Tutor:	Ok, now we have 'get cut off', 'put someone through' and 'get through'	scaffolding
Tutor:	I was talking to her, but suddenly we _____ (I couldn't hear her anymore) Can you choose one?	eliciting
Student:	got cut off	.
Tutor:	yes, good! Well done today! Have a lovely day!	closing

(b) An example of interactions between tutor and student

Figure 1: Examples of teaching strategy and interactions between tutor and student. Teaching strategies in Figure 1(b) are in red.

oriented dialogue systems (Zhao et al., 2017; Lei et al., 2018; Peng et al., 2020), conversational tutoring systems have not benefited from the development of these technologies (Macina et al., 2023).

Human teachers use a number of nuanced teaching strategies in the classroom during interactions with students; these strategies are tailored to keep the students engaged in the conversation and learn knowledge efficiently. We show some examples of teaching strategies and interactions between the tutor and the student in Fig. 1. Previous work has attempted to model these teaching strategies in different ways – e.g., Suresh et al. (2019) contributed a teaching strategy classification model and Stasaski et al. (2020) proposed a response generation model based on given teaching strategies of next response.

In this work, we benchmark several neural dialog models on three conversational tutoring datasets, CIMA (Stasaski et al., 2020), TSCC (Caines et al., 2020) and TalkMoves (Suresh et al., 2019, 2022), and contribute a unified framework based on pre-trained language models, where teaching strat-

egy prediction and response generation are jointly trained. As predicting a teaching strategy merely by the historical context is more difficult than when we are also given the target tutor response, we also propose a pedagogy distillation mechanism that allows teaching strategy prediction to learn from the soft labels which are produced by the prediction with target response. The soft labels learned from the target response provides the model knowledge about various interrelationships between teaching strategies that hard labels lack. This approach is believed to be able to alleviate the learning difficulty (Hinton et al., 2015), which is particularly important, especially when the data imbalance and scarcity issues are severe – often the case in conversational tutoring data.

In summary, we are the first to benchmark¹ several competitive models for conversation tutoring system on all three datasets that are currently available. Besides, we propose a unified framework that can predict teaching strategy and generate tutoring responses accordingly, which is enhanced by a self-distillation mechanism. Our experiments validate the positive effects of teaching strategy to guide generation and the importance of predicting strategy first and then generate response accordingly.

2 Related Work

A classical Intelligent Tutoring System generally has three modules (Brown, 2009; Polson and Richardson, 2013): (i) expert module that includes the knowledge that the student wants to learn (Carter, 2014). (ii) student module that can adjust the level of student (e.g., primary/middle school, non-native/native speaker), student’s knowledge deficiency, etc. (iii) pedagogical module that focuses on the strategies of teaching. In expert module, the knowledge is usually domain specific, such as computer programming (Costello, 2012), mathematics (Grawemeyer et al., 2016; Suresh et al., 2022), Italian (Stasaski et al., 2020), English (Caines et al., 2020). Many technologies have been used in the expert module, such as Bayesian techniques with rule engines (Jeon and Su, 2010; Weragama and Reye, 2014) and hybrid neural networks (Kose and Arslan, 2017; Stasaski et al., 2020). For pedagogical module, to our best knowledge, there are only three publicly available datasets that provide the pedagogy information. They are CIMA (Stasaski

¹The code can be found in <https://github.com/Lingzhi-WANG/TutorSystem>

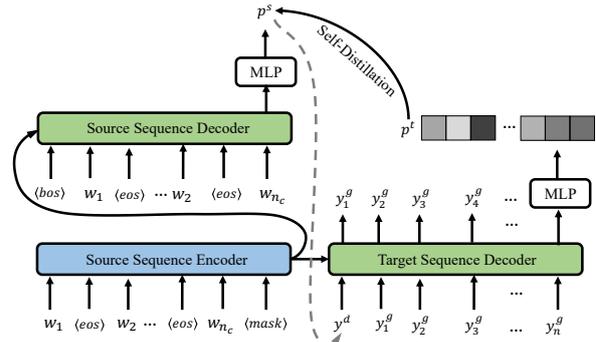

Figure 2: Our overall framework. The self-distillation leverages predictions based on target to improve predictions based on source. The enhanced strategy prediction is further utilized to facilitate the generation.

et al., 2020), TSCC (Caines et al., 2020) and Talk-Moves (Suresh et al., 2022) datasets and all of them are based on single pedagogy. There has been very little work on neural dialog tutoring. Two exceptions to this are Suresh et al. (2022), who propose a simple BiLSTM-based module to predict the pedagogy of the next sentence that teachers are meant to say, and Stasaski et al. (2020) who use various generative models to generate responses given the pedagogical strategies. In contrast, in this work, we propose a joint approach for modelling the pedagogy and response generation that outperforms the previous approaches using a novel pedagogy distillation mechanism.

3 Our Model

3.1 Problem Formulation

Our conversational tutoring system takes conversation context C and teaching strategy list D as input. C is formalized as a sequence of turns $\{t_1, t_2, \dots, t_{n_c}\}$ where n_c represents the number of turns. t_i ($1 \leq i \leq n_c$) denotes the i -th turn of the conversation, and we use w_i to indicate the word tokens contained in it. The teaching strategy list D covers all the possible strategies and contain n_d teaching strategies. Our model will first output one or several strategy labels, each $y^d \in \{1, 2, \dots, n_d\}$, to indicate what teaching strategy to use. Then the generation module generates a target response $y^t = (y_1^t, \dots, y_{n_t}^t)$ based on the predicted strategy.

3.2 Conversational Tutoring System (CTS)

PLM-based Generation Module. The generation module follows a Transformer (Vaswani et al., 2017) sequence-to-sequence framework. As the currently available tutoring datasets are quite small

(containing about 3k conversations), we choose to finetune pretrained language models (PLM) to alleviate data scarcity and enhance context modeling. We finetune BART (Lewis et al., 2020) and multilingual BART(mBART) (Liu et al., 2020) models for our generation module. During finetuning, we concatenate the utterances t_i ($1 \leq i \leq n_c$) in context C with appended $\langle \text{eos} \rangle$ tokens in their chronological order as input, and maximize the probability of the ground-truth target sequence. The whole process is summarized as follows:

$$\mathbf{H}^c = \text{Transformer_Encoder}(\mathbf{w}^c) \quad (1)$$

$$y_k^t = \text{Transformer_Decoder}(y_{<k}^t, \mathbf{H}^c) \quad (2)$$

$$\mathcal{L}_{target}^{gen} = \sum_{k=1}^{n_t} -\log(p(y_k^t | y_{<k}^t, \mathbf{H}^c)) \quad (3)$$

where $\mathbf{w}^c = [w_1; \langle \text{eos} \rangle; w_2; \dots; w_{n_c}; \langle \text{mask} \rangle]$, and $y_{<k}^t$ represents the target tokens before y_k^t . We add $\langle \text{mask} \rangle$ at the end of context, to simulate the operation in pre-training (Schick and Schütze, 2021).

Besides, to summarize the representation of the conversation context, we employ an additional source sequence decoder as follows:

$$y_k^s = \text{Transformer_Decoder}(y_{<k}^s, \mathbf{H}^c) \quad (4)$$

$$\mathcal{L}_{source}^{gen} = \sum_{k=1}^{n_s} -\log(p(y_k^s | y_{<k}^s, \mathbf{H}^c)) \quad (5)$$

where $y_{<k}^s$ represents the source tokens before y_k^s .

Teaching Strategy Prediction Module. We use the representation of the $\langle \text{eos} \rangle$ token (i.e. the final token) produced by the decoder as the representation for teaching strategy prediction, denoted as $\mathbf{h}^{(\text{eos})}$. This is fed into a two-layer MLP for prediction:

$$\mathbf{r}^d = \mathbf{W}_2 \times \alpha(\mathbf{W}_1 \mathbf{h}^{(\text{eos})} + \mathbf{b}_1) + \mathbf{b}_2 \quad (6)$$

where \mathbf{W}_1 , \mathbf{W}_2 , \mathbf{b}_1 and \mathbf{b}_2 are learnable parameters, and α is a non-linear activation function. The output representation \mathbf{r}^d will be an n_d -dimension vector and the probability for each teaching strategy in list D is computed based on \mathbf{r}^d :

$$p(y^d = j) = \text{softmax}(\mathbf{r}^d)_j \quad (7)$$

where y^d denotes the predicted strategy and $j \in \{1, 2, \dots, n_d\}$.

We denote $\mathbf{h}^{(\text{eos})}$ produced by source and target generation as $\mathbf{h}_s^{(\text{eos})}$ and $\mathbf{h}_t^{(\text{eos})}$, respectively. With $\mathbf{h}_s^{(\text{eos})}$, it means that we predict the teaching

strategy without knowing the corresponding content; while with $\mathbf{h}_t^{(\text{eos})}$, we summarize the teaching strategy based on the target content. Obviously, predicting with $\mathbf{h}_s^{(\text{eos})}$ is what we need, but this is quite challenging. Thus we design a self-distillation mechanism which uses prediction based on $\mathbf{h}_t^{(\text{eos})}$ for enhancing the generation model.

Teaching Strategy Enhancement with Distillation. We denote the predicted probability for each strategy (derived with Eq. 7) using $\mathbf{h}_s^{(\text{eos})}$ and $\mathbf{h}_t^{(\text{eos})}$ as $p_s(\cdot)$ and $p_t(\cdot)$, respectively. Our self-distillation is defined as guidance from $p_t(\cdot)$ to $p_s(\cdot)$:

$$\mathcal{L}^{sd} = -\sum_{j=1}^{n_d} p_s(y^d = j) \log p_t(y^d = j) \quad (8)$$

where we define $p_t(\cdot)$ as teacher distribution and $p_s(\cdot)$ as student distribution, and Eq. 8 makes the student distribution similar to the teacher distribution. In this way, our teaching strategy prediction model can also learn from the soft labels produced by the target sequence.

Multiple Teaching Strategies Guided Generation. To guide the response generation with teaching strategy, we regard the teaching strategies as prompt tokens and display them at the beginning of generation. In this way, the target tokens will be generated autoregressively according to the giving teaching strategy. Specifically, during training, we use the ground-truth strategy (denoted as d^c , and it will be masked in distillation to avoid information leakage) for teacher forcing (i.e. $y_0^t = d^c$ in Eq. 3); during inference, we use the predicted strategies produced by the prediction module as prompt tokens.

To enable multiple teaching strategies guidance, we define a threshold θ , where all the strategies satisfying $p_s(y^d = j) \geq \theta$ ($1 \leq j \leq n_d$) will be used to guide the response generation. To that end, we weightedly sum over the embeddings of those strategies as prompt based on their predicted probabilities produced by Eq. 7 and then use it to guide the generation.

3.3 Learning Objectives

The learning objective for teaching strategy prediction is defined as follows:

$$\mathcal{L}^{pred} = -(\log p_s(y^d = d^c) + \log p_t(y^d = d^c)) + \lambda \cdot \mathcal{L}^{sd} \quad (9)$$

where d^c is the ground-truth strategy for context C and λ is a hyper-parameter to control the weights

of self-distillation loss. Our model is jointly trained on both generation and prediction, with the overall objective summarized as:

$$\begin{aligned}\mathcal{L} &= \mathcal{L}^{gen} + \gamma \cdot \mathcal{L}^{pred} \\ &= \mathcal{L}_{target}^{gen} + \delta \cdot \mathcal{L}_{source}^{gen} + \gamma \cdot \mathcal{L}^{pred}\end{aligned}\quad (10)$$

where δ and γ are tradeoff hyper-parameters.

4 Experimental Setup

Datasets. We use three datasets to do the experiments. They are CIMA (Stasaski et al., 2020), TSCC (Caines et al., 2020) and TalkMoves (Suresh et al., 2019, 2022). CIMA contains one-to-one conversations that focus on teaching students to translate a phrase from English to Italian. TSCC focuses on teaching English for eight non-native English-speaking students. TalkMoves is constructed by transcripts of math classrooms.

Parameter Setting. Our implementation is based on Fairseq (Ott et al., 2019). We split the data into 8:1:1 for training, validation and test. All the hyper-parameters are chosen by grid-search based on the validation performance.

We use BART-Base² and mBART-Large³ models to initialize our model, respectively. BART-Base model has 6 layers of encoder and decoder with 768 hidden dimension, while mBART-Large has 12 layers of encoder and decoder with 1024 hidden dimension. The parameter sizes for the two models initialized with BART and mBART are 199M and 816M, respectively.

We use one NVIDIA RTX 3090 GPU to train our model. During training, we set the max tokens of each batch to 1024 (for BART, or 512 for mBART) with an update frequency of 4. We adopt Adam optimizer (Kingma and Ba, 2015) with learning rate selected in $\{1e-4, 5e-5, 2e-5, 1e-5\}$ and warm-up updates selected in $\{200, 500, 1000\}$ followed by a polynomial decay scheduler. Dropout strategy (Srivastava et al., 2014) with dropout rate selected in $\{0.2, 0.4\}$ and L_2 regularization with 0.01 effect value, as well as early stopping based on validation performance, are used to alleviate overfitting. We set the tradeoff values among the losses as $\lambda = 1.0$, $\gamma = 1.0$ and $\delta = 0.2$. During inference, predicting threshold $\theta = 0.3$ and beam size is set to 5.

5 Experimental Results

5.1 Teaching Strategy Prediction Results

We report the accuracy and Macro F1 scores for teaching strategy prediction task in Table 1. We can find that prediction based on the target tutor response performs much better than merely on source context (comparing BART[†] and BART), which indicates that prediction with target content is much easier and also validates our motivation of the self-distillation mechanism. With the help of our proposed distillation mechanism, our models with pre-trained BART or mBART achieve the best performance in the prediction based on source context.

5.2 Tutor Response Generation Results

We then report case-sensitive detokenized sacreBLEU (Post, 2018) and BERTScore (Zhang et al., 2019) for tutor response generation in Table 2.

Three Evaluation Settings. We show results in three settings in Table 2. “W/O TS” means we don’t include teaching strategy (TS) labels in training and testing. “With Golden TS” means providing ground truth TS labels for training and testing. “Need TS Prediction” means models have to predict TS labels in testing and generate the follow-up tutor responses based on the predicted TS labels.

Analysis on Generation Results. From Table 2, we can draw the following main observations.

- *Teaching strategy shows positive effects in generation.* By comparing the results in “W/O TS” and “With Golden TS” settings, we observe that guidance from golden teaching strategies improves the generation performance in general, which validates the effects of teaching strategy in guiding generation. Besides, our models further improve their corresponding baselines (e.g. Our Model(BART) v.s. BART), which should result from the joint learning of generation and strategy prediction.

- *Successful guidance requires accurate teaching strategies.* By comparing results in “With Golden TS” and “Need TS Predict”, we can find that most of the models perform worse when they need to predict strategies first, especially for the baselines with poor strategy prediction performance (refer to results of BiLSTM and Transformer in Table 1). This shows that guidance from inappropriate strategies might even hurt performance, which raises the need for accurate prediction in real-world applications and our proposed method can alleviate the gap significantly.

Student: how to say under in Italian?		
CTS:	[Hint]	“Is under the” is “e sotto il”. Do you know how to say box?
CTS:	[Question]	“Is under the” is “e sotto il”.
Student: La pianta e accanto al coniglio giallo.		
CTS:	[Correction]	You’re very close. but remember that adjective follows the noun.
CTS:	[Confirmation]	Yes, that’s right!

Figure 3: Our CTS generates different responses when giving different teaching strategies (in red).

5.3 Effects of Teaching Strategy

We explore how teaching strategy affects the generation in Fig. 3. We feed our conversational tutoring system (CTS) with different teaching strategies and find that CTS generates totally different responses

regarding the same context input. This also validates that teaching strategy is important for a CTS and strategizing before teaching is also essential.

6 Conclusion

In this work, we benchmarked neural models on various conversational tutoring datasets and proposed a self-distillation based model that jointly trains a teaching strategy prediction model and a response generation model. Experiments on three conversational tutoring datasets show that our model outperforms various standard baselines by a significant margin. Finally, we ended with an interesting case study to demonstrate the importance of strategizing before teaching.

Limitations

There are only three publicly available datasets (CIMA, TSCC and TalkMoves) for conversational tutoring task and they are quite small (less than 10K instances). There are significant data imbalance problems in these datasets – some teaching strategies occur much more frequently than others. These small and imbalanced datasets bring a lot of challenges to this task, but we did not discuss these issues in our paper due to the space limit. Besides, there are no standard teaching strategy annotation schemes, which prevents us from combining these three datasets together for more interesting experimental analyses. Another limitation of our work is that we only evaluate our approaches on automatic generation metrics. In the future, it would be interesting to also evaluate the model on learning related evaluations.

Abstract

In the task of incremental few-shot relation classification, model performance is always limited by the incompatibility between the base feature embedding space and the novel feature embedding space. To tackle the issue, we propose a novel model named ICA-Proto: Iterative Cross Alignment prototypical network. Specifically, we incorporate the query representation into the encoding of novel prototypes and utilize the query-aware prototypes to update the query representation at the same time. Further, we implement the above process iteratively to achieve more interaction. In addition, a novel prototype quadruplet loss is designed to regulate the spatial distributions of embedding space, so as to make it easier for the relation classification. Experimental results on two benchmark datasets demonstrate that ICA-Proto significantly outperforms the state-of-the-art baseline model.

1 Introduction

Relation classification (RC) is an important sub-task of relation extraction (RE), aims at classifying the relation between two marked entities in a given sentence. For example, the instance “[Newton]_{e1} served as the president of [the Royal Society]_{e2}” expresses the relation *member_of* between the two entities *Newton* and *the Royal Society*. Some conventional methods (Zeng et al., 2014; Gormley et al., 2015; Soares et al., 2019) for relation classification adopt supervised training and usually suffer from the scarcity of manually annotated data. To alleviate this problem, distant supervision (DS) is adopted to automatically label abundant training instances by heuristically aligning knowledge graphs (KGs) with texts (Mintz et al., 2009). However, existing DS-based methods fail to deal with the problem of long-tail relations in KGs and still suffer from data deficiency (Han et al., 2018).

* Equal contribution.

† Corresponding authors.

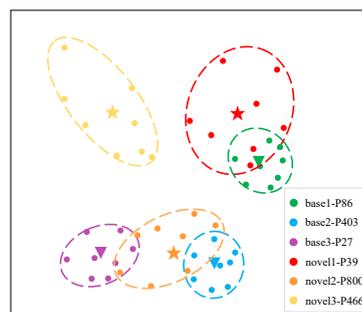

Figure 1: Visualization of the representations of the query instances and prototypes of BERT-IncreProto. We randomly sampled three base relations and three novel relations from the real-world dataset FewRel 1.0, each relation with its corresponding prototype (triangles for base relations and stars for novel relations) and eight query instances (points).

To address the above long-tail problem, few-shot RC was proposed, which formulates RC in a few-shot learning scenario. This task requires the models trained with base relations to generalize well to novel relations with only few labeled instances. Base relations are those relations that contain adequate instances and can be utilized effectively in the training phase to mimic the test phase on novel relations with few samples. Fine-tuning pre-trained models (Bengio, 2012; Gao et al., 2020) is straightforward while suffering from the overfitting problem. Therefore, metric-based methods (Ravi and Larochelle, 2017; Dong et al., 2020; Geng et al., 2020; Liu et al., 2020b) were proposed to grasp the fast-learning ability from previous experiences and then quickly generalize to new concept. These methods have been experimentally proven to be effective.

Taking a step further, incremental few-shot RC (Ren et al., 2020) considers a more realistic scenario, where the model is required to dynamically recognize the novel relations with a few samples, without reducing the base relation identification

capability learned on the large-scale data of base relations. Hence in the test phase, the query set consists of instances of not only base relations but also novel relations, which is more challenging. Several related works (Liu et al., 2020a; Chen and Lee, 2020; Kukleva et al., 2021) have been proposed in the field of computer vision, focusing on image classification task. As for the task of incremental few-shot RC, InceProtoNet (Ren et al., 2020) is the first work, which proposes a two-phase prototypical network model.

Specifically, InceProtoNet contains two separate prototypical networks (Snell et al., 2017). One is pre-trained in the first phase to acquire the base prototypes and base feature extractor, and the other obtains the novel prototypes and novel feature encoder with few-shot episode training in the second phase. However, InceProtoNet suffers from insufficient interaction between the class prototypes and the query instances. Therefore, in the embedding space, the novel relations often overlap significantly with the base relations, and the query representations are scattered, as shown in Figure 1. In addition, the triplet loss used by InceProtoNet may be affected by noise samples, and its effectiveness decreases on tasks with domain shift. As a result, a low accuracy in the recognition of novel relationships has been observed.

To alleviate the above problem, we propose a novel model named ICA-Proto that contains a specially-designed ICA module. ICA module consists of two sub-modules, i.e., *Cross Alignment* (CA) and *Iterative Alignment* (IA). Specifically, CA is built to dynamically and interactively encode the novel prototypes and query instances. On the one hand, the obtaining of novel prototypes is query-aware, namely that the query-related support instances contribute more to the final prototypes. On the other hand, the encoding of query instances is prototype-aware, since the query-related prototypes have more influence on the query representations. Furthermore, to achieve sufficient interaction and alignment, we construct IA, which is to implement the above CA iteratively. In addition, *Prototype Quadruplet* (PQ) loss is proposed to enlarge the distance between different types of prototypes, while making the distance between query and prototype of the same class as close as possible.

The contributions of this paper can be summarized below:

- We propose a novel incremental few-shot clas-

sification model ICA-Proto, which is able to dynamically recognize the novel relations with a few support instances.

- We design a novel and effective ICA module which learns the representations of the query instances and the novel prototypes interactively and iteratively. Besides, a novel prototype quadruplet loss is presented to regulate the feature space distribution.
- Experiments on FewRel 1.0 and 2.0 datasets demonstrate that our method significantly outperforms the state-of-the-art method.

2 Task Formulation

In the task of incremental few-shot RC, first we are given a large dataset containing N_{base} base relations: $D_{base} = \cup_{b=1}^{N_{base}} \{I_{b,i} = (x_{b,i}, h_{b,i}, t_{b,i}, r_b)\}_{i=1}^{K_b}$, in which K_b is the number of instances of relation r_b , and $I_{b,i}$ represents its i -th instance consisting of the sentence $x_{b,i}$ and the mentioned entity pair $(h_{b,i}, t_{b,i})$. Then we are given a support set

$S = \cup_{n=1}^{N_{novel}} \{I'_{n,i}\}_{i=1}^{K'_n}$ of N_{novel} novel relations,

where K'_n is the number of support instances of novel relation r'_n and $I'_{n,i}$ is the i -th supporting instance. With D_{base} and S , the task is to recognize the relations of the instances in the query set

$Q = \cup_{q=1}^{N_{base}+N_{novel}} \{I''_{q,i}\}_{i=1}^{K''_q}$, in which K''_q is the

number of query instances of relation r''_q and $I''_{q,i}$ is its i -th query instance. Therefore, the model is required to dynamically recognize the novel relations based on a few novel support instances while keeping the base relation identification capability learned on the large base dataset.

3 Method

In this section, we elaborate on the details of our proposed ICA-Proto model for incremental few-shot RC. First, we give a brief introduction to the InceProtoNet in Section 3.1. Then, we introduce the overall framework of our model in Section 3.2. Next, we present the proposed ICA module with CA and IA sub-modules in Section 3.3. Moreover, the proposed PQ loss is discussed in Section 3.4.

3.1 Introduction to InceProtoNet

InceProtoNet (Ren et al., 2020) is the first work focusing on incremental few-shot RC. The proposed model is a two-phase prototypical network.

In the first phase, a deep prototypical network, consisting of a convolutional neural network based encoder and a prototype based classifier, is pre-trained on a large training dataset for base relations in a supervised manner to learn the feature embedding space of base relations. Therefore, the base prototypes, denoted $P_{base} = \{p_1, p_2, \dots, p_{N_{base}}\}$, can be obtained by averaging the representations of all training instances within each base class b :

$$p_b = \frac{1}{K_b} \sum_{i=1}^{K_b} x_{b,i}, \quad (1)$$

where $x_{b,i}$ is the embedding of $I_{b,i}$ through the base encoder.

In the second phase, another prototypical network, named incremental few-shot prototypical network, is proposed to learn the feature embedding space of novel relations. The support set is encoded to obtain the novel prototypes $P_{novel} = \{p'_1, p'_2, \dots, p'_{N_{novel}}\}$ as follows:

$$p'_n = \frac{1}{K'_n} \sum_{i=1}^{K'_n} x'_{n,i}, \quad (2)$$

where $x'_{n,i}$ is the embedding of $I'_{n,i}$ through the novel encoder. For a query instance q from the query set, the representation x_q is calculated as the weighted sum of the x_q^{base} from the base feature embedding space and x_q^{novel} from the novel feature embedding space:

$$x_q = \omega_b x_q^{base} + \omega_n x_q^{novel}, \quad (3)$$

where the weights ω_b and ω_n are determined by considering the similarity of the query representation with the base prototypes P_{base} and novel prototypes P_{novel} , respectively. To better show the relationships, we summarize and rewrite the query representation calculation equation (3) as:

$$x_q = f(x_q^{base}, x_q^{novel}, P_{base}, P_{novel}), \quad (4)$$

where f is a composite function and represents a series of attention operations. More details can be found in the original paper (Ren et al., 2020). Lastly, the probability of q belonging to the i -th relation r_i can be measured as:

$$p_\theta(r_i | q) = \frac{\exp(-d(\mathbf{x}_q, \mathbf{p}_i^{all}))}{\sum_{j=1}^{N_{base} + N_{novel}} \exp(-d(\mathbf{x}_q, \mathbf{p}_j^{all}))}, \quad (5)$$

where \mathbf{p}_i^{all} is the i -th prototype in $\mathbf{P}_{all} = \{P_{base}, P_{novel}\}$.

Although IncreProtoNet performs well in recognizing instances of base relations, it is still difficult for this model to deal with novel relations. The experimental results in Ren et al. (2020) show that the accuracy for novel relations is much lower than that of base relations, which is unsatisfactory. There are several reasons as follows. First, IncreProtoNet obtains the novel prototypes independent of the query instance, lacking interaction between them. Second, IncreProtoNet ignores the alignment between base relations and novel relations, which is vital in incremental learning scenarios. Third, there is no effective regulation to the feature embedding spaces of base relations and novel relations, which causes discrepancy between them.

3.2 Overall Framework of ICA-Proto

To tackle the above issues, we propose the ICA-Proto model on the basis of IncreProtoNet. Similar to IncreProtoNet, our model contains two stages, including the base pretraining stage and the few-shot episode training stage. Furthermore, we innovatively propose the ICA module and PQ loss, of which ICA module is demonstrated in the dashed boxes in Figure 2.

3.3 Iterative Cross Alignment

In the task of incremental few-shot RC, it is important to make an alignment between the base feature embedding space and the novel feature embedding space so as to flexibly encode the query instance and further make correct relation classification. This requires full interaction between base relations and novel relations. To this end, we propose the ICA module, which consists of CA and IA sub-modules.

Cross Alignment. To this end, the CA sub-module is designed to encode the novel prototypes and the query instance in an interactive manner. To be specific, we first initialize the novel prototypes P_{novel} and the query instance embedding x_q with equations (2) and (4), respectively. Then, CA updates $p'_n \in P_{novel}$, encouraging the model pay more attention to those query-related supporting instances,

$$p'_n = \sum_{i=1}^{K'_n} \gamma_{n,i} x'_{n,i}, \quad (6)$$

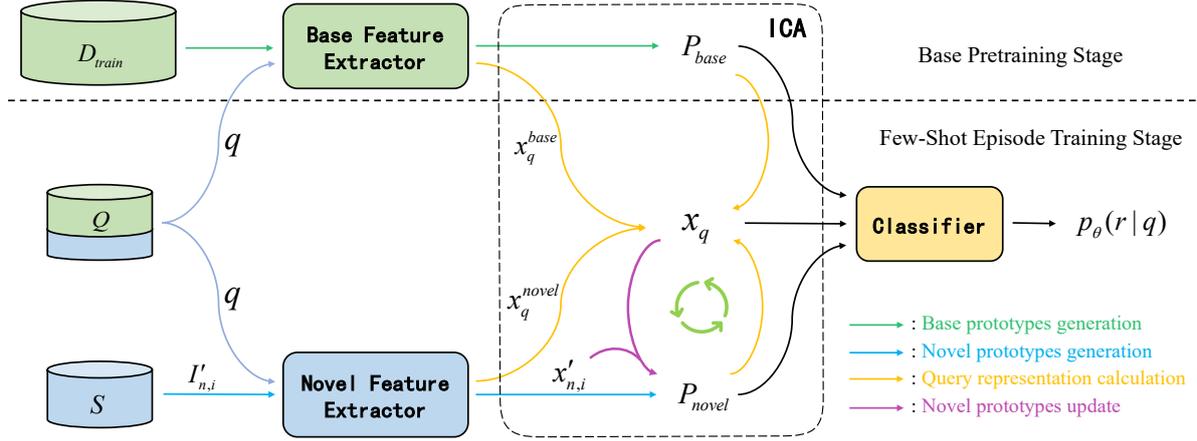

Figure 2: The framework of ICA-Proto. In the dashed box representing ICA module, the yellow arrows refer to the process of the query representation calculation, while the purple arrows means the process of the novel prototypes update. The green loop arrows represents the iterative refining of both query representation and novel prototypes.

where $\gamma_{n,i}$ is defined as:

$$\gamma_{n,i} = \frac{\exp(-d(x_q, x'_{n,i}))}{\sum_{i=1}^{K'_n} \exp(-d(x_q, x'_{n,i}))}, \quad (7)$$

where d is the euclidean distance. In short, the novel prototype embedding process can be summarized as:

$$P_{novel} = g(x_q, \cup_{n=1}^{N_{novel}} \{I'_{n,i}\}_{i=1}^{K'_n}). \quad (8)$$

Correspondingly, the query instance representation x_q is further updated with equation (4), which requires the model to pay more attention to the query-related base prototypes and novel prototypes. Since most of the query instances belong to base relations, CA actually enhances the interaction between instances of base relations and novel relations, achieving better alignment between the two feature embedding spaces.

Iterative Alignment. The aligned query representation can help group the different support samples from the same novel class together to optimize the novel prototype. Meanwhile, the optimized novel prototype can further help align query representations from different encoders. Inspired by traditional iterative cross-optimization algorithms, such as the EM (McLachlan and Krishnan, 2007) or k -means (Hartigan and Wong, 1979) algorithms, we further propose to carry out the above CA in an iterative way, namely Iterative Alignment (IA). The implementation is straightforward, since we just need to iteratively update P_{novel} and x_q with equations (6) and (4), respectively, until the predefined

Algorithm 1 Iterative Cross Alignment

Input: Base prototypes P_{base} , support set S , query instance q and predefined maximum iteration number N .

Parameter: Base encoder Θ_1 and novel encoder Θ_2 .

Output: Novel prototypes P_{novel} , query instance representation x_q and probability distribution for relation of q : $p_{\theta}(r | q)$.

- 1: Initialize novel prototypes P_{novel} with equation (1).
 - 2: Initialize query instance representation x_q with equation (2).
 - 3: **for** $t = 1 \rightarrow N$ **do**
 - 4: Update query representation x_q^t :
 $x_q^t = f(x_q^{base}, x_q^{novel}, P_{base}, P_{novel}^{t-1})$,
 - 5: Update novel prototypes P_{novel}^{t+1} :
 $P_{novel}^{t+1} = g(x_q^t, \cup_{n=1}^{N_{novel}} \{I'_{n,i}\}_{i=1}^{K'_n})$.
 - 6: **end for**
 - 7: **return** P_{novel} , x_q and $p_{\theta}(r | q)$.
-

maximum number of steps is reached. Finally, the refined novel prototypes and query instance representations are obtained. The IA expands CA from single round to multiple rounds, further promoting the interaction and alignment.

Algorithm 1 outlines the key steps of our ICA module.

ICA for Increment Few-Shot Domain Adaptation. In the real world, especially in the few-shot

scenario, the test domain (new classes) and training domain (base classes) are often different, so how to improve the ability of our model to transfer across domains is also very important. Since the test domain usually has no annotations and could differ vastly from the training domain, we first initialize novel class prototypes with average representation of support set instances and query representations with initialized novel class prototypes. Then CA cross-aligns novel support instances and query from different domains. Furthermore, in the cross-domain scenario, the initial query and the novel prototypes are more likely to be incompatible; therefore, the ICA module can significantly improve the representations of the novel prototypes and the query from different domains.

3.4 Prototype Quadruplet Loss

In our method, there are two feature embedding spaces for base and novel classes separately and the query instance is encoded by the two jointly. Therefore, it is important to measure which embedding space contributes more and further estimate which prototype is the nearest. In addition, the feature spaces of base classes and novel classes should be separated as much as possible when they are embedded into the same space. To this end, we design a novel *Prototype Quadruplet* loss (\mathcal{L}_{PQ}), denoted as follows:

$$\mathcal{L}_{PQ} = \sum_{i=1}^M \sum_{k=1}^{N_{novel}} \max(0, \delta_1 + d_1 - d_2) + \max(0, \delta_2 + d_1 - d_3), \quad (9)$$

where δ_1 and δ_2 are hyper-parameters, M is the total number of training episodes, and three distances d_1, d_2, d_3 are defined as follows:

$$d_1 = d\left(f\left(a_i^k\right), P_{p,i}^k\right), \quad (10)$$

$$d_2 = d\left(f\left(a_i^k\right), P_{n,i}^k\right), \quad (11)$$

$$d_3 = d\left(P_{n,novel,i}^k, P_{n,base,i}^k\right), \quad (12)$$

where $\left(a_i^k, P_{p,i}^k, P_{n,novel,i}^k, P_{n,base,i}^k\right)$ is a quadruplet consisting of the anchor instance, the positive prototype from the same novel class, the first negative prototype from another novel class and the second negative prototype from one of the base classes, $f(\cdot)$ is the feature extractor, and $P_{n,i}^k$ is

randomly selected from $P_{n,novel,i}^k$ or $P_{n,base,i}^k$. Unlike IncreProtoNet, inspired by the triplet-center loss (He et al., 2018), which can further enhance the discriminative power of the features, we also learn the center representation of each class and then require that the distances between anchors and centers from the same class are smaller than those from different classes. Note that $P_{p,i}^k, P_{n,novel,i}^k, P_{n,base,i}^k$ are all virtual instances and denote the corresponding prototypes.

In addition, to enhance the abilities of our model to transfer across domains, inspired by the quadruplet loss (Chen et al., 2017) which introduces the absolute distance between the positive and negative sample pairs, we add d_3 to better align different domains, which narrows the domain gap and further alleviates the issue of incompatible feature embedding between base classes and novel classes, so as to achieve more effective domain adaptation.

Finally, the joint loss function \mathcal{L} is a trade-off between the cross-entropy loss \mathcal{L}_{CE} and the above \mathcal{L}_{PQ} by a hyper-parameter λ :

$$\mathcal{L} = \mathcal{L}_{CE} + \lambda \cdot \mathcal{L}_{PQ}. \quad (13)$$

4 Experiments

4.1 Datasets and Evaluation Metrics

Datasets. We carry out extensive experiments on two benchmark datasets. The first one is FewRel 1.0 (Han et al., 2018), which contains 80 relations and provides 700 instances for each relation. We adopt the same split as Ren et al. (2020). To be specific, 54 relations are randomly selected as the base relations each with 550 instances for base pre-training, 50 instances for episode training and 100 instances for testing. 10 other relations each with 700 instances are sampled as the novel relations for the episode training. The rest 16 relations each with 700 instances are used as the novel relations in testing. The other dataset is FewRel 2.0 (Gao et al., 2019b), which is constructed on top of the FewRel 1.0 by adding a new test set in a quite different domain (i.e., medicine), requiring the models to transfer across domains.

Evaluation Metrics. To compare our proposed method with the state-of-the-art methods, we adopt the same evaluation metrics as Ren et al. (2020), namely, three kinds of classification accuracy, including classification accuracy for instances of base relations, novel relations, and all relations. Since

Table 1: Average classification accuracy (%) on the FewRel 1.0 dataset.

BERT-ICA-Proto	82.56 ± 0.02	63.25 ± 0.09	80.93 ± 0.08	84.89 ± 0.05	69.49 ± 0.06	83.59 ± 0.04

the number of base relations is much larger than that of novel relations, the classification accuracy for instances of all relations depends largely on that of base relations.

4.2 Implementation Details

To systematically validate the effectiveness of the proposed ICA-Proto model, we experiment with two kinds of word embedding initialization methods, namely, GloVe (Pennington et al., 2014) and BERT (Devlin et al., 2019). Besides, the compared methods are all evaluated in both 1-shot and 5-shot learning. The hidden dimension of feature extractor is 230, as well as the prototype dimension. The stochastic gradient descent (SGD) is employed for optimization and the initial learning rate in episode training is set as 0.1, except for BERT as 0.001. For the PQ loss, the two margins δ_1 and δ_2 are set as 5.0 and 10.0 respectively, while the balance weight λ is set as 1.0.

4.3 Comparison Methods

First of all, we compare with several few-shot learning models, namely, Proto (Han et al., 2018), HATT-Proto (Gao et al., 2019a) and BERT-PAIR (Gao et al., 2019b) and the incremental few-shot learning model ProtoNet (Increment) (Snell et al., 2017). Besides, following (Ren et al., 2020), we compare with Imprint (Qi et al., 2018) and LwoF (Gidaris and Komodakis, 2018), which are the incremental few-shot learning models in the computer vision field. Finally, we take IncreProtoNet as our baseline, which is the current state of the art.

4.4 Main Results

Our model gains significant improvement in incremental few-shot learning tasks. From Table 1, we can observe that for the FewRel 1.0 dataset, our model achieves the best in both 1-shot and 5-shot tasks. Compared with the best baseline model IncreProtoNet, our model remarkably improves the novel class classification accuracy by 3-10%, while maintaining high accuracy on base class recognition. This shows that the proposed ICA module and PQ loss can greatly promote the models' recognition capabilities for novel classes. We conjecture this is because the ICA module can obtain more effective novel prototypes and better align the query representations from different encoders.

The more support set instances, the larger the improvement for novel class classification. As can be seen from Table 1, using either GloVe or BERT as the initial text encoder, the improvement on the 5-shot learning is more significant than that of 1-shot learning for novel class. This is because when there are more support set samples, the ICA module and PQ loss can help separate the base and novel classes, reduce the distance between similar classes, and make the query of novel class and corresponding prototype as close as possible.

4.5 Domain Adaptation Results

To further demonstrate the superiority of our method, we extend the few-shot domain adaptation (few-shot DA) task in FewRel 2.0 (Gao et al., 2019b) to the incremental few-shot domain adaptation (inre-few-shot DA) task in our work. Different from the original incre-few-shot RC, the novel instances in the test set are replaced by new instances from the medical domain. Since the do-

BERT-IncreProtoNet	82.10 ± 0.04	60.15 ± 0.11	80.65 ± 0.10	84.64 ± 0.04	65.77 ± 0.09	82.26 ± 0.08
BERT-ICA-Proto †	82.20 ± 0.13	62.72 ± 0.15	80.67 ± 0.08	84.04 ± 0.12	68.06 ± 0.28	82.15 ± 0.10
BERT-ICA-Proto ‡	82.15 ± 0.14	63.07 ± 0.09	80.92 ± 0.13	84.98 ± 0.10	69.36 ± 0.12	83.25 ± 0.15
BERT-ICA-Proto	82.56 ± 0.02	63.25 ± 0.09	81.50 ± 0.08	84.90 ± 0.05	69.50 ± 0.06	83.64 ± 0.04

main of novel instances in the test set is no longer consistent with the training set, the models are required to be able to transfer across domains, which is more challenging.

Table 2 illustrates the comparison results of Incre-ProtoNet and our model, and we have two observations: (1) Huge drops on almost all metrics have been witnessed for both IncreProtoNet and our model, which demonstrates the difficulty of incre-few-shot DA. However, the performance of our method deteriorates much slower than that of IncreProtoNet. (2) Our model outperforms Incre-ProtoNet on all metrics. Especially in 5-shot settings, the accuracy of novel relation recognition is improved by more than 7% in absolute percentage. It indicates that our proposed ICA module provides more accurate, robust and general representations for the relation prototypes and query instances.

4.6 Ablation Studies

As shown in Table 3, on the FewRel 1.0 dataset, compared with the baseline IncreProtoNet, our model can get a large improvement with either the ICA module or the PQ loss. Especially for the ICA module, benefited from the full interaction brought by it, better query representation and novel prototype representation greatly improve the model’s ability in incremental few-shot learning tasks. Fur-

thermore, these two designs are complementary to each other, and combining them together, we can achieve even larger improvement.

4.7 Visualization Analysis

We visualize different types of query representations and prototype representations. As shown in Figure 3, benefited from the ICA module and PQ loss, prototypes of different classes are pushed apart, and the representations of different queries are more accurate and fall close to the corresponding prototype of the same class.

4.8 Impact of the Iteration Number in ICA

As shown in Table 4, the ICA module with two (N=2) or three (N=3) iterations achieves better results than the single iteration (N=1). This shows that the ICA module which optimizes query representation and novel prototype representation step by step can effectively improve the accuracy of incremental few-shot learning. In addition, when N is greater than 3, the accuracy of the model decreases. The reason is probably that larger N leads to overfitting of the model. Finally, it can be seen from Table 4 that no matter how many times the model is iteratively aligned, our models are significantly better than the current best baseline IncreProtoNet.

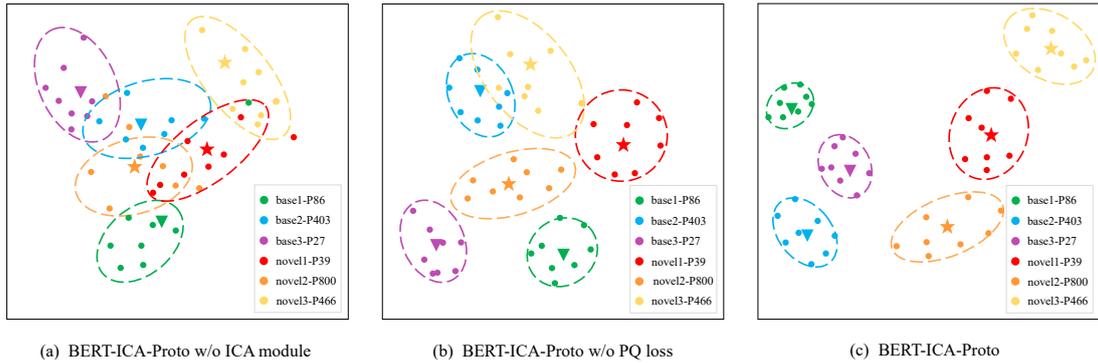

Figure 3: Visualization of the representations of the query instances and prototypes when BERT-ICA-Proto is equipped (a) without ICA module and (b) without PQ loss.

5 Related Work

RC is a fundamental task in natural language processing, aiming to recognize the semantic relation between two marked entities in a sentence. With the development of deep learning in recent years, many models based on neural networks have been proposed for this task and achieved great progress. For example, Zeng et al. (2014) and dos Santos et al. (2015) utilized convolutional neural networks to capture the global and local semantic information. Later, some attention-based models (Wang et al., 2016; Zhou et al., 2016; Jin et al., 2020) have been proposed to better capture the more useful semantic information. These models may suffer from the scarcity of high-quality training data. To mitigate the problem, some works (Mintz et al., 2009; Jia et al., 2019; Qin et al., 2018) adopt DS to construct large-scale datasets, while ignore the effect of long-tail relations.

Few-shot RC aims to learn high-quality features with only a small number of training samples. Early

works employed the paradigm of pretraining and fine-tuning (Bengio, 2012; Donahue et al., 2014; Gao et al., 2020), which aimed to acquire and transfer knowledge from support set containing instances of common relations. Later, metric learning methods (Vinyals et al., 2016; Snell et al., 2017) were proposed to learn different representations across relations. One representative work is prototypical networks (Snell et al., 2017), aiming to learn robust class representations and classify the query set based on the distance to the class prototypes in the feature space. A series of works (Han et al., 2018; Gao et al., 2019a,b) employed prototypical network in few-shot RC and achieved excellent performance.

Incremental learning is a setting where new information is arriving continuously while prior knowledge needs to be maintained. Combining incremental learning with few-shot RC, incremental few-shot RC constitutes a more realistic scenario, where the model is required to leverage the representations of base relations learned from large-scale training dataset meanwhile effectively learn the representations of novel relations from a few support instances. To deal with this task, Ren et al. (2020) proposed a prototypical network based model consisting of two encoders for base relations and novel relations, respectively. In this paper, we argue that the previous work (Ren et al., 2020) is sub-optimal and introduce a preferable solution.

6 Conclusion

In this paper, we presented a novel and effective approach with iterative cross alignment module and prototype quadruplet loss for the task of incremental few-shot learning. Benefit from the extensive interaction offered by the iterative cross alignment

and the feature space regulation brought by the prototype quadruplet loss, our method outperformed the state-of-the-art baseline method significantly, as verified in our extensive experiments. In future work, we aim to further improve the performance of our model under the one-shot task setting, as well as accelerate the training process.

Limitations

In this paper, we propose a novel model named ICA-Proto for the task of incremental few-shot relation classification. Experimental results have shown that our method outperforms the existing best baselines. However, there are two major limitations. First, our method iteratively calculates the representations of query instances and relation prototypes, which is more time-consuming. Second, the best iteration number in ICA module may vary with different datasets. Therefore, we should conduct extra experiments to determine the best iteration number when applying our method in a new dataset, which is not convenient enough to some degree.

Abstract

We present a large, multilingual study into how vision constrains linguistic choice, covering four languages and five linguistic properties, such as verb transitivity or use of numerals. We propose a novel method that leverages existing corpora of images with captions written by native speakers, and apply it to nine corpora, comprising 600k images and 3M captions. We study the relation between visual input and linguistic choices by training classifiers to predict the probability of expressing a property from raw images, and find evidence supporting the claim that linguistic properties are constrained by visual context across languages. We complement this investigation with a corpus study, taking the test case of numerals. Specifically, we use existing annotations (number or type of objects) to investigate the effect of different visual conditions on the use of numeral expressions in captions, and show that similar patterns emerge across languages. Our methods and findings both confirm and extend existing research in the cognitive literature. We additionally discuss possible applications for language generation. We make our codebase publicly available.¹

1 Introduction

In recent years, vision and language models have been shown to outperform models trained on a single modality in a variety of domains, such as language modeling (Ororbia et al., 2019), document quality assessment (Shen et al., 2020), and visual classification and segmentation (Frome et al., 2013; Radford et al., 2021; Berger et al., 2022).

While empirical evidence exists, including from the studies cited above, that each modality can benefit the other for task performance, less attention has been devoted to the broader question of *how* the two modalities influence and constrain one another. In this study, we focus on one aspect of this question: *How does vision constrain language?*

¹github.com/SLAB-NLP/visual_constraints_on_descriptions

Figure 1: A demonstration of how visual cues in images may constrain linguistic choices in their captions. The image on the left in which the agent is visible is described using an active voice “A man... is *throwing* a child... in the air”, while in the right image the agent is not visible and the annotator chose a passive construction: “A little boy... is *thrown* in the air”. Images and captions taken from Flickr30k.

We study the relation between the semantic content of an image and the language used to describe it. As an example, consider Figure 1. Captions of the right image, which crops the agent, use passive voice more frequently than those of the left (taken from Flickr30k, Young et al., 2014). We aim to study such trends by examining the influence of visual features of the image on the linguistic choices taken when describing it.

A number of psycholinguistic studies have aimed to answer this question by systematically varying visual conditions (such as image cropping) and analyzing verbal descriptions of the scenes by human participants for recurring differences (e.g., Chesney and Gelman, 2015; Rissman et al., 2019). Although such controlled studies allow for precise measurement, the visual stimuli are synthetic (rather than depicting natural scenes), the manual annotation of descriptions limits the size of the dataset, and typically only one linguistic property is investigated in a single language.

We address this gap by proposing a scalable methodology that uses existing image-caption corpora in multiple languages. We measure the correlation of visual features and linguistic properties of

the caption by training visual classifiers to predict, for a given raw image, whether a linguistic property is expressed in its captions. We compare the impact of different training sets (single vs. multiple languages) and different types of pre-training (none vs. object categories vs. visual vs. textual pre-training objectives). We use 9 large-scale image-caption datasets (overall 2.9M captions for 604K images), covering four languages (English, German, Chinese, Japanese), to study lexical properties (use of numerals and negation words) and structural properties (use of passive voice, transitivity of the main verb, choice of verbal vs. nominal constructions), which we automatically annotate in the captions. To the best of our knowledge, this is the first large-scale, multilingual study of the impact of visual input on linguistic choice. We find evidence showing that the visual input imposes constraints on linguistic properties, and that such trends are detectable using the proposed methodology.

In a complementary corpus study, we link the prevalence of linguistic properties to existing, high-level visual annotations (number and type of objects), and find that these properties can be linked to the use of numeral expressions in similar patterns across languages, and in accordance with small-scale, highly-controlled psycholinguistic studies.

Our findings have both cognitive and computational implications. On the cognitive side, this study confirms findings from small-scale cognitive studies at scale: for naturalistic scenes, typologically diverse languages, and descriptions from thousands of native speakers. The magnitude of the data that can be studied with our method also allows the derivation of new insights, which can motivate additional controlled studies, making the proposed practice an effective exploration method.

On the computational side captioning models have been shown to generalize better when first predicting the syntactic structure of the generated caption (Bugliarello and Elliott, 2021). This research direction may benefit from the signal provided by our classifiers of linguistic properties.

2 Background

The notion that grammatical and lexical phenomena can be characterized semantically, at least in their prototypical instances, has a long tradition in linguistics (Dixon, 1979; Goldberg, 1995; Croft, 2012, among many others). For example, transitive clauses are often characterized as corresponding to

actions instigated by volitional agents over passive objects, that are affected by the action. However, formally defining these semantic features in a non-linguistic way and showing empirically that the presence of these features indeed entails the presence of the corresponding linguistic feature, has proven to be methodologically challenging. One possible direction to address this is the use of images that implicitly define a type of non-linguistic semantics. This section briefly reviews different approaches for studying visual constraints on our set of five phenomena from a cognitive and computational perspective (omitting phenomena that have not been previously covered).

2.1 Cognitive Studies

Numerals. *Subitizable* numbers are numbers that are rapidly and accurately visually counted by humans. Studies have shown that the threshold for subitizability is 4 (Kaufman et al., 1949; Mandler and Shebo, 1982), with Barr et al. (2013) showing that humans tend to describe non-subitizable numbers using quantifiers (e.g., *many*). In Section 5.2 we confirm this result at scale. Chesney and Gelman (2015) asked participants to count objects in a given image, and found that participants were less likely to include objects located in frames (windows, mirrors or picture frames) in their count, suggesting that visual cues influence linguistic choices.

Negation. Several studies have challenged the traditional view that images cannot express negation (Worth, 1981; Khemlani et al., 2012). Giora et al. (2009) use visual negation markers (e.g., red cross road signs) to study neural processing of visual negation. Oversteegen and Schilperoord (2014) ask Dutch native speakers to describe images of objects missing integral parts (e.g., a woman without a mouth) and show that the descriptions are likely to contain a negation word.

Passive voice. Myachykov et al. (2012) show that English native speakers have a stronger preference for using passive-voice when describing transitive events with visual cueing of their attention toward the agent (compared to the control condition).

Transitivity. Rissman et al. (2019) show that participants had a preference for intransitive descriptions of visual events (a person acting on an inanimate object) when the person was removed by cropping the image (whereas transitive descriptions were preferred in the base condition).

2.2 Computational Studies

Computational studies on how vision constrains language are rare. However, several studies examined various aspects of the linguistic properties studied in this work, typically focusing on individual properties and/or languages.

Negation. A series of studies (van Miltenburg et al., 2016, 2017), investigated negation in Flickr30k image descriptions using a smaller set of negation words compared to our study, comparing the use of negation in English, German, and Dutch, and finding no significant differences. Dobrev and Keller (2021) show that the performance of vision and language models decreases when the text contains negation, but did not show that this decrease is caused by negation-related visual features. Text-only models also have difficulty processing negations (e.g., Ettinger (2020)), and the drop in performance could be due to the text encoder alone.

The line of work most similar to this study train models to predict whether images from comics (Sato et al., 2021) or real life (Sato and Mineshima, 2021) express negation, achieving chance-level results. In contrast to the current study, they used a single dataset, a single language (Japanese), and a single linguistic property (negation).

Transitivity. Nikolaus et al. (2019) show that captioning models generalize better to unseen action – object pairs when the action is transitive, hypothesizing that this improvement is due to the additional arguments (e.g. cake) that images describing transitive events (e.g. eating) contain.

Verbal vs. nominal constructions. Su et al. (2021) study syntactic parsing and compare the Part-Of-Speech (POS) tag of the root of predicted and gold dependency trees of MSCOCO English captions, showing that the gold distribution is approximately 60:40 in favour of nouns, while models tend to never produce trees with a verb root.

3 Approach

We draw inspiration from the cognitive studies presented in Section 2.1. These studies carefully design visual scenes that differ only in terms of the visual feature of interest (e.g., visibility of the agent), ask participants to describe the scenes, and compare the linguistic properties of the descriptions across different conditions. If a linguistic property is significantly more prevalent in one condition, it is assumed that this visual feature constrains that linguistic property.

While such setups allow careful control over the experimental design, they are also less ecologically valid in that they impose (1) synthetic visual stimuli and (2) limitations on the number and diversity of participants, phenomena and languages to include. We address both shortcomings by (1) using large existing image caption datasets as a corpus of diverse language descriptions of naturalistic scenes, and (2) annotating the captions automatically, yet accurately, with linguistic properties.

Using a large amount of data instead of a controlled experiment raises an issue. Unlike in controlled cognitive studies, the sets of images we use are not arranged into ‘minimal pairs’, which are identical except for a visual feature of interest. To overcome this limitation, we exploit the large amount of data available via the automatic annotation of linguistic properties. We train visual classifiers to predict if a linguistic property is expressed in image captions when only the image is provided. If the classifiers achieve high accuracy on a held out test set, it is an indication that the visual features are informative enough to predict the linguistic property.² Figure 2 gives a high-level depiction of our approach.

To complement our analysis, we also conduct a corpus study. First, we use semantic annotations (object classes and bounding boxes) already available in existing datasets to group images by high-level properties and analyze the prevalence of linguistic properties in each group. Second, we compare the linguistic properties of captions for the same image in different languages. If a property is salient in the captions of all languages for a given image, it is likely that its visual content constrains descriptions that use that property. We present a corpus analysis using both approaches in Section 5.2.

4 Experimental Setup

In this section we describe the languages (4.1), linguistic properties (4.2) and datasets (4.3) used in our experiments.

4.1 Languages

We study English (**En**), German (**De**), Chinese (**Zh**), and Japanese (**Ja**) for three main reasons. First, multiple language families are required to

²However, if the accuracy is low, we cannot determine the cause; our modeling or data annotation assumptions may have led to this result, rather than the absence of a statistical relation.

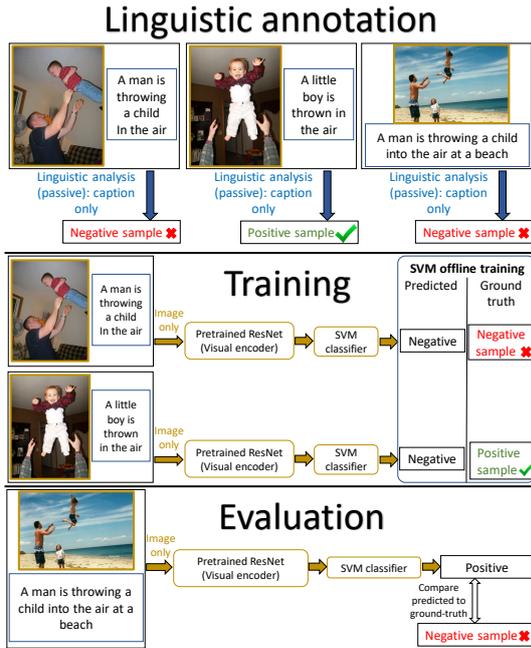

Figure 2: High-level depiction of our approach, demonstrating one linguistic property (passive voice). Top: Samples are annotated as expressing (positive) or not expressing (negative) the property. Middle: The SVM classifier is trained to predict whether an image expresses the property. Bottom: The classifier is evaluated; high classification accuracy indicates a strong relation between visual features and the linguistic property.

study language-agnostic constraints imposed by images. Second, all of these have large image-caption datasets with non-translated captions. Third, all of these have publicly available tools for annotation of some of the linguistic properties we study.

4.2 Annotation of Linguistic Properties

Below, we describe the automatic annotation of occurrences of linguistic properties in captions. All annotation methods were validated by asking in-house native speakers to verify a random sample of 100 (50 positive and 50 negative) instances per property and language. Across all languages and properties, accuracy exceeded 92%, confirming that our automatic annotations are of high quality.

For Japanese we only study the use of numerals since we were not able to achieve accurate annotation for the other properties.

Numerals (Num). We use Microsoft’s Recognize-Text package³ to identify the use of numerals in all languages. We ignore numerals with value of 1 for the following reasons: (1) In German and Chinese, the same word can refer to the

³github.com/microsoft/Recognizers-Text

number *one* or the determiner *a*; (2) In Japanese, several non-numeral words contain the character for 1 (一), confusing the recognizing algorithm.

Negation words (Neg). We use the list of English negation words composed by Dobрева and Keller (2021), and add the word *nope*. We translate all words in the English list into the other languages, and verify the resulting lists with a native speaker.⁴

Verbal vs. nominal descriptions (Verb). We label captions with the root part-of-speech tag of their dependency tree, identified using Stanza’s dependency parser (Qi et al., 2020). We only consider captions with a single root which is a verb or a noun, filtering 0.8% of the captions. Note that we consider sentences where the root corresponds to the English verb *to be* (*sein* in German, 有 in Chinese) as noun roots, as no activity is described.

Transitivity of main verb (Tran). We use Stanza’s dependency parser and filter all captions with at least one of the following: (1) a non-verb root, (2) more or less than a single root, (3) the verb *be* (or its equivalents in languages other than English) as a root, filtering 47% of the captions. After filtering, a caption is labeled as transitive if its root verb has a child labeled as a direct object, and intransitive otherwise.⁵

Passive voice (Pass). We use the passive voice identifier tool for English and German (Ramm et al., 2017). For Chinese we search for the passive indicator 被, filtering cases where it is part of another word.⁶

4.3 Datasets

We use the following datasets: Pascal (Rashtchian et al., 2010), MSCOCO (Lin et al., 2014), Flickr30k (Young et al., 2014), Multi30k (Elliott et al., 2016), Flickr8kcn (Li et al., 2016), AIC-ICC (Wu et al., 2017), COCO-CN (Li et al., 2019), YJCaptions (Miyazaki and Shimizu, 2016), STAIR-captions (Yoshikawa et al., 2017). Table 1 presents additional information. We only use datasets with original captions generated by native speakers and avoid using datasets with captions translated from English.⁷ In addition to captions, MSCOCO and Flickr30k contain object classes and bounding box annotations. A description of the data collection

⁴All negation words are listed in Appendix A.1.

⁵In German and Chinese we automatically identify edge cases missed by the parser, see Appendix A.1.

⁶Words containing 被 are listed in Appendix A.1.

⁷See Appendix D for a comparison of original and translated captions.

Lan	Name	Based on	Size (im,cap)
En	Pascal		1k, 5k
	MSCOCO		123k, 616k
	Flickr30k		31k, 158k
	Overall		156k, 779k
De	Multi30k	Flickr30k	31k, 155k
	Overall		31k, 155k

	AIC-ICC		240k, 1.2M
	COCO-CN	MSCOCO	20k, 22k
	Overall		268k, 1.262M
Jp	YJCaptions	MSCOCO	26k, 131k
	STAIR-captions	MSCOCO	123k, 616k
	Overall		149k, 747k

Table 1: The list of datasets used in this study. For non-English datasets based on images from an English dataset, the *Based on* column indicates the name of the original dataset. The *Size* column indicates the number of images and the number of captions in the dataset.

process for each dataset is provided in Appendix B.

Property expression probability. Given an image I , a set of captions c_1, \dots, c_{N_I} , and an annotation function $f_p(c_i)$ mapping caption c_i to 1 if it expresses property p , and to 0 otherwise, we define the probability that image I expresses p as

$$P_p(I) = \frac{\sum_{i=1}^{N_I} f_p(c_i)}{N_I}$$

Given a language \mathcal{L} we denote with $P_{p,\mathcal{L}}$ the same computation with the set of captions filtered to include only captions in \mathcal{L} . Given a set of images S we denote the expected probability of expressing property p across all images in S as

$$\mathbb{E}_{I \in S}[P_p(I)] = \frac{\sum_{I \in S} P_p(I)}{|S|}$$

Table 2 presents the expected probability of each property p occurring in captions in language \mathcal{L} , $\mathbb{E}_{I \in S_{\mathcal{L}}}[P_{p,\mathcal{L}}(I)]$, where $S_{\mathcal{L}}$ is the set of all images in all datasets of language \mathcal{L} .

5 Experiments

We now describe our experiments and analyses. In Section 5.1 we train visual classifiers to predict linguistic properties, Section 5.2 presents a complementary corpus analysis, and Section 5.3 presents additional insights that may lead to future research.

5.1 Predicting Properties from Images

We study the task of predicting, given an image, whether human annotators will use a particular linguistic property when describing it. The input is

	Num	Neg	Pass	Tran	Verb
En	0.13 (156k)	0.0046 (156k)	0.076 (148k)	0.35 (137k)	0.41 (156k)
De	0.19 (31k)	0.0024 (31k)	0.012 (31k)	0.25 (31k)	0.78 (31k)
Zh	0.34 (268k)	0.0002 (268k)	0.002 (268k)	0.48 (245k)	0.60 (268k)
Jp	0.13 (123k)	–	–	–	–

Table 2: Expected probability of images expressing each property, in each of the 4 languages. Number of images are in parentheses.

a raw image and the output is binary, indicating whether the descriptions express the property.

Models. Our model consists of a visual encoder (ResNet50, He et al., 2016) to embed the raw image, followed by a set of binary SVM classifiers, one per linguistic property.⁸ We investigate four different pre-training methods with varying levels of supervision from different modalities.

First, we randomly initialize the visual encoder (no pre-training; **None**), avoiding unwanted bias through pre-training with human annotated information. Using a random encoder renders the task for the classifier more difficult, and the classifier might perform poorly even if linguistic properties are highly correlated with visual features, so we consider **None** as a lower bound.

To equip our model with some prior visual knowledge, we use MoCo (He et al., 2020), a self-supervised pre-training method based only on visual signals (**MoCo**). MoCo creates multiple manipulated versions of an image and trains the encoder to predict if two manipulated images correspond to the same original.

We also include ImageNet (Deng et al., 2009) pre-training (**IN**). The visual encoder is first trained to classify images in the ImageNet dataset, and then the classification head is discarded. Although semantic information is provided in ImageNet pre-training through class-labels, no textual input is provided which *describes* the visual scene.

Finally, we use CLIP (Radford et al., 2021) pre-training. CLIP is a multimodal self-supervised model, trained to project images and corresponding captions to similar vectors in a joint space. We use CLIP’s visual encoder, discarding the text encoder. This method is pre-trained with explicit textual

⁸We also experimented with neural classifiers, but SVM performed significantly better: see Appendix A.2.2 for details.

	En	De	Zh	Jp	Mul
Numerals	88k	21k	224k	86k	337k
Passive	47k	2k	2k	–	50k
Negation	6k	0.7k	0.3k	–	7k
Transitivity	128k	29k	223k	–	339k
Verb Root	150k	20k	198k	–	333k

Table 3: Number of images used in the experiments, for all properties and languages (Mul: Multilingual).

input, and hence its predictions will be skewed by the prior probability of linguistic properties in general language, obscuring the correlation with image features. In terms of raw performance, we consider CLIP as an upper bound.

We study two settings: monolingual (all images from datasets in a single language) and multilingual (all images from all datasets). In each setting, for each linguistic property p , we compute the probability of all relevant images to express p and binarize the data by using the median probability value as a threshold above which the image is considered to express p . Finally, we create a balanced dataset⁹ of images that express p and those that do not. We evaluate our models using 5-fold cross-validation. Table 3 shows the statistics of the generated datasets (note that the size of the datasets is smaller than in Table 2 because the data was balanced using down sampling). Implementation details are in Appendix A.2.

Multilingual results. Results are presented in Table 4. First, we observe that except for the model without pre-training, all models predict all properties above chance levels, supporting the hypothesis that linguistic properties are constrained by visual context. Second, results for the two non-textual pre-training methods (MoCo, IN) were significantly higher than the lower bound (None) and lower than the upper bound (CLIP) in all properties. Finally, numerals seem easiest to predict, which concurs with our corpus analysis where we find that mentions of numerals were easiest to link to visual properties (Section 5.2).

Monolingual results. We applied MoCo, the best performing method without human annotated pre-training, individually to each language (Table 5). Note that model performance does not always correlate with training data size (Table 3): in English,

⁹Although balancing the test set is usually considered a bad practice, in this study we only study image-text correlation and our classifiers would not be used for classifying new samples in the future.

	Num	Pass	Neg	Tran	Verb
None	60.5 ±0.9	52.7 ±0.3	51.0 ±1.6	54.3 ±0.5	54.2 ±0.3
MoCo	76.4 ±0.2	66.2 ±0.4	62.6 ±1.2	64.7 ±0.3	63.1 ±0.2

Jp	67.4 ±0.3	–	–	–	–

Table 5: Monolingual classification 5-fold cross-validation accuracy on all linguistic properties and languages, using the MoCo pre-training method. In all configurations, chance level is 50. In all languages, the use of numerals was predicted most accurately (in bold).

the verb root dataset was the largest but the classifier achieved the lowest accuracy; and prediction accuracy was high for passive voice in Chinese despite a small dataset. Across all languages, use of numerals was predicted most reliably.

5.2 Corpus Analysis

In this section we show that large image captioning corpora not only allow us to build predictive models to test hypotheses about the constraints of visual properties on language, but also support large-scale corpus studies. Our goal is to correlate image properties (e.g., the type or number of objects in an image) with linguistic choice (e.g., the use of numerals). The ground truth image properties are typically unavailable, but we can use additional information in MSCOCO and Flickr30k as proxies. In particular, we use the fact that the corpora are multilingually aligned (each image contains captions in different languages, all generated by native speakers) and they contain additional annotations (class labels and bounding boxes).

We take the expression of numerals as a test case, since it was the one most accurately predicted in Section 5.1. We emphasize, however, that the approach generalizes to other properties as well.

Although both MSCOCO and Flickr30k contain object classes and bounding box annotations, MSCOCO’s granularity is much higher (80 classes compared to 10 classes), so we only use

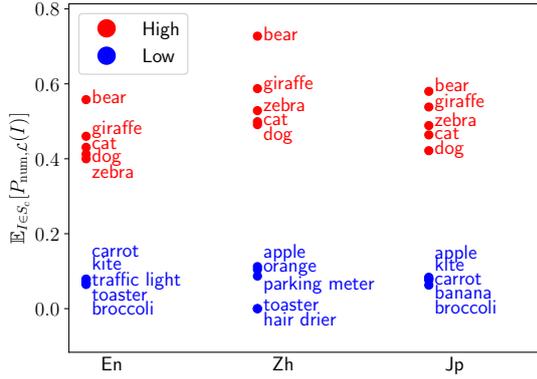

Figure 3: MSCOCO classes with highest and lowest expected numeral expression probability $\mathbb{E}_{I \in S_c}[P_{\text{num}, \mathcal{L}}(I)]$, for $\mathcal{L} \in \{\text{En}, \text{Zh}, \text{Jp}\}$. The probability of classes of animals is high in all languages.

MSCOCO’s class and bounding box annotations in our analysis. German is excluded from the class and bounding box analysis as there is no German version of MSCOCO with original captions.

Images containing animals are most likely to be described using numerals across languages.

For each MSCOCO class c , we find the set S_c of all images instantiating that class and compute $\mathbb{E}_{I \in S_c}[P_{\text{num}}(I)]$. We note that the expected $P_{\text{num}}(I)$ of some classes might be lower simply because they are more likely to occur in singles, and avoid this bias by filtering out images with a single instantiation of c from S_c .¹⁰

Figure 3 shows the 5 classes with the highest and lowest $\mathbb{E}_{I \in S_c}[P_{\text{num}}(I)]$ for each language. In all languages, images depicting animals are most likely to be described with numerals.

Our findings corroborate cognitive findings, placing the human subitizability threshold at 4.

We use MSCOCO bounding boxes annotation to investigate whether the use of numerals in image descriptions reflects the subitizability threshold (see Section 2.1). For each integer k , we find the set S_k of all images with k labeled bounding boxes, and compute $\mathbb{E}_{I \in S_k}[P_{\text{num}}(I)]$. We also label captions with quantifiers (e.g., *some*, *a few*¹¹) and compute $\mathbb{E}_{I \in S_k}[P_{\text{quant}}(I)]$. Figure 4 shows the results, for all k where $|S_k| \geq 100$. In all languages, $\mathbb{E}_{I \in S_k}[P_{\text{num}}(I)]$ initially increases with

¹⁰No classes were completely filtered out; only two classes (*toaster*, *hair-drier*) were left with less than 80 images.

¹¹The full lists are in Appendix A.1.

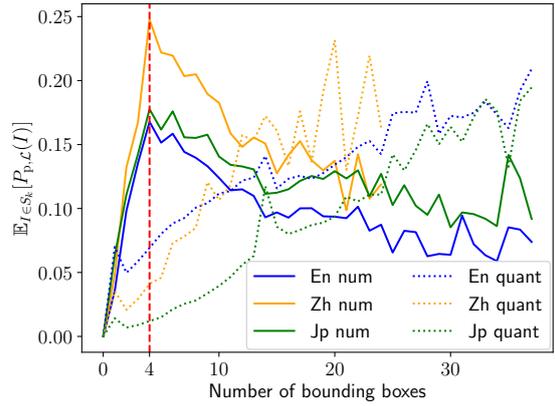

Figure 4: Expected probability of expressing the use of numerals and quantifiers $\mathbb{E}_{I \in S_k}[P_{p, \mathcal{L}}(I)]$ as a function of the number of bounding boxes in MSCOCO, for $\mathcal{L} \in \{\text{En}, \text{Zh}, \text{Jp}\}$ and $p \in \{\text{num}, \text{quant}\}$. All k with $|S_k| < 100$ were removed from the plot. Red line: subitizability threshold. In all languages, the probability increases up to 4 objects (consistent with cognitive studies) and then decreases. Quantifiers expression probability increases steadily.

Flickr30k (7k)			MSCOCO (13k)		
Zh/De	Zh/En	De/En	Zh/En	Zh/Jp	Jp/En
0.75	0.72	0.87	0.59	0.52	0.68

Table 6: Pearson correlation of the probability of use of numerals across pairs of languages in Flickr30 and MSCOCO. Number of images in parentheses.

a clear peak at 4, while quantifiers expression steadily increases.

Captions of the same image in different languages tend to agree on numerals usage.

We use the multilingual datasets Flickr30k (En, De, Zh) and MSCOCO (En, Zh, Jp), identify a list of images with captions in all respective languages $\{I_k\}_{k=1}^N$, and compute the list of probabilities of numerals expression for each image $L_{\mathcal{L}} = \{P_{\text{num}, \mathcal{L}}(I_k)\}_{k=1}^N$, in each language \mathcal{L} . Next, we compute the Pearson correlation coefficient of $L_{\mathcal{L}_1}, L_{\mathcal{L}_2}$ for each pair of languages $\mathcal{L}_1, \mathcal{L}_2$. The results are shown in Table 6. The correlation is *high* (> 0.5 ; Cohen (2013)) across all languages and datasets.

5.3 Additional Insights

The proposed methodology can also be used as an exploration method for further cognitive research. In this section, we present findings obtained by manually investigating extreme cases of property

Figure 5: Top: images described using numerals in all languages. Bottom: images described without numerals. Images taken from Flickr30k.

expression. This is an exploratory analysis, presenting preliminary findings that may lead to future research in a more controlled setting.

Use of numeral expressions. We manually inspect all images that use numerals in all captions across all languages in Flickr30k (N=105). The top images in Figure 5 are representative examples. All images depict multiple participants taking similar roles and positioned in a regular pattern (e.g., all the children in the upper right image in Figure 5 are swinging and facing the camera). The bottom of Figure 5 shows comparable images, which were never described using numerals. Here, participants appear in different poses and roles. We hypothesize that people count more easily and accurately when objects are arranged in a regular pattern, compared to a random formation (Burgess and Barlow, 1983).

We also present differences in the use of numerals across languages. We analyze images for which at least two captions use numerals with the same numeral value in each language, but different values across languages (N=46). We find two main reasons for cross-language inconsistencies: First, different languages tend to either count all participants in a single group or split them into smaller groups based on gender, role, or age.¹² These differences may be due to different annotation guidelines or different cultural backgrounds of the annotators.

Second, the multilingual datasets were originally created for English captioning, making the selected images highly related to English and especially North American culture.¹³ For example, in the sports domain, the datasets contain mainly images of Basketball and Baseball, popular sports in the United States. While English annotators use a de-

¹²Examples for all partition types are in Appendix C.

¹³This is a well known problem in multimodal datasets, previously discussed by Liu et al. (2021).

En: Basketball player wearing a white, number 23 jersey jumps up with the ball while guarded by number 13 on the opposite team
De: Zwei Männer spielen Basketball
Zh: 有两个男人正在打篮球

Figure 6: An image of a basketball game. The English captions are highly detailed, while both the German and Chinese caption translates to *Two men are playing basketball*. Image taken from Flickr30k, captions taken from Flickr30k (En), Mutli30k (De), Flickr8kcn (Zh).

tailed description, commonly mentioning the players' shirt number, German and Chinese descriptions are mostly short and count the number of players in the image (Figure 6).

Passive. We notice that in images with high probability for using passive voice, the patient is commonly located at the center of the scene either by the pose of the camera or the borders of the image. We hypothesize that this visual feature is correlated with the use of passive voice. The right image of Figure 1 shows one example. More examples are in Appendix C.

5.4 Discussion

Our experiments suggest that various linguistic properties are predictable from visual context, most notably in the case of the use of numeral expressions. Our classifiers were able to predict the presence of numerals in captions with high accuracy. Correspondingly, our corpus analysis provides evidence that the type and number of objects in the image constrain the use of numerals. Both results hold across different languages, and present high agreement between languages in the selection of images that are described with numerals. This lends support to the hypothesis that visual context constrains the use of numerals across a variety of languages from different families, and that such trends can be studied using the proposed methodology.

A surprising result is that without pretraining of the visual encoder (**None**), above chance-level performance can be obtained, most notably for the numerals property. A randomly initialized visual encoder applies a random dimensionality reduction to the input image, and the fact that the SVM classifier was able to learn to predict the presence of numerals in the captions of images at above chance level following this random transformation supports the hypothesis that this property correlates with visual features.

6 Conclusion

The synergistic relation between vision and language has been shown in the cognitive literature and leveraged in computational models, but *how* the two modalities inform each other has not been sufficiently studied at scale. We present a large scale study of the correlation of visual properties with linguistic phenomena, using naturalistic images described by a large crowd of native speakers of four languages.

In addition to confirming results of previous cognitive studies, we present new findings, e.g., the effect of object type on the use of numerals in visual scene description and the cross-lingual correlation of the use of numerals. Considering the effort needed to execute a controlled study, our proposed method can be used as an effective exploration technique for finding hypotheses for future controlled studies. In addition, our framework is general, and extends naturally to more languages and properties.

Beyond the cognitive contribution, our work can inform NLP models. Recent work suggests that in captioning models, training the model to predict a structured representation of the caption (e.g., based on POS prediction) before the text improves compositional generalization (Bugliarello and Elliott, 2021). In future work, we will study the utility of predicting our proposed linguistic properties for improving captioning models.

Limitations

We acknowledge several limitations of our suggested methodology. First, confounding factors may have affected our results, e.g., the difference in wording of the annotation guidelines for the original image-caption dataset could have a significant impact on the linguistic properties of the descriptions. In cognitive research, there is a well-known trade-off and ongoing discussion on the merits of highly-controlled, yet often oversimplified settings and the larger-scale, yet typically confounded, studies. The “reproducibility crisis” has highlighted that controlled studies are often difficult to reproduce, and initiated a discussion about the (complementary) utility of large-scale experiments which are typically more realistic. We propose such a method in the context of language/vision research, which can complement small-scale cognitive studies by considering natural scenes, while covering several languages and linguistic phenomena. We present empirical results that support the validity

of the methodology, in the sense that it often accords with established findings from the literature, as well as small scale qualitative analysis, that suggests trends for future work. We emphasize the importance of both paradigms, which should coexist and complement one another.

Second, with the exception of AIC-ICC, all image collections for all languages are based on original English image-caption datasets and hence are Anglocentric in their selection of concepts. The impact of such bias on NLP research has recently been discussed (Liu et al., 2021). We hope to extend the analysis with additional culture- and language-specific datasets in the future.

Finally, we do not distinguish between differences in linguistic properties that are due to annotators’ focus choices (i.e., the selection of what details in the image to describe) and those that are due to linguistic choices. The prevalence of linguistic properties could be influenced by the content that the annotator chose to describe (e.g., some annotators describe the background in addition to the main object(s), and others do not). This is a challenging and important line of future work, but outside the scope of this study.

Acknowledgements

We would like to thank the anonymous reviewers for their helpful comments and feedback. We would also like to thank Rotem Dror, Sharon Goldwater and Grzegorz Chrupała for consulting, and the native speakers that consulted and validated our annotation tool: Assaf Porat, Kozue Watanabe, Arie Cattan, and Yilin Geng. This work was supported in part by the Israel Science Foundation (grant no. 2424/21), the Israeli Ministry of Science and Technology (grant no. 2336), and by the HUJI-UoM joint PhD program.

Ethics Statement

We use publicly available resources in our experiments, in accordance with their license agreements. The datasets are fully anonymized and do not contain personal information about the caption annotators or any information that could reveal the identity of the photographed subjects.

A Implementation Details

A.1 Linguistic Properties Annotation

Use of numerals In the bounding boxes experiment in section 5.2 we search for quantifiers. Following are the lists of quantifiers we search for in each language. English: *some, a lot of, many, lots of, a few, several, a number of*. Chinese: 些, 多. Japanese: 多くの, たくさん, いくつか.

Use of negation words Following are the lists of negation words for each language.

English: *not, isn't, aren't, doesn't, don't, can't, cannot, shouldn't, wont, wouldn't, no, none, nobody, nothing, nowhere, neither, nor, never, without, nope*.

German: *nicht, kein, nie, niemals, niemand, nirgendwo, nirgendwohin, nirgends, weder, ohne, nein, nichts, nee*. We lemmatize the words in the sentence before searching in this list.

Chinese: 不, 不是, 不能, 不可以, 没, 没有, 没什么, 从不, 并不, 从没有, 并没有, 无人, 无处, 无, 别, 绝不. We use the Jieba tokenizer¹⁴. We also identify cases where one of the words above is part of a longer non-negation word and filter those cases. Following is the list of non-negation words: 别着, 不小心, 不一样.

¹⁴github.com/fxsjy/jieba

Use of passive verbs In Chinese we search for the passive indicator 被, filtering cases where it is part of the 被子 word (meaning quilt), a common word in the AIC-ICC dataset.

Transitivity In German and Chinese we identify several important edge cases in which the Stanza parser is consistently incorrect, which we fix manually. All edge cases were verified by native speakers.

In German we identify sentences containing a node which is a child of the root and labeled with the *PTKVZ* POS tag, and label these as intransitive.

In Chinese we identify sentences where (1) the lemma of the root word ends with the preposition token 在; (2) the lemma of the word following the root word is 在; or (3) the lemma of the word following the root word starts with the preposition token 向, and label these as intransitive.

A.2 Model Details

A.2.1 SVM Classifier

We use the SVC model from the sklearn Python package with the RBF kernel and default hyperparameters.

A.2.2 Neural Classifier

We use a feed-forward neural network with 1 or 2 hidden layers, with different activation functions (ReLU, Sigmoid, Tanh). In all configurations, the SVM classifier performed better.

A.2.3 Pre-trained Backbone Models

For MoCo and CLIP we use the models provided in the officially published code. For ImageNet pre-training we use the pre-trained model provided by the PyTorch package. In all cases, model contains 25.6M parameters.

A.3 Training

Training with the largest training set (the transitivity multilingual setting, see table 3) took 30 hours on a single GM204GL GPU.

B Dataset Collection Details

Following is a brief description of the process of data collection for each of the datasets.

Pascal Sentences (Rashtchian et al., 2010) contains the set of images from the PASCAL Visual Object Classes Challenge (Everingham et al., 2008) with captions generated by Amazon's Mechanical Turk workers. The annotators were instructed to (1)

describe the image in a single sentence including the main characters, the setting or the relation of the objects; (2) If possible, include adjectives such as colors, spacing, emotion, or quantity; (3) pay attention to grammar and spelling.

Flickr30k (Young et al., 2014) is a large English image-caption dataset. The objects in each image are segmented using bounding boxes and classified into one of 10 classes. Annotators were crowdsource workers and were asked to “write sentences that describe the depicted scenes, situations, events and entities (people, animals, other objects)”.

Multi30k (Elliott et al., 2016) is a German version of Flickr30k. It contains both original and translated captions. Translations are generated by professional translators, original captions were generated by crowdworkers via the Crowdfunder platform. Instructions were translated from the English instructions of Flickr30k.

Flickr8kcn (Li et al., 2016) is a Chinese version of the smaller Flickr8k dataset on which the Flickr30k dataset was based. Descriptions were generated by crowdworkers that were asked to “write sentences describing salient objects and scenes in every image, from their own point of views”.

MSCOCO (Lin et al., 2014) is another large English image-caption dataset with additional annotations (object classes and bounding boxes). The captions were generated using human subjects on Amazon’s Mechanical Turk. The annotators were given the following instructions:

- Describe all the important parts of the scene.
- Do not start the sentences with “There is”.
- Do not describe unimportant details.
- Do not describe things that might have happened in the future or past.
- Do not describe what a person might say.
- Do not give people proper names.
- The sentences should contain at least 8 words.

COCO-CN (Li et al., 2019) is a Chinese version of MSCOCO, annotated by a group of volunteers and paid undergraduate students. Annotators were instructed that the caption shall cover the main objects, actions and scene in a given image, and were provided with suggested captions retrieved in

the following process: all the captions in the original MSCOCO dataset were machine-translated to Chinese, and the 5 most relevant suggestions for each image were chosen by a model. However, they were asked to provide their own descriptions, and only draw inspiration from the suggestions. In addition, they manually translated 5000 captions.

YJCaptions (Miyazaki and Shimizu, 2016) is a Japanese version of MSCOCO. Captions were generated using Yahoo! crowdsourcing, where signing up requires a Japanese proficiency, leading the authors to assume that participants were fluent in Japanese. Annotation guidelines can be translated to English as “Please explain the image using 16 or more Japanese characters. Write a single sentence as if you were writing an example sentence to be included in a textbook for learning Japanese. Describe all the important parts of the scene; do not describe unimportant details. Use correct punctuation. Write a single sentence, not multiple sentences or a phrase”.

STAIR-captions (Yoshikawa et al., 2017) is another Japanese version of MSCOCO. Annotation guidelines can be translated to English as “(1) A caption must contain more than 15 letters. (2) A caption must follow the da/dearu style (one of the writing styles in Japanese). (3) A caption must describe only what is happening in an image and the things displayed therein. (4) A caption must be a single sentence. (5) A caption must not include emotions or opinions about the image”.

AIC-ICC (Wu et al., 2017) is a large Chinese image-caption dataset. The annotators were instructed to (1) include key objects/attributes, locations and human actions; (2) generate fluent captions; (3) use Chinese idioms or descriptive adjectives.

C Additional Visual Examples

Numerals disagreement Further to the numerals disagreement analysis in Section 5.3, we present examples of images that were described by captions in multiple languages with numeral value disagreement caused by differences in partition of the participants. For each of these images, the captions in one language do not partition the participants while the captions in the other is partitioning based on gender (Figure 7), role (Figure 8) or age (Figure 9).

Passive voice Figure 10 shows three images with high probability for the use of passive voice. In the upper right image the passive participant is

Figure 7: An image taken from Flickr30k. The English caption splits participants based on gender: “A man in a beret and thin mustache gestures to two women in conversation”. The Chinese caption does not split participants at all: “三个人正在谈话” (Three people are talking).

Figure 8: An image taken from Flickr30k. The English caption splits participants based on role: “One dog is chasing another dog that is carrying something in its mouth along the beach”. The German caption does not split participants at all: “Zwei weiß-braune Hunde, die am Strand laufe” (Two white and brown dogs running on the beach).

centered by the pose of the camera, while in the other two images the borders of the image locates the passive participant in the center.

D Original vs. Translated Captions

When studying multimodal tasks in non-English languages (e.g., multimodal machine translation (Hitschler et al., 2016), visual question answering (Gupta et al., 2020)), it is common to translate an existing English image-caption corpus into the target language using crowd sourcing or translation APIs. We show that captions generated in this setting are not representative of the target language. We use the Multi30k dataset (De) and the COCO-CN dataset (Zh), both of which contain

Figure 9: An image taken from Flickr30k. The English caption splits participants based on age: “A man and two children in life jackets in a boat on a lake”. The Chinese caption does not split participants at all: “坐在船上出海的三个人” (Three people on a boat going out to the sea).

original as well as translated captions in the target language. We use the statistical method described in Section 5.2 in the Cross-lingual analysis paragraph to compute the agreement of English and translated captions, and compare it with the agreement of original and translated captions. As shown in Figure 11, in 9/10 cases the English-Translated agreement is higher than Original-Translated agreement, suggesting that translated captions are not representative of the target language. The effect is most pronounced with negation.

Figure 10: images with high probability for the use of passive voice. In all images, the passive participant is centered by the pose of the camera or the borders of the image.

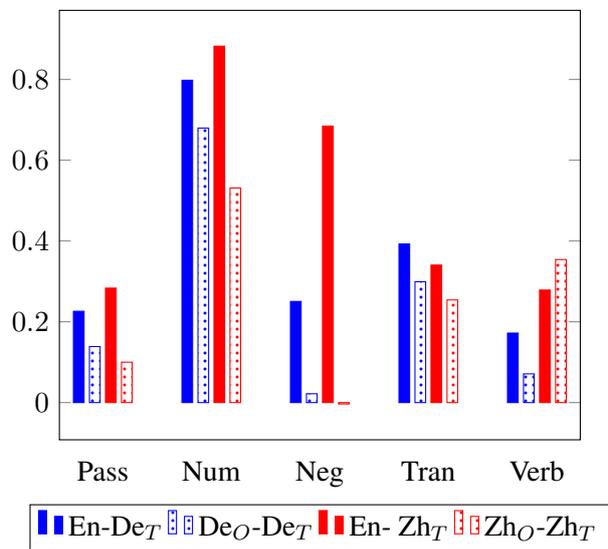

Figure 11: English – Translated agreement (En-De_T and En-Zh_T) and Original – Translated agreement (De_O-De_T and Zh_O-Zh_T) for German and Chinese, in different linguistic properties.

How Much Syntactic Supervision is “Good Enough”?

Abstract

In this paper, we explore how much syntactic supervision is “good enough” to make language models (LMs) more human-like. Specifically, we propose the new method called *syntactic ablation*, where syntactic LMs, namely Recurrent Neural Network Grammars (RNNGs), are gradually ablated from full syntactic supervision to zero syntactic supervision (\approx unidirectional LSTM) by preserving NP, VP, PP, SBAR non-terminal symbols and the combinations thereof. The 17 ablated grammars are then evaluated via targeted syntactic evaluation on the SyntaxGym benchmark. The results of our syntactic ablation demonstrated that (i) the RNNG with zero syntactic supervision underperformed the RNNGs with some syntactic supervision, (ii) the RNNG with full syntactic supervision underperformed the RNNGs with less syntactic supervision, and (iii) the RNNG with mild syntactic supervision achieved the best performance comparable to the state-of-the-art GPT-2-XL. Those results may suggest that the “good enough” approach to language processing seems to make LMs more human-like.

1 Introduction

In the literature on targeted syntactic evaluation (Linzen et al., 2016; Marvin and Linzen, 2018), recurrent neural networks (RNNs) such as LSTMs have been demonstrated to implicitly learn syntactic structures of natural language (e.g., subject-verb agreement), despite the lack of explicit syntactic supervision (cf. Hewitt and Manning, 2019). Moreover, those RNNs also turned out to benefit from explicit syntactic supervision. RNNs integrated with explicit syntactic supervision, namely Recurrent Neural Network Grammars (RNNGs; Dyer et al. 2016), have received considerable attention for their cognitive plausibility and outperformed

RNNs in not only targeted syntactic evaluation (Kuncoro et al., 2018; Wilcox et al., 2019) but also psychometric predictive power (Hale et al., 2018; Wilcox et al., 2020; Yoshida et al., 2021).

However, despite the previous debate over the dichotomy between the presence and absence of syntactic supervision, how much syntactic supervision is necessary and sufficient remains to be investigated. Especially, there are two potential reasons to believe that full syntactic supervision is suboptimal. Theoretically, full syntactic supervision may override lexical heuristics implicitly learned with RNNs, where information on terminal symbols vanishes via recursive composition operations (cf. Kuncoro et al., 2017). Empirically, full syntactic supervision seems to destroy the performance of long-distance dependencies, especially (pseudo-)cleft constructions, where both acceptable (e.g., *What he **did** was prepare the meal.*) and unacceptable (e.g., **What he **ate** was prepare the meal.*) sentences share the exactly same syntactic structure (Figure 1) and should be distinguished via lexical heuristics alone (cf. Noji and Oseki, 2021). Therefore, it is reasonable to hypothesize that optimal syntactic supervision lies somewhere between full and zero syntactic supervision in order to balance syntactic structures and lexical heuristics. Intuitively speaking, if we teach too much syntax to language models, those models will forget lexicon.

In this paper, we explore how much syntactic supervision is “good enough” to make language models more human-like. Specifically, we propose the new method called *syntactic ablation*, where RNNGs are gradually ablated from full syntactic supervision to zero syntactic supervision (\approx unidirectional LSTM) by preserving NP, VP, PP, SBAR nonterminal symbols and the combinations thereof. The 17 ablated grammars are then evaluated via targeted syntactic evaluation on the SyntaxGym benchmark (Gauthier et al., 2020). The results demonstrate that the RNNG with mild syntactic

^{*}Denotes equal contribution.

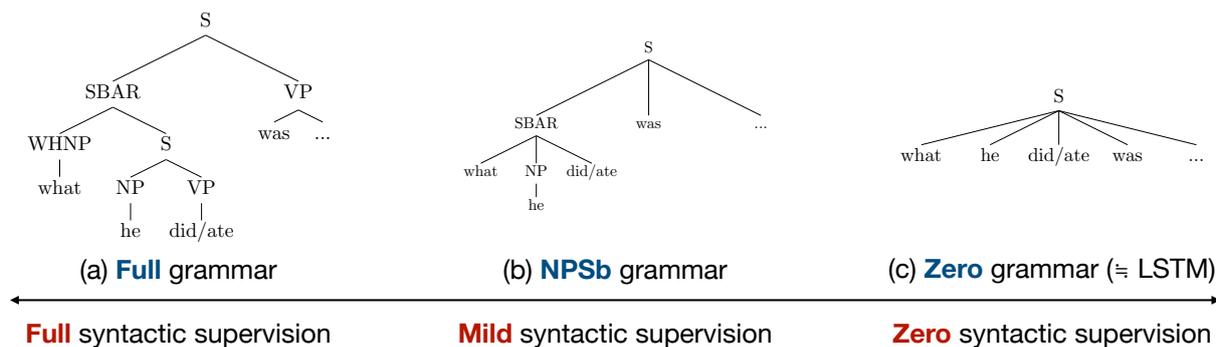

Figure 1: Our proposed method of syntactic ablation. RNNGs are gradually ablated from (a) full syntactic supervision, through (b) mild syntactic supervision, to (c) zero syntactic supervision (\approx unidirectional LSTM) by preserving NP, VP, PP, SBAR nonterminal symbols and the combinations thereof, hence the 17 ablated grammars.

supervision achieved the best performance comparable to the state-of-the-art GPT-2-XL, which are then discussed in the broader context of the computational psycholinguistic literature (Ferreira et al., 2002; Ferreira and Patson, 2007).

2 Methods

2.1 Recurrent Neural Network Grammars

Recurrent Neural Network Grammars (RNNGs; Dyer et al. 2016) are deep generative models of sentences and structures. RNNGs employ the stack LSTM (Dyer et al., 2015) to compute probability distributions over 3 parsing actions below:

- NT: Open nonterminal symbols.
- GEN: Generate terminal symbols.
- REDUCE: Close nonterminal symbols.

For the REDUCE action, RNNGs adopt the bidirectional LSTM to encode terminal and nonterminal symbols both left-to-right and right-to-left into phrasal representations. For inference, RNNGs utilize word-synchronous beam search (Stern et al., 2017) implemented in Noji and Oseki (2021).¹

2.2 Syntactic ablation

Our proposed method of syntactic ablation is summarized in Figure 1. RNNGs are gradually ablated from full syntactic supervision to zero syntactic supervision by preserving NP, VP, PP, SBAR nonterminal symbols and the combinations thereof, hence 17 ablated grammars below:

- Zero: Zero grammar.
- N: NP nonterminal symbol only.

- V: VP nonterminal symbol only.
- P: PP nonterminal symbol only.
- Sb: SBAR nonterminal symbol only.
- NV: NP and VP nonterminal symbols.
- NP: NP and PP nonterminal symbols.
- NSb: NP and SBAR nonterminal symbols.
- VP: VP and PP nonterminal symbols.
- VSb: VP and SBAR nonterminal symbols.
- PSb: PP and SBAR nonterminal symbols.
- NVP: NP, VP, and PP nonterminals.
- NVSb: NP, VP, and SBAR nonterminals.
- NPSb: NP, PP, and SBAR nonterminals.
- VPSb: VP, PP, and SBAR nonterminals.
- NVPSb: NP, VP, PP, and SBAR nonterminals.
- Full: Full grammar.

RNNGs are trained on the parsed sentences. We created the training data for each grammar, which only provides designated nonterminal symbols. Our original dataset is the same as the XL dataset of Hu et al. (2020), which is about 42M tokens from BLLIP corpus (Charniak et al., 2000) and re-parsed by Berkeley neural parser (Kitaev et al., 2019), from which we only kept the ablated nonterminals to create the dataset. For each grammar, we trained an RNNG with three different random seeds. For the other training settings, we follow Noji and Oseki (2021)’s 100M token experiment.

2.3 Targeted syntactic evaluation

Those ablated grammars were then evaluated via targeted syntactic evaluation on the SyntaxGym benchmark (Gauthier et al., 2020) which includes 6

¹<https://github.com/aistairc/rnng-pytorch>

syntactic *circuits*: Agreement, Garden-Path Effects, Licensing, Center Embedding, Gross-Syntactic State, and Long-Distance Dependencies.

We adopted the “perfect match” evaluation metric proposed in Hu et al. (2020), not the “partial match” evaluation metric utilized in the SyntaxGym leaderboard, which seems to overestimate the accuracies of syntactic generalization.

3 Results

3.1 Overall accuracies

Overall accuracies of our syntactic ablation experiments are summarized in Figure 2. Accuracies of SyntaxGym (the vertical axis) are plotted against grammars with different amounts of syntactic supervision (the horizontal axis), together with the accuracies of RNNG and GPT-2-XL reported in Hu et al. (2020). Zero (leftmost) and Full (rightmost, except RNNG and GPT-2-XL) represent zero and full grammars, respectively, the former of which is equivalent to the unidirectional LSTM.² N, V, P, and Sb indicate grammars with NP, VP, PP, and SBAR nonterminal symbols preserved, respectively. Therefore, NP represents the grammar with NP and PP nonterminal symbols preserved, not to be confused with the grammar with the NP nonterminal symbol preserved.

²They are practically equivalent because the REDUCE action does not occur except the end of the sentence, where the only difference affecting each word probability is the existence of “(ROOT)” symbol at the beginning of the sentence.

There are three key observations here. First, the Zero grammar, which is equivalent to the unidirectional LSTM, underperformed the grammars with some syntactic supervision, suggesting that syntactic supervision plays an important role for human-like syntactic generalization. Second, the Full grammar also underperformed the grammars with less syntactic supervision and GPT-2-XL in Hu et al. (2020), meaning that full syntactic supervision does not always make LMs human-like. Finally, and most importantly, the NPSb grammar achieved the best performance (84.585417) comparable to (or even numerically larger than) the state-of-the-art GPT-2-XL (84.241459).

3.2 Circuit accuracies

Circuit accuracies of our syntactic ablation experiments are summarized in Figure 3. Accuracies of 6 circuits on SyntaxGym (the vertical axis) are plotted against 4 grammars with different amounts of syntactic supervision (the horizontal axis).

Interestingly, the NPSb grammar outperformed the Full grammar for 5 among 6 syntactic circuits (Agreement, Center Embedding, Garden-Path Effects, Licensing, Long-Distance Dependencies). Notice that the performance advantage of the NPSb grammar is significantly larger in Long-Distance Dependencies, especially (pseudo-)cleft constructions, corroborating the hypothesis that optimal syntactic supervision lies somewhere between full and zero syntactic supervision in order to balance syntactic structures and lexical heuristics.

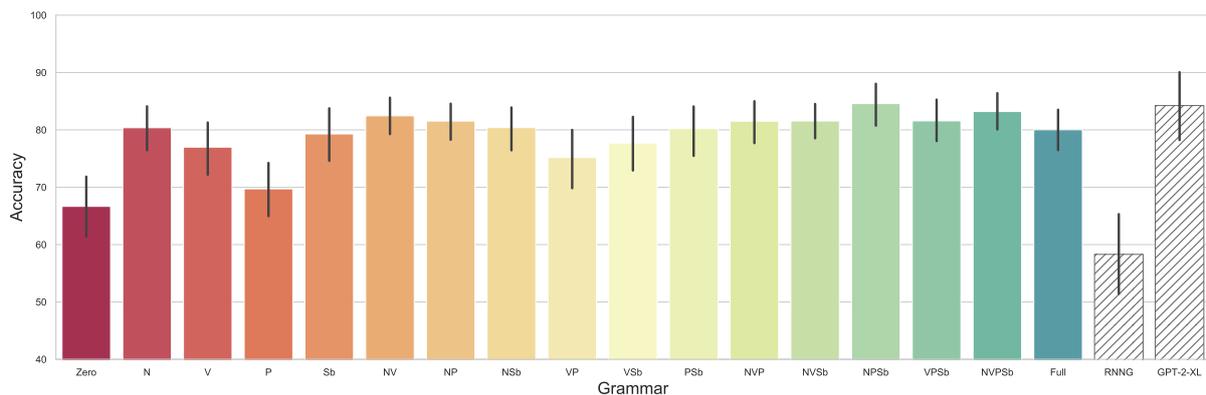

Figure 2: Overall accuracies of our syntactic ablation experiments. Accuracies averaged over 6 circuits on SyntaxGym and random seeds (the vertical axis) are plotted against grammars with different amounts of syntactic supervision (the horizontal axis), together with the accuracies of RNNG and GPT-2-XL reported in Hu et al. (2020). Error bars denote bootstrapped 95% confidence intervals. Zero (leftmost) and Full (rightmost, besides RNNG and GPT-2-XL) represent zero and full grammars, respectively. N, V, P, and Sb indicate the grammars with NP, VP, PP, and SBAR nonterminal symbols preserved, respectively. Therefore, NP represents the grammar with NP and PP nonterminal symbols preserved, not to be confused with the grammar with the NP nonterminal symbol preserved.

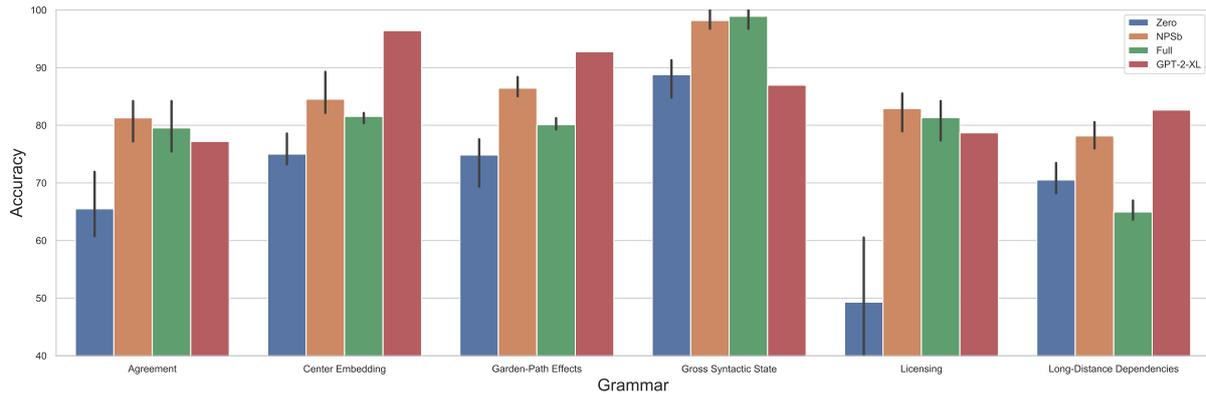

Figure 3: Circuit accuracies of our syntactic ablation experiments. Accuracies of 6 circuits on SyntaxGym (the vertical axis) are plotted against 4 grammars with different amounts of syntactic supervision (the horizontal axis).

4 Discussion

In summary, we performed the syntactic ablation experiments where RNNs were gradually ablated from full syntactic supervision to zero syntactic supervision (\approx unidirectional LSTM), and then evaluated via targeted syntactic evaluation on the SyntaxGym benchmark. In this section, the results of our syntactic ablation experiments will be discussed in the broader context of the computational psycholinguistic literature.

4.1 The “good enough” language processing

The overall accuracies reported in Section 3.1 demonstrated that the RNN with mild syntactic supervision, especially the NPSb grammar, outperformed the RNNs with zero and full syntactic supervision, as well as GPT-2 XL in Hu et al. (2020). Those results are consistent with the “good enough” approach to language processing (Ferreira et al., 2002; Ferreira and Patson, 2007), where human language processing does not always generate deep syntactic structures, but rather employs shallow syntactic structures and frugal lexical heuristics. Here, we suggest that the RNN with mild syntactic supervision serves as the mechanistic model of the “good enough” approach to language processing, in that neither deep/hierarchical syntax is necessary nor shallow/flat syntax is sufficient; rather, some syntax in between is “good enough”.

4.2 Long-Distance Dependencies

The circuit accuracies reported in Section 3.2 revealed that the NPSb grammar outperformed the Full grammar for 5 syntactic circuits such as Agreement, Center Embedding, Garden-Path Effects, Licensing, Long-Distance Dependencies.

Upon closer inspection (cf. Hu et al., 2020), those 5 syntactic circuits share the isomorphic syntactic structure with long-distance dependencies between dependents inside and outside “heavy” subjects (where the *dependents* are italicized):³

- **Agreement:** [_{NP} The *farmer* [_{PP} near the clerks]] *knows* many people.
- **Center Embedding:** [_{NP} The *painting* [_{SBAR} that the artist painted]] *deteriorated*.
- **Garden-Path Effects:** [_{NP} The *child* [_{SBAR} kicked in the chaos]] *found* her way back home.
- **Licensing:** [_{NP} *No* managers [_{SBAR} that respected the guard]] have had *any* luck.
- **Long-Distance Dependencies:** [_{SBAR} What he *did*] was *prepare* the meal.

Importantly, NP, PP, and SBAR representations effectively make linearly distant dependents hierarchically close, while VP representations have no designated *raison d’être* and, moreover, may override lexical heuristics of verbs (e.g., *knows*, *deteriorated*) via recursive composition operations (cf. Kuncoro et al., 2017; Noji and Oseki, 2021). Thus, at least for those 5 syntactic circuits, the NPSb grammar is the optimal syntactic supervision that balances syntactic structures and lexical heuristics.

³While those 5 syntactic circuits are not named long-distance dependencies (except the Long-Distance Dependencies circuit which includes filler-gap dependencies and cleft constructions), they all involve long-distance dependencies.

5 Conclusion

In this paper, we explored how much syntactic supervision is “good enough” to make language models more human-like. Specifically, we performed the syntactic ablation experiments where RNNs were gradually ablated from full syntactic supervision to zero syntactic supervision (\approx unidirectional LSTM), and then evaluated via targeted syntactic evaluation on the SyntaxGym benchmark. The results demonstrated that the RNN with mild syntactic supervision achieved the best performance comparable to the state-of-the-art GPT-2-XL. We hope that the “good enough” approach to language processing (Ferreira et al., 2002; Ferreira and Patson, 2007) provides the promising direction for future research.

Limitations

There are several limitations with this paper. First, the evaluated models are limited; the syntactic ablation was applied to only one model (i.e. RNN) and remains to be generalized to other models (cf. Sartran et al., 2022). Second, the evaluation datasets are also limited; our ablated RNNs were evaluated against only one dataset (i.e. SyntaxGym) and remain to be extended to other datasets (cf. Warstadt et al., 2020). In addition, from engineering perspectives, our ablated RNNs, though lightweight, still require some syntactic supervision, which may induce the scalability bottleneck.

Abstract

Dense vector representations for textual data are crucial in modern NLP. Word embeddings and sentence embeddings estimated from raw texts are key in achieving state-of-the-art results in various tasks requiring semantic understanding. However, obtaining embeddings at the document level is challenging due to computational requirements and lack of appropriate data. Instead, most approaches fall back on computing document embeddings based on sentence representations. Although there exist architectures and models to encode documents fully, they are in general limited to English and few other high-resourced languages. In this work, we provide a systematic comparison of methods to produce document-level representations from sentences based on LASER, LaBSE, and Sentence BERT pre-trained multilingual models. We compare input token number truncation, sentence averaging as well as some simple windowing and in some cases new augmented and learnable approaches, on 3 multi- and cross-lingual tasks in 8 languages belonging to 3 different language families. Our task-based extrinsic evaluations show that, independently of the language, a clever combination of sentence embeddings is usually better than encoding the full document as a single unit, even when this is possible. We demonstrate that while a simple sentence average results in a strong baseline for classification tasks, more complex combinations are necessary for semantic tasks. Our code is publicly available.¹

1 Introduction

Semantic representations, especially embeddings, are crucial for natural language processing (NLP). In fact, the field has exploded since the success of dense word embeddings (Mikolov et al., 2013). For some tasks like finding semantic or syntactic relations among words, high quality word embeddings

are enough. Other tasks, like question classification or paraphrase detection, benefit from sentence embeddings. Finally, lots of tasks deal with documents: summarisation, document classification, question answering, etc. Document representations are difficult to be learned, especially multilingually, given the amount of available training data and the length of each training instance.

For these reasons, document embeddings usually resort to sentence embeddings. Since some of the state-of-the-art techniques for language modelling and sentence embeddings are based on self-attention architectures such as BERT (Devlin et al., 2019), and self-attention scales quadratically with the input length, one cannot afford arbitrarily long inputs. Training is usually constrained to input fragments up to 512 tokens (subunits). This limit goes well beyond an average sentence length and can cover several paragraphs. However, full documents can be significantly longer. The average length of a Wikipedia article in English is 647 words (not subunits) for example,² and the average for two of the tasks that we consider in this work, document alignment and ICD code classification, is around 800 words, with documents up to 40k words.

In order to be able to process long inputs, more efficient architectures such as Linformer (Wang et al., 2020), Big Bird (Zaheer et al., 2020) or Longformer (Beltagy et al., 2020) implement sparse attention mechanisms that scale linearly instead of quadratically. These architectures accept at least 4096 input tokens. With this length, one can embed most Wikipedia articles, news articles, medical records, etc. These architectures are available as pre-trained models in English³ and can be fine-tuned for NLP tasks such as document classification, question answering or summarisation. How-

ever, multilingual or non-English versions are rare. For most languages, it is not just a matter of training a model from scratch, but the amount of documents is just not enough to train high quality models.

LASER (Artetxe and Schwenk, 2019; Heffernan et al., 2022), Sentence BERT (Reimers and Gurevych, 2019, 2020) and LaBSE (Feng et al., 2022) are representative and state-of-the-art models which largely adapt language models to be used as task-independent sentence representations. These models are available as pre-trained models and, contrary to the long sequence models introduced before, they are multilingual. LASER, which is not transformer-based, allows longer inputs.

These observations explain why the two main approaches to obtain multilingual (or non-English) document embeddings are simply (i) truncating the input to 512 tokens and feeding it into a sentence-level encoder or (ii) splitting the document in shorter fragments and then combine their embeddings. There are few works that do a systematic comparison among methods. Park et al. (2022) perform a systematic study for document classification in English and found that the most sophisticated models such as Longformer do not always improve on a baseline that truncates the input to fit it into a fine-tuned BERT. The results mostly depend on how the information is distributed along a document and therefore varies from dataset to dataset.

In this work we explore multilingual document-level embeddings in three tasks in detail: *document alignment*, a bilingual semantic task; *ICD code (multi-label) classification* in 2 languages; and *cross-lingual document classification* in 8 languages. We compare input token number truncation, sentence averaging as well as some simple windowing and in some cases new augmented and learnable approaches. Our results show that a simple sentence average is a very strong baseline, even better than considering the whole document as a single unit, but that positional information is needed when the distribution of information across a document is not uniform.

2 Related Work

Word embeddings have been exceptionally successful in many NLP applications (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017). Subsequent works developed methods to learn continuous vector representations for longer sequences such as sentences or even documents. Skip-thought

embeddings (Kiros et al., 2015) train an encoder-decoder architecture to predict surrounding sentences. Conneau et al. (2017) showed that the task on which sentence representations are learnt significantly impacts their quality. InerSent (Conneau et al., 2017), a Siamese BiLSTM network with max pooling, and Universal Sentence Encoder (Cer et al., 2018), a transformer-based network, are trained over the SNLI dataset which is suitable for learning semantic representations (Bowman et al., 2015).

These methods primarily work on a single language but as multilingual representations have attracted more interest, sentence-level embeddings have been extended to obtain a wider language coverage. Artetxe and Schwenk (2019) (LASER) learn joint multilingual sentence representations for 93 languages based on a single BiLSTM encoder with a shared BPE vocabulary trained on publicly available parallel corpora. However, this architecture was shown to underperform in high-resource scenarios (Feng et al., 2022). LASER is especially interesting for our work as, being LSTM-based, it does not have the 512-length constraint. Li and Mak (2020) introduce T-LASER, which is a version of LASER that uses a transformer encoder in place of the original bidirectional LSTM. However, this model was tested only on the Multilingual Document Classification (MLDoc) corpus (Schwenk and Li, 2018), which does not have significantly long documents. Similarly, Reimers and Gurevych (2019) (sBERT in the following) extended a transformer-encoder architecture, BERT, by using a Siamese network with cosine similarity for contrastive learning in order to derive semantically meaningful sentence representations. More recently, Feng et al. (2022) (LaBSE) explored cross-lingual sentence embeddings with BERT by introducing a pre-trained multilingual language model component and show that on several benchmarks, their method outperforms many state-of-the-art embeddings such as LASER.

While sentence-level representations have been widely explored in literature, document-level representations are less well-explored. The earliest approaches in learning document-level vector representations included an extension of the Word2Vec algorithm named Doc2Vec (Le and Mikolov, 2014) with two variants proposed, a bag-of-words and a skip-gram based model. However, while these methods worked well at the word-level,

the document-level counterpart led to issues in scaling due to large vocabulary sizes (Lau and Baldwin, 2016). Due to these limitations, further works have attempted to improve the computational bottlenecks involved with training on long sequences such as documents. Linformer (Wang et al., 2020) is a transformer-based architecture with linear complexity due to a sparse self-attention mechanism making it significantly more memory- and time-efficient in comparison with the original transformer (Vaswani et al., 2017). Works such as Big Bird (Zaheer et al., 2020) and Longformer (Beltagy et al., 2020) introduced a sparse attention mechanism and localised global attention respectively. BigBird is able to handle sequences of up to 4,096 tokens and Longformer scales linearly with the sequence length, with experiments on sequences of length upto 32,256. To the best of our knowledge, to date not much has been done to extend them beyond English. Shen (2021) and Romero (2022) made available Chinese and Spanish Longformer models, respectively, while Sagen (2021) trained a multilingual version starting from a RoBERTa checkpoint and not from scratch. We use Longformer as a comparison system in our experiments but we do not consider the multilingual model given that multilinguality was achieved by fine-tuning on question answering data and we do not explore this task.

3 Sentence Embeddings

We use three multilingual sentence-level embedding models that cover different languages, architectures and learning objectives:

LASER (Schwenk and Douze, 2017; Artetxe and Schwenk, 2019) uses max-pooling over the output of a stacked BiLSTM-encoder. The encoder is extracted from an encoder-decoder machine translation setup trained on parallel corpora over 93 languages. Since it is not based on transformers but on LSTMs, the maximum number of input tokens can in principle be arbitrary and is set to 12,000.

LaBSE Feng et al. (2022) train a multilingual BERT-like model with a masked LM and translation LM objective functions. A dual-encoder transformer is initialised with the model and fine-tuned on a translation ranking task. The final model covers 109 languages. The maximum number of input tokens is 512.

sBERT Reimers and Gurevych (2019) use the output of BERT-base with mean pooling to create a fixed-size sentence representation. A Siamese-BERT architecture trained on NLI is used to obtain the final sentence-embedding model. The maximum number of input tokens is 512, with a default value of 128. We use the multilingual version (Reimers and Gurevych, 2020).

4 Document Embeddings

We divide our approaches to build document embeddings into three families: in (i) *Document Excerpts*, we feed token sequences as they are directly into LASER, LaBSE and sBERT to obtain a document-level representation, in (ii) *Sentence Weighting Schemes*, we divide documents into sentences represented using base sentence embeddings and then explore different combination and weight strategies to obtain document embeddings, in (iii) *Windowing Approaches*, we study different distributions to learn document-level positional and semantic information.

(i) Document Excerpts

All Tokens: The full document is fed into the system (no truncation). We explore this option only with LASER which does not have the 510-token-length restriction⁴ and when possible (English, Spanish and Chinese) with Longformer.

Top-N Tokens: The document is truncated to the first $n = 510$ tokens.

Bottom-N Tokens: The last $n = 510$ tokens are fed into the system.

Top-N + Bottom-M Tokens: We select $N = 128$ and $M = 382$ to use the first N and last M tokens of the documents. These values are based on empirical explorations by Sun et al. (2019).

(ii) Sentence Weighting Schemes

Sentence Average: Each base sentence embedding (obtained with LASER, LaBSE or SBERT) is given a uniform weight. This computes the vanilla average embedding vector of all sentences in the document.

⁴That is the maximum length of tokens accepted by transformer-style embedding models, 512 without the [CLS] and [SEP] tokens.

Top/Bottom-Half Average: Only the top (bottom) half of the sentences in the document are considered for averaging.

TF-IDF Weights: We compute TF-IDF scores for all terms in a document, and average their values at sentence level. The base sentence embeddings (LASER, LaBSE, SBERT) are then weighted by the normalised value of the TF-IDF averages. Following [Buck and Koehn \(2016b\)](#), we use different TF-IDF computations based on variations of term frequency tf and inverse document frequency idf definitions. For words w in a document d belonging to a collection D we report results using:

$$tf_2(w, d) = \text{freq}(w, d) \quad (1)$$

$$tf_4(w, d) = 0.4 + 0.6 \frac{\text{freq}(w, d)}{\max_{\tilde{w}} \text{freq}(\tilde{w}, d)} \quad (2)$$

$$idf_4(w, d) = \log\left(1 + \frac{|D|}{df(w, |D|)}\right), \quad (3)$$

with $df(w, D) = |\{d \in D | w \in d\}|$, and

$$tf_i idf_j(S_k) = \frac{\sum_{w \in S_k} tf_i(w, d) idf_j(w, d)}{\#w_k}, \quad (4)$$

where S_k is a sentence in a given document d , and $\#w_k$ is the number of words in sentence S_k .

The weights of these models are fixed for the static tasks and used as initialisation when training a classifier.

(iii) Windowing Approaches

TK-PERT: [Thompson and Koehn \(2020\)](#) introduced a windowing approach that weights the contribution of each sentence according to the modified PERT function ([Vose, 2008](#)) and a down-weighting function for boilerplate text. The latter was introduced to deal with webpages but it can be ignored for other types of documents. The smoothed overlapping windowing functions based on a cache of the PERT distribution (PERT-cache) encode fine-grained positional information into the resultant document vector.

A document with N sentences $S_{i|i \in \{0, \dots, N-1\}}$ is split uniformly into J parts and the final representation D for a document is given by a concatenation of normalised position-weighted (via PERT) sub-vectors where each sub-vector D_j is

$$D_j = \sum_{n=0}^{N-1} \text{emb}(S_n) P_j(n) B(S_n), \quad (5)$$

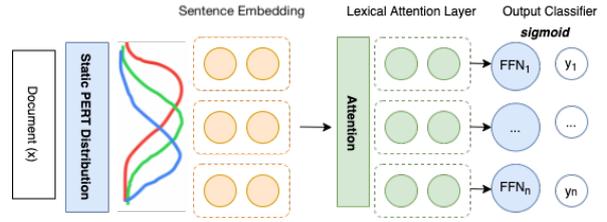

Figure 1: ATT-PERT model for classification. A static modified PERT distribution is used to extend the sentence embeddings to documents. Afterwards, an attention-weighted classifier is learnt.

emb is the (LASER, LaBSE, SBERT) embedding of sentence n , P is the modified PERT function for part j and B is a boilerplate function if there is one. In cases when no boilerplate text is present, we set it to 1.

Following [Thompson and Koehn \(2020\)](#) setting for the modified PERT distribution, we use $J = 16$ and set its shape parameter to $\gamma = 20$.

TF-PERT: is a new extension of TK-PERT to further incorporate semantics. PERT focuses on positional information encoded in the document while TF-IDF focuses on the semantic information, therefore a combined metric would likely be able to consider both features. We combine the two contributions with a multiplication at sentence level:

$$D_j = \sum_{n=0}^{N-1} \text{emb}(S_n) P_j(n) B(S_n) tfidf(S_n), \quad (6)$$

where we use the same notation as in Eqs. 4 and 5.

ATT-PERT: is a new extension of TK-PERT to further incorporate a global learnable attention. Figure 1 illustrates the basic architecture. The PERT distribution encodes global positional information of the document. By adding an attention layer over it, we introduce a *global attention* that weights the different parts of the document and that is combined with the standard *local attention* at word level performed by the sentence encoder. Mathematically,

$$D_j = \sum_{n=0}^{N-1} \text{emb}(S_n) P_j(n) a_j(n), \quad (7)$$

where S_n refers to the sentence embedding that has been trained for a classification task and $a_j(n)$ is the respective global attention weight.

In TK-PERT, the static PERT distribution is multiplied by the fine-tuned sentence embeddings. In

contrast, in ATT-PERT, the distribution is multiplied with the embeddings prior to training a classifier without freezing the embedding layer, as this allows the positional weights in the PERT distribution to be trained for the specific task.

ATT-TF-PERT: is a new extension of TF-PERT to further incorporate a global learnable attention as in ATT-PERT. In this configuration, we learn combined TF-IDF-PERT weighted embeddings whose attention weights are further updated while training the classifier. We use the same *global attention* $a_j(n)$ as in ATT-PERT, however here it is multiplied with both the TF-IDF weight of the sentence $tfidf_j(w, S_n)$ as computed in the TF-IDF set up and the PERT distribution $P_j(n)$ as in TK-PERT:

$$D_j = \sum_{n=0}^{N-1} \text{emb}(S_n) P_j(n) a_j(n) \text{tfidf}(S_n). \quad (8)$$

5 Evaluation Tasks

We apply the different configurations discussed above across the following tasks:

Bilingual Document Alignment aims at aligning documents from two collections in language L1 and language L2 according to whether they are

parallel or comparable. In our experiments, we use the data given for the WMT 2016 Shared Task on Bilingual Document Alignment to align French web pages to English web pages for a given crawled webdomain (Buck and Koehn, 2016a). In these experiments we do not perform any learning using the training data, but just estimate document-level semantic similarity between the pairs of documents in the test set. To compute this, we find the top $K=32$ candidate translations using approximate nearest neighbor search via FAISS⁵ as in (Buck and Koehn, 2016a). We use cosine similarity to quantify semantic similarity on the document embeddings.

Multi-label ICD Code Classification aims at assigning one or more ICD-10 codes to medical-domain texts (electronic health records). Here there can be an arbitrary number of ICD-10 codes assigned to the input text. In particular, out of all the possible ICD-10 Codes, 4 account for more than 90% of the documents, making this an imbalanced classification task and leading to the ‘tail end problem’ (Chapman and Neumann, 2020). We use the CLEF eHealth 2019 task for German non-technical summaries (Neves et al., 2019) and CANTEMIST-CODING (Miranda-Escalada et al., 2020) for Spanish electronic health records. Here, we learn a weighted-attention classifier layer (Lee et al., 2022) on top of the base document embeddings consisting of a feed-forward neural network with a single hidden layer of 10 units.

Cross-lingual Document Classification aims at classifying documents in a set of predefined categories in a language (usually English) and then transfer the model to unseen languages. We use the MLDoc dataset for this purpose (Schwenk and Li, 2018). The corpus contains 1,000 development documents and 4,000 test documents in eight languages (English, German, French, Italian, Spanish, Japanese, Russian and Chinese), divided in four different genres with uniform class priors. For zero-shot transfer, we train a classifier on top of the multilingual document representations estimated as described in Section 4 by using only the English training data and the hyperparameters optimised in Artetxe and Schwenk (2019). Similar to the previous classification task, we use a feed-forward neural network with one hidden layer with 10 units.

Table 2: Document recall on WMT-16 Shared Task on English–French document alignment. Best score for each family is in bold.

We use this classifier on top on the multilingual embeddings to evaluate the system on the remaining languages.

Table 1 shows the statistics for the datasets used in the three tasks as well as an average length of training instances in terms of sentencepiece tokens.⁶ The average document length in the document alignment and ICD code classification tasks is larger than 512 tokens, making the usage of sentence embeddings alone insufficient. This is not the case for document classification, but we still consider it in order to compare the different approaches and add a highly multilingual setting.

6 Results and Discussion

Thompson and Koehn (2020) empirically obtained the best trade-off between accuracy and inference time when using PCA-reduced sentence embeddings of 128 dimensions in the bilingual document alignment task. We performed equivalent experiments with 128 and 256 dimensions for selected configurations in the three tasks and confirmed the trend. As we obtained no major gains in using more dimensions, we report all the results for the three tasks with 128-dimensional sentence embeddings.

We report confidence intervals at 95% confidence level using bootstrap resampling with 1000 samples for document alignment, 500 samples for ICD code classification and 1000 samples for document classification.

⁶<https://github.com/google/sentencepiece>

Bilingual Document Alignment quality ranges from 65% to 96% recall depending on the document embedding method. Table 2 shows the results obtained for all the configurations considered. A simple sentence average achieves a recall around 82% (depending on the sentence embedding used). When using LASER, the only method that allows the comparison, the recall with sentence average is larger but not statistically significantly over embedding the full document as a single unit (81.8% vs 81.2%). Taking a token-based excerpt of the document is 10 percentage points below sentence-averaging the same excerpt. The information in webpages seems to be more densely distributed towards the top of the page. Looking at the top-half versus the bottom-half of the sentences of the webpages, there is a 17% reduction in the scores obtained. In these unweighted and average configurations in both the token and sentence-based methods, we do not encode any positional information: sentence order and semantic relevance is not considered in the final document embeddings. However, intuitively, these factors are indicative of each sentence’s contribution to the larger document embedding. In order to incorporate semantic relevance into our final embeddings, we consider the weighted average using TF-IDF. We explore several TF-IDF forms and obtain a difference of 7% on average among them. Table 2 shows the 2 most promising ones. With the best option ($tf_4 - idf_4$), TF-IDF weighting improves between 3 and 5 percentage points with respect to the sentence averaging which uses uniform weights. We use $tf_4 - idf_4$ for the next experiments when required as these formulae empirically performed the best. To include sentence order, we use the PERT-window based approach. TK-PERT outperforms all other methods by a margin of 11.7%. This result attests the relevance of contextual information, sentence order, and positional importance. Although we find improvements over the baseline models by introducing TF-IDF weights and the PERT distribution, a combination of the two in TF-PERT does not lead to further improvements.

The other dimension of the study, the particulars of sentence embeddings, is less important to the recall. LASER, LaBSE and sBERT achieve similar results. As we are working with French and English documents, both languages being high-resource, all base sentence embeddings are high-quality and therefore they do not impact the final

Table 3: F1 scores for the Multi-label ICD code classification task for German (de) and Spanish (es) documents. Best scores are in bold, and best scores per family are in italics.

model strongly in a consistent way.

Multi-label ICD Code Classification shows the same trend with respect to different sentence embeddings as above for German and Spanish, with a slight preference towards LaBSE embeddings. Table 3 shows the results for this task. There is a large discrepancy between the scores for the German and the Spanish datasets, as already noticed by the evaluations in the original corresponding shared tasks. The classification in Spanish achieves much lower results probably because of a very small training corpus. Our results indicate that the information is spread throughout documents in this case. The difference between only using the top of the document and only using the bottom part is small, and using the whole document either by sentence averaging or considering it a single unit is always better than any of its parts at a 95% significance level. Semantic (TF-IDF) and positional (TK-PERT) information is less relevant. For the German task, either considering the full document as a whole (*All tokens*) or averaging all the sentences gives the highest performance. For the Spanish task, even with a very low overall quality, learning specific weights for different parts of the document (ATT-PERT) boosts the quality. Comparing ATT-PERT with TK-PERT, we find that the trainable alternative performs better for all languages and base embeddings considered, however, the improvements are not statistically significant for all base embeddings in the case of German. In general, the windowing approaches that combine semantics with position (TF-PERT and ATT-TF-PERT) do not perform significantly better than the pure positional methods

(TK-PERT and ATT-PERT). This can be explained by looking a concrete example. Figure 2 shows the distribution of weights across a document from the CANTEMIST health record corpus for 8 configurations based on LASER embeddings. The example shows that the effect of the *tfidf* component in ATT-TF-PERT (configuration 7) is equivalent to move weight mass from ATT-PERT (configuration 6) into TF-IDF (configuration 3). When this happens, the result is a score in the middle of the way between ATT-PERT and TF-IDF. In this document, a medical diagnostic evaluation is detailed and includes patient information, past diagnoses, family medical history, as well potential evolution of the disease. We observe that while the ‘Sentence average’ configuration places largely equivalent weights on all the sentences, the TF-IDF weights place more emphasis on the beginning and end of the document which stores information about the patient and the evolution of the disease respectively. This behaviour is similar to the one exhibited by the PERT family of methods: the weight pattern observed for configurations 3-7 remain quite consistent but vary in their intensity.

Cross-lingual Document Classification data allows us to test the embedding methods on 8 languages (Table 4). The languages belong to three families, Indo-European (Germanic, Romance and Slavic), Japonic and Sino-Tibetan. All languages are high-resourced and included in our pre-trained sentence representation models. MLDoc documents are shorter than 1,000 tokens with an average length of 275 tokens for English and 562 for Chinese; the other languages stay in the middle.

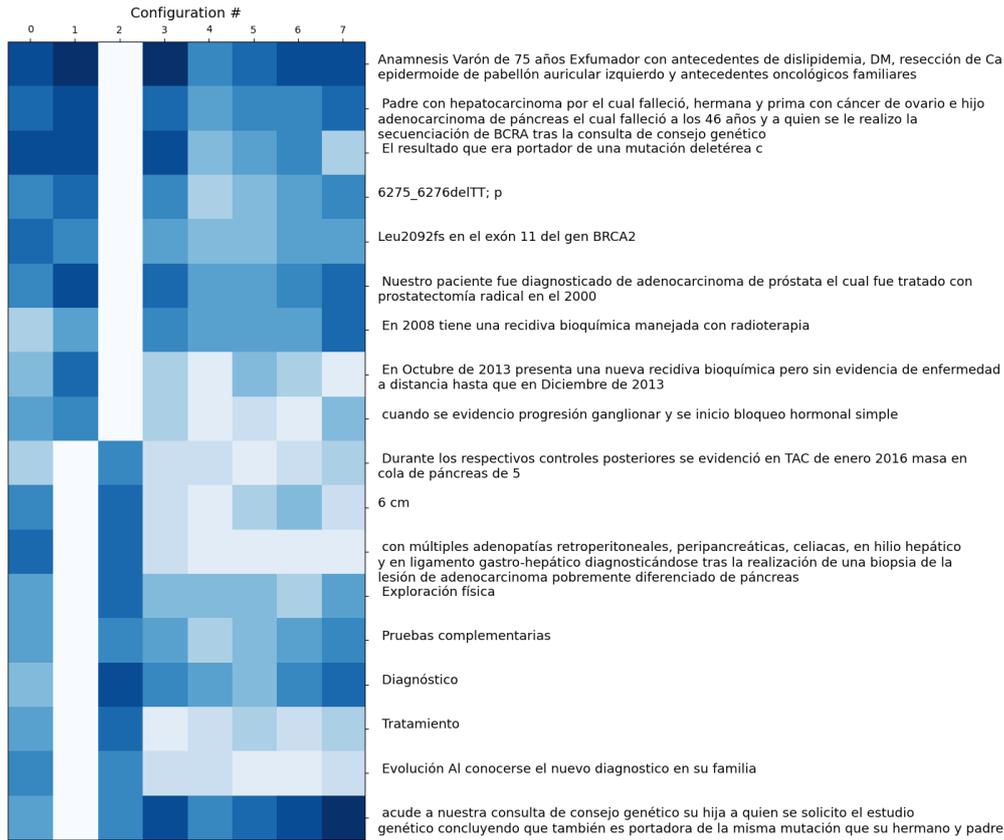

Figure 2: Sentence weights for an example document with LASER embeddings and the configurations: 0-Sentence average, 1-Top-Half, 2-Bottom-Half, 3-TF-IDF weighted, 4-TK-PERT, 5-TF-PERT, 6-ATT-PERT, 7-ATT-TF-PERT.

Given that length, the methods that use different 510-sized excerpts of the documents do not differ much as all the excerpts are—for most of the documents—the same.

Accuracies in Table 4 show that the documents convey slightly more meaning at the top part than at the bottom (*Top-Half Avg.* vs *Bottom-Half Avg.*). The sentence average is a very strong baseline and, for half of the languages (English, German, Russian and Chinese), this is statistically significantly better at 95% confidence level than treating the document as a single unit with LASER. The TF-IDF version is worse than the simple sentence average except for Japanese. Japanese has the lowest accuracy for all the languages and a high difference between the information at the top and the bottom of its documents. In general, position (TK-PERT) is more important than semantics (TF-IDF) and learning task-specific weights (ATT-PERT) further increases accuracy. Additional experiments with TF-PERT and ATT-TF-PERT do not show statistically significant improvements over their counterparts TK-PERT and ATT-PERT, similarly to the trend observed in the previous tasks. For English, Chinese

and Spanish, we are further able to compare the performance of pre-trained large-input transformers. Longformer achieves 92.3% of accuracy for English, which is 4.1% better than the 88.7% that LASER achieves in the *All tokens* configuration and about 2% better than the best performing architecture, the sentence average of LaBSE embeddings (90.9%). However, the latter is not statistically significant at 95% confidence level. The result is different for Chinese and Spanish. In both cases, considering all tokens with LASER and sentence average are better than Longformer, although the difference is not statistically significant for Spanish. This indicates that smaller amounts of training data can prevent native full document-level embeddings to be extended to languages other than English.

7 Summary and Conclusions

In this work, we studied effective methods for developing multilingual document-level representations. We used state-of-the-art sentence-level embeddings as basic units and systematically compare different pooling methods to evaluate these representations at the document level. We performed

Table 4: Accuracy for MLDoc classification on the zero-shot transfer task. Best results per language are shown in bold and per family in italics.

exhaustive evaluations across three sentence embedding models, three tasks and eight languages.

Our experiments show that specific **base sentence embedding models** (LASER, LaBSE, sBERT) do not impact the performance of the document-level embeddings much. We observe similar performance amongst them across all experiments. However, it is to be noted that we experiment with languages that while being morphologically distinct, are well resourced and covered by the three base sentence-embedding models. It would be interesting to explore how models behave when embeddings have a lower quality. For this, one would need to create evaluation datasets at the document level for low-resourced languages but this is out of the scope of this work.

We observed that a simple sentence average is a very strong **pooling strategy**, specially for classification tasks. Positional and contextual information is more important than semantic information for the final performance as exemplified by the fact that PERT-based weightings perform better than TF-IDF’s in all the tasks. When combining both,

positional and semantic information, we do not observe statistically significant improvements with respect to only including positional information. For the classification tasks which include a learnable layer, we extend TK-PERT to ATT-PERT (and the semantic counterparts) and include global trainable attention on the positional information. This global attention is beneficial in all the cases.

The **type of document** is also relevant to chose the best method. Long documents might have the most crucial information stored in different parts. For instance, webpages have a majority of their information in the first half of the document as we observed in the document alignment task. In this case, the positional information significantly outperforms any model that does not take it into account.

Limitations

One of the main focal points of this work is multilinguality. In the presented approaches, the multilinguality of the resultant document embeddings depends solely on the language coverage and cross-

lingual transfer ability of the pre-trained sentence embeddings used as basic units. Document-level representations are as robust to new languages and scripts as the base sentence embeddings are. Cross-lingual transfer is a perpendicular dimension not studied in this work.

We introduce ATT-PERT, a new learnable approach for the combination of sentence embeddings. This model is therefore of use for tasks with a learning/fine-tuning phase but it is not intended for ready-to-use multilingual document-level embeddings in contrast to the existing pre-trained sentence-level counterparts.

Abstract

In this work we study user controlled table-to-text generation where users explore the content in a table by selecting cells and reading a natural language description thereof automatically produce by a natural language generator. Such generation models usually learn from carefully selected cell combinations (clean cell selections); however, in practice users may select unexpected, redundant, or incoherent cell combinations (noisy cell selections). In experiments, we find that models perform well on test sets coming from the same distribution as the train data but their performance drops when evaluated on realistic noisy user inputs. We propose a fine-tuning regime with additional user-simulated noisy cell selections. Models fine-tuned with the proposed regime gain 4.85 BLEU points on user noisy test cases and 1.4 on clean test cases; and achieve comparable state-of-the-art performance on the ToTTo dataset.¹

1 Introduction

The goal of table-to-text generation is to provide the user with a description of the most relevant content in a given table (Lebret et al., 2016; Wiseman et al., 2018; Perez-Beltrachini and Lapata, 2018; Puduppully et al., 2019). Recently, Parikh et al. (2020) proposed a controlled table-to-text generation task where the goal is to automatically create a description for a determined subset of the table, namely the highlighted table cells. The main focus on Parikh et al.’s 2020 work is to assess the performance of neural text generators in a more controlled setting, i.e., when given an input table with explicit instructions (i.e., highlights) on what should be expressed in the output description. In this work, we view this task in the context of a natural language interface, as a *user controlled table-to-text* generation task, where users provide those

Target Text: Craig finished his eleven NFL seasons with 8,189 rushing yards and 566 receptions for 4,911 receiving yards.

Figure 1: An example in the ToTTo dataset. The figure is retrieved from (Parikh et al., 2020). The cells coloured in yellow are the highlight cells.

highlights interactively by exploring the content of a given table and study these user interactions. Figure 1 illustrates the case where a user selects some cells (highlighted in yellow) and the generator provides a description thereof (shown below the table).

A crucial aspect of usability assessment for a generator in this interactive table-to-text task is robustness. In a recent study by (Mille et al., 2021), it has been shown that neural generation models fail to maintain their in distribution performance when confronted with realistic scenarios at test time such as typos in the input text. In the case of user controlled table-to-text generation, users may introduce noise when exploring the table content and select cell combinations that turn out to be unexpected, redundant, or incoherent. For example, in Figure 1, when the user wants to express "eleven seasons", they might miss one year or highlight the header cell. They may also select unrelated headers, for instance adding the header "LNG" ¹ to the current selection. Existing controlled table-to-text generation models (Parikh et al., 2020; Su et al., 2021; Kale and Rastogi, 2020) are trained on carefully selected cell combinations (**clean** cell highlights) from the ToTTo dataset (Parikh et al., 2020). We argue that these models will not generalize well in practice with user **noisy** highlights. No previous work has study model robustness under this practical set up.

We carry out a usability study to observe how users highlight cells in a table. Based on the imperfect cell selections that users produce, we automatically create additional data examples by corrupting examples from the original ToTTo dataset. We then fine-tune state-of-the-art table-to-text neural generation models with this additional data. We compare the performance of models fine-tuned only with clean cell highlights versus those trained with additional noisy cell highlights, both on a test set with clean and noisy highlights. Experimental results show that models fine-tuned with clean cell highlights only perform well on clean test cases (i.e., performance drops dramatically when evaluated on noisy cell highlights). That is, these models do not generalise well in practice with user noisy cell selections. In contrast, the proposed training scheme with additional noisy cell highlights not only makes user controlled table-to-text models achieve better performance in practical scenarios, but it also boosts performance on perfect inputs. Experimental results show that models fine-tuned with our proposed training regime gain 4.85 BLEU points on noisy and 1.4 BLEU points on clean highlights; and achieve comparable state-of-the-art performance on the ToTTo dataset.²

2 Methodology

We describe the process for creating user noisy cell highlights from examples in ToTTo (Parikh et al., 2020) (§2.1 and §2.2). Then, we evaluate models optimized with the standard training scheme (i.e., only on clean cell highlights) on the created noisy test cases. Results show that these models perform poorly. To improve model robustness, we propose a new learning regime described in §2.3. To further improve performance, we fine-tune with Reinforcement Learning (RL) based optimisation (§2.4). Finally, §2.5 summarises the learning schemes and objective functions we propose for robust user controlled table-to-text generation.

2.1 How Do Users Select Cells?

To understand how users proceed when exploring a table and selecting cells we carry out a human study using examples from the ToTTo dataset. Participants are given a plain table (i.e., without highlights) and asked to highlight cells according to an exploratory intention. For a more controlled setting, we give the sentence associated to the ta-

ble as the exploratory intention. In this way, we avoid ambiguous post-selection analysis of what the user intention was. In addition, this allows us to compare user selections with reference highlights as well as differences (if any) in model generated texts given user and reference highlights.

We conduct this study on Amazon Mechanical Turk (the interface is described in Appendix C). We collect 90 user highlights (3 participants, volunteers known by the authors, and 30 examples from the validation set) and observe the following noise in their highlights. Participants apply different criteria to include (or not) table headers; select additional cells in columns/rows around cells containing relevant content; and do not select cells that contain content relevant to the intention.

2.2 Creating User Noisy Cell Selections

Given the input table T , the reference text S , and the reference highlight cells $H \in T$ relevant for generating S , we create noisy user cell selections as follows. We provide an example illustrating each noise type in Figure 2.

Noise 1: Additional Table Cells In practical scenarios, users may accidentally select random cells that are not related to their exploration intention. Thus, we randomly select k cells from the table cells in T that are not in H and add them into H to form a corrupted input H_1 . H_1 can be viewed as adding irrelevant information in the generation of the target text S .

Noise 2: Table Headers as Additional Inputs Reference highlight cells in the ToTTo dataset do not cover table headers. As we have observed, users may decide to include (or not) table headers in different cases. To simulate this, we first retrieve table headers corresponding to highlight cells in H . Then, we randomly select k unique headers and add them into H to get the corrupted input H_2 .

Noise 3: Similar Table Cells For this type of noise, we select cells that are in the same row/column as the highlight cells. The intuition, as seen in the user study, is that these cells will have similar semantics to those cells underlying the exploratory intention and users tend to select them. For H_3 , we first retrieve table cells that are in the same row/column as highlight cells. Then, we randomly select k unique cells thereof and add them into H .

²ToTTo leaderboard.

Noise 4: Remove Cells from H Users also miss some of the highlight cells in H . For this type of noise, we first retrieve those cells in H that are irrelevant (i.e., their content is not expressed in) for generating S . After getting the irrelevant cells in H , we randomly choose k thereof and remove them from H to create H_4 .

2.3 Augmenting the Training Dataset

We propose to fine-tune models on the training set augmented with noisy data. We extend the original ToTTo training set $\mathcal{D} = \{(T, S, H)\}_{j=1}^{|\mathcal{D}|}$ with data instances with user noisy cell selections. Specifically, we replace data instances with clean cell selections H in \mathcal{D} with corrupted data instances with noisy cell selections H_i . This results in a training set \mathcal{D}_i consisting of noisy cell selections of noise type i . The final training set \mathcal{D}_{final} contains both clean and corrupted data instances, its size is 603,805 (5 times the size of the original training set), and it is defined as $\mathcal{D}_{final} = \mathcal{D} \cup \mathcal{D}_1 \cup \mathcal{D}_2 \cup \mathcal{D}_3 \cup \mathcal{D}_4$. We set $k = 1$ for creating data instances of type Noise 1, Noise 2, and Noise 3. This is because the average number of highlight cells in ToTTo dataset is small (3.55). To create instances of type Noise 4, we remove all irrelevant cells found in H .

2.4 Robustness via Sequence Level Training

Inspired by PlanGen (Su et al., 2021), to further enhance the robustness of table-to-text models on clean and noisy cell selections, we further fine-tune model parameters with Reinforcement Learning (RL) (Williams, 1992). Formally, given an input data pair $\{T, S, H\} \in \mathcal{D}_{final}$ and a sampled output sequence $S' = (S'_1, \dots, S'_{|S'|})$, the RL training objective is formulated as:

$$\mathcal{L}_{RL} = -R(S, S') \sum_{i=1}^{|S'|} \log P \left(S'_i \mid S'_{<i}, E(T, H) \right) \quad (1)$$

where $E(\cdot)$ denotes the encoder module of a table-to-text generator. The reward function $R(S, S')$ measures the similarity between the reference text and the text generated by the model; it is formulated as $R(S, S') = B(S, S')$ where $B(\cdot, \cdot)$ is the BLEU score (Papineni et al., 2002). By doing this, we make the outputs of both clean and noisy cell selections to be more similar to the reference texts. This implicitly improves the similarity between outputs of clean and noisy cell selections.

Model	Clean	Noise	Noise	#Param
		Avg.	Var.	
BART-BASE (clean)	47.8	44.0	9.09	141M
BART-LARGE (clean)	48.6	43.9	14.43	408M
BART-BASE (\mathcal{D}_{final})	48.5	48.03	0.16	141M
BART-BASE + RL (\mathcal{D}_{final})	49.2	48.85	0.14	141M
BART-LARGE (\mathcal{D}_{final})	49.1	48.16	0.69	408M
BART-LARGE + RL (\mathcal{D}_{final})	49.6	48.75	0.60	408M

Table 1: BLEU scores on clean and noisy development sets. Average BLEU score across the four noisy development sets (Noise Avg.). Variance of BLEU scores across the four noisy development sets (Noise Var.). Model parameters (#Param). The attribute in parenthesis indicates the dataset used for model fine-tuning.

2.5 Table-to-Text Generation Models

Our models are based on BART (Lewis et al., 2020). We fine-tune them for user controlled table-to-text generation as follows. Given a training data pair $\{T, S, H\}$, the fine-tuning process proceeds in two stages. The first stage fine-tunes the model with a conventional conditional language modelling training objective:

$$\mathcal{L}_{LM} = - \sum_{i=1}^{|S|} \log P \left(S_i \mid S_{1:i-1}, E(T, H) \right) \quad (2)$$

where E denotes the encoder of the table-to-text generator. The second stage further adjusts model parameters by using $\mathcal{L}_{mix} = \mathcal{L}_{LM} + \mathcal{L}_{RL}$.

3 Experimental Results

Implementation details for our table-to-text generation models can be found in Appendix B. We use the same hyperparameters as the baseline in the ToTTo (Parikh et al., 2020).

As shown in Table 1 (detailed results per Noise type are given in Appendix A), when using the training scheme with clean cell highlights, the average BLEU score of **BART-BASE (clean)** drops from 47.8 to 44 when tested on noisy cell selections. Similar trend can be seen for **BART-LARGE (clean)** with a BLEU score drop from 48.6 to 43.9. In addition, the ‘‘Noise Variance’’ of **BART-BASE (clean)** and **BART-LARGE (clean)** is large, indicating that these models are not stable (or robust) to different types of noisy cell selections. All this suggests that a training scheme with carefully selected cells alone results in systems that perform poorly in practical scenarios with user interactions.

In contrast, we observe that our proposed learning scheme makes generators achieve better performance both on clean and noisy cell selections. On

Table 3: ToTTo test set results. All reported results can be found in the ToTTo leaderboard.

clean cell selections (ToTTo original development set), the model trained using the proposed learning scheme **BART-BASE** (\mathcal{D}_{final}) outperforms the model using the same pre-trained model but fine-tuned with the standard learning scheme **BART-BASE (clean)** by 0.7 BLEU scores. On noisy cell selections, **BART-BASE** (\mathcal{D}_{final}) outperforms **BART-BASE (clean)** by 4.03 BLEU points on average. In addition, **BART-BASE** (\mathcal{D}_{final}) has a

small “Noise Variance” score across four noisy and one clean development sets, suggesting that the proposed learning scheme can make controlled table-to-text generators more robust and less sensitive to various types of noisy cell selections. Fine-tuning with RL, **BART-BASE + RL** (\mathcal{D}_{final}), can further boost models’ performance.

In Appendix A we provide additional experiments on ablation results on the contribution of each Noise dataset, training with a subset of \mathcal{D}_{final} (i.e., training with one fifth of the data also improves robustness), and evaluating on cases with different amount of noise (i.e., our approach generalises better to cases with higher values of k).

To gain insights on how the improvements are perceived in generated descriptions, we conduct a human evaluation. We follow the setup described in (Parikh et al., 2020). We sample 100 development instances and have five human judges (voluntary MSc level students fluent in English) to annotate them across three criteria. **Fluency** (users select amongst *Fluent*, *Mostly Fluent*, and *Not Fluent*; we report the percentage of outputs annotated as *Fluent*); **Faithfulness** (a candidate sentence is considered to be faithful if all the information in it is supported by the highlight cells and metadata of the table; we

report the percentage of outputs that users annotate as faithful); and **Covered Cells** (the percentage of highlighted cells that the candidate sentence covers; we report average percentage of covered cells across all sampled instances). Table 2 shows that judges find outputs by the model variants fine-tuned with the proposed regime more faithful, fluent and with better cell coverage.

We choose the best performing model, **BART-LARGE + RL** (D_{final}), fine-tuned with the proposed approach and compare it with state-of-the-art models on the ToTTo test set. These are NCP (Puduppully et al., 2019), Pointer-Generator (See et al., 2017), Bert-to-Bert (Parikh et al., 2020), and T5-3B (Raffel et al., 2020), LATTICE (Wang et al., 2022), and PlanGen (Su et al., 2021). Table 3 shows overall results (detailed overlap/non-overlap results are provided in Appendix A). Our model performs in par with T5-3B and PlanGen despite the fact that the first one has more parameters and the second one possesses a dedicated planning step.

Figure 2 shows two instances of synthetic noisy cell selections of type Noise 1 (i.e., accidentally selected random cell not related to the exploration intention) and type Noise 2 (i.e., random criteria for header selection); and two instances of user noisy cell selection from the human study of type Noise 3 (i.e., highlight 2014 semantically close to cells in the exploratory intention) and Noise 4 (i.e., *won* is not highlighted). Cells in yellow indicate original highlights from the ToTTo dataset and those in orange are noisy selections. In both cases, the outputs produced by the model fine-tuned with the proposed regime are not affected by noise and show better coverage, factual accuracy, and lexicalisation. This illustrates human evaluation preferences.

4 Conclusion

We study the performance of user controlled table-to-text generation. We show that standard training schemes with only carefully selected cells causes poor robustness of generators in practice when confronted with user noisy cell selections. To address this, we introduce a training scheme with simulated user noisy cell selections. Experimental results show that generators optimized with our proposed scheme can achieve better performance on both clean and noisy cell selections. In the future, it would be interesting to investigate how to apply our approach to other data-to-text datasets to improve model generalisation.

We thank the anonymous reviewers for their feedback. We gratefully acknowledge the support of the UK Engineering and Physical Sciences Research Council (award number 681760).

Limitations

We create synthetic data simulating real users interactions (i.e., user cell selections on a table). However, the automatic noise generation method does not cover all possible user interactions and may fail to exactly reproduce them in some cases. For example, our process for creating Noise 3 randomly highlights cells in the same row/column as a reference highlighted cell. However, the probability distribution of a user highlighting a cell around a reference highlighted cell is not always uniform, but in some cases based on some reasoning process about the concerned cells. In the future, it would be interesting to investigate how to simulate this reasoning process to predict where the user is likely to highlight cells. Nevertheless, the set of noise types that we propose in this work shows that models trained only on cleaned data are brittle.

A Detailed and Ablation Results

Table 4 provides detailed results for the different model variants (**clean**) and (\mathcal{D}_{final}) evaluated on different development sets with different types of noise (cf., Table 1 in Section 3). Table 5 provides detailed results comparing our model **BART-LARGE + RL** (\mathcal{D}_{final}) with other state-of-the-art methods in ToTTo’s leaderboard (cf., Table 3 in Section 3).

We conduct an ablation study to investigate the impact of each type of noise in \mathcal{D}_{final} (see Section 2.2). Specifically, we remove one of the four noise types at a time from \mathcal{D}_{final} , then train the **BART-BASE** model using the remaining data. This study shows that all types of user noisy cell selections help to improve performance and robustness (Table 6).

We construct corrupted ToTTo development datasets with *different amount of noise* (i.e., different number k of noisy cells) added to each original input highlighted cells. In the ToTTo dataset, there are on average 3.5 highlighted cells for each table; when $k = 3$, the injected noise has roughly the same proportion as the original highlight cells. We then examine BLEU scores for **BART-BASE** trained with our approach and the baseline on these noisy development sets. As shown in Table 7, performance drops significantly as more noise is injected, from 47.8 when $k = 0$ (clean) to 34.8 when $k = 3$, for the model trained only on clean cell selections, **BART-BASE** (clean). It also indicates that the models trained with our proposed method, **BART-BASE** (\mathcal{D}_{final}) and **BART-BASE + RL** (\mathcal{D}_{final}), can reduce this performance drop.

We also combine all noise types with clean data for training in a way that the resulting dataset has the same size as the original clean dataset. Specifically, we randomly divide the original dataset into five equal parts and replace four of them each by a different type of noisy data subset; one of the parts is not replaced (i.e., one part of the original clean set is kept). We merge these five parts together and call this the mixed dataset \mathcal{D}_{mix} . Results in Table 8 indicate that training the model on a substantially smaller subset of clean and noisy data (i.e., a subset of \mathcal{D}_{final}) still yields comparable performance on clean data and significant better performance on noisy data.

Model	Clean	Noise1	Noise2	Noise3	Noise4	Noise	Noise	#Param
	Dev set	Average	Variance					
BART-BASE (clean)	47.8	40.6	45.6	42.5	47.3	44	9.087	141M

B Implementation Details

The examined models are based on the Hugging-face Library (Wolf et al., 2020) with default model hyperparameters provided by the Library. We fine-tune BART (Lewis et al., 2020) using the proposed learning scheme. We use the Adam (Kingma and Ba, 2014) optimizer, with a learning rate of $2e^{-5}$ and a batch of size 32. We fine-tune with the $\mathcal{L}_{\mathcal{LM}}$ objective for 100k steps and \mathcal{L}_{mix} for 50k steps.

C Human Study Interface

Figure 3 shows the Amazon Mechanical Turk interface, instructions and annotation form, we use for the human study described in Section 2.1.

Instructions

Given a table and a sentence describing part of its content, you should highlight those table cells that you think the sentence is describing. You can "highlight" a cell by entering its header and content between square brackets: [cell0_header, cell0_content]. You can list all cells that you consider as been described in the sentence by entering one cell highlight after the other: [cell0_header, cell0_content], [cell1_header, cell1_content],

It is worth noting that you are allowed to highlight the content of both headers and content cells of the table. You should not highlight meta information (details that appear above the table); usually, these are included in the sentence but you need not select them.

It is also worth noting that there are some cases where the sentence contains some sort of aggregation or summarisation of information. For instance, in the following table, eleven seasons corresponds to highlighting the eleven year values in the column YEAR in the example table below.

Table Title: Robert Craig (American football)
Section Title: National Football League statistics
Table Description: None

YEAR	TEAM	RUSHING					RECEIVING				
		ATT	YDS	AVG	LNG	TD	NO.	YDS	AVG	LNG	TD
1983	SF	176	725	4.1	71	8	48	427	8.9	23	4
1984	SF	155	649	4.2	28	4	71	655	9.5	64	3
1985	SF	214	1050	4.9	62	9	92	1016	11	73	6
1986	SF	204	830	4.1	25	7	81	624	7.7	48	0
1987	SF	215	815	3.8	25	3	66	492	7.5	35	1
1988	SF	310	1302	4.8	46	9	76	534	7.0	22	1
1989	SF	271	1054	3.9	27	6	49	473	9.7	44	1
1990	SF	141	439	3.1	26	1	25	201	8.0	31	0
1991	RAI	162	590	3.6	15	1	17	136	8.0	20	0
1992	MIN	105	416	4.0	21	4	22	164	7.5	22	0
1993	MIN	38	119	3.1	11	1	19	169	8.9	31	1
Totals	-	1991	8189	4.1	71	56	566	4911	8.7	73	17

Target Text: Craig finished his eleven NFL seasons with 8,189 rushing yards and 566 receptions for 4,911 receiving yards.

You should always highlight all those cells that you consider give rise to the information expressed/summarised in the sentence.

In this example, if you want to highlight the header "YEAR", you can type [YEAR, YEAR]. If you want to highlight the cell with the content of "1983", you can type [YEAR, 1983].

Abstract

In this work, we revisit the Transformer-based pre-trained language models and identify two different types of information confusion in position encoding and model representations, respectively. Firstly, we show that in the relative position encoding, the joint modeling about relative distances and directions brings confusion between two heterogeneous information. It may make the model unable to capture the associative semantics of the same distance and the opposite directions, which in turn affects the performance of downstream tasks. Secondly, we notice the BERT with Mask Language Modeling (MLM) pre-training objective outputs similar token representations (last hidden states of different tokens) and head representations (attention weights¹ of different heads), which may make the diversity of information expressed by different tokens and heads limited. Motivated by the above investigation, we propose two novel techniques to improve pre-trained language models: Decoupled Directional Relative Position (DDRP) encoding and MTH² pre-training objective. DDRP decouples the relative distance features and the directional features in classical relative position encoding. MTH applies two novel auxiliary regularizers besides MLM to enlarge the dissimilarities between (a) last hidden states of different tokens, and (b) attention weights of different heads. These designs allow the model to capture different categories of information more clearly, as a way to alleviate information confusion in representation learning for better optimization. Extensive experiments and ablation studies on GLUE benchmark demonstrate the effectiveness of our proposed methods.

*Equal contribution.

¹"attention weights" mainly refer to the dot product between Key and Query in the self-attention module.

²MTH is the abbreviation of our proposed MLM with Token Cosine Differentiation (TCD) and Head Cosine Differentiation (HCD) pre-training task. TCD and HCD are described in detail in sec. 1(2) and sec.3.2.

1 Introduction

The paradigm of pre-training on large-scale corpus and fine-tuning on specific task datasets has swept the entire field of Natural Language Processing (NLP). BERT (Devlin et al., 2018) is the most prominent pre-trained language model, which stacks the encoder blocks of Transformer (Vaswani et al., 2017) and adopts MLM and Next Sentence Prediction (NSP) pre-training tasks, achieving the SOTA results in 2018. After that, a large number of Pre-trained Language Models (PLMs) (Liu et al., 2019; Lan et al., 2020; Raffel et al., 2019; Clark et al., 2020; He et al., 2021) that optimize the Transformer structure and pre-training objectives have emerged, which further improves the performance of the pre-trained language models on multiple downstream tasks. In this work, we identify two different types of information confusion in language pre-training, and explore two conceptually simple and empirically powerful techniques against them as follows:

(1) **Decoupled Directional Relative Position (DDRP) Encoding.** It is well known that relative position encoding is competitive and has been widely used in real PLMs (Shaw et al., 2018; Yang et al., 2019; Wei et al., 2019; Raffel et al., 2019; Su et al., 2021; He et al., 2021; Ke et al., 2021). Despite its great performance, we still notice relative position encoding methods utilizes completely separate parametric vectors to encode different relative position information, which indicates that every single parametric vector needs to learn both distance and directional features. We consider this paradigm of utilizing a single parametric vector to represent both relative distance and direction as a kind of information confusion, and question its rationality. Since relative distance features and the directional features are apparently heterogeneous information that reflects different aspects of positional information, we argue that existing methods may impose

difficult in establishing connections explicitly between parametric vectors of the same distances and the opposite directions, which in turn result in serious information losses in position encoding. Inspired by this, we propose a novel Decoupled Directional Relative Position (DDRP) encoding. In detail, DDRP decomposes the classical relative position embedding (Shaw et al., 2018) into two embeddings, one storing the relative distance features and the other storing the directional features, and then multiply the two together explicitly to derive the final decoupled relative position embedding, allowing originally confused distance and directional information to be as distinguishable as possible.

(2) **Model Representation Differentiations.** We analyze that there is non-negligible confusion in the representation of pre-trained BERT, as evidenced by the high consistency in last hidden states across different tokens and attention weights across different heads, respectively. Similar last hidden states will introduce the *anisotropic problem* (Mimno and Thompson, 2017), which will bound the token vectors to a narrow representation space and thus make it more difficult for the model to capture deep semantics. Considering attention weights contain rich linguistic knowledge (Clark et al., 2019; Jawahar et al., 2019), we argue that high consistency in attention weights also constrains the ability of the model to capture multi-aspect information. To alleviate the representation confusion between different tokens and heads caused by high information overlap, we propose two novel pre-training approaches to stimulate the potential of the pre-trained model to learn rich linguistic knowledge: Token Cosine Differentiation (TCD) objective and Head Cosine Differentiation (HCD) objective. Specifically, TCD attempts to broaden the dissimilarity between tokens by minimizing the cosine similarities between different last hidden states. In contrast, HCD attempts to broaden the dissimilarity between heads by minimizing the cosine similarities between different attention weights. We apply TCD and HCD as two auxiliary regularizers in MLM pre-training, which in turn guides the model to produce more discriminative token representations and head representations. Formally, we define our enhanced pre-training task as MLM with TCD and HCD (MTH).

Extensive experiments on the GLUE benchmark show that DDRP achieves better results than classi-

cal relative position encoding (Shaw et al., 2018) on almost all tasks without introducing the additional computational overhead and consistently outperforms prior competitive relative position encoding models (He et al., 2021; Ke et al., 2021). Moreover, our proposed MTH outperforms MLM by a 0.96 average GLUE score and achieves nearly 2x pre-training speedup on BERT_{BASE}. Both DDRP and MTH are straightforward, effective, and easy to deploy, which can be easily combined with existing pre-training objectives and various model structures. Our contributions are summarized as follows:

- We propose a novel relative position encoding named DDRP, which decouples the relative distance and directional features, giving the model a stronger prior knowledge, fewer parameters, and better results compared to conventional coupled position encodings.
- We analyze the trend of self-similarity of last hidden states and attention weights during pre-training, and propose two novel Token Cosine Differentiation and Head Cosine Differentiation objectives, motivating pre-trained Transformer to better capture semantics in PLMs.
- We experimentally verified by our proposed techniques (DDRP and MTH) that decomposing heterogeneous information and extending representation diversity can significantly improve pre-trained language models. We also analyze the characteristics of DDRP and MTH in detail.

2 Related Work

In recent years, pre-trained language models have made significant breakthroughs in the field of NLP. BERT (Devlin et al., 2018), which proposes MLM and NSP pre-training objectives, is pre-trained on large-scale unlabeled corpus and has learned bidirectional representations efficiently. After that, many different pre-trained models are produced, which further improve the effectiveness of the pre-trained models. RoBERTa (Liu et al., 2019) proposes to remove the NSP task and verifies through experiments that more training steps and larger batches can effectively improve the performance of the downstream tasks. ALBERT (Lan et al., 2020) proposes a Cross-Layer Parameter Sharing technique to lower memory consumption. XL-Net

(Yang et al., 2019) proposes Permutation Language Modeling to capture the dependencies among predicted tokens. ELECTRA (Clark et al., 2020) adopts Replaced Token Detection (RTD) objective, which considers the loss of all tokens instead of a subset. TUPE (Ke et al., 2021) performs Query-Key dot product with different parameter projections for contextual information and positional information separately and then added them up, they also add relative position biases like T5 (Raffel et al., 2019) on different heads to form the final correlation matrix. DEBERTA (He et al., 2021) separately encodes the context and position information of each token and uses the textual and positional disentangled matrices of the words to calculate the correlation matrix.

3 Method

In this section, we analyze in turn two different types of information confusion that exist in the real PLMs: (i) The paradigm of utilizing a single parametric vector of relative position embedding to represent both relative distance and direction. (ii) The high similarity and overlap in model representations. Based on above two investigations, we propose two techniques, **Decoupled Directional Relative Position (DDRP)** Encoding and **MLM with TCD and HCD (MTH)**, respectively, to help the PLMs alleviate information confusion and enhance representation clarity and diversity.

3.1 Decoupled Directional Relative Position (DDRP) Encoding

We first start to introduce DDRP by formulating multi-head attention module of BERT and BERT-R (Shaw et al., 2018). Specifically, BERT formulates multi-head attention for a specific head as follows:

$$Q = HW^Q, K = HW^K, V = HW^V, \quad (1)$$

$$A = \frac{QK^T}{\sqrt{d}}, \quad (2)$$

$$Z = \text{softmax}(A)V, \quad (3)$$

where $H \in R^{S \times D}$ represents the input hidden states; $W^Q, W^K, W^V \in R^{D \times d}$ represent the projection matrix of Query, Key, and Value respectively; $A \in R^{S \times S}$ represents attention weight; $Z \in R^{S \times d}$ represents the single-head output hidden states of self-attention module; S represents input sequence length; D represents the dimension of input hidden states; d represents the dimension of single-head hidden states. Unlike BERT, which

adds the absolute position embedding to the word embedding as the final input of the model, BERT-R first applies relative position encoding. It adds relative position embedding into K in the self-attention module of each layer to make a more interactive influence. Its formulations are as follows:

$$A_{i,j} = \frac{Q_i (K_j + K_{\sigma(i,j)}^r)^T}{\sqrt{d}}, \quad (4)$$

$$\sigma(i,j) = \text{clip}(i-j) + r_s, \quad (5)$$

where Q_i represents Query vector at the i -th position; K_j represents Key vector at the j -th position; r_s represents maximum relative position distance; $\sigma(i,j)$ represents the index of relative position embedding $K^r \in R^{2r_s \times d}$; relative position embedding for K are shared at all different heads. Note that Shaw et al. (2018) has experimentally demonstrated that adding relative position embedding to the interaction between A and V gives no further improvement in effectiveness, so the relative position embedding in V space is eliminated in all our experiments to reduce the computational overhead.

Compared with BERT, BERT-R models the correlation between words and positions more explicitly, and thus further expands the expression diversity between words. However, we notice that in BERT-R, the vectors from the same distance on both left and right sides are encoded in isolation (as shown in Figure 1(a)), which indicates that every single parametric vector from K^r is forced to maintain distance and direction, two different types of information. Since it is confirmed that directional information is crucial in language modeling (Vu et al., 2016; Fuller, 2002; Shen et al., 2018), we argue that such an approach causes unnecessary information confusion and faces several constraints: (i) Mixing relative distance and directional information for modeling makes information originally in different spaces entangled, which in turn makes the learning of parametric vectors more difficult. (ii) Dot products between word vectors and directionally confused positional vectors bring unnecessary randomness in deep bidirectional representation models.

To alleviate the confusion of distance and direction that exists in BERT-R and allow the model to perceive distances and directions more clearly, we propose a novel Decoupled Directional Relative Position (DDRP) encoding. Specifically, DDRP decouples the relative distance and directional information and maintains them with two different

embeddings. Its formula is as follows:

$$A_{i,j} = \frac{Q_i (K_j + K_{\delta(i,j)}^d)^T}{\sqrt{d}}, \quad (9)$$

$$K_{\delta(i,j)}^d = D_{\rho(i,j)} \odot K_{\delta(i,j)}^{rd}, \quad (10)$$

$$\rho(i,j) = \begin{cases} 1, & \text{if } i-j < 0 \\ 0, & \text{if } i-j = 0 \\ 2, & \text{if } i-j > 0 \end{cases}, \quad (11)$$

$$\delta(i,j) = \text{abs}(\text{clip}(i-j)), \quad (12)$$

where $\rho(i,j)$ represents the index of directional embedding $D \in R^{3 \times d}$; $\delta(i,j)$ represents the index of relative distance embedding $K^{rd} \in R^{r_s \times d}$; K^d represents the relative position matrix. Note that in terms of implementation details, the only difference between DDRP and BERT-R is that DDRP decouples K^r in BERT-R into the element-wise multiplication of D and K^{rd} . We also provide a specific comparison example in Figure 1.

Compared to previous relative position encodings, we summarize the advantage of DDRP as follows: (i) DDRP explicitly extracts the commonalities (relative distances) and differences (directions) in the positional information, leading the model to produce attention that better match the real semantic distributions, which reduces the difficulty of model learning and unlocks the potential of the model. (ii) DDRP compresses the total number of parametric vectors from $2r_s$ to $r_s + 3$.

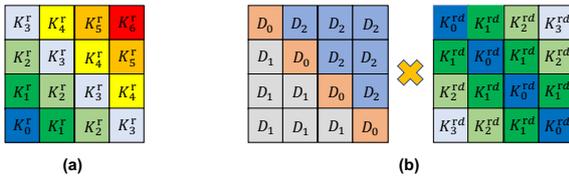

Figure 1: Fig.1(a) represents the classical relative position matrix; Fig.1(b) represents the decoupled relative position matrices we proposed. Note that the parametric vectors of the same color have the same values.

3.2 Model Representation Differentiations

Token representations. Isotropic distributions have been proved theoretically to be beneficial to token representations, which ensures that the different token vectors are directional uniform, thus maximizing the diversity of token representations. (Mimno and Thompson, 2017). In practice, Mu et al. (2017) have also empirically confirmed the effectiveness of isotropic distributions on static token representations, such as WORD2VEC (Mikolov et al., 2013) and GLOVE (Pennington et al., 2014).

Inspired by the above studies, we also wonder whether contextualized token representations (e.g., last hidden states of BERT) are isotropic. Following Mimno and Thompson (2017), we utilize the cosine similarity to evaluate the degree of isotropy in token representations. The higher similarity, the smaller isotropy; the lower similarity, the greater isotropy. For an input sequence $S = [x_1, \dots, x_n]$, we formulate the last hidden states' average self-similarity as follows:

$$f(S) = \frac{2}{n(n-1)} \sum_{i=1}^{n-1} \sum_{j=i+1}^n \cos(h_i, h_j), \quad (15)$$

where h_i and h_j are the last hidden states of x_i and x_j ; \cos represents cosine similarity.

Head representations. Multi-head attention, is aimed at capturing information in different heterogeneous subspaces and has been experimentally verified different heads correspond well to different linguistic notions (Clark et al., 2019). However, some studies point out that some heads contribute almost nothing to downstream tasks (Kovaleva et al., 2019; Michel et al., 2019; Voita et al., 2019; Correia et al., 2019). We are surprised by this, and speculate that the above problem may be caused by the heavy overlap of information that some heads are concerned about. To verify our point, we utilize cosine similarity to evaluate the degree of overlap in head representations, following token representations. The higher similarity, the higher overlap; the lower similarity, the lower overlap. For multiple heads $H = [H_1^1, \dots, H_m^1, \dots, H_1^L, \dots, H_m^L]$, we formulate the attention weights' average self-similarity as follows:

$$f(H) = \frac{2}{Lm(m-1)} \sum_{l=1}^L \sum_{i=1}^{m-1} \sum_{j=i+1}^m \cos(a_i^l, a_j^l), \quad (16)$$

where L represents the number of Transformer layers; a_i^l and a_j^l are the attention weights of the i -th head and j -th head of the l -th layer.

Analysis on the similarities between different tokens and heads. With curiosity about the similarity of token representations and head representations, we analyze the self-similarity trends of tokens and heads during the original MLM BERT pre-training. Specifically, we sample 5,000 sentences from the validation set and evaluate the average self-similarity of last hidden states and attention weights under multiple checkpoints during the pre-training stage as shown in Figure 2. We

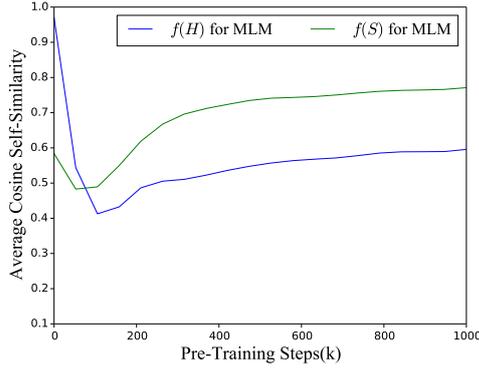

Figure 2: Average self-similarity of last hidden states and attention weights during MLM pre-training.

can notice that although $f(S)$ and $f(H)$ decrease at the beginning of pre-training, soon they start to rise gradually until the end of the training, and the similarities are always high throughout the training process. These fully demonstrates that in the MLM-based BERT, the overlap between different tokens and heads is strong and information confusion in model representations has become a problem worth to be solved.

Training objectives. To guide the model to produce more discriminative token representations and head representations, we propose a novel MTH pre-training objective, which combines original MLM with two novel Token Cosine Differentiation (TCD) objective and Head Cosine Differentiation (HCD) objective. Specifically, MTH applies the average cosine self-similarity of sampled last hidden states and attention weights as two auxiliary pre-training regularizers besides MLM³. For an input sequence $S = [x_1, \dots, x_n]$, TCD samples n' ($n' \leq n$) tokens uniformly in sequence order to obtain a subsequence $\tilde{S} = [\tilde{x}_1, \dots, \tilde{x}_{n'}]$ and calculates the average cosine self-similarity of the subsequence’s last hidden states as follows:

$$\mathcal{L}_{TCD} = \frac{2}{n'(n'-1)} \sum_{i=1}^{n'-1} \sum_{j=i+1}^{n'} \cos(\tilde{h}_i, \tilde{h}_j), \quad (17)$$

where \tilde{h}_i and \tilde{h}_j are the last hidden states of \tilde{x}_i and \tilde{x}_j . For multiple heads $H^l = [H_1^l, \dots, H_m^l]$ of a specific layer l , HCD randomly

³We have empirically verified that this below sampling strategy can greatly reduce the computational overhead with only a slight performance drop, comparing with regularizing all tokens and heads. In practice, we notice that setting $n' = 50$, $m' = 2$ is fine on both BERT and DDRP, which will compress the additional computational overhead from about 30% to 4%.

samples m' ($m' \leq m$) different heads $\tilde{H}^l = [\tilde{H}_1^l, \dots, \tilde{H}_{m'}^l]$ (Note that HCD samples by layers, so sampled heads may be different across different layers.) and then calculate the average cosine self-similarity of attention weights of sampled heads as follows:

$$\mathcal{L}_{HCD} = \frac{2}{Lm'(m'-1)} \sum_{l=1}^L \sum_{i=1}^{m'-1} \sum_{j=i+1}^{m'} \cos(\tilde{a}_i^l, \tilde{a}_j^l), \quad (18)$$

\tilde{a}_i^l and \tilde{a}_j^l are the attention weights of the i -th head and j -th head in the sampled headset of the l -th layer. Ultimately, we define the global pre-training objective MTH as follows:

$$\mathcal{L}_{MTH} = \mathcal{L}_{MLM} + \alpha_1 \mathcal{L}_{TCD} + \alpha_2 \mathcal{L}_{HCD}, \quad (19)$$

where α_1 and α_2 are hyperparameters.

4 Experiments

4.1 Pre-training Text Corpora

Follow Devlin et al. (2018), we use Wikipedia and BooksCorpus (Zhu et al., 2015), a roughly 16G uncompressed text corpus for pre-training.

4.2 Baselines

We compare DDRP with competitive pre-trained models. BERT (Devlin et al., 2018) equips Transformer (Vaswani et al., 2017) with parametric absolute position encoding. BERT-R uses the relative position encoding proposed by Shaw et al. (2018), which couples relative distance information and directional information for modeling. TUPE (Ke et al., 2021) performs Query-Key dot product with different parameter projections for contextual information and positional information separately and then adds them up, plus the relative position biases like T5 (Raffel et al., 2019). DEBERTA (He et al., 2021) uses two vectors to encode content and position and uses disentangled matrices on their contents and relative positions respectively to compute the attention weights among words.

4.3 Experimental Settings

Following the previous practice, we use a base-size model for training, which consists of 12 Transformer encoder layers, each containing 12 heads with an input dimension of 768. During pre-training, we directly use the maximum training length of 512 without taking any form of random

BERT (MTH)	1M	73.64	90.16	88.48	62.31	92.43	91.21	91.12	84.67	84.25
DDRP (MLM)	1M	72.20	90.01	88.25	62.82	92.41	92.31	91.24	86.02	84.41
DDRP (MTH)	1M	75.09	90.41	88.72	63.36	92.66	92.24	91.22	86.22	85.00

Table 2: Development scores on GLUE benchmark. BERT (MLM/MTH) represents pre-trained BERT_{BASE} with MLM/MTH pre-training objective. DDRP (MLM/MTH) represents pre-trained DDRP_{BASE} with MLM/MTH pre-training objective.

injection, and for examples less than 512 in length, we do not use the next document for padding. We remove Next Sentence Prediction (NSP) task and only keep Masked LM (MLM) as our pre-training task for all models unless noted otherwise. Considering that shorter documents may be missing semantics, we discard documents of length less than 8. We adopt the whole word masking strategy and split the whole words longer than 4 into individual subtokens. Following Devlin et al. (2018), we set the batch size to 256 sequences, the peak learning rate to $1e-4$, and the training steps to 1M. We grid search α_1 and α_2 of TCD and HCD in $\{0.01, 0.1, 1.0\}$. Eventually, we set $\alpha_1 = 1.0$ for TCD and set $\alpha_2 = 0.01$ for HCD. All the models are implemented based on the code practice of BERT⁴ in Tensorflow. We conduct all experiments on 16 Tesla-V100 GPUs (32G). All the pre-training hyperparameters are supplemented in Appendix A. To make a fair comparison, we implement BERT, BERT-R, TUPE, DEBERTA, and DDRP⁵ with the same pre-training hyperparameters and model configurations, which are consistent with vanilla BERT.

4.4 Results on GLUE Benchmark

We evaluate models on eight different English understanding tasks from General Language Under-

standing Evaluation (GLUE) benchmark (Wang et al., 2019). The datasets cover four types of tasks: natural language inference (RTE, QNLI, MNLI), paraphrase detection (MRPC, QQP), linguistic acceptability (CoLA), and sentiment classification (SST-2). For all experiments, STS-B and CoLA are reported by Pearson correlation coefficient and Matthews correlation coefficient, and other tasks are reported by Accuracy. All the fine-tuning hyperparameter configurations can be found in Appendix B. Following Ke et al. (2021), we fine-tune with five random seeds and report the median results.

4.4.1 Comparing Prior Competitive Models with DDRP

The overall comparison results are shown in Table 1. Firstly, we can notice that all the various relative position encoding models perform better than BERT, which proves that relative position encoding is a more competitive approach to encode position information. Sencodly, it is easy to find that DDRP outperforms all the strong baselines, which demonstrates modeling relative position encoding by clarifying the originally confused relative distance and directional information more clearly is more effective. Thirdly, DDRP pre-trained with MTH can consistently outperform BERT-R/DEBERTA by a 1.11/0.91 average GLUE score, which indicates that DDRP can be effectively compatible with better pre-training objectives to perform stronger.

⁴<https://github.com/google-research/bert>

⁵Following Shaw et al. (2018) and Raffel et al. (2019), we set $r_s = 64$ for all the relative position encoding models.

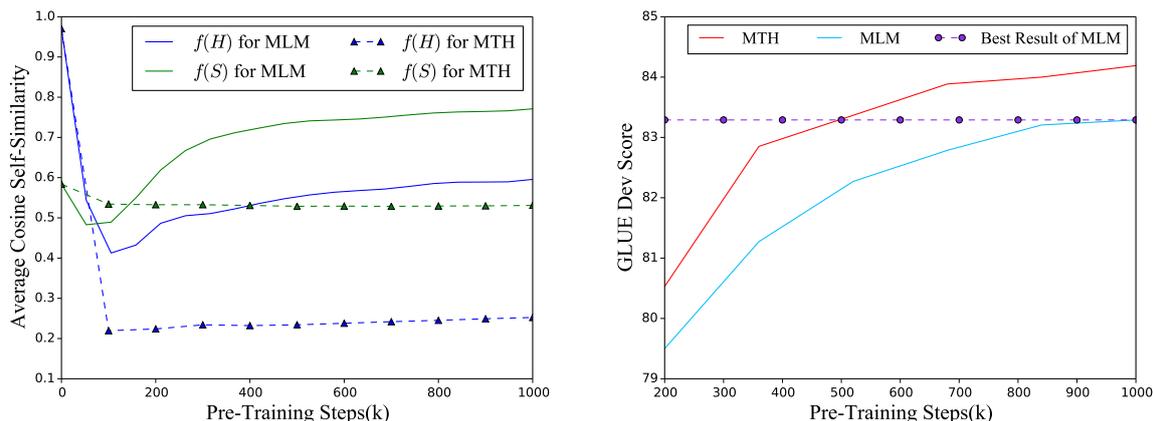

Figure 3: The left figure (a) represents the trend of average cosine self-similarity of token representations and head representations during pre-training. The right figure (b) represents the trend of GLUE average score during pre-training.

Moreover, compared to BERT-R, DDRP introduces nothing in complexity while DEBERTA increases the computational cost about 25%, we also consider DDRP is a more time-efficient alternative than the recent state-of-the-art model DEBERTA (as analyzed in Sec.5.4).

4.4.2 Comparing MTH with MLM

As illustrated in Table 2, BERT (MTH) outperforms BERT (MLM) by a 0.96 average GLUE score and is consistently better on 7 out of 8 tasks. When combining MTH with strong DDRP, it still brings an improvement by 0.59 GLUE average score. Notably, BERT (MTH) can achieve better results compared with well-trained BERT (MLM) while only using 50% training steps. Since MTH utilizes cosine similarity and sampling strategy for the penalty, only a very slight computational cost is introduced. All the above statistics can fully verify that decreasing the similarity in model representations can effectively alleviate information overlap and increase representation diversity, which in turn leads to consistent and stable improvement across different model structures.

5 Analysis and Discussion

5.1 Ablation Studies

Effect of DDRP. As shown in Table 1, BERT-R outperforms BERT by 0.6 points on average. Based on BERT-R, our proposed DDRP outperforms BERT-R by 0.52 points averagely without imposing additional computational costs. It is worth noting that compared to BERT-R, DDRP helps a great deal on low-resource tasks, such as CoLA, while further

improving the performance on high-resource tasks, such as QNLI and MNLI. These fully demonstrate utilizing separate parametric vectors to represent distances and directions, two apparently heterogeneous information, can be beneficial to the model, and further justifies the value of dissociating confusing information that is confounded in similar spaces.

Effect of TCD and HCD. MTH brings in two additional TCD and HCD regularizers besides the original MLM task. To further evaluate the relative contributions of the HCD and TCD, we develop one variation, which is BERT pre-trained with MLM and TCD. Table 3 summarizes the results on the base-size models. Firstly, it shows a 0.42 average GLUE score drop when HCD is removed from MTH, especially on MRPC, CoLA, and MNLI. Secondly, there is a 0.54 average GLUE score drop when TCD is progressively removed, especially on RTE, STS-B, and CoLA. These results indicate that both TCD and HCD regularizers play a crucial role in improving performance.

5.2 Analysis on MTH

To further understand why MTH works, we compare MLM and MTH in terms of average self-similarity of token representations and head representations and performance during pre-training in Figure 3. As shown in Figure 3.(a), it is easy to find that MTH’s average self-similarity is much lower than MLMs’. We can also clearly notice from Figure 3.(b) that the average GLUE score of MTH is always about one point higher than MLM’s during the whole pre-training process. These confirm that

Model	RTE	STS-B	MRPC	CoLA	SST-2	QNLI	QQP	MNLI	Avg.
MTH	73.64	90.16	88.48	62.31	92.43	91.21	91.12	84.67	84.25
w/o HCD	73.28	90.41	87.25	60.85	92.23	91.37	91.00	84.22	83.83
w/o TCD&HCD	70.75	89.66	87.50	59.65	92.20	91.23	91.00	84.33	83.29

Table 3: Ablation study for MTH. Note that MTH (w/o TCD&HCD) equals simply using MLM in pre-training.

(i) the differentiation of tokens and heads is important for model optimization; (ii) MTH can help to produce more discriminative token representations and head representations, extend the representation space of tokens and heads, and thus improve the performance.

5.3 Analysis on DDRP

In this subsection, we intend to analyze the attention maps of DDRP as a way to investigate why making only slight modifications on BERT-R can bring great gains. To better examine and explain the ability of DDRP to capture information in both left and right directions, we divide multiple heads into two groups evenly, where group 1 consists of the heads that focus most on the right side, and group 2 consists of the heads that focus most on the left side. As shown in Figure 4, it is easy to observe a distinct upper triangle effect in group 1 and a distinct lower triangle effect in group 2, which indicates that DDRP may allow the model to be more precise in the perception of direction, a piece of information that is crucial to understanding semantics. To further confirm our point, we sample 5,000 sentences from the validation set and count the percentage of sentences with upper and lower triangular effects according to Algorithm 1 (more details can be seen in Appendix C). It is observed that 92.11% of sentences have an up-down triangle effect. We also count the percentage for BERT-R with the same process and observe only 78.94% of the sentences have an up-down triangle effect. All the phenomena and statistics fully reveal that DDRP can make different heads focus on the token information interaction in different directions and reduce confusion between heads, thus improving the effectiveness and rationality of the model.

5.4 Complexity Analyses

DDRP. Compared with BERT, DDRP introduces additional parameters: $D \in R^{3 \times d}$ and $K^{rd} \in R^{r_s \times d}$. The total increase in parameters is $3 \times d + r_s \times d$. For base-size model ($D = 768, L = 12, S = 512, N = 12, d = 64$)⁶, the total increase

⁶N is the number of head.

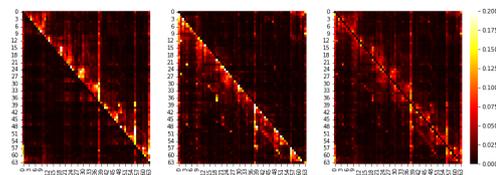

Figure 4: Attention visualization for a sampled batch of sentences. From left to right is the attention visualization for group 1, group 2, and global, respectively.

amounts to 0.0043M, which is negligible. Compared with BERT, the additional computational complexity for both BERT-R and DDRP is $O(SD)$. Since DEBERTA equips different heads with unshared K^r s, the additional computational complexity for DEBERTA is $O(NSD)$. Overall, BERT-R and DDRP increase the computational cost about 5%, and DEBERTA increases the computational cost about 30%. Although DDRP introduces a slight computational cost compared to BERT, it is more time-efficient than DEBERTA and outperforms all the above models.

MTH. Since the two regularizers of TCD and HCD are based on cosine similarity and sampling strategy, they do not introduce too much computational cost. Compared with MLM, MTH only increases a slight computational cost of about 4% while bringing excellent improvement.

6 Conclusion

In this work, we analyze and identify potential information confusion in the relative position encoding and model representations, respectively, and design two novel techniques to address these problems: DDRP (Decoupled Directional Relative Position) encoding and MTH (MLM with TCD and HCD) pre-training objectives. Specifically, DDRP decouples relative distance features and directional features to eliminate unnecessary randomness in the self-attention module. MTH utilize TCD and HCD as two regularizers to supervise the model to always maintain a certain level of critical thinking. The experimental results show that DDRP achieves better performance compared with various relative

position encoding models and MTH outperforms MLM by a large margin. We believe that reducing information confusion in representation learning may have broader application scenarios, and leave this area of exploration for future work.

7 Limitations

Our limitations lie in inducing additional computational costs. Compared with BERT, the additional computational complexity for DDRP is $O(SD)^7$, which is reflected in the 5% increase in computational cost. Compared with MLM, MTH with sampling strategy increases the computational cost by about 4%.

A Appendix A. Hyperparameters for Pre-Training

As shown in Table 4, we list the pre-training hyperparameter configurations. To make a fair comparison, all models’ pre-training hyperparameter configurations in our experiments are identical to vanilla BERT (Devlin et al., 2018).

Hyperparameter	
Vocab size	3,0522
Hidden size	768
Attention heads	12
Layers	12
Training steps	1M
Warmup ratio	0.01
Batch size	256
Learning rate	1e-4
Adam ϵ	1e-6
Adam (β_1, β_2)	(0.9, 0.999)
Learning rate schedule	linear
Weight decay	0.01
Clip norm	1.0
Dropout	0.1

Table 4: Hyperparameters used for pre-trained models.

B Appendix B. Hyperparameters for Fine-Tuning

As shown in Table 5, we enumerate the hyperparameter configurations to fine-tune the tasks on the GLUE benchmark (Wang et al., 2019). We grid search these fine-tuning hyperparameter configurations for all models. Following the BERT, we do not show results on the WNLI GLUE task for the Dev set results.

Hyperparameter	GLUE
Batch size	{16, 32}
Learning rate	{ $1e-5$, $2e-5$, $3e-5$ }
Epoch	{4, 6}
Adam ϵ	1e-6
Adam (β_1, β_2)	(0.9, 0.999)
Learning rate schedule	linear
Weight decay	0.01
Clip norm	1.0
Dropout	0.1
Warmup ratio	0.1

Table 5: Hyperparameters used for fine-tuning on the GLUE benchmark.

C Appendix C. Details for Up-Down Triangle Effect

Here we provide more details for the up-down triangle effect (in Sec. 5.3). It is rather difficult and non-intuitive to analyze the directional information in 12 different attention heads. Since previous studies have considered to group multiple heads in the self-attention module (Devendra Singh Sachan, 2018; H Gong, 2021), we thereby attempt to divide the heads into two groups evenly. Specifically, we divide the heads that focus more on the right side information into group 1 and the heads that focus more on the left side information into group 2, wishing to reveal the directional information encoded in attention weights more explicitly. We experimentally verified that this grouping approach could provide a better presentation of the directional information. Therefore, we combined this approach to conduct a comparative analysis of DDRP and BERT-R to demonstrate the more powerful directional perception of DDRP.

As illustrated in Figure 4, group 1 is more focused on the right information (greater attention values in the upper triangle region) and group 2 is more focused on the left information (greater attention values in the lower triangle region). To further analyze the universality of this phenomenon, we design the Algorithm 1 to quantitatively analyze the ability of DDRP to capture information on the both left and right sides. To make a fair comparison, we also conduct the same process for BERT-R.

Algorithm 1 Count up-down triangle percentage

Require: N : total number of sentences; n : total number of sentences that have been processed; ms : maximum sentence length; mn : total number of sentences that match the upper and lower triangle; t : the threshold value that satisfies the up-down triangular effects; amp : attention map obtained by averaging attention maps in specific group.

```
1: Initialize  $ms \leftarrow 64, n \leftarrow 1, mn \leftarrow 0, t \leftarrow 0.7$ 
2: while  $n \leq N$  do
3:   Divide heads in equal with greater attention values in
   the (upper/lower) triangle region into (group 1/group 2)
   and obtain ( $amp1/amp2$ ).
4:   // prepare for the upper and lower triangle
5:   Sum the values in upper and lower triangles of  $amp1$ 
   respectively and obtain  $amp1_{up}, amp1_{down}$ .
6:   Sum the values in upper and lower triangles of  $amp2$ 
   respectively and obtain  $amp2_{up}, amp2_{down}$ .
7:    $amp1_{up} \leftarrow amp1_{up}/ms, amp1_{down} \leftarrow$ 
    $amp1_{down}/ms$ 
8:    $amp2_{up} \leftarrow amp2_{up}/ms, amp2_{down} \leftarrow$ 
    $amp2_{down}/ms$ 
9:   // compute for the upper and lower triangle
10:  if  $amp1_{up} \geq t$  and  $amp2_{down} \geq t$  then
11:     $mn \leftarrow mn + 1$ 
12:  else
13:    Continue
14:   $n \leftarrow n + 1$ 
15: return  $float(mn/N)$ 
```

MAFiD: Moving Average Equipped Fusion-in-Decoder for Question Answering over Tabular and Textual Data

Sung-Min Lee[†], Eunhwan Park[†], Daeryong Seo[‡], Donghyeon Jeon[‡],
Inho Kang[‡], Seung-Hoon Na^{†*}

Abstract

Transformer-based models for question answering (QA) over tables and texts confront a “long” hybrid sequence over tabular and textual elements, causing long-range reasoning problems. To handle long-range reasoning, we extensively employ a fusion-in-decoder (FiD) and exponential moving average (EMA), proposing a Moving Average Equipped Fusion-in-Decoder (MAFiD). With FiD as the backbone architecture, MAFiD combines various levels of reasoning: *independent encoding* of homogeneous data and *single-row* and *multi-row heterogeneous reasoning*, using a *gated cross attention layer* to effectively aggregate the three types of representations resulting from various reasonings. Experimental results on HybridQA indicate that MAFiD achieves state-of-the-art performance by increasing exact matching (EM) and F1 by 1.1 and 1.7, respectively, on the blind test set.

1 Introduction

While most studies have focused on text question answering (QA), where unimodal textual passages are provided as a source of evidence for an answer (Joshi et al., 2017; Yang et al., 2018; Rajpurkar et al., 2018; Welbl et al., 2018; Dua et al., 2019; Karpukhin et al., 2020; Zhu et al., 2021b; Pang et al., 2022), realistic questions often need to refer to “heterogeneous” evidences based on both tabular and textual contents to generate an answer, motivating researchers to address *table-and-text* QA (Chen et al., 2020; Wenhua Chen, 2021; Talmor et al., 2021; Zhu et al., 2021a; Nakamura et al., 2022).

Among the various tasks for table-and-text QA, we address the *multi-hop* table-and-text QA described in HybridQA (Chen et al., 2020), which is a large-scale table-and-text QA dataset focusing on the multi-hop reasoning across tabular and textual contents to extract an answer.

*Corresponding author

However, a table usually contains a nontrivial number of rows and relevant passages; thus linearization of all relevant heterogeneous contents easily exceeds the maximum length limit for transformers, thereby causing *long range reasoning* problems.

To address long range reasoning, we present a novel encoder-decoder model that deploys fusion-in-decoder (FiD) (Izacard and Grave, 2021) and exponential moving average (EMA) (Ma et al., 2022), the Moving Average Equipped Fusion-in-Decoder (MAFiD). Armed with FiD as the backbone architecture, MAFiD combines various levels of reasoning:

- **Independent encoding of homogeneous data**, which independently encodes tabular and textual contents separately for each row, without being fused in the encoder step. Inherited from FiD, the resulting encoded representations are jointly fused in the decoder, which significantly reduces the computational time required for self-attention, thereby allowing us to use a longer sequence as an input for the encoder.
- **Single-row heterogeneous reasoning** (also referred to as *single-row reasoning*), which performs in-depth interaction between tabular and textual contents per row; it first concatenates the tabular and textual representations for each row and then applies the “self-attention” layer over the concatenated sequence. Thus, single-row heterogeneous reasoning is performed in a restricted manner only on heterogeneous contents within a specific row.
- **Multi-row heterogeneous reasoning** (also referred to as *multi-row reasoning*), which performs light interaction across tabular and textual contents of “multiple” rows based on the EMA layer; it concatenates the heteroge-

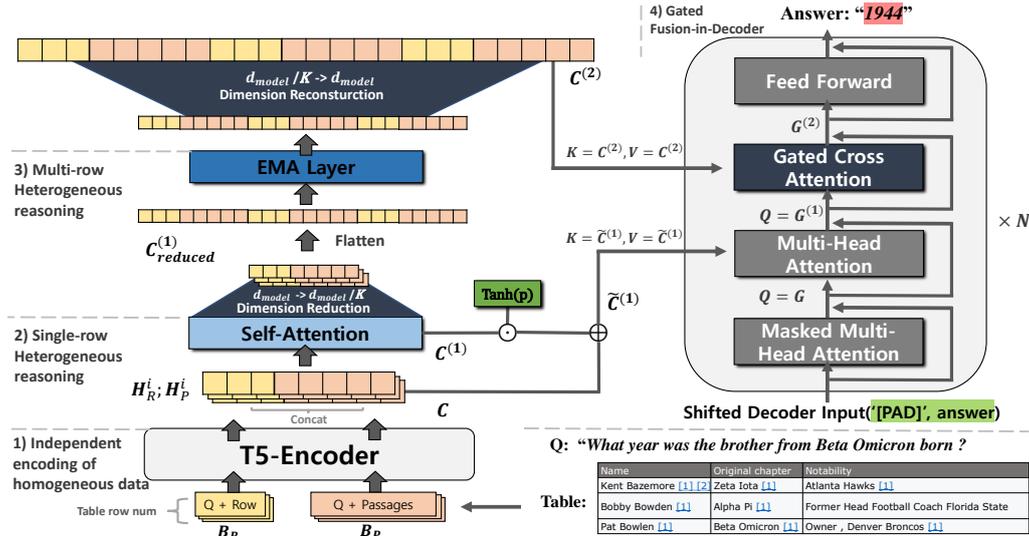

Figure 1: The overall neural architecture of the proposed MAFiD: 1) Independent encoding applies T5’s encoder on the tabular and textual blocks in i -th row, separately (i.e., $b_R^i \in \mathcal{B}_R$ and $b_P^i \in \mathcal{B}_P$) and the resulting contextual representations are concatenated to obtain the i -th row’s heterogeneous representation, C_i (Eq. (1)). 2) Single-row reasoning performs the row-specific cross-modal interaction by applying the single-head attention over C_i to generate $C_i^{(1)}$ (Eq. (2)). 3) Multi-row reasoning preforms the between-row cross-modal interaction by applying the low-dimensional EMA over the long hybrid sequence $C^{(1)}$ (Eq. (3)) to produce the $C_i^{(2)}$ (Eq. (4)). 4) The gated FiD aggregates all types of representations of C (Eq. (4)), $C^{(1)}$, and $C^{(2)}$ using the gated cross-attention layer to finally yield the decoder’s contextual representation $G^{(2)}$ (Eq. (5)) which is fed to generate an output token.

neous contents of all rows in a table to obtain a “long” hybrid sequence and then applies the EMA layer over the resulting long sequence to produce aggregated representation. To process a long sequence more efficiently, we further propose a *low-dimensional* EMA, which additionally performs a *dimensionality reduction* and *reconstruction*.

In the decoder, we further propose the use of a *gated cross-attention* layer to effectively aggregates the aforementioned three representations resulting from various reasoning, motivated by the work of (Alayrac et al., 2022).

Our contributions are summarized as follows: 1) We propose MAFiD, which augments FiD with EMA and the gated cross-attention layer, thus effectively combining various types of reasoning. 2) We propose a low-dimensional EMA to efficiently process long sequences for table-and-text QA. 3) The proposed MAFiD achieves state-of-the-art performance on the HybridQA dataset.

2 Related Works

Recently, many datasets such as HybridQA (Chen et al., 2020), OTT-QA (Wenhu Chen, 2021), MultiModalQA (Talmor et al., 2021), HybriDialogue (Nakamura et al., 2022), and TAT-QA (Zhu et al.,

2021a) have been presented for table-and-text QA. Various works on table-and-text QA have enhanced “pretraining” to strengthen the cross-modal matching and numerical reasoning, by learning on tables and texts jointly (Herzig et al., 2020; Yin et al., 2020) and exclusively on tables (Iida et al., 2021).

To handle the long range reasoning on table-and-text QA, early works employed “efficient” transformers based on *sparse attention* with selective attention masks, such as the LongFormer (Beltagy et al., 2020) in the work of (Huang et al., 2022) and ETC (Ainslie et al., 2020) in the work of (Wenhu Chen, 2021). MATE (Eisenschlos et al., 2021b) uses *structure-based* sparse attention that attends to either rows or columns in a given table. Recently, *truncation-based* approaches have been employed in MITQA (Kumar et al., 2021) where the *passage filter* module is additionally applied such that only the filtered passages are used as textual contents of a table’s row.

Compared to these existing approaches, which rather limitedly reduce the computational cost in the encoder part, MAFiD significantly lightens the encoder part by minimizing the interaction between different rows and instead fuses the encoded representations in the decoder part under the framework of FiD. Equipped with the low-dimensional EMA,

MAFiD only performs the “shallow” interaction across rows, thus mostly maintaining the efficiency of the interaction-less encoder.

3 Moving Average Equipped Fusion-in-Decoder

Figure 1 shows the overall neural architecture of the proposed MAFiD model, which combines three types of representation. Here, we present the details of the MAFiD components.

3.1 Problem Definition

Suppose that \mathcal{B}_R and \mathcal{B}_P are a set of tabular and textual blocks in a given table, where $b_R^i \in \mathcal{B}_R$ indicates the tabular block for the i -th row (i.e., a list of its cells), $b_P^i \in \mathcal{B}_P$ indicates the textual block for the i -th row (i.e., a set of its linked passages), and $L = |\mathcal{B}_R| = |\mathcal{B}_P|$ is the number of rows in a table. Given question q , the goal is to generate a correct answer by considering \mathcal{B}_R and \mathcal{B}_P as heterogeneous evidence.

3.2 Independent Encoding of Homogeneous Data: the Basic Encoder for FiD

Following the independent encoding in FiD (Izacard and Grave, 2021), independent encoding linearizes tabular and textual blocks into a sequence independently and concatenates each of them with q as follows:

$$\text{row}^i = [q; [\text{SEP}]; b_R^i], \text{psg}^i = [q; [\text{SEP}]; b_P^i]$$

where $;$ is the concatenation operator. The tabular and textual sequences are then fed into the encoder of T5 independently and concatenated as follows:

$$\begin{aligned} H_R^i &= \text{T5-enc}(\text{row}^i) \in \mathbb{R}^{|\text{row}^i| \times d_{\text{model}}} \\ H_P^i &= \text{T5-enc}(\text{psg}^i) \in \mathbb{R}^{|\text{psg}^i| \times d_{\text{model}}} \\ C_i &= [H_R^i; H_P^i] \in \mathbb{R}^{(|\text{row}^i| + |\text{psg}^i|) \times d_{\text{model}}} \end{aligned} \quad (1)$$

where $|\times|$ is the length of sequence \times and d_{model} is the dimensionality of the encoder of T5.

3.2.1 Single-row Heterogeneous Reasoning

In single-row reasoning, we perform an in-depth interaction between tabular and textual blocks for each row, b_R^i and b_P^i , using self-attention as follows:

$$C_i^{(1)} = \text{SHA}(C_i, C_i, C_i) \quad (2)$$

where $C_i^{(1)} \in \mathbb{R}^{(|\text{row}^i| + |\text{psg}^i|) \times d_{\text{model}}}$ and SHA is the *single*-head attention defined in Eq. (6) in Appendix D.

3.3 Multi-row Heterogeneous Reasoning by the Low-dimensional EMA

In multi-row reasoning, we first concatenate the contextual representations of all tabular and textual blocks as follows:

$$C^{(1)} = [C_1^{(1)}; \dots; C_L^{(1)}] \quad (3)$$

where $C^{(1)} \in \mathbb{R}^{N \times d_{\text{model}}}$, provided $N = \sum_i (|\text{row}^i| + |\text{psg}^i|)$ for notational convenience.

We then adopt the low-dimensional EMA as a variant of EMA using dimensionality reduction and reconstruction based on linear layers as follows:

$$\begin{aligned} C_{\text{reduced}}^{(1)} &= \text{Linear}(C^{(1)}) \\ C_{\text{reduced}}^{(2)} &= \text{EMA}(C_{\text{reduced}}^{(1)}) \\ C^{(2)} &= \text{Linear}(C_{\text{reduced}}^{(2)}) \end{aligned}$$

where $C_{\text{reduced}}^{(1)}, C_{\text{reduced}}^{(2)} \in \mathbb{R}^{N \times d_{\text{model}}/K}$, $C^{(2)} \in \mathbb{R}^{N \times d_{\text{model}}}$, Linear is a linear layer, and EMA is the damped EMA of (Ma et al., 2022) defined in Appendix E.

3.4 Gated Fusion-in-Decoder

In the decoder, we first concatenate the row-wise representations of independent encoding before feeding them to the FiD as follows:

$$C = [C_1; \dots; C_L] \quad (4)$$

In the decoder, we aggregate all representations of C (Eq. (1) and (4)), $C^{(1)}$ (Eq. (2) and (3)) $C^{(2)}$ (Eq. (4)) using a gating mechanism similar to that of (Alayrac et al., 2022) as follows:

$$\begin{aligned} \tilde{C}^{(1)} &= C + \tanh(p) \odot C^{(1)} \\ G^{(1)} &= \text{MHA}(G, \tilde{C}^{(1)}, \tilde{C}^{(1)}) \\ G^{(2)} &= G^{(1)} + \\ &\quad \tanh(q) \odot \text{MHA}(G^{(1)}, C^{(2)}, C^{(2)}) \end{aligned} \quad (5)$$

where $G \in \mathbb{R}^{|N^{(\text{dec})}| \times d_{\text{model}}}$ is the output of the masked multi-head attention in the decoder part, $|N^{(\text{dec})}|$ is the sequence length of the decoder input, $\tanh(\cdot)$ is the tanh function, p and q are learnable parameters, and $G^{(1)}, G^{(2)} \in \mathbb{R}^{|N^{(\text{dec})}| \times d_{\text{model}}}$.

4 Experiments

4.1 Experimental Setup

The details of the implementation and experiment setup is presented in Appendix A.

	Table				Passage				Total			
	Dev		Test		Dev		Test		Dev		Test	
	EM	F1										
HYBRIDER	51.5	58.6	52.1	59.3	40.5	47.9	38.1	46.3	43.7	50.9	42.5	50.2
HYBRIDER-Large	54.3	61.4	56.2	63.3	39.1	45.7	37.5	44.4	44.0	50.7	43.8	50.6
DocHopper	-	-	-	-	-	-	-	-	47.7	55.0	46.3	53.3
POINTR + TAPAS	68.1	73.9	67.8	73.2	62.9	72.0	62.0	70.9	63.3	70.8	62.7	70.0
POINTR + MATE	68.6	74.2	66.9	72.3	62.8	71.9	62.8	71.9	63.4	71.0	62.8	70.2
MITQA	68.1	73.3	68.5	74.4	66.7	75.6	64.3	73.3	65.5	72.7	64.3	71.9
Ours	69.4	75.2	68.5	74.9	66.5	75.5	65.7	75.3	66.2	74.1	65.4	73.6
Human	-	-	-	-	-	-	-	-	-	-	88.2	93.5

Table 1: Comparison results on the dev and blind test dataset in HybridQA. The best is bolded text.

	Table		Passage		Total	
	EM	F1	EM	F1	EM	F1
Ours	68.48	74.92	65.75	75.34	65.38	73.56
w/o Multi-row reasoning	67.44	73.74	65.50	75.23	64.86	73.08
w/o Multi-row, Single-row reasoning	41.97	49.46	60.20	69.42	51.46	59.86
w/o Single-row tanh gate	67.21	73.44	64.86	74.82	64.45	72.75
w/o Multi-row tanh gate	67.58	73.96	66.43	75.47	65.46	73.29
w/o Single-row, Multi-row tanh gate	66.09	72.51	64.81	75.22	64.01	72.65

Table 2: Ablation study on blind test dataset in HybridQA. “w/o Single-row tanh gate” and “w/o Multi-row tanh gate” correspond to the runs of fixing $\tanh(p) = 1$ and $\tanh(q) = 1$ in Eq. (5), respectively.

4.2 Baselines

In the experiment, we compare MAFiD and other baseline systems on HybridQA as follows:

- **HYBRIDER** (Chen et al., 2020) employs a sparse passage retriever (i.e., TF-IDF and a longest-substring matching) to find relevant cells and performs the reasoning step consisting of the ranking, the hop, and the reading comprehension models to extract an answer.
- **DocHopper** (Sun et al., 2021) uses the “iterative hierarchical attention” to retrieve short or long contents in a multi-step navigational manner.
- **POINTR + (TAPAS or MATE)** (Herzig et al., 2020; Eisenschlos et al., 2021a). POINTR extends the cell with its entity description and performs a two-stage method that consists of “cell selection” and “passage reading” steps. Either TAPAS (Herzig et al., 2020) or MATE (Kumar et al., 2021) is considered as a transformer encoder.
- **MITQA** (Kumar et al., 2021) uses the pipelined module including a retriever, a reader, and a joint row+span reranker, etc., being trained using the multi-instance distant supervision approach.

4.3 Main Results

As summarized in Table 1, MAFiD shows the state-of-the-art performance by increasing EM and F1 by 1.1 and 1.7 over MITQA (Kumar et al., 2021) on the blind test set. It is observed that MAFiD outperforms POINTR + (TAPAS or MATE) (Herzig et al., 2020; Eisenschlos et al., 2021a) that relies on the pretrained TAPAS, likely indicating that the long-range reasoning needs to be importantly handled on HybridQA, thus motivating the literature to go towards “reasoning”-enhanced pretraining in addition to the existing self-supervised tasks.

4.4 Ablation Studies

Single-row & Multi-row Heterogeneous Reasoning. To examine the effect of single-row and multi-row reasoning, we further evaluate MAFiD by removing either or both reasonings. As shown in Table 2, MAFiD without multi-row reasoning slightly decreases EM and F1 by 1.04 and 1.18, respectively. Importantly, MAFiD without both reasonings significantly deteriorates the performance of EM and F1 by 13.92 and 13.7, respectively. The results confirm that the cross-modal interaction should be performed at least within a specific row, whereas the between-row interaction is somehow effectively proceeded by the proposed EMA module, although its effect is not large.

Single-row & Multi-row Tanh Gating. We further examine the effect of using the gated flows

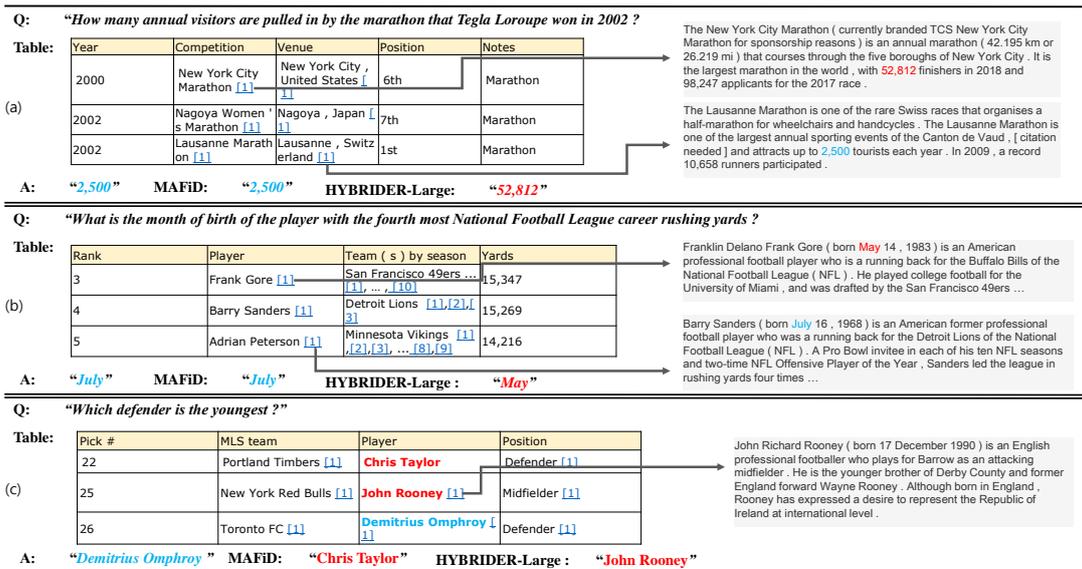

Figure 2: Illustrating examples of HYBRIDER-Large (Chen et al., 2020) and MAFiD in HybridQA.

	Total			
	Dev		Test	
	EM	F1	EM	F1
EMA	66.2	74.1	65.4	73.6
sliding window attention	65.7	73.3	65.3	73.1
Human	-	-	88.2	93.5

Table 3: Comparison results on the dev and blind test sets in HybridQA between EMA and the sliding window attention of (Beltagy et al., 2020) for long-range reasoning.

	Total			
	Dev		Test	
	EM	F1	EM	F1
original rows	66.2	74.1	65.4	73.6
permuted rows	51.5	59.4	51.1	59.2
Human	-	-	88.2	93.5

Table 4: Comparison results of MAFiD on HybridQA between the case using original rows and that with permuted rows for tabular contents.

by evaluating MAFiD by fixing $\tanh(p) = 1$ and $\tanh(q) = 1$ without being learned in Eq. (5). In particular, MAFiD without the single-row tanh gate ($\tanh(p) = 1$) slightly decreases EM and F1 by approximately 11.5, indicating that the gated FiD is helpful for further improvements.

Impact of EMA. To examine the impact of EMA for multi-row reasoning, we evaluate the sliding window attention of (Beltagy et al., 2020) as the baseline to handle long-range reasoning. As shown in Table 3, the use of EMA increases F1 and EM by 0.1 and 0.5, respectively, suggesting that EMA is more helpful for promoting the enhanced local sequence representation.

Impact of Sequential Order. To examine the impact of using the sequential order of rows in tabular contents, Table 4 further shows the results of a variant of MAFiD by randomly permuting rows in tabular contents both for training and inference, referred to as "permuted row", comparing to the original case; the results strongly indicate that keeping original row orders is important for MAFiD.

4.5 Error Analysis

Figure 2 shows some illustrating QA examples in HybridQA dataset comparing the results of HYBRIDER-Large (Chen et al., 2020) and MAFiD; (a)-(b) require only keyword matching and numerical comparison, where HYBRIDER is failed; (c) requires sophisticated multi-hop reasoning across table rows and passages where both MAFiD and HYBRIDER are incorrect.

5 Conclusion

In this paper, we address long range-reasoning for the multi-hop table-and-text QA and propose MAFiD, which extends FiD by equipping EMA and the gated cross-attention layer for the encoder and decoder parts, respectively, to design an effective way of combining various types of encoded representations. The experimental results on HybridQA showed that the proposed MAFiD achieved state-of-the-art performances in both the development and blind test sets. In future work, we will extend MAFiD to open-domain table-and-text QA and explore a unified approach that integrates single-row and multi-row reasoning.

Limitations

This paper proposes the use of EMA under FiD to tractably perform multi-row reasoning; however, EMA simply puts strong weights on nearby contexts, thus performing a restricted type of the long-range reasoning. Thus, our EMA-based method heavily depends on the sequential order of tables and texts, so hardly performing matching between long-distance but semantically related tokens in a long hybrid sequence. In using EMA, the current limitation of our method is that we only used the “damped EMA” of MEGA (Ma et al., 2022), which is only one of the basic components in MEGA. Because MEGA additionally combines the single-head attention unit over a long sequence, using MEGA could allow us to handle long-distance semantic matching. In the future work, it will be valuable to explore such extensions of EMA, such as MEGA, to strengthen the long-range reasoning.

In MAFiD, we show that EMA can be applied over a maximally long sequence in HybridQA (Chen et al., 2020). However, when moving to OTT-QA (Wenhu Chen, 2021), EMA cannot be naively applicable over retrieved long sequences without any truncation, because the size of a retrieved set of tables and texts is significantly larger than that of HybridQA. Given that OTT-QA more closely matches the real-world situation, the EMA-based reasoning should be extended further by incorporating retrieval and selection modules. Thus, our current framework needs to be extended further to handle open-domain table-and-text QA, under the retriever-reader framework.

A Implementation Details

We used the HybridQA dataset, which is a large-scale multi-hop question answering dataset over tabular and textual data. Table 5 presents detailed

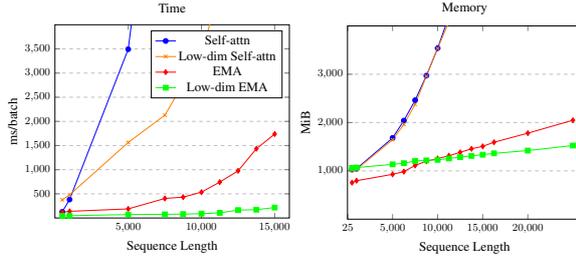

Figure 3: Comparison of memory and time complexities of self-attention, EMA, and their low-dimensional versions.

statistics of the HybridQA dataset. We used the T5-base¹ transformer encoder-decoder model as a pre-trained language model. Additional parameters were initialized from $\mathcal{N}(0, 0.2)$ and the bias was set to 0. To prepare the input of the encoder, we set the maximum sequence lengths of the tabular and textual blocks to 300 and 800, respectively. All the models were trained using the AdamW optimizer with a learning rate of $1e - 4$. All trainings were conducted for 3 epochs, and the random seed number was fixed at 42 to reproduce the results. The batch size was four with two accumulation steps. Training was conducted for 1.5 days on 4 NVIDIA Quadro RTX 8000. For answer generation, we employed a greedy decoding method. For the evaluation, we used exact matching (EM) and F1 metrics. Evaluations were conducted every 500 steps on the dev dataset and the best model with the highest EM score was chosen.

The maximum number of rows in a given table in HybridQA is 20, that is, $L \leq 20$. In our experiments, L was fixed at 20 by adding padding sequences when the number of rows was less than 20. The rate of the dimensionality reduction for the low-dimensional EMA, i.e., K , was fixed to 6.

B Dataset Statistics

Split	Train	Dev	Test	Total
In-Passage	35,215	2,025	20,45	39,285
In-Table	26,803	1,349	1,346	29,498
Missing	664	92	72	828
Total	62,682	3,466	3,463	69,611

Table 5: Hybrid QA dataset statistics. In-Passage and In-Table indicate that exact answer span is founded in a passage or table. Missing is the exact answer span not founded in given source.

¹<https://huggingface.co/t5-base>

Split	min	mean	max	Count
Table	137	763	8,298	3,466
Row	14	48	1,454	55,036
Passages per row	2	656	10,797	55,036

Table 6: Statistics of length of tokenized sequence on dev dataset. ‘Passages per row’ is the length of all concatenated passages in a row.

C An Example of Linearized Blocks

Specifically the i -th table row block is defined as follows:

$$b_R^i = [\text{TITLE}] t [\text{SECTITLE}] t_{(sec)} \\ [\text{ROW}] h^1 \text{'is' } v^{i,1} [\text{SEP}] \dots [\text{SEP}] h^N \text{'is' } v^{i,N}$$

where h and v are the head and value, t and $t_{(sec)}$ are the title and section title, respectively.

Passage block is defined as follows:

$$b_P^i = [\text{PSG}] psg_{linked}^{i,1} [\text{PSG}] \dots [\text{PSG}] psg_{linked}^{i,N}$$

where psg is a linked passage at row.

D Single-head and Multi-head Attentions

The single-head and multi-head attentions (Vaswani et al., 2017) are defined as follows:

$$\text{SHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = [\text{head}_1] \mathbf{W}^O, \\ \text{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = [\text{head}_1; \dots; \text{head}_h] \mathbf{W}^O, \\ \text{head}_i = \text{Attn}(\mathbf{Q} \mathbf{W}_i^Q, \mathbf{K} \mathbf{W}_i^K, \mathbf{V} \mathbf{W}_i^V) \quad (6)$$

E EMA

EMA has widely been applied in time series and long range text modeling. Among variants of EMA presented in the work of (Ma et al., 2022), we employed the ‘‘damped EMA’’² for proceeding long range sequences. The damped EMA is based on the recursive calculation for computing the output \mathbf{Y} as follows:

$$\mathbf{y}_t = \alpha \odot \mathbf{x}_t + (1 - \alpha \odot \delta) \odot \mathbf{y}_{t-1} \quad (7)$$

where \odot is the element-wise multiplication operator, $\alpha \in (0, 1)^d$ is a decaying factor for making exponentially decreasing effects from older tokens, $\delta \in (0, 1)^d$ is the damping factor, and α and δ are learnable weight parameters. This recursive computation of EMA can be efficiently implemented as the convolution and the fast Fourier transforms.

²This is different from the further extended multi-dimensional damped EMA (Ma et al., 2022)

Transformer-based Models for Long-Form Document Matching: Challenges and Empirical Analysis

Abstract

Recent advances in the area of long document matching have primarily focused on using transformer-based models for long document encoding and matching. There are two primary challenges associated with these models. Firstly, the performance gain provided by transformer-based models comes at a steep cost – both in terms of the required training time and the resource (memory and energy) consumption. The second major limitation is their inability to handle more than a pre-defined input token length at a time. In this work, we empirically demonstrate the effectiveness of simple neural models (such as feed-forward networks, and CNNs) and simple embeddings (like GloVe, and Paragraph Vector) over transformer-based models on the task of document matching. We show that simple models outperform the more complex BERT-based models while taking significantly less training time, energy, and memory. The simple models are also more robust to variations in document length and text perturbations.

1 Introduction

Matching long documents (*e.g.*: research papers, Wikipedia articles, patents, etc.) is an important task that can help understand the (dis)similarity between documents for downstream tasks like long document search. The first step towards better document matching is obtaining meaningful long document representations. Recent advances in this area have primarily focused on using transformer-based models for long document encoding and matching (Beltagy et al., 2020; Jha et al., 2022; Yang et al., 2020b; Zaheer et al., 2020). We use the term transformers to mean pre-trained transformers. Despite promising results, there are two primary challenges associated with such models. First, the performance gain provided by the huge transformer-based language models (LMs), like BERT (Devlin et al., 2019), GPT-2 (Radford et al., 2019), and

Longformer (Beltagy et al., 2020) come at a steep cost – both in terms of the required training time, and the resource (memory and energy) consumption. For example, the smaller $BERT_{BASE}$ model has 110 million parameters, whereas the bigger $BERT_{LARGE}$ model has a total of 340 million parameters and fine-tuning a single $BERT_{BASE}$ model on GPU can take hours. The second major limitation of transformer-based models is their inability to handle more than a pre-defined input token length at a time (512 tokens for BERT, and 4096 tokens for Longformer). This is a big drawback as they cannot handle long documents like research papers, patents, long articles, etc., without using aggregation techniques (Reimers and Gurevych, 2019).

In this work, we empirically demonstrate that *embeddings obtained from GloVe (Pennington et al., 2014), and Paragraph Vectors (Le and Mikolov, 2014)* along with simple neural models, such as feed-forward networks, and CNNs, *outperform several transformer-based models for the document matching task*. We define these models as simple as they take significantly less time to train and consume less memory and energy overall when compared to complex transformer-based models. Our long document matching setting is fundamentally different from long-form question answering and sentence similarity tasks. For the latter tasks the query is ‘short’, unlike the long document matching task where both the query and the target text are ‘long’. We experiment with three different kinds of semi-structured long document datasets in English: (i) ACL Anthology research papers, (ii) English Wikipedia articles, and (iii) Patents from US Patent and Trademark Office (USPTO). Our primary contributions are summarized as follows:

- We provide insights into the challenges of using transformer-based models for the task of long document matching. For this task, simple neural models are as effective and take a

fraction of the training time and resources to outperform transformer-based models.

- We provide insights into the best input embeddings for the simpler models in this task.
- We demonstrate that simple models are also more robust to changes in document length and text perturbation.
- We create benchmark long document datasets (by pre-processing ACL Anthology 2014 papers and Wikipedia articles) that will be made publicly available.

2 Related Work

Early work on long document matching focused on clustering techniques (Friburger et al., 2002; Huang et al., 2008; Strehl et al., 2000). Recently, Guo et al. (2016) proposed a deep learning based architecture for ad-hoc retrieval when comparing documents. Some works have also used convolutional networks (Hu et al., 2014; Pang et al., 2016; Yu et al., 2018), with weighting mechanism (Yang et al., 2016a) to generate a final query-document score. Mitra et al. (2017) propose a combination model that uses weighted sum representation-based and interaction-based results. Yang et al. (2016b) propose HAN, a hierarchical attention network for document matching. Jiang et al. (2019) propose SMASH, a multi-depth attention based hierarchical recurrent neural network for long-document matching. However, Yang et al. (2020b) pre-train SMITH, a transformer based hierarchical model for text matching that outperforms SMASH across multiple datasets. Jha et al. (2022) use supervised contrastive learning for interpretable long document matching. We compare several of these models on the required training time and resources.

A growing body of literature has used transformer based model for long document encoding (Child et al., 2019; Ho et al., 2019; Kitaev et al., 2019; Liu and Lapata, 2019; Qiu et al., 2020; Yang et al., 2020a). Longformer (Beltagy et al., 2020) adapts transformers to use an attention mechanism that scales linearly with sequence length. Big bird (Zaheer et al., 2020) uses a sparse attention mechanism that reduces BERT’s quadratic dependency on the sequence length to linear. CogLTX (Ding et al., 2020) uses text blocks for rehearsal and decay over key sentences to overcome the insufficient long-range attentions in BERT. Transformer-XL (Dai et al., 2019) and Compressive Transformers (Rae

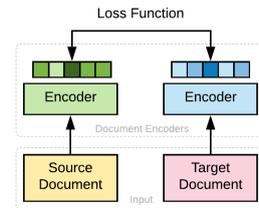

Figure 1: A schematic siamese comparison model

et al., 2019) compress the transformers to use attentive sequence over long text. Although promising, we demonstrate that transformer-based models are not considerably better than simple neural models on the task of long document matching.

3 Empirical Evaluation

Here we provide details of the simple and the transformer-based models and present an empirical comparison between them based on their overall performance, training time, resource consumption, and robustness on the document matching task.

Task Formulation We define the task of document matching as follows. Given a source document s , and a set of target documents D_T , the goal is to estimate the semantic match $\hat{y} = sim(s, t)$, where $t \in D_T$ for every document pair (s, t) . Similar target documents will have a higher similarity score. The document matching problem can be seen as a binary classification task, where the model predicts 1 for similar documents, and 0 for dissimilar documents. We use the term “matching” in the broad sense of document relevance (see Appendix A.2). The models take as input a pair of documents (source and target), and compute the cosine similarity between the encoded document representations. If the cosine similarity is greater than a similarity threshold θ , they are considered similar; otherwise they are considered dissimilar.

Models We pick a representative set of models from different categories and compare them by building their siamese versions (shown in Figure 1). The siamese network has three primary components: (i) Input (Source and Target Document), (ii) Document Encoder, and (iii) Loss Function. The source and target document encoder networks share weights. We experiment with three simple neural models: (i) DSSM: A simple feed-forward network (Huang et al., 2013), (ii) ARC-I: A CNN-based model (Hu et al., 2014), and (iii) HAN: An RNN-based Hierarchical Attention Network (Yang et al., 2016b) designed for long documents. Their performance is compared with three state-of-the-art transformer-based models: (i)

Model	AAN				WIKI				PAT			
	P	R	F1	Acc	P	R	F1	Acc	P	R	F1	Acc
HAN-G	0.504	0.881	0.641	0.607	0.566	0.584	0.575	0.775	0.609	0.848	0.709	0.522
DSSM-T	0.768	0.809	0.787	0.780	0.823	0.939	0.877	0.869	0.869	0.957	0.911	0.905

SMITH	0.726	0.565	0.635	0.676	0.949	0.982	0.965	0.963	0.892	0.939	0.865	0.939

Table 1: Performance on the document matching task up to the model’s maximum allowed input token length (512 for BERT; 4096 for Longformer, > 8000 for all other models). We experiment with Trigrams (T), GloVe (G), and Doc2Vec (D) Embeddings as input for the simple neural models. The best performance is highlighted in bold.

BERT (Devlin et al., 2019), (ii) LONG: Longformer (Beltagy et al., 2020), and (iii) SMITH: Siamese Multi-depth Transformer based Hierarchical Encoder (Yang et al., 2020b). We report the mean precision, recall, F1, and accuracy over 5 folds for the best performing hyper-parameters. The code can be found here: <https://github.com/AkshitaJha/SimpleModelsforLongDocumentMatching>.

Datasets We follow the previous literature (Yang et al., 2016b; Jiang et al., 2019; Yang et al., 2020b) and experiment with the following three standard long document datasets: (i) ACL Anthology Network Corpus (AAN)¹, (ii) Wikipedia Articles (WIKI)², and (iii) USPTO Patents (PAT)³. Each dataset consists of balanced 15,000 pairs of documents with 50% of them being similar pairs, and the remaining being dissimilar. The PAT dataset is an industry gold standard but we will publicly release the pre-processed AAN and the WIKI datasets (see Appendix A.2 for details). The dataset can be found here: <https://github.com/AkshitaJha/SimpleModelsforLongDocumentMatching>

Performance on Document Matching Task We experiment with three input representations for simple neural models: (i) char-Trigram Hashing (T) (Huang et al., 2013), (ii) GloVe Embeddings (G) (Pennington et al., 2014), and (iii) Paragraph Vector/Doc2Vec Embeddings (D) (Le and Mikolov, 2014) (See Appendix 4). Unlike most transformer-based models that take as input tokens up to a pre-defined length (512 for BERT, and 4096 for Longformer), simple models and SMITH have the ability to take the entire long document (> 8000 tokens) as input. Table 1 demonstrates the performance of different models on the task of docu-

ment matching up to their maximum allowed input document length (see Appendix A.8 for different document lengths.) We observe that despite being relatively simple and not taking into account contextual embeddings, *DSSM and ARC-I outperform the transformer based models using GloVe and Doc2Vec Embeddings* on the AAN, WIKI, and the PAT dataset.

Training Time Figure 2a shows the training time taken to reach the best performance for every model for their maximum allowed input token lengths. We only report the fine-tuning time after downloading the pre-trained models. All experiments were done on a 16GiB Tesla V100. *The simple models like DSSM, ARC-I, and HAN take 1/12 to 1/15 of the training time taken by the transformer-based models to outperform them on all three datasets* (see Appendix A.4 for the training time for different document lengths on all datasets.)

Memory and Energy consumption Memory consumption on a 16GiB Tesla V100, for a batch size of 1, for different models can be seen in Figure 2b. Compared to transformer-based models simple neural models consume significantly less memory for the same document length (12 GiB for Longformer vs. a maximum of 8 GiB for DSSM for 4000 tokens). We also compute the overall energy required for training the models to achieve their best performance (Figure 2c) by measuring the power consumption of the GPU over their training lifetime. Longformer consumes > 6MJ of energy for fine-tuning on documents with 4096 tokens, BERT consumes \approx 500kJ of energy for fine-tuning on documents with just 512 tokens, and the SMITH model consumes \approx 200kJ of energy for fine-tuning on longer documents; whereas the simple models consume < 100kJ of energy for training from

³<https://github.com/google/patents-public-data>

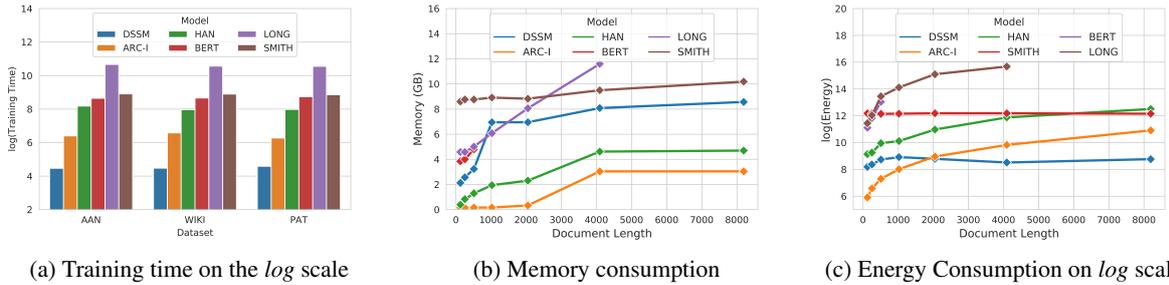

Figure 2: Comparison of simple neural models with transformer-based models based on (a) Training Time, (b) Memory Consumption, and (c) Energy Consumption.

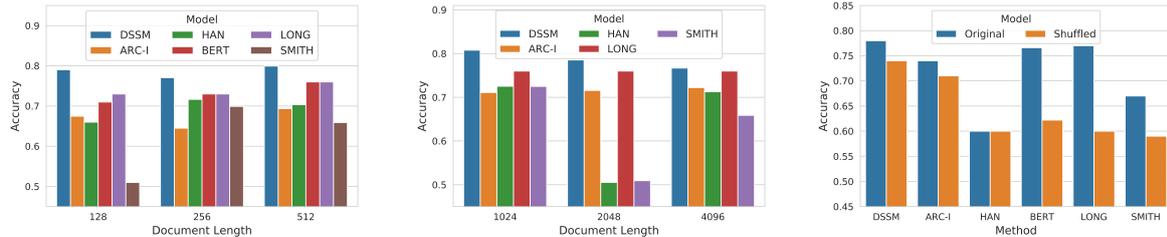

Figure 3: Comparison between the robustness of simple neural models and transformer-based models w.r.t. document length and text perturbation on the AAN dataset.

scratch for documents with > 8000 tokens.

Robustness to Document Length We limit the maximum number of tokens in each document during training and testing, and observe the final test accuracy on the document matching task. It should be noted that documents of different lengths are actually ‘truncated long documents’ without the complete contextual information needed to compute the actual similarity between two long documents. Figure 3 compares the model accuracy of simple models (with their default input embeddings) with transformer-based models upto their maximum allowed token lengths for the AAN dataset – 512 tokens for BERT (Figure 3a), and 4096 tokens for Longformer (Figure 3b). DSSM outperforms the baseline models for all documents lengths. BERT and Longformer have a consistent performance on AAN for different input lengths, unlike HAN and SMITH that are not as robust to the variations in document length, although they were designed specifically for long documents. We found similar results for WIKI and PAT dataset (see Appendix A.5). We also experiment with documents of length > 512 tokens for BERT, and > 4096 tokens for Longformer by aggregating the chunk representations upto their maximum allowed token length. We used the SUM and AVG aggregation techniques and observed an overall performance drop (see Table 5).

Robustness to Text Perturbation For text perturbation, we split documents into paragraphs of 512 tokens and randomly shuffle the order of these paragraphs before training different models to check for learned positional bias. We measure their test accuracy on the original document matching task. Figure 3c shows the model performance for all the baseline methods on AAN dataset. We observe a significant drop in the model performance for transformer-based models (BERT, Longformer, and SMITH). There is no significant change in the accuracy for the simple models – DSSM, ARC-I, and HAN. The transformer based models are more sensitive to text perturbation. The simple models, on the other hand, use non-contextual embeddings, such as GloVe, and Doc2Vec and are more robust to text perturbation (see Appendix A.6).

4 Conclusion

We empirically demonstrate the trade-off of using transformer-based models for semi-structured long English documents like research papers, Wikipedia articles, and patents. Transformer-based models have an overall strong performance and smaller variability across datasets. However, we observe that for the task of long document matching, using contextual embeddings do not provide any added advantage. **A simple feed-forward network or a CNN-based model using GloVe or Doc2Vec embedding outperforms several state-of-the-art**

pre-trained transformer-based models at a fraction of their overall training time and resources (memory and energy). These simple neural models are also more robust to changes in document length and text-perturbation.

5 Limitations

One of the limitations of our work is that we experimented only with long documents in English. Comparing simple neural models and transformer-based models in different languages would be an interesting study but is outside the scope of this short paper. We would also like to highlight that we use classification metrics instead of information-retrieval metrics due to the limitations of the dataset which has very few positive samples (2-3) for every document.

A Appendix

A.1 Model Description

The encoder networks and their default inputs have been described below:

A.1.1 Simple Models

- **DSSM (Huang et al., 2013)**: A *simple three-layered feed forward network* that takes as input the vectorized representation of a document.
- **ARC-I (Hu et al., 2014)**: A *CNN-based model* that takes as input a 2D-matrix representation of a document where words in the sentences are represented using *GloVe embeddings (Pennington et al., 2014)*. These are then passed through convolutional and max-pooling layers to finally obtain a document representation for both source and target documents, independently. The document representations are concatenated and passed through a multi-layer perceptron to predict if the pair of documents are similar or not.
- **Hierarchical Attention Network (HAN) (Yang et al., 2016b)**: A hierarchical *GRU-based model* with attention mechanism that aggregates *GloVe embeddings* at word level into sentence representations to arrive at the final document representation.

A.1.2 Transformer-Based Models

- **BERT (Devlin et al., 2019)**: A siamese matching model with *BERT*. For long document inputs, BERT only uses the first 512 tokens of each document. We use a pre-trained *BERT_{BASE}* model which is fine-tuned during training.
- **Longformers (LONG) (Beltagy et al., 2020)**: A siamese model with transformer-based *Longformers* for long sequences. It has an attention mechanism that scales linearly with sequence length and takes as input a maximum of 4096 tokens. We consider an attention window of size 256.
- **Siamese Multi-depth Transformer based Hierarchical Encoder (SMITH) (Yang et al., 2020b)**: A *transformer-based hierarchical encoder* which is the current SOTA model for long-form document matching task.

A.1.3 Implementation Details

For all the models presented in the paper, we use the same architecture as the original papers. We tune the hyperparameters and report the best results. The DSSM, ARC-I, HAN, and SMITH models were implemented in Tensorflow. BERT and Longformer were implemented in PyTorch. DSSM has hidden units of dimension 300 for its hidden layers and an output dimension of 128. The learning rate was 0.0075. ARC-I takes as input a 2D matrix of the size [no. of sentences x sentence length]. This is given as input to two 1D-convolutional (filter size of 200, kernel size 3) and MaxPooling layers of size 2, in order to get the final document representations. The representations of both the source and the target documents are concatenated and passed through a two-layer multi-layer perceptron. The first hidden layer of the MLP has a dimension of 64 with ReLU activation. The second layer has 1 node and sigmoid activation which predicts if the pair of documents are similar or not. The learning rate was set to 0.00075. HAN uses a bi-Directional GRU layer and applies attention mechanism to arrive at final sentence representation for the source and the target documents with a learning rate of 0.001. We use the pre-trained BERT_{BASE}⁴ and the Longformer⁵ models provided by the Huggingface library. The SMITH code was publicly available. The BERT, Longformer, and SMITH models are fine-tuned during training. All other models are trained from scratch. The learning rate is set to 5e-5 for the transformer based models. We use an Adam optimizer for all models with a weight decay of 0.01. We use binary cross entropy as the loss function for the simple models, pairwise loss for BERT and Longformer, and triplet loss for SMITH. These loss functions resulted in the best performance for the model. The three datasets are split into 80-10-10 for train, validation, and test sets, respectively. We use cosine similarity and the similarity threshold θ is set to 0.5. We perform 5 fold cross-validation and use early stopping on the validation set to prevent over-fitting. The models were trained on one 16GB Tesla V100 GPU.

A.2 Dataset

- **ACL Anthology Network Corpus (AAN)⁶**: The AAN corpus (Radev et al., 2013) consists

⁴https://huggingface.co/transformers/model_doc/bert.html

⁵<https://huggingface.co/transformers/longformer.html>

⁶<https://aan.how/download/#aanNetworkCorpus>

of 23,766 papers written by 18,862 authors in 373 venues related to NLP and forms a citation network. Each paper is represented by a node with directed edges connecting a paper (the parent node) to all its cited papers (children nodes). Papers that have been cited by the parent paper are treated as similar samples (Jiang et al., 2019). For every similar sample, an irrelevant paper is randomly chosen to create a balanced dataset. Sets of similar papers are given the same labels. To prevent leakage of information and make the task more difficult, the references and the abstract sections are removed. Papers without any content are also removed. We then randomly sample 15,000 research paper pairs for our experiment.

- **Wikipedia (WIKI)**⁷: We use the Wikipedia dump, and adopt a similar methodology proposed by Jiang *et al.* (Jiang et al., 2019) to process this data. From the Wikipedia dump containing 6 million articles, we randomly sampled 250,000 articles along with the articles present in their outlinks. We create a dataset of similar Wikipedia articles by assuming that similar articles have similar outgoing links. The Jaccard similarity between the outgoing links of the source and the target articles is calculated. If the Jaccard similarity > 0.5 , the documents are assumed to be similar, otherwise they are considered dissimilar. Only articles with two or more similar articles are selected. We then randomly sample 15,000 research paper pairs for our experiment.
- **Patent (PAT)**⁸: The patent dataset is an internally curated industry gold-standard. This dataset consists of patents sampled from the publicly available USPTO patents belonging to four different categories: video, wireless, image compression, and network compression. A patent document is extremely long and primarily consists of (i) Abstract, (ii) Claims, and (iii) Description sections. We only make use of the Claims and the Description sections for our experiments to prevent leakage of information from Abstracts. Three internal human annotators, with expert domain knowl-

edge, were given pairs of documents and were asked to label them as similar or dissimilar based on the technology presented in the patents. They referred to the Abstract, Claims, and CPC Codes⁹ of the patents to measure the similarity. The final document content similarity label was based on majority vote.

The dataset statistics can be found in Table 2. We would like to note that although considering only the cited papers and outgoing links for AAN and Wikipedia articles, respectively is not the most optimal approach for creating similar document pairs, we adopt it for the following two reasons: (i) We do not have annotated fine-grained similarity scores for AAN and WIKI datasets, and (ii) We follow an approach similar to the previously published work (Jiang et al., 2019; Yang et al., 2016b, 2020b). We use the term “document matching” or “document similarity” in the broad sense of “citation matching” or “document relevance” – Given a pair of documents, are the two documents relevant to each other and should they be cited by each other.

A.3 Performance on Document Matching Task

Table 3 shows the average performance of simple models when compared to transformer based models on the document matching task for AAN, WIKI, and PAT datasets. ARC-I with Doc2Vec embeddings has the best average precision and accuracy. The average F1 score is comparable to BERT which re-emphasizes the benefits of using simple models for document matching.

A.4 Training Time for Different Document Lengths

The training time for different document lengths for all three datasets can be seen in Figure 4. BERT can only take up to 512 tokens. DSSM, ARC-1, and HAN take considerably less time to train when compared to transformer-based.

A.5 Robustness to Document Length

We check the robustness of simple models and transformer-based models for different document lengths on the task of document matching. From Figure 5 and Figure 6, we observe that the simple

Table 3: Average performance across AAN, WIKI, and PAT datasets on the document matching task (shown in Table 1). We experiment with Trigrams (T), GloVe (G), and Doc2Vec (D) Embeddings as input for the simple neural models. The best performance is highlighted in bold.

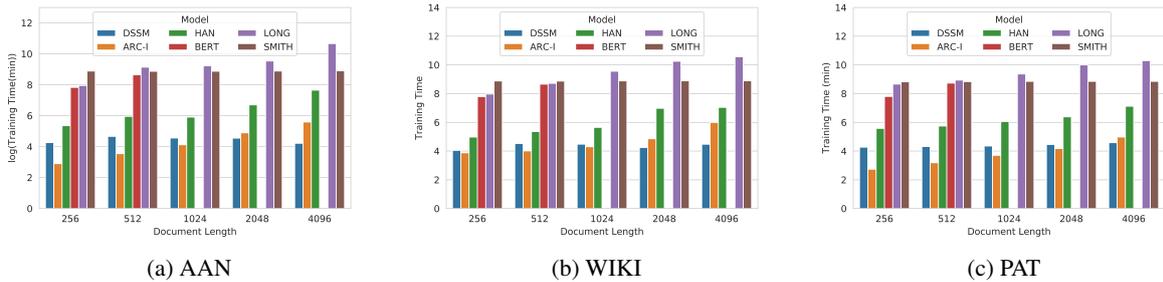

Figure 4: Doc Length vs Training Time (in *log* scale) for different document lengths.

models DSSM and ARC-I, and the transformer-based models BERT and Longformer, though not specifically designed for long documents are robust for different document lengths. BERT can only handle up to 512 tokens at a time, and Longformer can only handle up to 4096 input tokens. HAN and SMITH, on the other hand, were specially designed for long documents and have a high variance in their performance on the document matching tasks for different document lengths.

We also experimented with longer documents (> 512 tokens for BERT, and > 4096 tokens for Longformer). We obtained the final document representation by dividing the document into chunks of their maximum allowed token length. We then aggregated these chunk representations. We experimented with the SUM and AVG aggregation techniques by taking the representations of the ‘[CLS]’ token and ‘the pooler output’ for these models. We

observed an overall performance drop because of aggregation. The results were the same for both SUM and AVG aggregation techniques (Table 5).

A.6 Robustness to Text Perturbation

We randomly shuffle the documents before training different models and measure their test accuracy on the original document matching task (Figure 7) for all three datasets. The first few paragraphs in Wikipedia articles, research papers, and patents are highly informative. We wanted to verify if the models give too much importance to the position of the initial text. In the context of long documents, just re-ordering the paragraphs of a document spanning pages should not have an effect on the downstream tasks of document matching. (Note: We use the term document matching broadly to refer to citation matching or document relevance. Given a document pair, we would like to verify if the two

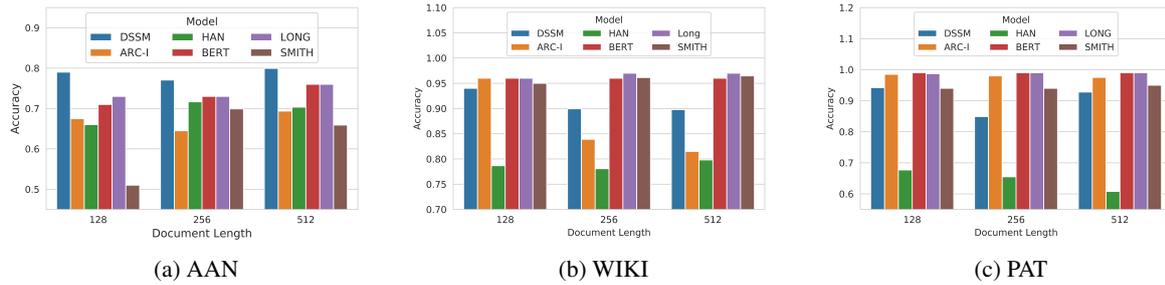

Figure 5: Document Length vs Accuracy upto 512 tokens

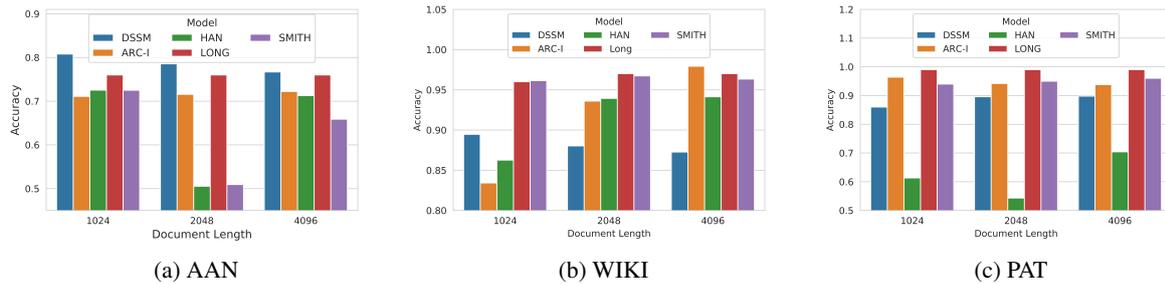

Figure 6: Document Length vs Accuracy upto 4096 tokens

documents are relevant to each other.) In order to verify this assumption, we shuffle the paragraphs to distribute the important texts randomly and check the performance of all models on this downstream task. Although, we do observe a small drop after paragraph shuffling because the simple models do take into account a shallow context of the input text, the simple neural models overall prove more robust to text perturbation when compared to transformer-based models that take into account deep contextual information.

A.7 Best Input Embeddings for Simple Models

For simple models, we evaluate if the input vector representations play a role in the final results. We use the following input representations.

- **Tri-Gram Hashing (T):** Bag-of-charTrigrams is a technique for word hashing (Huang et al., 2013) where each word is broken down into character trigrams (charTrigrams). Since, the number of possible charTrigrams are fixed and limited, this is a scalable solution for long documents. The charTrigrams are obtained for every token in the input text after appending the symbol ‘#’ before and after every token. For example, the word ‘good’ [#good#]

is split into [#go, goo, ood, od#] and then mapped to a 30,621 dimensional hash table. This vector representation for the document is then given as input to the models. For DSSM, each document is represented as a bag-of-charTrigrams and given as input to the model. For ARC-I and HAN, we split each document into n chunks which are represented in the form of a trigram hash. We construct a matrix of size $n \times$ trigram hash for the entire document which is given input to ARC-I and HAN.

- **GloVe Embeddings (G):** GloVe (Pennington et al., 2014) is an unsupervised learning algorithm for obtaining vector representations for words. We download the pre-trained GloVe embeddings and get the vector representations for words in a long document. These vector representations are given as input to different models. For DSSM, we divide the document into chunks of a specified maximum length. We then take GloVe embedding representation of tokens for each chunk upto a maximum length and average them to get a document representation. For ARC-I and HAN, each document is represented as a matrix of size [embedding dimension \times max length] in each document.

Table 5: Aggregation using the [CLS] token, and the pooler output [POOL] from BERT and Longformer for documents > 512 and > 4096 tokens for BERT and Longformer, respectively. The results were the same for SUM and AVG aggregation techniques.

- **Doc2Vec Embeddings (D):** Doc2Vec (Le and Mikolov, 2014) embeddings can be used to get vector representations for a document. We train Doc2Vec models from scratch on different datasets to get relevant document representations. These document representations are then given as input to different document matching models.

Table 4 shows the model performance of the simple models for the above three input representations. We observe that using GloVe (G) and Doc2Vec (D) input embeddings improve the model performance of the simple models overall.

A.8 Different Aggregation Techniques for Transformer Based Models

We experiment with different aggregation techniques (SUM and AVG) for > 512 tokens for BERT, and > 4096 tokens for Longformer. We

chunk the documents and aggregate the representations from the ‘[CLS]’ token and ‘the pooler output’. The results can be seen in Table 5 and were the same for SUM and AVG aggregation techniques. Aggregation resulted in an overall performance drop when compared to just truncating the documents up to 512 tokens and 4096 tokens for BERT and Longformers, respectively for the document matching.

Simple and Effective Multi-Token Completion from Masked Language Models

Abstract

Pre-trained neural masked language models are often used for predicting a replacement token for a given sequence position, in a cloze-like task. However, this usage is restricted to predicting a single token, from a relatively small pre-trained vocabulary. Recent Sequence2Sequence pre-trained LMs like T5 do allow predicting multi-token completions, but are more expensive to train and run. We show that pre-trained masked language models can be adapted to produce multi-token completions, with only a modest addition to their parameter count. We propose two simple adaptation approaches, trading parameter counts for accuracy. The first method generates multi-token completions from a conditioned RNN. It has a very low parameter count and achieves competitive results. The second method is even simpler: it adds items corresponding to multi-token units to the output prediction matrix. While being higher in parameter count than the RNN method, it also surpasses current state-of-the-art multi-token completion models, including T5-3B, while being significantly more parameter efficient. We demonstrate that our approach is flexible to different vocabularies and domains and can effectively leverage existing pre-trained models available in different domains. Finally, a human evaluation further validates our results and shows that our solution regularly provides valid completions, as well as reasonable correctness for factual-sentence completions.

1 Introduction

Multi-Token-Completion (MTC) is the task of filling masked sentences with a sequence of tokens such that the completed sentence is probable and coherent. e.g., for the masked sentence *"The 46th president of the US, [MASK], was elected in 2020"*

a good completion would be any of *"Biden"*, *"Joe Biden"*, *"president Biden"* and more.

While Masked Language Models (MLMs) such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) successfully deal with a simpler variation of this task (single-token completion) these models were pre-trained on a limited vocabulary, not containing multi-word phrases. It is technically possible to complete numerous tokens simultaneously with MLMs by introducing a sequence of [MASK] tokens, but there are no clear methods of conditioning the tokens on each other, and, more importantly, the length of the completion needs to be pre-determined. Expanding MLMs' effective completion vocabulary – the actual vocabulary they are capable of completing well – will help a recent line of work using MLMs to extract knowledge/information from corpora (Jiang et al., 2020; Petroni et al., 2019; Kushilevitz et al., 2020).

Most existing works using MLMs to complete sentences either avoid the problem by limiting the completions to single tokens or use sub-optimal heuristics for MTC (e.g. presetting the length of the sequence and filling one token at a time). A trivial solution is to increase the number of tokens used in the pre-processing tokenization step, and also include multi-word phrases as tokens. However, apart from the longer tokenization time¹, the main problem with this approach is that changing the input level of the model requires adapting the weights of the full MLM to the new input.² A recent family of seq2seq pre-trained LMs, the prevalent of which is T5 (Raffel et al., 2020), are trained directly on the MTC task, and indeed perform quite well on it, especially with larger model sizes. However, the seq2seq objective, coupled with very high parameter counts, make such models expensive to train

¹Expanding BERT's tokenizer vocabulary from 30K to 100K phrases leads to a degradation of $\times 30$ in tokenization time. Further details are in Appendix A.

²This requires either full pre-training of the MLM or long, end-to-end fine-tuning using a considerable amount of data.

* Authors contributed equally.

and to run inference on, compared to MLMs.

In this work, we demonstrate how pre-trained MLMs can be *adapted* to produce multi-token completions from (large) fixed vocabularies, using a self-supervised training objective and only a modest parameter count. Specifically, we demonstrate an effective adaptation of pre-trained MLMs to predict, on top of their pre-trained vocabularies, additional $\sim 100K$ noun-phrases (NP-chunks) and entities ranging in length from 1 to 10 tokens. The only requirement is a textual corpus in which each of the desired phrases appears over k times (we used $k = 50$ in this work). The adapted model surpasses the accuracy of T5-3B predictions, while using a fraction of the parameter count and being significantly more efficient to run. Apart from evaluating with automatic measures, we also use human-annotators to explore different aspects of the proposed completions.

After experimenting on the prediction of general-purpose phrases, we also show our methods can be used to predict phrases in a specific domain. This is a significant benefit of the adaptation approach since the completion vocabularies can be tailored to a specific project's needs, using domain-specific pre-trained MLMs, even in domains where huge T5-like models are not available³.

We use any pre-trained MLM for MTC by extracting the informative representations the MLM uses for completing a single token, and feeding them into a small and simple model that chooses appropriate multi-token completions. We offer two different completion models. Depending on the scenario, both are useful; the first solution, which expands the MLM's decoder matrix, achieves SOTA accuracy. The second solution, using a small iterative generation model, is well suited for large completion-vocabularies while achieving competitive results.

The core reason for the success of our methods, despite being trained on less data and for less time than other solutions, is the fact that the MLM's pre-training is well suited for the MTC task. We provide two types of evidence to support this claim: In section 2 we present an experiment suggesting that MLMs incorporate information regarding

³For example, an e-commerce company could adapt a pre-trained general purpose MLM to complete multi-token product names, while a biomedical researcher could adapt a pre-trained biomedical MLM such as SciBERT (Beltagy et al., 2019) or BioBERT (Lee et al., 2019) to complete multi-token drug or disease names.

multi token phrases. In section 6, we show that pre-training on in-domain data helps our methods perform better. Both of these signals indicate that, as expected, the MLM pre-training captures information required for MTC. Therefore, what is left for our MTC adaptation models is only to extract this information from the MLM, an easier task that does not require a long training with a vast amount of data.

Our main contributions are MTC datasets (general purpose, PubMed-based, and a $3K$ dataset with human labeling), demonstrating that MLMs learn the meaning of Multi Token phrases, and two methods for adapting any pre-trained MLMs for MTC. We publish⁴ our datasets, models and code⁵.

2 MLMs Learn Multi-Token Phrases

Our work relies on the assumption that MLMs are capable of holding information about multi-token phrases. Despite being a common belief and an essential property for the MLMs to have in order to be as successful as they are, to the best of our knowledge this was not shown explicitly. How do we show that a token-completion MLM is encoding the semantics of multi-token phrases? Looking at completions will fail, because we cannot directly probe for MTC. Instead, we came up with the following experimental design, which measures the encoding of multi-token phrases indirectly by looking at masked positions influenced by them.

We use multi-token phrases that have single token synonyms. We construct a dataset containing quadruples, each quadruple consisting of a multi-token phrase (e.g. "New York city"), a single-token synonym (e.g. "NYC"), a phrase similar in meaning to the synonyms (e.g. "Chicago") and a random phrase (e.g. "Dog"). We collect sentences containing the multi-token phrases, and in each sentence mask out an NP-chunk different from the multi-token phrase (e.g. "[MASK] is in New York city"). Next, we replace each multi-token phrase with each of its other corresponding quadruple phrases, forming four similar masked sentences, each containing a different quadruple phrase (e.g. "[MASK] is in NYC").

Finally, we ask an MLM to complete the missing token in each masked sentence, and compare the suggested completions. If the MLM is aware that

⁴<https://registry.opendata.aws/multi-token-completion/>

⁵<https://github.com/amzn/amazon-multi-token-completion/>

the multi-token phrase is semantically similar to the single-token synonym, we expect it to suggest similar completions regardless of which of the two it sees in the sentence. Indeed, the model treats the multi-token phrase similar to the single-token synonym; We use a similarity measure comparing the MLM’s suggested completions for the multi-token phrase sentences and each of the other types of sentences. We find that the average similarity between multi-token phrase sentences and single-token synonym sentences is 0.76, while for similar-phrase sentences it is 0.71 and for random-phrase sentences it is 0.63. Our main conclusion from this experiment is that, as expected, MLMs learn semantic meaning of multi-token phrases. Full experiment details (including the similarity measure used) are in Appendix B.

3 Masked Language Modeling Data

In absence of a known dataset for the MTC task, we curate one. We follow (Devlin et al., 2018) and use data from two sources: Wikipedia articles and the Books corpus (Zhu et al., 2015).

Completion Vocabulary. We start by building a vocabulary of phrases. As we aim for general-purpose MTC, and following (Trask et al., 2015) by considering phrases as NP-chunks or entities, we simply focus on phrases that appear frequently in the corpus. We use spacy (Honnibal and Montani, 2017) to extract 64M unique NP-chunks and entities. We keep phrases appearing 500 times or more in the corpus, leaving us with $\sim 93K$ phrases. Only 10.2% are single tokens using BERT’s cased tokenizer, indicating the importance of MTC. 52.9% of the phrases consist of 2 tokens, 36.9% consist of 3 or more. 53% of the phrases are single-words, 47% span two words or more. Further statistics regarding the number of words and the number of tokens assembling the phrases selected are reported in Table 1.

Masked sentences. We split the corpus using spacy’s sentencer. We sample 50 unique sentences containing each vocabulary-phrase. We eliminate recurring sentences and mask out the vocabulary phrase to form masked sentences, using the masked span as the label. We randomly split the data into train (90%), validation (5%) and test (5%) sets.

4 Adapting MLMs for MTC

We propose two simple yet effective solutions, capable of integrating with any pretrained MLM and

#Tokens	%Phrases	#Words	%Phrases
1	$\sim 10.2\%$	1	$\sim 53.3\%$
2	$\sim 52.9\%$	2	$\sim 38.3\%$
3	$\sim 23\%$	3	$\sim 5.4\%$
4	$\sim 9.5\%$	4	$\sim 2.1\%$
5	$\sim 2.8\%$	5	$\sim 0.5\%$
> 5	$\sim 1.6\%$	> 5	$\sim 0.4\%$

Table 1: **Expanded completion vocabulary.** Number of tokens and words assembling the phrases collected.

extending its completion vocabulary to perform MTC. Both solutions utilize the MLM by using the contextual embedding vector of the masked place, which was originally pre-trained to be relevant for completion tasks. Instead of using it to choose the appropriate single token replacement (see Figure 1 (1)) like the MLM, we use it as an input to extension models tuned for completing out of an expanded vocabulary. We train only the relatively small extensions and use the pre-trained MLMs as is, allowing short and effective training.

4.1 Extended-Matrix (EMAT) decoder

Our first extension model is based on extending the decoder matrix of the MLM to include the new multi-token phrases in the completion vocabulary. We assign each new multi-token phrase to an embedding vector, which is added only to the output token-prediction matrix. This is in contrast with simply adding it to the base-model’s vocabulary, which results in longer training due to the full model being affected and in increased tokenization time (see Appendix A for tokenization time evaluation). An illustration of the architecture can be found in Figure 1 (2), where we use the MLM to compute the contextual embedding of the masked token and feed it to the extended-matrix decoder. Even though each multi-token phrase is assigned with its own embedding vector, this solution allows us to adapt MLMs trained with a smaller vocabulary (with all mentioned advantages this comes with) to complete phrases that are multi-token phrases in their *original* vocabulary.

During training, we extract the contextual embedding from the masked sentence and only train the extended-matrix decoder yielding a quick training phase. We train the decoder over the train set described in Section 3, expanding the completion vocabulary to $\sim 93K$ phrases. When BERT-base is the base MLM, this approach adds 138M parameters, considerably less than models comparable in performance such as T5-3B (3B parameters).

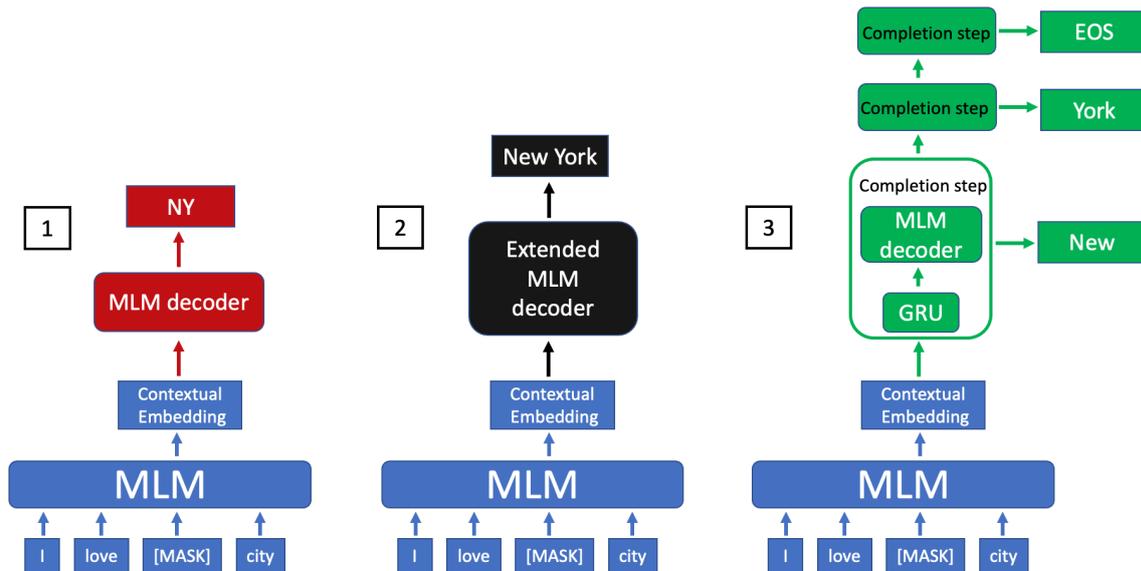

Figure 1: **Architectures.** The MLM body is shared across architectures. It outputs a contextual embedding for the [MASK] token, used by all decoding solutions. The MLM (1) predicts a single token from its vocabulary. EMAT (2) uses an extended decoder to predict a phrase from the extended vocabulary. The Generative extension (3) completes tokens until reaching [EOS]. Some arrows and layers are deducted for readability.

4.2 RNN decoder

Our second model is based on an RNN decoder, specifically a GRU (Cho et al., 2014). We use it to replace the MLM’s matrix decoder.

To train our GRU decoder for MTC, similarly to our first solution, we utilize the pretrained MLM by extracting the embedding vector corresponding with the masked token for each sentence. For the GRU-based solution we use this vector as the first hidden vector fed into the GRU. As the first input to the GRU, we wish to provide the context of the multi-token phrase to be generated and thus feed the static embedding of the token *preceding* the [MASK] token. For later steps, the input is the previous token completed by the generative model. The inputs to the GRU are depicted in Figure 1 (3), where the contextual embedding of [MASK] is fed as the first hidden state and the static embedding of ‘love’ is the first input of the GRU.

Next, at each step we concatenate: a) the output of the GRU; b) the previous vector embedding; and c) the masked token contextual embedding vector from the pretrained MLM, and feed them to a feed forward (FF) layer in order to reduce the dimension. We find that providing these three contexts to the decoder improves its accuracy. The output of the FF is then fed as input to the MLM decoder (For BERT, this is a FF layer followed by an embedding layer and a SoftMax layer) to obtain the

token predicted for this step of the autoregressive generation. We train the model to complete the next token of the missing multi-token phrase using a standard back propagation approach with Cross Entropy loss. We utilize the dev set to tune the batch size, number of GRU layers, teacher forcing rate, and learning rate (used parameters can be found in appendix C).

We find that initializing the GRU’s decoder embeddings with the same parameters used by the MLM we are plugging into, improves the performance. Also, it helps to pre-train the generative model on a vanilla Language Modeling task before starting MTC training. The idea is to give the fresh extension model some sense of the distribution of the language before the training on the MTC task. An ablation study demonstrating the benefit of these components is shown in Appendix C.

Our generative model consists of only 32M parameters when using BERT as a base model, which are the only trained parameters used for our solution (i.e. the pretrained base MLM is not fine-tuned) and independent of the vocabulary size. During inference, we simply use the MLM to extract the embedding vector corresponding with the masked token and feed it, along with the static embedding of the preceding token, as input to the trained GRU model. Next, we use beam-search to generate sequences until reaching an EOS token.

Model	Coverage	Size	Data size	$a@1$	$a@3$	$a@5$	$a@10$	$a@50$
BERT-cased	13.8%	110M	16G	13.5%/1.8%	21.8%/3.0%	25.9%/3.5%	31.2%/4.3%	43.1%/5.9%
RoBERTa	15.6%	110M	160G	19.3% /3.0%	30.6% /4.7%	36.1% /5.6%	43.2% /6.7%	59.4% /9.2%
Naive-MTC-BERT	66.1%	220M	16G	6.6%/ 4.3%	11.9%/ 7.8%	14.9%/ 9.8%	19.5%/ 12.8%	32.3%/ 21.3%

Table 2: **MLMs performing limited completion.** Coverage is the % of sentences from the test set that the model is capable of completing. MLMs are limited to single token completions. For computational reasons, we allow the Naive-MTC-BERT to generate only single tokens or two-token phrases. Accuracy is reported as x/y ; x is the accuracy out of the specific model’s limited coverage and y is the accuracy out of the full test set ($coverage * x$).

5 Results

Setup. Measuring success in completion tasks is not trivial since a masked-sentence can have many suitable replacements. In many cases returning the expected phrase in a top-k place, and not necessarily first, is acceptable. Hence, we measure $accuracy@k$ (sklearn): the percentage of masked sentences where the label is among the top-k predictions. To better ground our performance expectation from MTC, we first evaluate the accuracy of an easier completion task; Single Token Completion. We go on to evaluate Naive MTC using MLMs. As expected, results are not sufficient. Finally, we evaluate our methods, adapting MLMs for MTC.

5.1 Single Token Completion

Single Token Completion is an easier⁶ task than MTC, and MLMs like BERT and RoBERTa are trained directly to perform it. Therefore, results of these MLMs on the single token completion task can be considered as an upper limit for the performance of solutions adapting these models for MTC. We test BERT and RoBERTa on the single token completion task, results of these models on the test set are reported in Table 2.

5.2 Naive MTC with MLMs

A naive way to utilize MLMs for MTC is using a two-step method: given a masked sentence, first predict the number of missing tokens and then duplicate the masked token to the predicted number (e.g. "The US state [MASK]" becomes "The US state [MASK] [MASK]") and complete them using the MLM. We train a BERT-based classification model predicting the number of missing tokens by assigning a label to the data: for each masked sentence, the label assigned is the number of tokens the masked span splits into using BERT’s

⁶For example, BERT’s search-space size is $\sim 30K$ while some MTC solutions (e.g. our generation plugin and T5) have an infinite search space.

tokenizer. Due to computational limits of the generation phase, we are only interested in 3 classes: a single token missing, two tokens missing, and 3 or more tokens missing. The class distribution is (10%, 53%, 37%), respectively. We use BERT’s default hyper-parameters and train a classification model. This is a task with ambiguous labeling⁷, thus we do not expect high accuracy results. The model reaches 64.7% accuracy on the test set.

During inference, we use the model’s predictions with a SoftMax function to acquire a probability for a single token mask-replacement and a double token mask-replacement. We utilize these probabilities as follows. For each specific single token, we compute a replacement probability by simply multiplying the probability for any single token replacement by the probability BERT assigns the specific token to replace the mask in the masked sentence. For a double token term we multiply the probability of having a double token replacement by the probability BERT predicts for the specific term, estimated with a standard generating heuristic. After duplicating the mask, we complete the first missing token using the MLM. Then, we replace the first mask with each of the top-100 predicted tokens and complete the second mask. Finally, the probability for each double token term is the product of the probabilities the two tokens assembling it to replace the two missing [MASK] tokens.

Results on the test set are reported in Table 2. Even when considering only sentences where the missing phrase consists of one or two tokens, results are not sufficient and call for a different way to use MLMs for MTC. This is likely due to the fact that the first token replacement is computed in an unconditional manner to the second one.

5.3 Multi Token Completion

We use BERT, RoBERTa and SpanBERT as MLMs adapted for MTC with our methods described in section 4. MTC models are capable of completing

⁷e.g. for "The US state [MASK]" "New York" and "Texas" are adequate replacements resulting in different labels.

Model	Size	Data Size	Inf-time	$a@1$	$a@3$	$a@5$	$a@10$	$a@50$
ILM (GPT-2)	124M	1G/41G	120ms	1.3%	2.7%	3.7%	5.3%	10.8%
T5-base	220M	700G	224ms	5.2%	8.3%	9.7%	11.4%	15.6%
T5-3B	3B	700G	802ms	11.6%	18.5%	21.5%	25.4%	NA
BERT-Adapted-RNN	32M/142M	1G/17G	44ms	9.24%	14.64%	17.39%	21.32%	31.28%
BERT-Adapted-EMAT	138M/248M	1G/17G	15ms	12.64%	20.48%	24.63%	30.65%	45.85%

SPAN-BERT-Adapted-EMAT	138M/248M	1G/17G	15ms	6.91%	11.6%	14.12%	17.93%	27.45%

Table 3: **MTC results.** Models are described in Section 5.3. Adapted models are trained with our solutions as described in Section 4. Size is the number of parameters; Data size is the amount of data seen during training. For adapted models we report both of these numbers excluding/including the base MLM. Inf-time is the average inference time of a single sentence, measured using an Nvidia T4 GPU. T5-3B is too large for a beam of size > 10 .

a phrase of any length hence have a coverage of 100% on the test set. Apart from our methods, we also report on several baselines.

ILM (Donahue et al., 2020) is a GPT-2 based framework for infilling, a task similar to MTC. The LM is shown a sentence with missing places and is trained to generate text probable of replacing the missing parts. A crucial observation is that GPT-2 is an LM and not an MLM. Therefore, ILM’s pretraining seems less appropriate for completing relatively short phrases (a task similar to the MLM objective), and more appropriate for longer generation tasks (a task more similar to the LM objective). We fine-tune ILM on our dataset for a single epoch, taking ~ 3.5 days using an Nvidia T4 GPU.

T5(Raffel et al., 2020) is a transformer model pretrained on the MTC task. It is a strong baseline reaching SOTA on many NLP tasks. We report on two versions, T5-base and T5-3B, both trained on a dataset 1-2 order of magnitudes larger than ours.

Results and Discussion. Results are reported in Table 3. Our extended matrix (EMAT) solution performs best, even when compared to the huge T5-3B. The RNN plugin is slightly inferior, but still performs better than existing solutions comparable in size. Note that even though the size of the EMAT plugin is $\sim \times 4$ of the size of the RNN plugin, inference time for the tested vocabulary is shorter because of GPU optimizations and the fact that the RNN model may run several times (~ 3 in average on the test set) for each completion. However, increasing the completion vocabulary size will not affect the GRU size but will increase the size of the matrix extension, making the RNN plugin a better fit for large completion vocabularies⁸.

⁸For a completion vocabulary with 1M phrases and BERT as the MLM, the size of the RNN plugin remains 32M, while the size of the EMAT plugin grows to 769M.

6 Domain Specific MTC

We investigate MTC in a specific domain.

Datasets. We chose the Biology Domain, due to the availability of data and models. Using PubMed (pubmed) abstracts as a corpus, we extract two MTC datasets. Similarly to section 3, we first construct the completion vocabularies.

Key-phrase vocabulary: we use $\sim 20K$ MeSH vocabulary⁹ phrases appearing frequently as key-phrases in pubmed papers. This assures us phrases from the Biology domain. We discard phrases appearing less than 50 times as NP-chunks or entities in the corpus, leaving us with $\sim 12.5K$ phrases.

Frequent-phrases vocabulary: Similarly to section 3, we extract a vocabulary of phrases appearing more than 500 times as NP-chunks or entities in the corpus ($\sim 144K$ phrases). To make sure we are considering mostly phrases from the Biology domain, we discard phrases appearing in our general purpose vocabulary (described in section 3), leaving us with $\sim 118K$ phrases.

Finally, for both vocabularies we extract 50 sentences containing each of the vocabulary phrases, mask the phrase out in each sentence and split the data into train, development and test sets.

Base Models. To evaluate the impact that the domain-specific pre-training has on the performance of our methods, we test our adaptation methods on top of models pretrained on different datasets. *SciBERT* (Beltagy et al., 2019) is a BERT-like model trained on the Semantic Scholar data - data from the scientific domain, closer to the biology domain than the general purpose BERT. *BioBERT* (Lee et al., 2019) is a BERT-like model trained on PubMed abstracts.

⁹MeSH (Medical Subject Headings) is NLM’s controlled vocabulary of biomedical terms used to describe the subject of each journal article in MEDLINE.

Model	Dataset	$a@1$	$a@3$	$a@5$	$a@10$	$a@50$
T5-base	<i>key-phrases</i>	3.6%	5.2%	5.8%	6.7%	8.4%
T5-3B	<i>key-phrases</i>	10.3%	15.1%	16.9%	19.5%	NA
BERT-Adapted-EMAT	<i>key-phrases</i>	12.9%	20.7%	24.9%	31.1%	48.8%
SciBERT-Adapted-EMAT	<i>key-phrases</i>	13.4%	21.2%	25.2%	30.8%	44.9%
BioBERT-Adapted-EMAT	<i>key-phrases</i>	16.3%	26.9%	32.1%	39.5%	57.2%
T5-base	<i>NP-chunks and Entities</i>	3.9%	5.7%	6.6%	7.7%	10.5%
T5-3B	<i>NP-chunks and Entities</i>	8.2%	12.8%	15.0%	18.1%	NA
BERT-Adapted-EMAT	<i>NP-chunks and Entities</i>	7.1%	11.8%	14.4%	18.5%	30.5%
SciBERT-Adapted-EMAT	<i>NP-chunks and Entities</i>	8.2%	14.2%	17.5%	22.5%	35.4%
BioBERT-Adapted-EMAT	<i>NP-chunks and Entities</i>	8.0%	13.5%	16.4%	20.7%	31.77%

Table 4: MTC on the pubmed test sets. T5-3B is too large for a beam of size > 10 .

Results are reported in table 4. For brevity, we compare our Extended Matrix method, tuned on three base models (BERT, SciBERT, BioBERT), to the two primary baselines: T5-base and T5-3B. We report on the two PubMed datasets we curated.

Conclusions. First, our method outperforms the strong T5-3B baseline in the domain-specific scenario as well, showing MLMs can be effectively adapted for domain-specific MTC. Second, the success of *BioBERT* and *SciBERT* suggests that the pre-training of the MLM is in fact utilized by our methods (i.e. there is no catastrophic forgetting). Last, the *key-phrases* dataset is easier than the *frequent NP-chunks and Entities* one. This is likely due to the *key-phrases* dataset mostly containing phrases that are more frequent and significant.

7 Human Evaluation

Completion tasks are difficult to evaluate since a sentence can have many different valid completion options including, but not limited to, the original masked span. We use $accuracy@k$ to deal with this issue, but in some use-cases only the first completion is important. Thus, we define a manual task to more accurately evaluate sentence completions.

Human-annotators are presented with the masked sentence, the original masked span and the *first* completion suggested by each of the methods we evaluate (full annotation task is in Appendix D). Annotators were not aware which model provided each completion, and the completions were presented in a random order for each sentence. The sentences are divided between three expert English-speaking annotators. Prior to performing the annotations, the annotators met for a calibration session, each annotating the same 50 sentences and discussing results until reaching high agreement. We sample 750 sentences from the test set described in section 3. Each expert annotator is assigned with

250 sentences and the completions of each of the four methods, amounting to 1000 samples each.

First, we ask annotators whether the completions are grammatically correct and make sense in the context of the sentence, *regardless of whether they are factually correct* (denoted as a "Valid" completions). For example, any year or location is a valid completion for "*Jules Verne was born in [MASK]*".

In some cases, valid completions can be general and uninformative. For example, in the sentence "*On January 1, 1998, [MASK] was released publicly online as SGI freeware.*" the original span is "*Blender*". While any SGI freeware name would make sense, the word "*it*" (suggested by T5-3B) is also a valid completion. This happens with general words like "*he*", "*she*", or "*person*" but can also occur with entities, e.g. in the sentence "*Jules Verne was born in [MASK]*", the original masked span is "*Nantes*" and a suggested completion might be "*Europe*". We ask annotators to flag these cases, where the suggested completion is more general (less specific) than the original span.

Factual Correctness of completions is also important, since some works use completion methods for knowledge extraction (Petroni et al., 2019; Jiang et al., 2020). To evaluate this, we first ask annotators to mark whether the masked span is a part of a specific fact. For example, "*MLK, (born [MASK])*" should be marked as a fact, while "*he died aged [MASK]*" shouldn't. We find that 50.93% of the masked sentences are part of a fact¹⁰. For the factual sentences, we ask the annotators to label whether the proposed completion is factually correct. If they do not know, annotators are instructed to use the web to verify the correctness.

Results are reported in Table 5. As expected, the actual valid-completion percentage of the

¹⁰Recall that the evaluation data originates from both Wikipedia and books.

Model	Valid %	Valid Specific%	Correct %	Correct Specific %
ILM	52.2%	47.8%	9.4%	7.5%
T5-base	66.0%	49.0%	29.8%	18.5%
T5-3B	81.8%	66.8%	40.8%*	30.1%
BERT-Adapted-EMAT	84.1%	80.4%*	32.9%	31.6%

Table 5: **Human evaluation results.** Valid completions are ones that are grammatically correct and make sense. Specific completions are completions that were not annotated to be more general than the original masked span. Correct is the percentage of sentences labeled as facts that are valid completions and are also factually correct. * marks that the difference between best and second best is statistically significant.

first completions is much higher than the *accuracy@1* measured. An important observation is that while checking for valid completions using human-evaluation is obviously a more accurate measure than *accuracy@k*, the two are correlated. Models that perform well in one measure, do so also in the other. This means *accuracy@k* is a good proxy for the actual valid-completion measure. Specifically, our method performs impressively when annotating for validness as well, slightly better than the much larger T5-3B. Finally, it seems general purpose models like T5 tend to complete general phrases more than our method. This is likely due to the fact that during our MTC training, the model sees the same amount of examples for each phrase. Other methods see more examples of general phrases, since these are more common in the language.

As for factual correctness; while T5-3B completes more facts correctly than our methods, when eliminating cases where the completion is general¹¹ our method performs better. This is important since general completions are not as interesting and can be more easily acquired. It can be especially crucial for knowledge extraction methods using these models. For example, a method trying to extract presidents with the sentence “*US presidents such as [MASK]*” would benefit from completions like “*Obama*” or “*Trump*” and not “*the president*” or “*this person*” which are correct, but uninformative.

8 Related Work

Transformer-based LMs and MLMs (Peters et al., 2018; Devlin et al., 2018) have revolutionized NLP in the past couple of years. While most of the impact has been achieved using these pretrained

¹¹For example, for “Garson accepted the role, winning [MASK].” original span is “the Academy Award for Best Actress”. T5 completes “an academy award”- factually correct, but more general than the original span. Our method tries to pinpoint a specific award - a harder task. It completes “the Academy Award for Best Picture” which is factually wrong.

models as a source of meaningful contextual embeddings, recent works are using these models for the task they were pretrained for: Masked Language Modeling (Petroni et al., 2019; Kushilevitz et al., 2020; Lazar et al., 2021; Shani et al., 2021; Jiang et al., 2020).

While most MLMs are capable of completing multiple missing tokens simultaneously, they do so in an unconditional manner, yielding unsatisfying results. Therefore, some works using MLMs for Masked Language Modeling simply restrict themselves to single token completions (Petroni et al., 2019) while others use heuristics in order to generate multi token completions (Lazar et al., 2021; Jiang et al., 2020).

Some attempts towards making MLMs predict multi token units better by changing the masking technique during training include masking spans instead of tokens (Joshi et al., 2020) and masking whole words (Cui et al., 2019), but these methods still complete in an unconditioned manner during inference. XL-net (Yang et al., 2019) avoids interdependence between masked tokens using a Permutation Language Modeling pretraining objective.

Similarly to our solution, extending the decoder matrix with n-gram vocabulary items is done also by Xiao et al. (2020), but for a different purpose: they use them as an auxiliary signal during training, in order to improve BERT’s single-token pretraining. They mask n-grams, and predict a specific n-gram assigned id *together with the single tokens assembling the n-gram*, as to improve the single-token embeddings. The BERT model is pretrained end to end and the n-gram embeddings are discarded after pretraining and are not part of their final model used during fine-tuning and inference. While we share their extension of the decoder matrix, the MTC task adds additional requirements: to allow for easy MTC vocabulary support, we aim for a short MTC training and inference, building on the preexisting pretrained MLMs and avoiding

the need to pretrain from scratch. In addition, our solution does not distinguish between multi-token and single token-phrases during training since both are part of the completion vocabulary.

In Donahue et al. (2020), the ILM framework is introduced. This is a framework for infilling, a task similar to MTC. ILM is a GPT-2 (Radford et al., 2018) based solution, meaning the pre-trained model used is a LM and not an MLM, requiring it to adapt to a different task. Finally, T5 (Raffel et al., 2020) was pre-trained for the MTC task using a vast amount of data. It performs well but requires a lot of training data, time and memory, does not utilize existing MLMs and is not available in many domains and languages.

9 Conclusions

We show MLMs can be adapted for multi token completion even though they were trained for single token completion. We presented two simple but effective solutions that leverage the pretrained MLMs and offer quick adaptations to new vocabularies. The two solutions are trading-off performance and size: 1) an extended matrix decoder offering SOTA accuracy but size-dependent on the completion vocabulary; 2) an RNN decoder with slightly lower accuracy but size independent of the vocabulary size. We also demonstrate the flexibility of our approach to different vocabularies and domains by evaluating it on the PubMed dataset and showing that leveraging domain-pretrained MLMs offers significant accuracy improvement. Finally, we validate our results by conducting a human evaluation to account for valid completions that are not measured using our automatic metric. It shows that our extended matrix solution provides valid completions in 84% of the times, and can also correctly handle facts in 30% of the times, comparatively to the much larger T5-3B.

10 Limitations

The main limitation of our work is that it requires a fixed and pre-determined completion vocabulary. We acknowledge that this is a burden, and in some cases such a vocabulary might not be available. We believe a solution for adapting MLMs for MTC without such a prerequisite is feasible, and this is a goal for future work.

11 Ethical Considerations

Human Evaluation. In terms of fair-pay, the payment to the expert annotators was above the minimum wage in the US. Consent was given from the annotators to use their annotations and release them as part of this research. The annotators were not aware which solution generated each completion and the completions were presented in a random order as to avoid bias based on the order. To achieve high quality results, the annotators had a calibration session as to better understand the guidelines and requirements described in Appendix D.

Environmental. Compared to the massively large language models such as T5-3B, our models are lightweight and can be run on smaller more energy efficient hardware such as a CPU. In addition, this becomes more apparent when considering the superior inference-latency of our solutions. Since energy is composed of both time and power-consumption, our lightweight models should waste significantly less energy during inference.

Biases and Exclusion. The proposed models depend on a fixed and pre-determined vocabulary of potential multi-token completions, and the choice of this set in itself may result in omissions, exclusions under-representation of some groups or concepts, and over-representation of others. Care should be taken to select a set that alleviate such biases to the extent possible. Also after the selection of the set, the algorithm does not guarantee balanced, fair or unbiased selections of candidate completions. Users should be aware of this when designing algorithms whose predictions may influence certain groups.

Multi	Single	Similar	Random
new york city	nyc	chicago	disco
fish tank	aquarium	zoo	lena
every week	weekly	monthly	fruit
extort	blackmail	scam	cat
barman	bartender	waitress	mckenzie

Table 6: Experiment data sample. **Multi** is the multi-token phrase, **Single** is the single-token synonym, **Similar** is a term close in the sense2vec space and **Random** is a random single-token word.

A Tokenizing an expanded vocabulary

We experiment to see how tokenizing time is affected by larger vocabularies. We find that including multi word phrases as tokens actually has a worse effect than just adding more tokens, since the tokenizer cannot assume a word is the maximal span for each token. We sample 10K random sentences from Wikipedia and use huggingface’s¹² implementation for BERT’s standard cased tokenizer. When using the original vocabulary (of size $\sim 30K$) the tokenization takes 4.23 seconds. When expanding the vocabulary to our collected vocabulary (of size $\sim 100K$, including multi word phrases) the tokenization time jumps to 119.26 seconds using the same machine.

B MLMs Learn Multi-Token Phrases

In section 2, we report an experiment illustrating that MLMs are capable of treating multi-token phrases properly. The purpose and outline of the experiment are described in 2, further details are provided in this Appendix. BERT-base is the MLM used.

B.1 Data collection

We curate a dataset of multi-token phrases that have single-token synonyms. We start from Wordnet (Miller, 1995) synonyms, keep only synonyms where one phrase is a single-token and the other is a multi-token phrase using BERT’s tokenizer¹³, and manually select synonyms which are interchangeable. We collect 100 such synonyms. To each pair of synonyms we add a similar phrase chosen as the phrase closest to the single-token synonym

¹²https://huggingface.co/transformers/model_doc/bert.html#berttokenizer. We used the transformers package version 4.12.3.

¹³Multi-token phrases are not necessarily multi-word phrases. Uncommon words are also split to multiple tokens.

in the sense2vec¹⁴ vector-space which is manually verified as not a synonym of the pair, and not slang or an inappropriate phrase¹⁵. Finally, to each triplet we add a random single-token word forming a quadruple. A sample of the dataset is shown in Table 6.

B.2 Experimental setup

For each quadruple in our dataset, we conduct the following experiment: We collect k sentences containing the multi-token phrase from Wikipedia. For example, given the quadruple ("*fish tank*", "*aquarium*", "*zoo*", "*lena*"), the multi-token phrase is "*fish tank*" and one such sentence is "*nemo is placed in a fish tank in a dentist’s office.*". We use each of the collected sentences to compute a similarity score between the phrases as follows.

Masked sentence per quadruple term. We first form a masked sentence for the multi-token synonym, by masking out a random NP-chunk which is not the multi-token phrase (e.g. "*[MASK] is placed in a fish tank in a dentist’s office.*"). Then, we form a masked sentence for each of the other quadruple terms by replacing the multi-token phrase with it (e.g. for the phrase "*aquarium*" we form the sentence "*[MASK] is placed in a aquarium in a dentist’s office.*")

Similarity between masked sentences. We use the MLM to compute similarity between masked sentences. Following (Kushilevitz et al., 2020), for two masked sentences (m_i, m_j) we query the MLM to complete the mask in each and compare the predicted completions using the Sørensen-Dice coefficient (Dice, 1945; Sørensen, 1948):

$$\text{sim}(m_i, m_j) = \frac{|top_q(MLM(m_i)) \cap top_q(MLM(m_j))|}{q}$$

Where $MLM(m)$ is the list of tokens proposed by the MLM to complete the mask in the masked-sentence m , ranked by their probability. $top_q(MLM(m_i))$ is the top q tokens in the list (q being a parameter). An example for the similarity measure process for a single sentence is shown in Table 7.

¹⁴Sense2vec (Trask et al., 2015) is a twist on the word2vec algorithm.

¹⁵Sense2vec is trained on data from Reddit, which yields phrases that are slang or inappropriate. These will probably not be significantly found in BERT’s training data (Wikipedia and Books) and are therefore filtered out for this experiment.

Phrase type	Phrase	Masked sentence	MLM-suggestions	Intersection	Similarity
Multi-token synonym	fish tank	"a glass fish tank is sufficient for keeping [MASK]."	1.'fish', 2.'water', 3.'ducks', 4.'trout', ..., 8.'salmon', ... , 13.'eels', ..., 17.'turtles', ...	50	1
Single-token synonym	aquarium	"a glass aquarium is sufficient for keeping [MASK]."	1.'animals', 2.'fish', 3.specimens', ..., 8.'turtles', 9.'ducks', ..., 15.'water', ..., 31.'eels', ...	33	0.66
Similar phrase	zoo	"a glass zoo is sufficient for keeping [MASK]."	1.'animals', 2.'birds', 3.cats', ..., 8.'ducks', 9.'pigeons', ..., 30.'goats', ..., 37.'lions', ...	20	0.4
Random token	lena	"a glass lena is sufficient for keeping [MASK]."	1.'warm', 2.'dry', 3.'balance', 4.'water', ..., 7.'it', ..., 20.'safe', ..., 46.'records', ...	17	0.34

Table 7: **Similarity measure example.** Original sentence found in the corpus is "a glass fish tank is sufficient for keeping tarantulas.". MLM-suggestions shown are a sample of the top 50 (we use $q = 50$) suggestions for mask completions using BERT. The bold suggestions are ones that appear in the top-50 suggestions for the multi-token synonym sentence. Intersection is the size of the intersection between the top-50 tokens suggested for the sentence and the top 50 tokens suggested for the multi-token synonym sentence. Similarity is $intersection/q$.

hyperparameter	RNN-based method	EMAT method
Batch size	128	128
Learning rate	$1e^{-3}$	$1e^{-3}$
Epochs	10	2
GRU layers	2	-
Teacher forcing	0.5	-
Dropout	0.2	-

Table 8: **Hyperparameters.**

Similarity between terms. We define similarity between two terms as the average similarity across all pairs of masked sentences containing them.

B.3 Experiment results

For each quadruple, we compute the similarity between the multi-token phrase and the other quadruple terms. We use $k = 100$ (number of sentences for each quadruple) and $q = 50$ (number of top tokens considered for the similarity measure). For 82 out of the 100 quadruples in the dataset, the single-token synonym is the most similar to the multi-token phrase. 15 times the most similar is the similar phrase and only 3 times the most similar is the random term, showing the effectiveness of the similarity measure we use. The multi-token phrase is most similar to the single-token synonym: the average similarity measured between them is 0.766 while for the similar phrase it's 0.715 and for the random phrase it's 0.632. Results show the MLM treats multi-token phrases similarly to their single-token synonyms. This corroborates the assumption that the MLM is capable of storing information about multi-token phrases.

Version	$a@1$	$a@5$	$a@50$
lm_pretrain_unshared	7.79%	15.14%	28.10%
no_pretrain_shared	8.99%	16.67%	29.11%
lm_pretrain_shared	9.31%	17.15%	30.27%

Table 9: Ablation study. The results shown use BERT as the Base MLM.

C Model Details

In Section 4, we briefly describe our adaptation solutions. Herein, we describe the exact hyperparameters used and an ablation study of the RNN-based method. Table 8 presents the hyperparameters that were selected after tuning on the dev set. The hyperparameters had a larger impact on the RNN-based solution than the extended matrix (extended-matrix) solution.

In addition, we test to check the effectiveness of two components in our RNN-based solution. The First is pre-training the GRU on a vanilla Language Modeling task, we do this in order to give the model some sense of understanding of the language distribution before training it on the MTC task. The second component is sharing the embedding layers between the original MLM and the added completion GRU. As seen in Table 9 both of these are shown to help.

D Manual Annotation Instructions

In this task, you are given a sentence with a missing phrase (marked as `___`), a correct completion (which is not necessarily the only possible correct completion) and a proposed completion. The completed sentence is the sentence that is formed by planting the proposed completion in the location

of the missing phrase. Please answer the following questions:

1. Is the completed sentence grammatically correct and does it make sense? In this question, ignore the factual correctness of the completion. For example, in the sentence "*Barack Obama was born in ____*", any place or date is a valid completion.
2. Is the proposed completion more general than the given correct completion? For example, the word "*he*" is more general than a specific name. The phrase "*North America*" is more general than the phrase "*New York*". The phrase "*Los Angeles*" is not more general than the phrase "*New York*".
3. Is the missing phrase in the context of the sentence a part of a specific fact (geographical, physical, mathematical, etc.)? For example, in the sentence "*Barack Obama was born in ____*" the missing phrase is a part of a fact. In the sentence "*He was born in ____*" the missing phrase is not a part of a specific fact because "*He*" may refer to many different people.
4. If the answer to question 3 is yes, is the completed sentence factually correct? If you are not sure, please use the web to verify.

A Survey on Dynamic Neural Networks for Natural Language Processing

Canwen Xu, Julian McAuley
University of California, San Diego
{cxu, jmcauley}@ucsd.edu

Abstract

Effectively scaling large Transformer models is a main driver of recent advances in natural language processing. Dynamic neural networks, as an emerging research direction, are capable of scaling up neural networks with sub-linear increases in computation and time by dynamically adjusting their computational path based on the input. Dynamic neural networks could be a promising solution to the growing parameter numbers of pretrained language models, allowing both model pretraining with trillions of parameters and faster inference on mobile devices. In this survey, we summarize the progress of three types of dynamic neural networks in NLP: *skimming*, *mixture of experts*, and *early exit*. We also highlight current challenges in dynamic neural networks and directions for future research.

1 Introduction

Scaling up model capacity is an obvious yet effective approach for better performance in natural language processing (NLP) tasks (Brown et al., 2020; Kaplan et al., 2020; Ghorbani et al., 2021; Zhou et al., 2020b). However, the resulting increase in computational complexity and memory consumption becomes a bottleneck for scaling, making these models hard to train and use. On the other hand, it is not necessary to allocate the same amount of computation to all instances. For example, categorizing “I love you” as a positive sentence does not require a model containing dozens of Transformer layers. To resolve the aforementioned problems, *dynamic neural networks* have been a significant thrust of recent research in NLP. Dynamic networks can adjust their computational path based on the input for better efficiency, making it possible to train models with trillions of parameters and accelerate models in a low-resource setting.

In this survey, we review the latest state of research on three types of dynamic neural networks

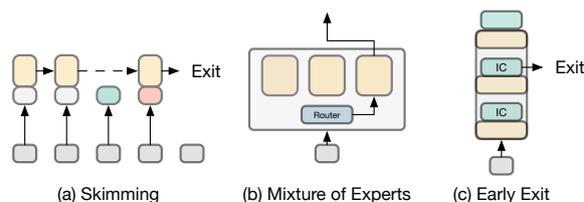

Figure 1: The three types of dynamic neural networks summarized in this paper. They dynamically adjust computation *timewise*, *widthwise* and *depthwise*, respectively.

that have been adopted in NLP: *skimming*, *mixtures of experts* (MoE), and *early exit*, as illustrated in Figure 1. These three types of techniques share a common idea of dynamically adjusting computation with respect to input, to save computation through bypassing unnecessary modules in a large neural network. However, they implement the goal via different approaches. **Skimming** was well-researched in the era of recurrent neural networks (RNN). Skimming models save computation *timewise* by dynamically allocating computation to different time steps, based on the input tokens. Since RNN models process the input sequence recurrently, it allows skimming models to achieve a substantial acceleration, especially when the sequence is long (Li et al., 2019). Different from RNN, recent works on Transformers skip tokens between layers instead of time steps.

For Transformer models (Vaswani et al., 2017; Devlin et al., 2019; Lan et al., 2020; Brown et al., 2020), the input tokens are fed into the model in parallel, while models have dozens of Transformer layers. This motivates the development of MoE and early exit. **MoE** horizontally extends a feedforward neural network (FFNN) with multiple sub-networks. During inference, only one or a few of these sub-networks will be activated for computation, thus can save *widthwise* computation. **Early exit**, on the other hand, terminates inference

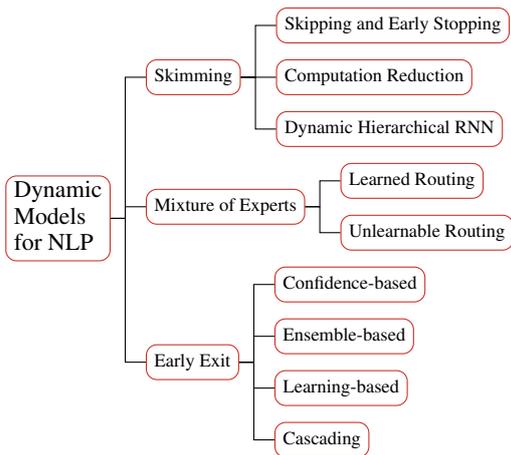

Figure 2: Taxonomy of dynamic neural networks for NLP.

at an early layer, without exhausting full computational capacity, thus saves *depthwise* computation. Early exit techniques often insert a series of lightweight classifiers which help decide when to exit, based on an exit strategy.

Note that this stream of works is distinct from static model acceleration, which is often referred to as *model compression*, including knowledge distillation, weight sharing, pruning and quantization (Sanh et al., 2019; Xu et al., 2020; Lan et al., 2020; Zafrir et al., 2019; Xu et al., 2021) (etc., see another survey (Xu and McAuley, 2022)). The major difference is that the computational path in a statically compressed model does not condition on the input and is invariable for all examples in inference. These two streams of research are in fact orthogonal and recent works Schwartz et al. (2020), Liu et al. (2020) and Zhu (2021) have shown that static and dynamic approaches can be combined for even faster inference and better performance.

To summarize, our contribution is two-fold: (1) We review the latest studies on the topic of dynamic neural networks for NLP by providing a comprehensive comparison and organize them with a new taxonomy, as shown in Figure 1. (2) We analyze current challenges in dynamic neural networks and point out directions for future research.

2 Skimming

Skimming techniques, as summarized in Table 1, skip some time steps or allocate different computation on them. Intuitively, skimming matches how human beings efficiently read text and extract information from it (Li et al., 2019). By em-

phasizing the important information within a sequence and ignoring parts with little importance, skimming helps the model achieve faster inference speed and better capture long-term dependencies. The three categories of skimming are *skipping and early stopping*, *computation reduction*, and *dynamic hierarchical RNN*, corresponding with three motivations: to skip unimportant input, to allocate less computation to unimportant input, and to increase computation to important input only.

Skipping and Early Stopping Skipping and early stopping aim to improve efficiency for a long sequence by skipping some tokens or stopping reading early. LSTM-Jump (Yu et al., 2017) is a skipping mechanism to ignore irrelevant information for natural language understanding (NLU). At each step, the current states are used to compute a “jumping softmax”, which decides how many steps to jump forward and whether to stop reading. LSTM-Jump employs policy gradient to train the model to make non-differentiable discrete jumping decisions. The reward is a binary function which rewards a correct prediction and penalizes an incorrect prediction of the label. Compared to a standard LSTM, LSTM-Jump achieves better accuracy with up to $6\times$ speed-up. Skip RNN (Campos et al., 2018) introduces a binary gate to learn whether to skip a state update. If the gate decides to skip a time step, the hidden states will be directly copied without any update.

To stop reading early as needed, ReasonNet (Shen et al., 2017) introduces a terminal state which decides whether to terminate early for machine reading comprehension on each time step at the token level. Jumper (Liu et al., 2018) first splits a paragraph to several sub-sentences and encodes them into sentence embeddings. They then apply early stopping at a sentence when the policy network decides to stop reading. Li et al. (2019) use eye-tracking devices and confirm that skipping and early stopping are common when humans read text. They propose Reading Inspired Model to mimic the behaviors of humans, which allows the model to decide whether to skip a single time step or stop reading early. Yu et al. (2018) add a re-reading operation to LSTM-Jump (Yu et al., 2017) which allows the model to stay on the current time step, allocating more computation to important information.

The aforementioned techniques can only go forward, which makes it impossible to regret if hav-

Method	Decision based on	Operation options
LSTM-Jump (Yu et al., 2017)	hidden states	skip multiple steps; stop reading
Skip RNN (Campos et al., 2018)	states of the update gate; hidden states	skip a single step
ReasonNet (Shen et al., 2017)	hidden states	stop reading
Jumper (Liu et al., 2018)	input sentence; hidden states	stop reading
RIM (Li et al., 2019)	input sentence; hidden states	skip a single step; stop reading
Yu et al. (2018)	hidden states	skip multiple steps; stop reading; re-read
LSTM-Shuttle (Fu and Ma, 2018)	hidden states	skip multiple steps; jump back multiples steps
Struc. Jump-LSTM (Hansen et al., 2019)	hidden states	stop reading; jump to next (;) or (!?)
PoWER (Goyal et al., 2020)	attention	drop tokens
TR-BERT (Ye et al., 2021)	hidden states	forward tokens
LAT (Kim and Cho, 2021)	attention	forward tokens
LTP (Kim et al., 2022)	attention	drop tokens
Transkimmer (Guan et al., 2022)	hidden states	forward tokens
VCRNN (Jernite et al., 2017)	input token; hidden states	partial update with zero-masked weights
Skim-RNN (Seo et al., 2018)	input token; hidden states	partial update with a small RNN
HM-RNN (Chung et al., 2017)	states of the gates	skip a single step; "flush"
FHRNN (Ke et al., 2018)	query; hidden states	update the upper RNN layer

Table 1: A summary of skimming techniques.

ing jumped over important information. LSTM-Shuttle (Fu and Ma, 2018) proposes a bidirectional shuttling mechanism, which can jump multiple time steps both forward and backward, allowing the model to ignore unimportant information and recover lost information if needed.

Structural information that naturally exists in sentences can also play a role in skimming. Structural Jump-LSTM (Hansen et al., 2019) can jump to the next word, next sub-sentence separator (a comma or colon), next sentence end symbols (a period, exclamation mark or question mark), or to the end of the text (i.e., stop reading).

In the era of Transformers, there have been works attempting to reduce computation by either skip tokens at higher layers or forward tokens to higher layers. The PoWER-BERT model (Goyal et al., 2020) reduces the number of tokens processed by each Transformer layer based on their attention scores. The number of tokens to be dropped, referred to as the "schedule," is optimized by combining the sparsity of a soft mask layer with the original loss function. This results in an improved balance between accuracy and processing time. TR-BERT (Ye et al., 2021) uses a dynamic approach to determine which tokens to skip, using reinforcement learning to train the model with a reward system that prioritizes classifier confidence while also penalizing the number of tokens retained. In contrast to PoWER-BERT, TR-BERT passes the skipped tokens to the final layer rather than discarding them. The Length-Adaptive Transformer (LAT, Kim and Cho, 2021)

utilizes LengthDrop to randomly skip tokens during pretraining, aiming to close the gap between pretraining and fine-tuning. The schedule for LAT is found through an evolutionary search algorithm. LTP (Kim et al., 2022) trains a threshold for each Transformer layer, instead of following a predetermined schedule. It simply drops tokens with attention scores lower than the learned threshold. Transkimmer (Guan et al., 2022) incorporates a skim predictor module, consisting of a small MLP and Gumbel-Softmax reparameterization, before each layer. This module outputs a mask to determine whether a token should be dropped, and a skim loss is used to optimize the ratio of skipped tokens to total tokens, promoting sparsity.

Computation Reduction Different from skipping, computation reduction applies a reduced computational workload for some time steps instead of skipping it completely. VCRNN (Jernite et al., 2017) explores a scheduler to decide which proportion of computation to use for each time step. Upon making the decision, only the corresponding proportion of the weight matrix will be used to update the hidden states while the rest part of the weight matrix will be masked out with zero.

Instead of using part of weights to update the hidden states, Skim-RNN (Seo et al., 2018) has a big RNN and a separate small RNN. At each time step, the model decides whether to read or skim based on hidden states from the last time step and the input token. If the model decides to skim, the small RNN will update only a fraction of the hid-

den states. Otherwise, a regular full update will be conducted by the big RNN.

Dynamic Hierarchical RNN Different from the aforementioned two categories of skimming, dynamic hierarchical RNN can *increase* computation by calling the upper layer RNN when needed. HM-RNN (Chung et al., 2017) automatically discovers the hierarchical multi-scale structure in the data for a hierarchical RNN architecture. In addition to the update and copy operations as in Skip RNN (Campos et al., 2018), they add a flush operation which ejects the summarized representation of the current time step to the upper layer and re-initializes the states for the next time step.

In question answering, only a small portion of tokens are relevant and can be used to answer the question while the rest can be safely skimmed. Based on this observation, Focused Hierarchical RNN (Ke et al., 2018) aims to only pick up information that is relevant to the query for question answering. It applies a binary gate to control whether to update the upper layer of the RNN, based on the current hidden states of the lower-level RNN and the question embedding.

3 Mixture of Experts

Increasing the number of parameters in a model often leads to increased computation and memory consumption. To take the advantages of parameter scaling without a proportional increase in computation, mixture of experts (MoE) (Jacobs et al., 1991) is introduced to large language models, as summarized in Table 2. In these models, a layer typically contains multiple sub-networks (i.e., “experts”). During inference, only part of these experts will be activated on a per-example basis.

The key element of MoE methods is the routing mechanism. The routing mechanism has to be lightweight, not to significantly slower the speed of the model. We categorize MoE methods into two groups: *learned routing* and *unlearnable routing*. Learned routing often requires some load balancing mechanisms to ensure that all experts are trained with enough examples thus are useful during inference. Unlearnable routing usually slightly underperforms learned routing but does not require complicated load balancing.

MoE Layers with Learned Routing A straightforward idea to implement MoE is to learn a router

to allocate inputs to experts. Sparsely-Gated MoE layer (Shazeer et al., 2017) contains up to thousands of feed-forward sub-networks with a trainable gating network which determines a sparse combination of these experts to use for each example. There are two major challenges to address: **(1) Sparsity.** The gating network predicts a softmax weight for the experts based on the input. The gating network is trained by simple back-propagation, together with other parts of the model. Then, only the top- k experts in the layer will be activated based on the softmax prediction of the gating network. They insert one MoE layer between stacked LSTM layers and achieve improvement on language modeling and machine translation tasks. **(2) Load balancing.** Shazeer et al. (2017) observe a self-reinforcing phenomenon that the gating network tends to converge to a state where it always produces large weights for the same few experts. They resolve the problem by defining the importance of an expert relative to a batch of training examples to be batch-wise sum of the *gate values* for that expert. Then, they introduce an additional loss, the square of the coefficient of variation of the set of importance values, to encourage a more balanced update during training. Besides encouraging a balanced update, the authors also introduce a loss function with a smooth estimator that estimate the number of examples assigned to each expert for a batch of inputs, to encourage experts to receive roughly equal *numbers of training examples*.

GShard (Lepikhin et al., 2021) enables scaling up multilingual neural machine translation Transformer beyond 600 billion parameters. It adapts Sparsely-Gated MoE (Shazeer et al., 2017) to Transformer (Vaswani et al., 2017) by replacing every other feed forward layer with an MoE layer, which routes to top-2 experts. When scaling to multiple devices, the MoE layer is sharded across devices, i.e., each device has different allocated experts, while all other layers are replicated. To achieve workload balance, GShard employs a threshold, namely expert capacity, to limit the maximum number of tokens processed by one single expert. They also introduce a local group dispatching mechanism, which partitions all tokens in a training batch evenly into groups to be processed independently in parallel, to balance the overall workload. Following (Shazeer et al., 2017), they use an additional loss to enforce even

Method	Base Model	Sparsity	Load Balance
Sparsely (Shazeer et al., 2017)	LSTM	top- k	auxiliary loss
GShard (Lepikhin et al., 2021)	Transformer (NMT)	top-2	expert capacity; local group dispatching; auxiliary loss; random routing
Switch (Fedus et al., 2021)	Transformer (T5)	top-1	expert capacity; auxiliary loss
BASE (Lewis et al., 2021)	Transformer (GPT)	top-1	linear assignment
M6-T (Yang et al., 2021)	Transformer (M6)	k top-1	expert capacity
DTS (Nie et al., 2021)	Transformer (GPT)	dynamic	sparsity scheduler
Hash (Roller et al., 2021)	Transformer	hash	deterministic hash
THOR (Zuo et al., 2022)	Transformer (NMT)	random	random selection

Table 2: A summary of Mixture of Experts (MoE) methods.

allocation for experts. Additionally, they propose a random routing mechanism, which only routes to the second-best expert with probability proportional to its weight, to simplify sparse training.

Switch Transformer (Fedus et al., 2021) aims to simplify the Sparsely-Gated MoE (Shazeer et al., 2017) for efficiency and performance. They propose a Switch Layer which only routes to one expert at a time, to reduce gating computation, batch size and communication costs. Switch Transformer inherits expert capacity and an auxiliary load balancing loss from GShard (Lepikhin et al., 2021). Combined with low-precision training, compared to T5-Base and T5-Large (Raffel et al., 2020), Switch Transformer obtains up to $7\times$ increases in pretraining speed with the same computational resources. They further scale Switch Transformer to more than 1.5 trillion parameters and achieve $4\times$ speed-up over T5-XXL.

The Balanced Assignment of Sparse Experts (BASE) layer (Lewis et al., 2021) formulates token-to-expert allocation as a linear assignment problem and solves it with the auction algorithm (Bertsekas, 1992). This allows an optimal assignment in which each expert receives an equal number of tokens, improving efficiency and getting rid of the expert capacity and auxiliary loss in previous works. The experiments show that BASE layers are more efficient for training compared to Sparsely-Gated MoE layers (Shazeer et al., 2017) and Switch Layers (Fedus et al., 2021), and can successfully learn a good balanced routing without any auxiliary balancing loss.

M6 (Lin et al., 2021) is a multi-modal multitask Transformer, trained in the same way as Switch Transformer (Fedus et al., 2021), scaling up to 100B parameters. Following this, M6-T (Yang et al., 2021) splits experts into k prototypes (i.e., groups of experts). In each forward pass, each token is sent to the k prototypes, within which the top-1 routing is done lo-

cally. The experiments demonstrate this “ k top-1” strategy outperforms the top-1 routing in Switch Transformer (Fedus et al., 2021) while being more computation-efficient than “top- k ” routing. They also claim that the load balancing loss may be ineffective for improving the performance of an MoE model, although it can indeed help balance the workload. They subsequently train a 1 trillion parameter model with the finding.

Dense-to-Sparse gate (Nie et al., 2021) begins as a dense gate that routes tokens to all experts then gradually learns to become sparser and route tokens to fewer experts, demonstrating higher training efficiency in experiments. Their experiments confirm the finding in Yang et al. (2021) that an auxiliary load balancing loss does not improve the model performance.

MoE Layer with Unlearnable Routing Although learning-based routing has shown effectiveness only with the help of complicated load balancing mechanisms, recent studies have attempted to get rid of those. Hash Layer (Roller et al., 2021) simplifies routing by using a parameter-free hashing function to route tokens to specific experts. This design eliminates the need for a load balancing loss and sophisticated assignment algorithms. They also study the performance of different hashing techniques, hash sizes and input features, and conclude that balanced and random hashes focused on the most local features work best. The experiments show that a Hash Layer achieves comparable performance with a Switch Layer (Fedus et al., 2021) and BASE Layer (Lewis et al., 2021).

THOR (Zuo et al., 2022) is a special form of MoE layer, which completely discards the conditional routing mechanism and instead optimizes the consistency between a randomly selected pair of experts. During inference, one expert will be randomly selected to be activated.

Applications and Analysis GLaM (Du et al., 2021) trains a family of GPT-style language models with up to 1.2 trillion parameters using GShard (Lepikhin et al., 2021). CPM-2 (Zhang et al., 2022b) trains a large Chinese language model with 198 billion parameters with BASE layers (Lewis et al., 2021).

Artetxe et al. (2021) conduct a detailed empirical study of how autoregressive MoE language models scale compared to dense models. They find MoEs to be substantially more efficient with the exception of fine-tuning. MoE models can match the performance of dense models with 25% of computation in a low-resource setting. Although the advantage fades at scale, their largest MoE model with 1.1 trillion parameters can consistently outperform its dense counterpart with the same amount of computation. Clark et al. (2022) examine the scaling law of BASE Layer (Lewis et al., 2021), Hash Layer (Roller et al., 2021) and earlier Reinforcement Learning-based routing algorithms providing suggestions for best-practices in training MoE models.

Zhang et al. (2021) propose MoEfication to split feedforward neural networks (FFNN) in a trained large model to experts. They find that a T5-Large (Raffel et al., 2020) model with 700 million parameters only activates 5% neurons for 80% inputs on a downstream task, indicating high redundancy within large pretrained language models. To transform a pretrained language model to an MoE model, they first construct a co-activation graph for each FFNN and then divide the graph into subgraphs with strong internal connections with graph partitioning algorithm. Each subgraph forms an expert. They train a router with oracle best routing for training data. Then, they further fine-tune the resulted model for better performance.

4 Early Exit

Early exit techniques aim to terminate model inference in early layers, to save computation and sometimes improve performance by resolving the overthinking problem (Kaya et al., 2019), i.e., possible performance degradation at a later layer. It can be useful especially in the era of pretrained language models (PLM), since increasing the size of PLMs can often lead to better performance, although a smaller model can already predict most examples (i.e., “easy examples”) correctly.

The main idea of early exit is to exit inference

at an earlier layer, rather than the last layer. Early exit often involves a series of internal classifiers inserted into a large network, providing signals for early exiting. The core of early exit methods is the exit criterion. Based on their exit strategies, we categorize the early exit methods into three classes: confidence-based, ensemble-based and learning-based, as listed in Table 3.

Despite better performance, speed and adversarial robustness (Zhou et al., 2020a), an additional benefit is that the speed-accuracy trade-off can be adjusted as needed by tuning the exit threshold (θ in Table 3), without the need of retraining the model. A main drawback is that early exit is often applied on a per-instance basis, meaning that to maximize the speed-up ratio, a small batch size (often 1) has to be used.

Confidence-based Early Exit Early works for early exit in computer vision (Park et al., 2015; Teerapittayanon et al., 2016; Kaya et al., 2019) often fall into this category. They define a metric as the proxy for confidence of a model prediction. The model exits early when the confidence hits a predefined threshold. DeeBERT (Xin et al., 2020b) applies BranchyNet (Teerapittayanon et al., 2016) to BERT inference. The training for DeeBERT is two-stage: they first train BERT on downstream tasks following standard fine-tuning. Then, they freeze the parameters of the Transformer and insert a linear classifier (i.e., internal classifier) after each Transformer layer. They train the classifiers by minimizing the sum of their cross-entropy loss. For inference, the model exits early when an internal classifier outputs a prediction probability distribution that has an entropy lower than a predefined threshold. RightTool (Schwartz et al., 2020) jointly fine-tunes BERT with internal classifiers. They use the temperature-calibrated maximum class probability as confidence. FastBERT (Liu et al., 2020) first trains the BERT backbone and the final classifier. Then, they distill the final classifier layer to the internal classifiers (Hinton et al., 2015). For inference, the model exits when the entropy of a prediction is below the threshold. RomeBERT (Geng et al., 2021) provides a simple fix for learning internal classifiers efficiently. Besides self-distillation as in FastBERT, they propose gradient regularization (GR) to facilitate distillation. SkipBERT (Wang et al., 2022) caches pre-computed representation of text chunks to re-

Method	Internal classifier training	Exit criterion
DeeBERT (Xin et al., 2020b)	two-stage; sum of CE loss	entropy $< \theta$
RightTool (Schwartz et al., 2020)	joint; sum of CE loss	calibrated max class probability $> \theta$
FastBERT (Liu et al., 2020)	two-stage; self-distillation	entropy $< \theta$
RomeBERT (Geng et al., 2021)	joint; self-distillation + GR	entropy $< \theta$
SkipBERT (2022)	joint; weighted sum of CE + KD	max class probability $> \theta$
PABEE (Zhou et al., 2020a)	joint; weighted sum of CE loss	patience (#consistent prediction $> \theta$)
Voting (Sun et al., 2021)	joint; sum of CE + diversity loss	accumulated votes $> \theta$
LeeBERT (Zhu, 2021)	joint; auto-weighted sum of CE + KD loss	patience (#consistent prediction $> \theta$)
Past-Future (Liao et al., 2021)	joint; weighted sum of CE + imitation learning	entropy $< \theta$
PCEE-BERT (2022a)	joint; weighted sum of CE	patience (#consistent IC confidence $> \theta$)
BERxiT (Xin et al., 2021)	alternate; sum of CE loss	estimated confidence $> \theta$
CAT (Schuster et al., 2021)	joint; avg. of CE loss	estimated conformity $> \theta$
CascadeBERT (Li et al., 2021a)	standard model FT with confidence calibration	calibrated max class probability $> \theta$

Table 3: A summary of early exit methods. θ is a predefined threshold for exiting. This table is extended from a table in Xu and McAuley (2022).

place lower BERT layers and uses confidence-based early exit for higher layers to achieve maximum acceleration.

Ensemble-based Early Exit One drawback in confidence-based early exit is wasted computation. That is to say, if the confidence of an internal classifier does not satisfy the exit criterion, it will be disregarded. Ensemble-based early exit recycles these predictions and considers output from multiple internal classifiers to make better predictions. Based on the similarity between overfitting and overthinking, PABEE (Zhou et al., 2020a) borrows early stopping from model training. They first jointly train the internal classifiers with BERT by a weighted sum of cross-entropy losses that assigns larger weights for upper classifiers. For inference, the model exits when k consecutive internal classifiers make the same prediction. Other than improvement on performance and efficiency, they find that PABEE can improve adversarial robustness, which they attribute to the ensemble effect. Sun et al. (2021) further introduce a diversity loss that encourages internal classifiers to have a diverse predicted probability distribution. They propose a voting mechanism to ensemble the internal classifiers by exiting early when a class has accumulated more votes than the threshold. Interestingly, LeeBERT (Zhu, 2021) adopts the opposite strategy: they promote consistency across internal classifiers by distilling them to each other. However, they introduce a learnable weight for the cross-entropy loss of each classifier and the distillation loss between each pair. They optimize these weights by a cross-level optimization algorithm.

They adopt PABEE’s patience-based strategy for exiting. Liao et al. (2021) train linear transformation layers called “imitation learners”, to approximate the hidden states of future layers based on current hidden states. For inference, the prediction after each layer is calculated by mixing the past predictions and the future predictions of the imitation learners. Entropy is used as the exit criterion. PCEE-BERT (Zhang et al., 2022a) borrows from both ensemble-based exit and confidence-based methods. The inference is terminated when multiple layers are confident.

Learning-based Early Exit Another stream of research is to *learn* a criterion for early exiting. BERxiT (Xin et al., 2021) alternates between joint fine-tuning and two-stage fine-tuning by freezing parameters of Transformer and the final classifier for even-numbered iterations and unfreezing them for odd-numbered iterations. They also train a linear layer called a *learning-to-exit* (LTE) module to predict whether the current internal classifier makes the correct prediction. It takes the hidden states as input and outputs a confidence score, which is used to decide whether to exit. CAT (Schuster et al., 2021) introduces a “meta consistency classifier” to predict whether the output of an internal classifier conforms to the final classifier and exits when the consistency classifier predicts a certain level of conformity.

Cascading Cascading can be seen as a special form of early exit, performed at the model level. Li et al. (2021a) find that shallow features and internal classifiers in the first few layers of BERT utilized by early exit methods like DeeBERT (Xin

et al., 2020b) are not sufficient and reliable, underperforming a fine-tuned BERT with the same number of layers. Therefore, they propose to use a suite of complete models with different numbers of layers for cascading. CascadeBERT executes models one by one, from the smallest to the largest. It stops when a model outputs a confidence score (calibrated maximum class probability) that reaches the threshold.

Applications Although early exit is originally developed for classification, there have been works extending it to more tasks and settings. Li et al. (2021b) propose Token-Level Early-Exit that targets early exiting for sequence labeling. They use the maximum class probability as confidence on a per-token basis. Once the confidence hits the threshold, the hidden states of the corresponding tokens will be frozen and directly copied to upper layers. These exited tokens will not attend to other tokens at upper layers but can still be attended by other tokens. The model completely exits when every token exits. A similar idea is also presented in Elbayad et al. (2020) and Liu et al. (2021b) where hidden states of some positions can be frozen and directly copied to upper layers, although the former is focused on generation and the latter is for classification. Xin et al. (2020a) apply DeeBERT (Xin et al., 2020b) to document ranking and set different thresholds to the negative and positive classes for early exiting, to accommodate the imbalanced class distribution in document ranking. ELUE (Liu et al., 2021a) is a benchmark which evaluates the Pareto Front of early exit models on the FLOPs-performance plane. They provide a BERT-like baseline with jointly pretrained internal classifiers, to mitigate the gap between pretraining and fine-tuning.

5 Challenges and Future Directions

Evaluation Evaluating dynamic neural networks can be difficult since we cannot pre-define a few break points to compare different methods at the exact same amount of computation or time. ELUE score (Liu et al., 2021a) may be a promising solution to this problem by considering both computation and performance, depicting the Pareto Front. Besides, different works have different calculation for speed-up ratio. For example, some works use the ratio of layers involved in computation to estimate speed-up ratio (Zhou et al., 2020a; Sun et al., 2021; Liao et al., 2021). This can

be misleading since internal classifiers introduce extra computational costs, especially when more complicated mechanism introduced, e.g., future-layer imitation (Liao et al., 2021). Also, the reported speed of MoE models, greatly differs on different hardware and distribution settings, making it hard to compare across papers.

Data Parallelism One drawback of dynamic neural networks is their inefficiency on data parallelism. To be specific, MoE methods introduce extra communication costs for dynamic routing and could be a bottleneck for efficiency. Skimming and early exit methods often employ an “online inference” setting where the batch size is fixed to 1, to achieve maximum acceleration. However, for batched inference, the efficiency of these methods will drastically degrade, since the already-exited instances will have to wait all instances to exit, which causes a low parallelism and low utilization of GPU.

Optimized Runtime Since dynamic neural networks are an emerging type of neural networks, most hardware and libraries are not well-optimized for these models. For example, sparse matrix multiplication in MoE needs specialized hardware and software support to achieve its theoretical efficiency. Also, current dynamic neural networks are often implemented in eager execution, which prevents them from low-level optimization of graph execution. There have been works exploring optimized runtime for MoE (Shazeer et al., 2018; Jia et al., 2020; He et al., 2021; Rajbhandari et al., 2022) and early exit (Paul et al., 2019) while more to be done in the future.

Theoretical Analysis and Support While the dynamic neural networks have demonstrated empirical improvement over static counterparts, dynamic networks are not solidly backed by theoretical analysis. For example, the theoretical analysis in PABEE (Zhou et al., 2020a) is based on an assumption that internal classifiers are independent to each other, which is unrealistic. More research should be done from the perspective of optimization and effect of data distribution on dynamic neural networks.

Explainability The decision-making process of the dynamic neural networks can be important to explain the model prediction and even understand

more fundamental research questions in machine learning, including scaling law and generalization. Can we use skimming to explain sequence classification? Is it consistent with attention-based explanation (Xu et al., 2015)? What does each expert in MoE learn and what makes them different? Why does a lower internal classifier make different prediction from an upper classifier despite equally trained with the same objective? These questions warrant further exploration, from both data and model perspectives.

Limitations

A limitation of this survey is that we do not draw a direct quantitative comparison for the methods surveyed in this paper since different methods have their own accuracy-speed curves, with their own unique limitations (e.g., many early exit methods can only handle a batch size of 1). Also, we do not discuss some works in depth and in detail due to space limit.

Abstract

Activation functions can have a significant impact on reducing the topological complexity of input data and therefore, improving a model’s performance. However, the choice of activation functions is seldom discussed or explored in Transformer-based language models. As a common practice, commonly used activation functions like Gaussian Error Linear Unit (GELU) are chosen beforehand and then remain fixed from pre-training to fine-tuning. In this paper, we investigate the impact of activation functions on Transformer-based models by utilizing rational activation functions (RAFTs). In contrast to fixed activation functions (FAF), RAFTs are capable of learning the optimal activation functions from data. Our experiments show that the RAFT-based Transformer model (RAFT) achieves a better performance than its FAF-based counterpart (FAFT). For instance, we find that RAFT outperforms FAFT on the GLUE benchmark by 5.71 points when using only 100 training examples and by 2.05 points on SQuAD with all available data. Analyzing the shapes of the learned RAFTs further unveils that they vary across different layers and different tasks; opening a promising way to better analyze and understand large, pre-trained language models.¹

1 Introduction

Activation functions introduce non-linearity and increase neural networks’ representational capacity, and therefore, play an essential role in designing deep learning models (Nwankpa et al., 2018; Sharma et al., 2020; Dubey et al., 2022). Naitzat et al. (2020) explain the importance of activation functions by proposing to consider data as a topology with its own shape. They empirically show that activation functions accelerate the data topology transformation through different layers of a neural network to simplify its complexity and make

¹Code, models, and datasplits are available on GitHub <https://github.com/UKPLab/2022-RAFT>.

it linearly separable in the output space. Their experiments show that choosing the right activation function can have a significant impact on the overall performance.

While any activation function can be used with Transformers (Vaswani et al., 2017), their choice is made before pre-training and remains fixed afterwards. Hence, the inductive bias an activation function imposes on the model cannot be adjusted during pre-training or fine-tuning. As many Transformer-based models are pre-trained on a large amount of data, and changing the activation function for or during fine-tuning may negatively impact the performance². Moreover, the simple case of finding the optimal combination of k different activation functions in n different feedforward layers results in k^n possible combinations and becomes intractable; e.g., 531,441 experiments for a 12-layer BERT model and three different activation functions. As a result, most Transformer-based pre-trained models adopt the GELU activation function that has been initially used for the BERT model (Devlin et al., 2019).

To overcome the limitation of using a potentially suboptimal activation function that remains fixed during training, we propose to use a learnable activation function, namely, the rational activation function (RAF, Molina et al. 2020). The RAF is a universal function approximator that can approximate any existing activation function. The advantage of using RAFTs over fixed activation functions (FAF) such as ReLU or GELU, is that the model can learn the optimal activation function from the data during (pre)training without the need to consider the choice of activation function as an additional dimension during hyperparameter tuning.³

²In our preliminary experiments, the performance of BERT becomes worse on downstream tasks when the activation functions are changed after pre-training.

³Liu et al. (2019a) consider different activation functions during Neural Architecture Search (Zoph and Le, 2017), but this becomes quickly infeasible for compute-intensive experi-

To evaluate the effectiveness of RAFs, we pre-train two encoder-only Transformers using RAF and GELU respectively, within an academic budget. In our experiments, we find that:

- The RAF-based Transformer (RAFT) learns different activation functions at different layers after pre-training with shapes that differ from frequently used activation functions.
- During fine-tuning, RAFT outperforms its fixed activation function counterpart (FAFT) on the general language understanding benchmark (GLUE) and the SQuAD machine reading comprehension dataset in various settings.
- After fine-tuning, the learned RAFs of the top layers are more task-specific and change the most, which are corresponding to layer behaviors of Transformers according to prior work (Mosbach et al., 2020; Merchant et al., 2020; Zhou and Srikumar, 2022). This provides new opportunities to analyze language models with respect to their learned activation functions at different layers for different tasks.
- RAFT boosts the performance when combined with a parameter-efficient fine-tuning approach, i.e., BitFit (Ben Zaken et al., 2022), which improves the model performance by 3.08 points in full-data scenario.

2 Related Work

Activation functions. There exists various predefined activation functions such as Sigmoid, Hyperbolic Tangent (Tanh), Rectified Linear Unit (ReLU, Fukushima 1969), and Gaussian Error Linear Unit (GELU, Hendrycks and Gimpel 2016). There are also approaches that leverage automatic search to obtain optimal combinations of several base activation functions in a predefined search space (Ramachandran et al., 2018; Manessi and Rozza, 2018; Sütfeld et al., 2020; Bingham and Miikkulainen, 2022; Bingham et al., 2020). For instance, Ramachandran et al. (2018) discovered the Swish activation function by using this method. Bingham et al. (2020) show that further extending the search space using evolutionary algorithms can also lead to an improvement. Finally, several search-based works investigate how to train a combination of a set of activation functions to better adapt to specific tasks and architectures (Manessi and Rozza, 2018; Sütfeld et al., 2020; Bingham and Miikkulainen, 2022). One substantial drawback of these search-based methods is that they are computationally expensive. Especially for pre-trained language models where pre-training is costly, it is infeasible to perform a hyperparameter search for selecting the best activation function (even more so their combination). In contrast, the flexibility of rational activation functions (RAFTs) allows them to be trained along with the model parameters in an end-to-end fashion (Molina et al., 2020). Therefore, they can learn the optimized activation function from data during training. RAFs have been successfully used in deep reinforcement learning for improving plasticity (Delfosse et al., 2021), cell detection models in biology (Prangemeier et al., 2020), and adapter architectures (Moosavi et al., 2022).

2018; Sütfeld et al., 2020; Bingham and Miikkulainen, 2022). One substantial drawback of these search-based methods is that they are computationally expensive. Especially for pre-trained language models where pre-training is costly, it is infeasible to perform a hyperparameter search for selecting the best activation function (even more so their combination). In contrast, the flexibility of rational activation functions (RAFTs) allows them to be trained along with the model parameters in an end-to-end fashion (Molina et al., 2020). Therefore, they can learn the optimized activation function from data during training. RAFs have been successfully used in deep reinforcement learning for improving plasticity (Delfosse et al., 2021), cell detection models in biology (Prangemeier et al., 2020), and adapter architectures (Moosavi et al., 2022).

Table 1: Activation functions in different NLP Transformer models. Models marked by * do not explicitly state the activation function but refer to GPT-1 as the base architecture (⁺ refers to BERT respectively). GeGLU is a variant that combines GELU and GLU.

Frequently used activation functions in NLP.

Table 1 shows a list of 20 different language models that have been introduced after BERT. As we see, the vast majority of the works (80%) use the GELU activation function. Moreover, many works even do not explicitly state the used activation function (45%). There are only a few works that investigate the impact of activation functions on pre-trained Transformer models. So et al. (2021) leverage automatic search methods to identify more efficient Transformer architectures. They find that a combi-

nation of squared ReLU used in the feedforward network (FFN) layer and a convolution layer added in self-attention can lead to a substantial boost in performance. Shazeer (2020) replace the FFN in the Transformer with a gated linear unit (GLU, Dauphin et al. 2017) combined with different activation functions and find a higher performance during pre-training as well as on downstream tasks. In our work, we do not change the structure of FFNs and only replace activation functions in them.

Closest to our work is the work by Moosavi et al. (2022) who investigate the use of RAF in adapters (Houlsby et al., 2019); i.e., lightweight layers that are added on top of pre-trained Transformer layers. They propose adaptable adapters that consist of RAFs and learnable switches to select a subset of adapter layers during training. They show that using both RAFs and a fewer number of adapter layers results in considerable performance gains, especially in low-data settings. However, only using RAF instead of ReLU does not result in a considerable gain in their experiments. Furthermore, adapter layers are only added and updated during fine-tuning, as a result using RAF in adapter layers has a limited impact compared to already applying them for pre-training.

In this work, we show that using RAF in Transformer layers brings additional flexibility to the model to learn the optimized activation function for each of its layers during training, and that this additional flexibility benefits both pre-training and fine-tuning steps.

3 RAFT: RAF-based Transformers

We adopt the BERT architecture (Devlin et al., 2019) where all activation functions in feedforward layers $Activation(W_1X)W_2$ are replaced with rational activation functions (illustrated in Appendix A). The equation of rational activation function $F(x)$ is as below:

$$F(x) = \frac{P(x)}{Q(x)} = \frac{\sum_{j=0}^m a_j x^j}{1 + |\sum_{k=0}^n b_k x^k|} \quad (1)$$

Where a and b are learnable parameters, and m and n are degrees of $F(x)$, which decide the complexity and fitting ability of rational functions. Following Molina et al. (2020), we use the *safe PAU* formulation that further stabilizes training.

Selecting m and n . Similar to Taylor series, the higher the degrees m and n are, the more precise

is the approximation of rational functions. However, indefinitely increasing the degrees also means adding more complexity and increasing training time. The challenge is to find suitable degrees that leads to rational functions with a strong fitting ability while keeping their complexity as low as possible. As this is still an open question, we set the search space of m and n to $\{4, 5\}$, and evaluate their ability to approximate the GELU function in the range of $[-3, 3]$. Our results show that using $m = 5$ and $n = 4$ perfectly fits the GELU function with a low complexity and thus, are adopted in this work (cf. Figure 5, Appendix B). This matches the findings in previous work (Telgarsky, 2017; Molina et al., 2020; Delfosse et al., 2021) as well. So overall, each rational activation function adds nine parameters, resulting in a total of 108 additional parameters in a 12-layer Transformer model (less than 0.000098% of its original parameters). The weights of $F(x)$ can further be initialized to approximate any existing activation functions. In our experiments, we initialize it with weights that approximate GELU.

4 Pre-training

To evaluate the viability of RAFT, we pre-train two comparable Transformer models from scratch—one using the common fixed GELU activation function (FAFT), and another one using RAFs (RAFT).

Model architecture. For our experiments, we use a frequently considered model configuration and train 12 Transformer encoder layers with a hidden size of 768 and 12 attention heads (Devlin et al., 2019; Liu et al., 2019b; Rae et al., 2021; Zhang et al., 2022). The only difference between RAFT and FAFT is the use of RAFs instead of GELUs as activation functions.

Data. We use English Wikipedia as our pre-training data.⁴ The dataset consists of 3.8×10^9 tokens from which we select 50k sentences containing 6.4×10^6 tokens as the validation data.

Pre-training objective. Following RoBERTa (Liu et al., 2019b), we use dynamic masked language modeling (MLM) as our learning task and randomly mask tokens in the input sentences at each step before feeding them into the model. We use the same masking probabilities and mask 15% of the tokens with an 80% chance of replacing them

⁴<https://dumps.wikimedia.org>

Model	Validation loss	Validation PPL
FAFT	1.645	5.18
RAFT	1.611	5.00

Table 2: Performance of the models on the validation set after pre-training.

with the [MASK] token, a 10% chance of replacing them with a randomly selected different token, and a 10% chance of not replacing them at all.

Training parameters. As our primary goal is to validate the effectiveness of RAFs in Transformers rather than releasing a RoBERTa-like model, we focus on training two comparable models within a limited training budget. Both models are optimized using AdamW (Loshchilov and Hutter, 2019) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and a weight decay of 0.01. The learning rate lr_θ is set to $7E-4$ for both models while the learning rate lr_{RAF} for the RAF coefficients is set to $5E-3$. Both learning rates are warmed up over the first 1% steps, then lr_θ decays linearly while lr_{RAF} remains constant.⁵ The batch size is set to 4096. Tuning hyperparameters during pre-training is expensive, to conduct hyperparameter tuning of both models with limited resources, we follow up 24hour BERT (Izsak et al., 2021) to pre-train the model for 23k steps equipped with various methods to accelerate training, including mixed-precision, sparse output prediction, fused linear layer, and tied embeddings (Press and Wolf, 2017). Detailed parameters and results of hyperparameter tuning are provided in Appendix C. It takes ~ 16 hours for RAFT and ~ 12 hours for FAFT using four A100 GPUs.

Results. Table 2 shows the MLM validation losses and validation perplexity of the best performing hyperparameter configuration for RAFT and FAFT. We observe that RAFT achieves a bit lower perplexity than FAFT during pre-training. The learned RAFs vary across different layers after pre-training (cf. Figure 6, Appendix E). More analysis is conducted in Section 6.

5 Fine-tuning

We conduct experiments on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019) and SQuAD (Rajpurkar

et al., 2016) to see how well pre-trained RAFs can adapt to downstream tasks. Dataset descriptions are provided in Appendix D. We further investigate the flexibility of the pre-trained RAFs by considering different training data sizes especially in a low-data regime. We fine-tune RAFT in two different settings:

- RAFT^{full}: We fine-tune the whole model, i.e., all model parameters including the RAFs.
- RAFT^{fixed}: We fix the pre-trained RAFs and only tune the rest of the parameters.

5.1 Evaluation on the GLUE Benchmark

We evaluate pre-trained models on GLUE benchmark in different data settings: (a) the full-data scenario, and (b) two low-data scenarios when only 100 or 300 labelled examples are available.

Experimental Setup. We split 75% of the training dataset as the training set and use the remaining 25% as the development set in the full-data scenario. Following previous works, we use the provided development set as the test dataset. For our low-data scenarios, we randomly sample 100 or 300 examples with ten different random seeds and report the average and standard deviation across all runs. For the full-data scenario, we report the average and standard deviation of the results across six runs with different random seeds. We use the same evaluation metrics as proposed in the GLUE benchmark; more specifically, for MRPC, QQP, and STSB, we use the average of the two corresponding metrics as the final score.⁶

Results. Table 3 shows the performance of RAFT and FAFT on the GLUE benchmark. We observe that on average, RAFT achieves consistent improvements in all data settings. We further find that especially in the low-data scenarios, the flexible activation functions of RAFT substantially outperform their static GLUE counterparts of the FAFT model. For 100 examples, RAFT achieves better results in seven out of eight tasks, outperforming FAFT by 5.31 points (RAFT^{full}) and 5.71 points (RAFT^{fixed}) on average, respectively. While the performance gap becomes smaller as the number of examples increases, the tendency remains the same with an average performance gain of 0.98

⁵We find in our preliminary experiments that a constant rational learning rate with warm up leads to better results.

⁶Note that the full-data scenario is computationally more expensive to run, but also more stable as the training instances experience less variability.

² Results are averaged over six random seeds: 5309, 202206, 20220602, 2259, 49, 2022

Table 3: The performance of RAFT and FAFT on the GLUE benchmark across different data sizes. RAFT^{full} fine-tunes all model parameters including RAFs. RAFT^{fixed} instead fixes the RAFs pre-training.

points (RAFT^{full}) and 1.59 points (RAFT^{fixed}) for 300 examples. In the full data scenario, RAFT still outperforms FAFT by 0.7 (RAFT^{full}) and 0.58 (RAFT^{fixed}) points on average.

Our experiments indicate that fixing the RAFs is a better choice for the GLUE benchmark in the low-data scenarios. We conjecture that one reason for this may be that the number of instances to tune all parameters of the model are insufficient. On the contrary, we find that in the full-data scenario tuning RAFs can lead to better results. The increasing number of instances especially benefit RAFs as they can better adapt to different downstream tasks and learn better features. We provide further analysis in Section 6.

5.2 Evaluation on SQuAD

Similar to GLUE, we evaluate models on SQuAD v1.1 in different data settings: (a) the full-data scenario, and (b) four low-data scenarios with 100, 300, 500, and 1000 training examples.

Experimental Setup. We split the official training data into separate training (75%) and development sets (25%)⁷ and use the official development set as the test data. We evaluate the results by computing the F1 score over the word overlap of the predicted answer and the gold answer. The hyperparameters search space is provided in Appendix C.

Results. Table 4 shows our results of RAFT and FAFT. Compared to GLUE, that consists of sentence-level text matching tasks, SQuAD is a more complex task in which the model needs to comprehend a longer text sequence to predict an answer span. The increased task difficulty is especially reflected in the low-data scenarios, as the

⁷Again, we use the development set to identify the best performing model across all epochs.

performances of both models are below 25 points when only 100 or 300 annotated examples are available. As a result, when there are not enough annotated examples available to learn the task, the use of RAFs instead of GELU is not beneficial for the Transformer model. However, we again see that RAFT outperforms the FAFT model as enough training examples become available.

In addition, we observe that tuning RAFs during fine-tuning (RAFT^{full}) is more beneficial compared to fixing RAFs (RAFT^{fixed}) when the task is more complex. Considering our findings on the GLUE benchmark, we conjecture that the task difficulty may play an additional role besides the amount of available training data for the performance of RAFT^{full} vs. RAFT^{fixed}; however, this remains to be investigated in future work.

6 Analysis

Impact of RAF initialization. To investigate how initialization affects the performance of RAFT, we train RAFT models initialized with GELU, RELU, and the identity function. Other hyperparameters are the same as those in section 4. Table 5 shows the performance of different initialization

	SNLI	Trivia QA

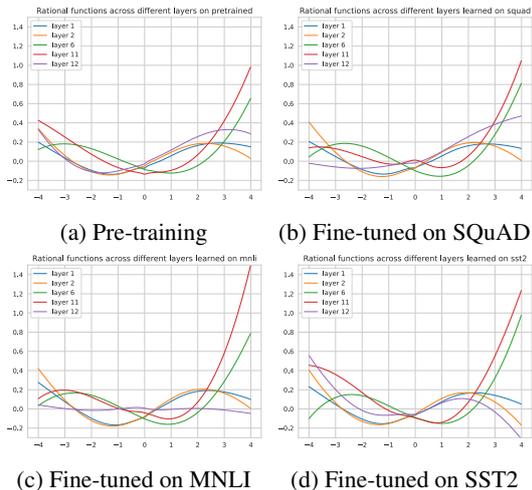

Figure 1: Rational activation functions of RAFT^{full} among different layers after pre-training and fine-tuning.

methods during pre-training. As we can see, choosing common activation functions such as ReLU or GELU leads to a similar performance while using the identity function for initialization leads to divergence.

Zero-shot generalization. To investigate if the higher performances of RAFT vs FAFT come from overfitting on the in-domain data, we conduct cross-domain zero-shot experiments. We use the models that have been fine-tuned on MNLI and SQuAD in the full-data scenario and evaluate them on the same tasks but for different data, namely, SNLI (Bowman et al., 2015) and TriviaQA (Joshi et al., 2017), respectively. MNLI and SNLI are both datasets that aim to evaluate natural language inference while SQuAD and TriviaQA contain examples for evaluating reading comprehension in different domains. Table 6 shows the results of our zero-shot evaluation. We observe that the increased flexibility and adaptivity of RAFT does not negatively impact its generalization capabilities. In fact, both variants of RAFT consistently achieve better performance than the corresponding FAFT model.

Visualizing learned RAFs. Next, we analyze how the shapes of RAFs change after pre-training and fine-tuning. First, we analyze the learned RAFs in different layers of RAFT after pre-training. As shown in Figure 1a, rational functions have different shapes across different layers, none of which are similar to GELU, or other commonly used activation functions in Transformers (cf. Table 1). This indicates that different layers may need different activation functions to achieve the optimal performance. Moreover, we see that some features like monotonicity that often are deemed to be good for predefined activation functions are not necessary, which is in line with the findings of the Swish activation function (Ramachandran et al., 2018).

Second, we analyze how the learned RAFs during pre-training change after fine-tuning in RAFT^{full}. Figures 1b–1d show learned RAFs after fine-tuning RAFT^{full} on SQuAD, MNLI and SST2 datasets. We observe that some of the learned RAFs trained on these three tasks differ from each other and the RAFs after pre-training. We further see that several RAFs between both tasks have similar shapes but different slopes across many layers.

To better understand the behavior of learned RAFs after fine-tuning in different layers on various tasks, we plot RAFs from the same layer together across all tasks. Figure 2 shows the learned RAFs in layer 1 (the bottom layer), layer 6, and layer 12 (the top layer) after pre-training and fine-tuning on different tasks. We observe that after fine-tuning, the RAFs in the top layer are more task-specific and change the most, compared to those in bottom layers. This is in line with prior work that analyzed the behavior of BERT layers during fine-tuning, which showed that higher layers exhibit more changes compared to lower layers (Mosbach et al., 2020; Merchant et al., 2020; Zhou and Sriku-mar, 2022). Our results confirm this finding from the perspective of learned activation functions. It also demonstrates that RAFs can self-adapt to different layers and tasks during fine-tuning. In addition, an interesting observation is that the output ranges of the RAFs of MNLI and QQP in the top layer are very close to zero. The output of the FFN layer $LayerNorm(FFN(x) + x)$ consists of two parts: the feedforward branch $FFN(x)$ and the skip connection branch x . The very small output of activation functions may indicate that the FFN branch of the top layer does not contribute much to the final model performance on MNLI and QQP and

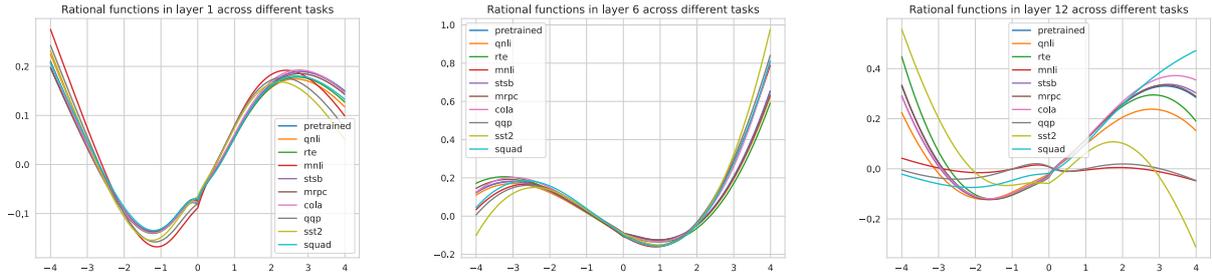

Figure 2: Learned rational activation functions of $\text{RAFT}^{\text{full}}$ in layers 1 (bottom), 6, and 12 (top) among different tasks.

Table 7: Comparison between RAFT and FAFT combined with BitFit.

thus could be pruned. We leave this as future work.

RAFT^{fixed} vs. RAFT^{full}. In our experiments on GLUE and SQuAD (Tables 3 and 4), we observe that fixing the RAFs after fine-tuning (RAFT^{fixed}) often achieves the best or second best performance compared to the full-tuning model (RAFT^{full}) and FAFT. Fine-tuning RAFs results in higher performances when (a) more data is available, i.e., the full-data scenario in GLUE, or (b) the input task is more complex such as in SQuAD. We hypothesize that training RAFs during fine-tuning will be more effective when evaluated on more complex tasks and datasets than the ones used this work.

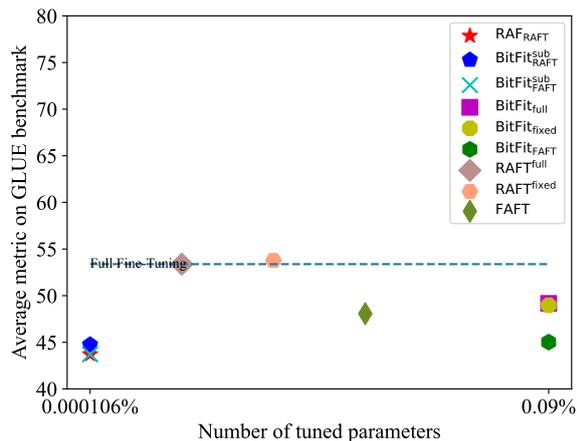

Efficiency comparison between RAFT and FAFT. In RAFT, RAFs are polynomial ratios and their coefficients are learned during training, which adds extra computation overhead. We use RAFs library with CUDA extension to accelerate. As shown in Table 8, RAFT is slower than FAFT during training since RAFs need to be updated (36.8% slower at pre-training, 14.8% slower at fine-tuning). However, RAFT is faster when doing inference due to the CUDA implementation (13.8% faster at pre-training, 3.9% faster at fine-tuning).

Parameter-efficient fine-tuning with RAFTs. In contrast to fine-tuning all parameters in a pre-trained language model, parameter-efficient tuning techniques that freeze the majority of

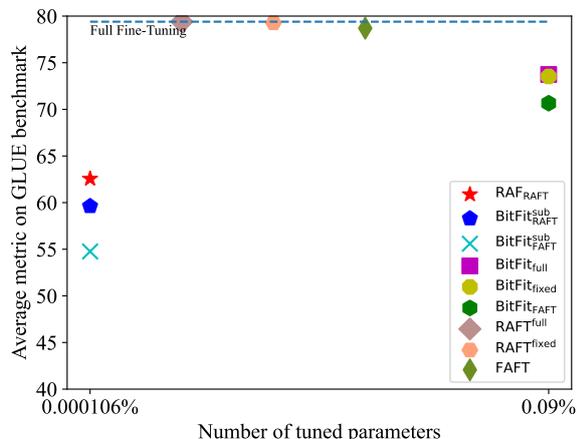

steps/second	Pre-training		Fine-tuning	
	Train	Inference	Train	Inference
RAFT	0.38	3.3	12.54	71.05
FAFT	0.52	2.9	14.4	68.38

Table 8: Number of steps per second for training and inference for RAFT and FAFT.

pre-trained parameters and only fine-tune a small set can be promising alternatives (Ding et al., 2022). One such method is BitFit (Ben Zaken et al., 2022) which only updates the bias terms in the Transformer model. To investigate the effectiveness of RAFT in a parameter-efficient fine-tuning paradigm, we fine-tune the FAFT and RAFT models with BitFit on the GLUE benchmark. We use the same settings as in our previous experiments and test RAFT and FAFT in three configurations in the low-data 100 and full-data scenario: (a) $\text{BitFit}_{\text{FAFT}}$ uses BitFit with FAFT, (b) $\text{BitFit}_{\text{full}}$ uses BitFit with RAFT^{full}, and (c) $\text{BitFit}_{\text{fixed}}$ uses BitFit with RAFT^{fixed}. As shown in Table 7, RAFT-based BitFit achieves higher performance than the FAFT on average in both data settings: $\text{BitFit}_{\text{fixed}}$ achieves 3.95 points improvements and $\text{BitFit}_{\text{full}}$ gets 4.15 points improvements in the low-data scenario while $\text{BitFit}_{\text{fixed}}$ performs better with a 2.87 points boost and $\text{BitFit}_{\text{full}}$ performs better with a 3.08

(a) Comparison performance in low-data 100 scenario

(b) Comparison performance in full-data scenario

Figure 3: The number of parameters vs. the performance for fine-tuning of RAFT and FAFT.

points boost in the full-data scenario. It is worth noting that in some tasks, the reported results have a very large standard deviation (e.g., 33.04 for $BitFit_{FAFT}$ on STSB) due to several random seed runs not converging. In our experiments, BitFit is not as stable as fine-tuning the whole model.

How much can we achieve by only fine-tuning RAFs? To see to what extent the model can learn from different tasks by only updating RAFs, we conduct experiments to only tune RAFs on the GLUE benchmark in low- and full-data settings. We call this setup where only 117⁸ parameters of the RAFs are updated during fine-tuning, RAF_{RAFT} .

For comparison, we tune our models with the BitFit setting using the same amount of parameters,

⁸Including RAF in the pooling layer for classification

i.e., 117.⁹ $BitFit_{FAFT}^{sub}$ represents tuning the subset of BitFit of FAFT, and $BitFit_{RAFT}^{sub}$ represents tuning the subset of BitFit of RAFT. The result is presented in Appendix F (Table 13). To compare it from a broader view, we plot Figure 3 based on Table 3, Table 7 and Table 13. We observe that if only a few annotated examples are available (100 examples), $BitFit_{fixed}$ and $BitFit_{full}$ can achieve better performance than full fine-tuning of FAFT. Only fine-tuning 117 parameters ($BitFit_{FAFT}^{sub}$, $BitFit_{RAFT}^{sub}$ and RAF_{RAFT})—i.e., a negligible number of parameters compared to 110M parameters in FAFT—results in a comparable performance as fine-tuning all the parameters with only a drop of 4.21–6.68 percentage points. In the full-data scenario, the performance of BitFit ($BitFit_{full}$, $BitFit_{fixed}$ and $BitFit_{FAFT}$) lags behind full fine-tuning of both models. Only tuning RAFs or a subset of BitFit cannot achieve comparable results as well. However, RAF_{RAFT} outperforms $BitFit_{FAFT}^{sub}$ by 7.8% and performs better than $BitFit_{RAFT}^{sub}$ by 2.94% in this setting.

7 Conclusion and Future Work

In this work, we propose to utilize rational activation functions (RAF) in Transformers to directly learn optimal activation functions from data during pre-training and fine-tuning. To evaluate the effectiveness of rational activation functions, we pre-trained a Transformer-based language model, namely, RAFT. RAFT achieves a lower validation perplexity than FAFT during pre-training. Our experimental results show that RAFT performs better than FAFT in general language understanding tasks and reading comprehension tasks across different data size scenarios. We further visualize and analyze rational activation functions across different layers and tasks after pre-training and fine-tuning and find that they can substantially vary across different layers and tasks. This provides us a new way to analyze and better understand Transformer-based language models. For instance, we can investigate whether layers with similar rational activation functions encode similar linguistic properties. We further find that some layers exhibit a close to zero throughput of the rational activation function which indicates that the corresponding feedforward layer does not contribute too much to a model’s prediction. We consider these as our future work.

⁹Note that we also update the classification head in all models and experiments.

Limitations

Limited training resources. This work evaluates the effectiveness of rational activation Transformers using limited GPU resources. To provide a fair comparison, we train and release RAF- and GELU-based models for a reduced GPU budget; hence, they are not comparable to publicly available large pre-trained models such as RoBERTa-base etc. Still, a fully pre-trained RAFT could be released once more GPU resources are available. We furthermore note that we use GELU activation functions and the original FFN architecture as our baseline as it is dominantly used in existing models.

Societal impact. The main focus of this work is the evaluation of trainable activation functions. While our visualization of the learned activation functions show that they exhibit substantial differences depending on the downstream task, further analysis is necessary to better understand and interpret the shapes. Moreover, it is unclear if the additional flexibility of the models may increase their susceptibility towards capturing biases in the data. At the same time, we conjecture that especially susceptible models could also be used as good indicators to detect such biases.

Acknowledgements

We thank Quentin Delfosse for his continued support and valuable advice regarding the existing implementation of rational activation functions. We further thank our anonymous reviewers and Stella Biderman, Fengyu Cai, Nils Dycke, Haau-Sing Li, Andreas Rücklé, Martin Tutek, Kexin Wang, and Neha Warikoo for their fruitful discussions and helpful feedback. This work has been funded by the German Research Foundation (DFG) as part of the UKP-SQuARE project (grant GU 798/29-1), the German Federal Ministry of Education and Research and the Hessian Ministry of Higher Education, Research, Science and the Arts within their joint support of the National Research Center for Applied Cybersecurity ATHENE and the hessian.AI Service Center.

A Model Architecture

Figure 4 shows the difference part of RAFT and FAFT.

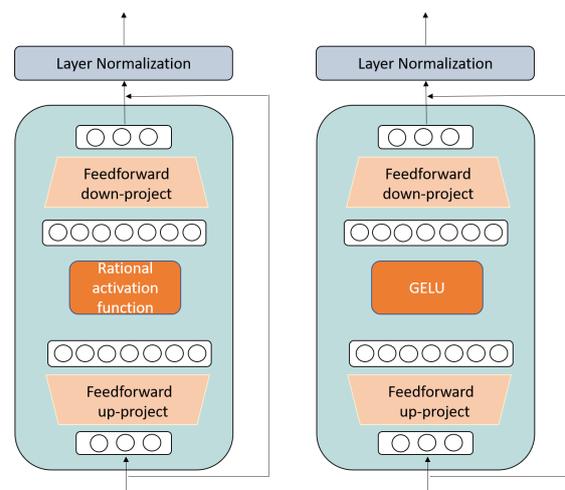

Figure 4: Rational activation function in the feed-forward layer (left) and the vanilla GELU counterpart (right).

B Fitting abilities of different degrees of Rational Functions

Figure 5 show the approximate functions of GELU using rational functions with different degrees. As we can see, when $m = 5$ and $n = 4$ or $n = 5$, rational function fit GELU very well in the same shape. Finally, it is important to note that rational functions are an universal approximator in a limited range, e.g., $[-5,5]$. Especially for out-of-bound inputs (i.e., values that are not guaranteed by rational functions), the output of rational functions may result in values very different from the approximated function (e.g., GELU). While pre-training a model from scratch with RAFs does not lead to any problem, directly replacing activation functions in pre-trained models with RAFs only for fine-tuning may lead to divergence due to out-of-bound inputs.

C Hyperparameters Tuning

C.1 Pre-training

In our preliminary experiments that some hyperparameter configurations can lead to instability during training due to diverging model updates (e.g., for $lr_\theta = 7E-4$ and batch size of 2048). To stabilize the training without having to rely on a larger warmup phase (e.g., 6% of the training steps), we instead adopt the DeepNorm (Wang et al., 2022) to initialize both models. DeepNorm stabilizes training by bounding the updates and further scaling the residual branches in Transformers. Using DeepNorm makes both models, FAFT and RAFT, achieve lower validation loss and leads to a more stable training.

We tune the learning rate lr_θ for model parameters and lr_{RAF} for RAFs, batch size, warmup steps, and learning rate scheduler as hyperparameters for both models separately. The hyperparameter search space for pre-training stage is as follows:

- Learning rate lr_θ for model parameters: 1E-4, 4E-4, 7E-4, 1E-3
- Learning rate lr_{RAF} for RAFs: 1E-3, 5E-3, 1E-2
- Batch size: 2048, 4096
- Warmup ratio: 0%, 1%, 6%

Some results of hyperparameters tuning are provided in Table 9.

Table 10 shows final hyperparameters we used for pre-training RAFT and FAFT.

	lr_θ	lr_{RAF}	Batch Size	Validation Loss
RAFT	1E-4	0.005	2048	2.217
RAFT	4E-4	0.005	2048	1.808
RAFT	7E-4	0.005	4096	1.732
RAFT	7E-4	0.005	4096	1.611
RAFT	1E-3	0.005	4096	1.638

Table 9: Part of Hyperparameters Tuning Results of RAFT

Hyperparameters	FAFT	RAFT
Peak lr_θ	7E-4	7E-4
Peak lr_{RAF}	n/a	5E-3
Learning rate decay	linear	constant
Gradient clipping	0	0
Batch size	4096	4096
Sequence length	128	128
Adam_beta1	0.9	0.9
Adam_beta2	0.98	0.98
Attention dropout	0.1	0.1
Warmup ratio	1%	1%
Training steps	23k	23k

Table 10: Hyperparameters for pre-training RAFT and FAFT

C.2 Fine-tuning

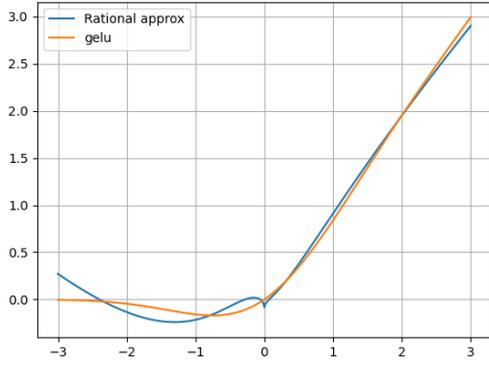

The hyperparameters search space for GLUE during fine-tuning stage is as follows:

- lr_θ : 2E-5, 5E-5
- lr_{RAF} : 1E-4, 5E-4, 1E-3, 5E-3
- Batch size: 32
- Weight decay: 0.1
- Number of epochs: 3, 10, 20

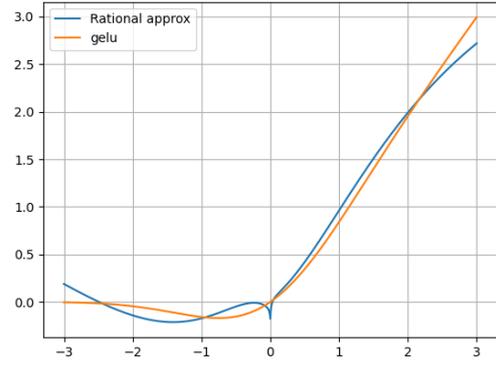

We further tune the learning rates and number of training epochs for RAFT and FAFT separately on a single random seed. For our low-data experiments we fix the number of training epochs to 20 and use early stopping with a patience of 10 epochs. For our full-data experiments, we train the large datasets (QQP, MNLI, and QNLI) for 3 epochs and the others for 10 epochs.

The hyperparameters search space for SQuAD during fine-tuning is as below:

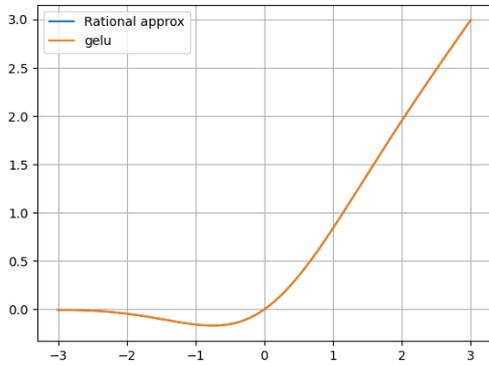

- lr_θ : 2E-5, 5E-5, 1E-4

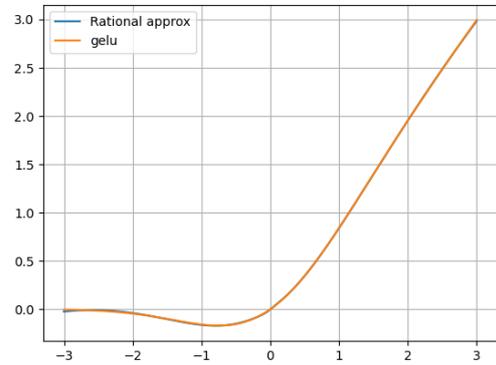

(a) Approximate function with degrees $m = 4$ and $n = 4$

(b) Approximate function with degrees $m = 4$ and $n = 5$

(c) Approximate function with degrees $m = 5$ and $n = 4$
Rational Function is overlapping with GELU

(d) Approximate function with degrees $m = 5$ and $n = 5$
Rational Function is overlapping with GELU

Figure 5: Approximate Functions of GELU using rational functions

- lr_{RAF} : 1E-4, 5E-4, 1E-3, 5E-3
- Batch size: 32
- Weight decay: 0.1
- Number of epochs: 10, 20

For our experiments, we fine-tune both models with their best performing $lr_{\theta} = 1E-4$ for 10 epochs in the full-data scenario and 20 epochs in the low-data scenario.

The hyperparameters search space for BitFit is as below:

- Learning rate lr_{θ} for model parameters: 5E-5, 1E-3, 5E-3, 1E-2
- Learning rate lr_{RAF} for RAFs: 1E-3, 5E-3, 1E-2
- Batch size: 32
- Training epochs: 3, 10, 20 epochs

We use 3 training epochs for large dataset (QQP, MNLI, QNLI), 10 epochs for other datasets and 20 epochs for low-resource scenarios. Both models can converge in the above settings.

D Data Statistics

GLUE is a collection of nine different language understanding tasks: CoLA (Warstadt et al., 2019), SST2 (Socher et al., 2013), MRPC (Dolan and Brockett, 2005), QQP¹⁰, STSB (Cer et al., 2017), MNLI (Williams et al., 2018), RTE (Dagan et al., 2005), and WNLI (Levesque et al., 2012). We exclude WNLI due to the adversarial nature of its development set and the still unbeaten majority vote upper bound.¹¹

The Solvability of Interpretability Evaluation Metrics

Yilun Zhou Julie Shah

MIT CSAIL

<https://yilunzhou.github.io/solvability/>

Abstract

Feature attribution methods are popular for explaining neural network predictions, and they are often evaluated on metrics such as comprehensiveness and sufficiency. In this paper, we highlight an intriguing property of these metrics: their *solvability*. Concretely, we can define the problem of optimizing an explanation for a metric, which can be solved by beam search. This observation leads to the obvious yet unaddressed question: why do we use explainers (e.g., LIME) not based on solving the target metric, if the metric value represents explanation quality? We present a series of investigations showing strong performance of this beam search explainer and discuss its broader implication: a definition-evaluation duality of interpretability concepts. We implement the explainer and release the Python `solvex` package for models of text, image and tabular domains.

1 Introduction

For neural network models deployed in high stakes domains, the explanations for predictions are often as important as the predictions themselves. For example, a skin cancer detection model may work by detecting surgery markers (Winkler et al., 2019) and an explanation that reveals this spurious correlation is highly valuable. However, evaluating the correctness (or faithfulness) of explanations is fundamentally ill-posed: because the explanations are used to help people understand the reasoning of the model, we cannot check it against the ground truth reasoning, as the latter is not available.

As a result, correctness evaluations typically employ certain alternative metrics. For feature attribution explanations, they work under a shared principle: changing an important feature should have a large impact on the model prediction. Thus, the quality of the explanation is defined by different formulations of the model prediction change, resulting in various metrics such as comprehensiveness and

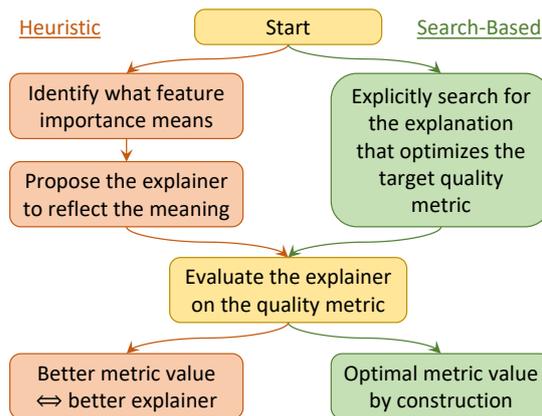

Figure 1: Left: the current process of developing new explainers. Right: the natural implication following our observation that evaluation metrics are *solvable*.

sufficiency (DeYoung et al., 2020). To develop new explanation methods (Fig. 1, left), people generally identify a specific notion of feature importance (e.g., local sensitivity), propose the corresponding explainer (e.g., gradient saliency (Simonyan et al., 2013)), evaluate it on one or more metrics, and claim its superiority based on favorable results vs. baseline explainers. We call these explainers *heuristic* as they are motivated by pre-defined notions of feature importance.

In this paper, we show that all these metrics are *solvable*, in that we can *define* an explanation as the one that optimizes a metric value and *search* for it. The obvious question is then: *if we take a specific target metric to represent correctness, why don't we just search for the metric-optimal explanation (Fig. 1, right) but take the more convoluted route of developing heuristic explanations and then evaluating them (Fig. 1, left)?*

There are several possible reasons. First, the optimization problem may be so hard that we cannot find an explanation better than the heuristic ones. The bigger concern, however, is that of Goodhart's Law. In other words, as soon as a metric is used in explicit optimization, it ceases to be a good

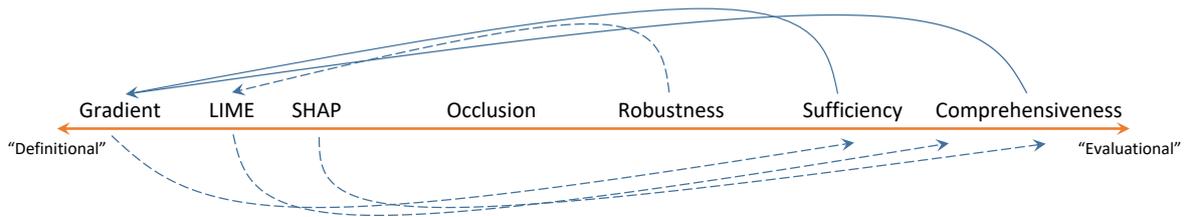

Figure 2: A definition-evaluation spectrum for various interpretability concepts currently as perceived by the community (see App. B for some justification). The proposed solvability property can move evaluational concepts towards the definitional side, for which we explore two in the paper (solid arrows). The more general definition-evaluation duality opens up new opportunities to move other concepts around (dashed arrows).

metric. Concretely, the explanation may overfit to the particular metric and perform much worse on closely related ones (Chan et al., 2022), or overfit to the model and effectively adversarially attack the model when assigning word importance (Feng et al., 2018). It may also perform poorly on evaluations not based on such metrics, such as ground truth alignment (Zhou et al., 2022a).

We assess these concerns, taking the widely used comprehensiveness and sufficiency metrics (DeYoung et al., 2020) as the optimization target. Our findings, however, largely dispel every concern. A standard beam search produces explanations that greatly outperform existing one such as LIME and SHAP on the target metric. On several other metrics, the search-based explainer also performs favorably on average. There is no strong evidence of it adversarially exploiting the model either, and it achieves competitive performances on a suite of ground truth-based evaluations.

Thus, we advocate for wider adoptions of the explainer, which is domain-general and compatible with models on image and tabular data as well. As an engineering contribution, we release the Python `solvex` package (*solvability*-based *explanation*) and demonstrate its versatility in App.A.

More broadly, the solvability phenomenon is one facet of the definition-evaluation duality, which asserts an equivalence between definitions and evaluations. Solvability recognizes that for each evaluation metric, we can define explainer that performs optimally on this metric. Conversely, for each explainer, we can also come up with an evaluation metric that ranks this explainer on top – a straightforward one would be the negative distance between the explanation under evaluation and the “reference explanation” generated by the explainer.

While the community has mostly agreed on a spectrum on which various interpretability concepts (Fig. 2) are located, duality allows every concept to be moved freely on the scale. We explored

two particular movements as represented by the solid arrows, but the more general investigation of this operation could be of both theoretical and practical interest. In addition, given that definitions and evaluations are really two sides of the same coin, we need to reflect how to best evaluate explanations. Sec. 6 argues to measure their *demonstrable utilities* in downstream tasks, and present potential ways and ideas to better align the interpretability research with such goals.

2 Background and Related Work

In this section, we give a concise but unified introduction to the popular feature attribution explainers and evaluation metrics studied in this paper.

2.1 Feature Attribution Explainers

We focus on feature attribution explanations, which explains an input $x = (x_1, \dots, x_L)$ by a vector $e = (e_1, \dots, e_L)$ where e_l represents the “contribution” of x_l to the prediction. Many different definitions for contribution have been proposed and we consider the following five.

- **Vanilla gradient (Grad)** (Simonyan et al., 2013; Li et al., 2016a) is the L2 norm of gradient of the prediction (in logit, following standard practice) with respect to the token embedding.
- **Integrated gradient (IntG)** (Sundararajan et al., 2017) is the path integral of the embedding gradient along the line segment from the zero embedding value to the actual value.
- **LIME** (Ribeiro et al., 2016) is the coefficient of a linear regression in the local neighborhood.
- **SHAP** (Lundberg and Lee, 2017) computes the Shapley value (Roth, 1988) for each word.
- **Occlusion (Occl)** (Li et al., 2016b) is the change in prediction when a word is removed from the input while all other words remain.

2.2 Feature Attribution Evaluations

Naturally, different definitions result in different explanation values. As findings (e.g., Adebayo

et al., 2018; Nie et al., 2018) suggest that some explanations are not correct (i.e., faithfully reflecting the model’s reasoning process), many evaluations are proposed to quantify the correctness of different explanations. Not having access to the ground truth model working mechanism (which is what explanations seek to reveal in the first place), they are instead guided by one principle: changing an important feature (as judged by the explanation) should have a large impact on the prediction, and the magnitude of the impact is taken as explanation quality. However, there are different ways to quantify the impact, leading to different evaluations, and we consider six in this paper.

Let $f : \mathcal{X} \rightarrow \mathbb{R}$ be a function that we want to explain, such as the probability of the target class. For an input $x = (x_1, \dots, x_L)$ of L words, according to an explanation $e = (e_1, \dots, e_L)$, we can create a sequence of $L + 1$ input deletions $\tilde{x}_e^{(0)}, \tilde{x}_e^{(1)}, \dots, \tilde{x}_e^{(L)}$ where $\tilde{x}_e^{(l)}$ is the input but with l most important features removed. Thus, we have $\tilde{x}_e^{(0)} = x$ and $\tilde{x}_e^{(L)}$ being the empty string.¹ The **comprehensiveness** κ (DeYoung et al., 2020) is defined as

$$\kappa(x, e) = \frac{1}{L + 1} \sum_{l=0}^L f(x) - f(\tilde{x}_e^{(l)}). \quad (1)$$

It measures the deviation from the original model prediction when important features (according to e) are successively removed, and therefore a larger value is desirable. It was also proposed for computer vision models as the area over perturbation curve (AoPC) by Samek et al. (2016).

Analogously, we can define the sequence of input insertions $\hat{x}_e^{(0)}, \hat{x}_e^{(1)}, \dots, \hat{x}_e^{(L)}$, where $\hat{x}_e^{(l)}$ is the input with the l most important features present. Thus, $\hat{x}_e^{(0)}$ is the empty string and $\hat{x}_e^{(L)} = x$, but otherwise the sequences of input insertions and deletions do not mirror each other. The **sufficiency** σ (DeYoung et al., 2020) is defined as

$$\sigma(x, e) = \frac{1}{L + 1} \sum_{l=0}^L f(x) - f(\hat{x}_e^{(l)}). \quad (2)$$

¹We define feature removal as the literal deletion of the word from the sentence, which is a popular practice. Other methods replace the token with [UNK], [MASK] or zero embedding, are more sophisticated such as performing BERT mask filling (Kim et al., 2020). While our current approach could lead to out-of-distribution instances, we adopt it due to its popularity. A thorough investigation for the best strategy is orthogonal to our paper and beyond its scope.

It measures the gap to the original model prediction that remains (i.e., convergence to the model prediction) when features are successively inserted from the most important to the least. Therefore, a smaller value is desirable.

Another interpretation of prediction change just considers decision flips. Let $g : \mathcal{X} \rightarrow \{0, \dots, K\}$ be the function that outputs the most likely class of an input. The **decision flip by removing the most important token** (Chrysostomou and Aletras, 2021) is defined as

$$\text{DF}_{\text{MIT}}(x, e) = \mathbb{1}_{g(\tilde{x}_e^{(1)}) \neq g(x)}, \quad (3)$$

which measures whether removing the most important token changes the decision. Across a dataset, its average value gives the overall decision flip rate, and a higher value is desirable.

The **fraction of token removals for decision flip** (Serrano and Smith, 2019) is defined as

$$\text{DF}_{\text{Frac}}(x, e) = \frac{\arg \min_l g(\tilde{x}_e^{(l)}) \neq g(x)}{L}, \quad (4)$$

and we define $\text{DF}_{\text{Frac}} = 1$ if no value of l leads to the decision flip. This metric represents the fraction of feature removals that is needed to flip the decision, and hence a lower value is desirable.

Last, two metrics evaluate correlations between model prediction and feature importance. For x and e , we define the sequence of marginal feature deletions $x_{-,e}^{(1)}, \dots, x_{-,e}^{(L)}$ such that $x_{-,e}^{(l)}$ is original input with only the l -th important feature removed. The **deletion rank correlation** (Alvarez-Melis and Jaakkola, 2018b) is defined as

$$\delta_f = [f(x) - f(x_{-,e}^{(1)}), \dots, f(x) - f(x_{-,e}^{(L)})], \quad (5)$$

$$\text{Rank}_{\text{Del}}(x, e) = \rho(\delta_f, e), \quad (6)$$

where $\rho(\cdot, \cdot)$ is the Spearman rank correlation coefficient between the two input vectors. Intuitively, this metric asserts that suppressing a more important feature should have a larger impact to the model prediction. A higher correlation is desirable.

The **insertion rank correlation** (Luss et al., 2021) is defined as

$$v = [f(\tilde{x}_e^{(L)}), \dots, f(\tilde{x}_e^{(0)})], \quad (7)$$

$$\text{Rank}_{\text{Ins}}(x, e) = \rho(v, [0, \dots, L]), \quad (8)$$

and recall that $\tilde{x}_e^{(L)}, \dots, \tilde{x}_e^{(0)}$ is the sequence of inputs with increasingly more important features inserted, starting from the empty string $\tilde{x}_e^{(L)}$ to the

full input $\tilde{x}^{(0)}$. This metric asserts that the model prediction on this sequence should increase monotonically to the original prediction. Also a higher correlation is desirable.

Related to our proposed notion of solvability is the phenomenon that some metric values seem to favor some explainers (Pham et al., 2022; Ju et al., 2022). While it is often used to argue *against* the use of certain evaluations, we take this idea to the extreme, which culminates in the solvability property, and find that metric-solving (Def. 3.1) explanations from some metrics can be high-quality.

3 The Solvability of Evaluation Metrics

Now we establish the central observation of this paper: the solvability of these evaluation metrics. Observe that each evaluation metric, e.g., comprehensiveness κ , is defined on the input x and the explanation e , and its computation only uses the model prediction function f (or g derived from f for the two decision flip metrics). In addition, the form of feature attribution explanation constrains e to be a vector of the same length as x , or $e \in \mathbb{R}^L$.

Without loss of generality, we assume that the metrics are defined such that a higher value means a better explanation (e.g., redefining the sufficiency to be the negative of its original form). We formalize the concept of solvability as follows:

Definition 3.1. For a metric m and an input x , an explanation e^* solves the metric m if $m(x, e^*) \geq m(x, e)$ for all $e \in \mathbb{R}^L$. We also call e^* the *m-solving* explanation.

Notably, there are already two explanation-solving-metric cases among the ones in Sec. 2.

Theorem 1. The occlusion explainer solves the DF_{MIT} and Rank_{Del} metrics.

The proof follows from the definition of the explainer and the two metrics. Occlusion explainer defines token importance as the prediction change when each the token is individually removed, thus the most important token is the one that induces the largest change, which makes it most likely to flip the decision under DF_{MIT} . In addition, because token importance is defined as the model prediction change, its rank correlation with the latter (i.e., Rank_{Del}) is maximal at 1.0.

Thm. 1 highlights an important question: if we take DF_{MIT} or Rank_{Del} as the metric (i.e., indicator) of explanation quality, why should we consider any other explanation, when the occlusion explanation provably achieves the optimum? A possible answer

is that the metrics themselves are problematic. For example, one can argue that the DF_{MIT} is too restrictive for overdetermined input: when redundant features (e.g., synonyms) are present, removing any individual one cannot change the prediction, such as for the sentiment classification input of “This movie is great, superb and beautiful.”

Nonetheless, the perceived quality of a metric can be loosely inferred from its adoption by the community, and the comprehensiveness and sufficiency metrics (DeYoung et al., 2020) are by far the most widely used. They overcome the issue of DF_{MIT} by also considering inputs with more than one token removed. Since a metric is scalar-valued, we combine comprehensiveness κ and sufficiency σ into comp-suff difference Δ , defined as (recall that a *lower* sufficiency value is better):

$$\Delta(x, e) = \kappa(x, e) - \sigma(x, e). \quad (9)$$

Again, we face the same question: if Δ is solvable, why should *any* heuristic explainers be used instead of the Δ -solving e^* ? In the next two sections, we seek to answer it by first proposing a beam search algorithm to (approximately) find e^* and then explore its various properties.

4 Solving Metrics with Beam Search

We first define two properties that are satisfied by some metrics: value agnosticity and additivity.

Definition 4.1. For an input $x = (x_1, \dots, x_L)$ with explanation $e = (e_1, \dots, e_L)$, we define the ranked importance as $r(x_l) = |\{e_i : e_i \leq e_l, 1 \leq i \leq L\}|$. In other word, the x_l with $r(x_l) = L$ is the most important, and that with $r(x_l) = 1$ is the least. A metric m is *value-agnostic* if for all e_1 and e_2 that induce the same ranked importance, we have

$$m(x, e_1) = m(x, e_2). \quad (10)$$

A value-agnostic metric has at most $L!$ unique values across all possible explanations for an input of length L . Thus, in theory, an exhaustive search over the $L!$ permutations of the list $[1, 2, \dots, L]$ is guaranteed to find the e^* that solves the metric.

Definition 4.2. A metric m is *additive* if it can be written in the form of

$$m(x, e) = \sum_{l=0}^L h(x, e^{(l)}), \quad (11)$$

for some function h , where $e^{(l)}$ reveals the attribution values of l most important features according to e but keeps the rest inaccessible.

Theorem 2. Comprehensiveness, sufficiency and their difference are value-agnostic and additive.

The proof is straightforward, by observing that both $\tilde{x}^{(l)}$ and $\hat{x}^{(l)}$ can be created from x and the ordering of $e^{(l)}$. In fact, all metrics in Sec. 2 are value-agnostic (but only some are additive).

A metric satisfying these two properties admits an efficient beam search algorithm to approximately solve it. As $e^{(l)}$ can be considered as a partial explanation that only specifies the top- l important features, we start with $e^{(0)}$, and try each feature as most important obtain $e^{(1)}$. With beam size B , if there are more than B features, we keep the top- B according to the partial sum. This extension procedure continues until all features are added, and top extension is then e^* . Alg. 1 documents the procedure, where $\text{ext}(e, v)$ extends e and returns a set of explanations, in which each new one has value v on one previously empty entry of e . Finally, note that e^* generated on Line 8 has entry values in $\{1, \dots, L\}$, but some features may contribute *against* the prediction (e.g., “This movie is truly innovative although slightly cursory.”). Thus, we post-process e^* by shifting all values by k such that the new values (in $\{1 - k, L - k\}$) maximally satisfy the sign of marginal contribution of each word (i.e., the sign of the occlusion saliency).

Algorithm 1: Beam search for finding e^* .

```

1 Input: beam size  $B$ , metric  $m$ , sentence  $x$ 
   of length  $L$ ;
2 Let  $e^{(0)}$  be an empty length- $L$  explanation;
3 beams  $\leftarrow \{e^{(0)}\}$ ;
4 for  $l = 1, \dots, L$  do
5   | beams  $\leftarrow \bigcup_{e \in \text{beams}} \text{ext}(e, L - l + 1)$ ;
6   | beams  $\leftarrow \text{choose\_best}(\text{beams}, B)$ ;
7 end
8  $e \leftarrow \text{choose\_best}(\text{beams}, 1)$ ;
9  $e^* \leftarrow \text{shift}(e)$ ;
10 return  $e^*$ ;

```

Without the additive property, beam search is not feasible due to the lack of partial metric values. However, Zhou et al. (2021) presented a simulated annealing algorithm (Kirkpatrick et al., 1983) to search for the optimal data acquisition order in active learning, and we can use a similar procedure to search for the optimal feature importance order. If the metric is value-sensitive, assuming differentiability with respect to the explanation value, meth-

ods such as gradient descent can be used. Since we focus on comprehensiveness and sufficiency in this paper, the development and evaluation of these approaches are left to future work.

5 Experiments

We investigate various properties of the beam search explainer vs. existing heuristic explainers, using the publicly available `textattack/roberta-base-SST-2` model on the SST dataset (Socher et al., 2013) as a case study. The sentiment value for each sentence is a number between 0 (very negative) and 1 (very positive), which we binarize into two classes of $[0, 0.4]$ and $[0.6, 1]$. Sentences with sentiment values in middle are discarded. The average sentence length is 19, making the exhaustive search impossible. We use a beam size of 100 to search for Δ -solving explanation E^* . All reported statistics are computed on the test set.

Fig. 3 presents two explanations, with additional ones in Fig. 11 of App. C. While we need more quantitative analyses (carried out below) for definitive conclusions on its various properties, E^* explanations at least looks reasonable and is likely to help people understand the model by highlighting the high importance of sentiment-laden words.

Figure 3: Two E^* explanations. The shade of background color represents feature importance.

5.1 Performance on the Target Metric

We compare E^* to heuristic explainers on the Δ metric, with results shown in Tab. 1 along with the associated κ and σ . A random explanation baseline is included for reference. We can see that E^* achieves the best Δ , often by a large margin. It also tops the ranking separately for κ and σ , which suggests that an explanation could be optimally comprehensive and sufficient at the same time.

To visually understand how the model prediction changes during feature removal and insertion, we plot in Fig. 4 the values of $f(x) - f(\tilde{x}_e^{(l)})$ and $f(x) - f(\hat{x}_e^{(l)})$ (i.e., the summands in Eq. 1 and 2), as a function of l/L . The left panel shows the curves averaged across all test set instances, and the right panel shows those for a specific instance. κ

Explainer	Comp κ \uparrow	Suff σ \downarrow	Diff Δ \uparrow

SHAP	0.612	0.034	0.578
Occl	0.509	0.040	0.469

E*	0.740	0.020	0.720
Random	0.218	0.212	0.006

Table 1: Comprehensiveness, sufficiency and their difference for various explainers.

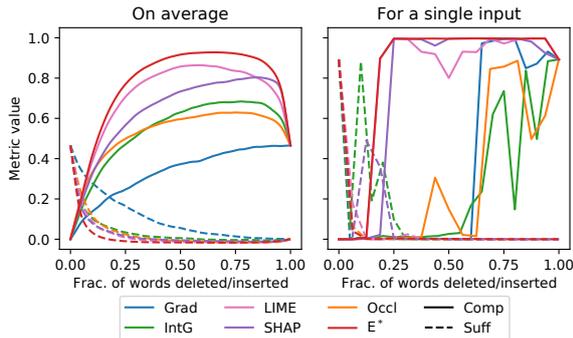

Figure 4: Comprehensiveness and sufficiency curves for the beam search optimal explainer vs. others.

and σ are thus the areas under the solid and dashed curves respectively. The curves for E* dominate the rest, and, on individual inputs, are also much smoother than those for other explanations.

One concern for beam search is its efficiency, especially compared to those that only require a single pass of the model such as the vanilla gradient. However, we note that explanations, unlike model predictions, are rarely used in real-time decision making. Instead, they are mostly used for debugging and auditing purposes, and incurring a longer generation time to obtain a higher-quality explanation is often beneficial. On a single RTX3080 GPU card without any in-depth code optimization, the metric values and time costs for various beam sizes are presented in Tab. 2, with statistics for the best explainer LIME also listed for comparison.

Expectedly, the metric values increase with increasing beam size, but the improvement is meager after 10 beams. More importantly, beam search is

B	1	5	10	20	50	100	LIME
κ	0.717	0.731	0.734	0.736	0.739	0.740	0.682
σ	0.020	0.020	0.020	0.020	0.020	0.020	0.033
Δ	0.697	0.711	0.714	0.716	0.719	0.720	0.649
T	0.38	0.77	1.15	1.72	2.85	4.37	4.75

Table 2: Effect of beam size B on κ , σ , Δ and computation time T (in seconds), compared against the statistics of the best heuristic explainer LIME.

not slow – it is still faster than LIME even with 100 beams, and the single-beam version outperforms LIME by a decent margin while being more than 10 times faster. Thus, these results establish that *if we take comprehensiveness and sufficiency as the quality metrics*, there is really no reason not to use the beam search explainer directly.

5.2 Performance on Other Metrics

Sec. 2 lists many metrics that all operationalize the same principle that changing important features should have large impact on model prediction, but in different ways. A potential argument against the explicit beam search optimization is the fulfillment of Goodhart’s Law: E* overfits to the metric by exploiting its realization (i.e., Eq. 1 and 2) of this principle and not truly reflecting its “spirit.”

To establish the legitimacy of this opposition, we evaluate all the explainers on the remaining four metrics in Sec. 2, and present the results in Tab. 3.

Explainer	DF _{MIT} \uparrow	DF _{Frac} \downarrow	Rank _{Del} \uparrow	Rank _{Ins} \uparrow
Grad	10.5%	54.5%	0.162	0.521
IntG	16.9%	39.6%	0.369	0.468
LIME	25.5%	28.1%	0.527	0.342
SHAP	23.0%	36.1%	0.369	0.458
Occl	26.4%	40.6%	1.000	0.396

E*	25.0%	25.2%	0.438	0.423
Random	3.4%	72.3%	0.004	0.599

Table 3: Performance on non-target metrics of the beam search optimal explainer vs. others.

Since the occlusion explainer solves DF_{MIT} and Rank_{Del} (Thm. 1), it ranks the best on these two metrics, as expected. Nonetheless, E* still ranks competitively on these two metrics and comes out ahead on DF_{Frac}. The only exception is Rank_{Ins}, on which the random explanation surprisingly performs the best. We carefully analyze it in App. D and identify a fundamental flaw in this metric.

Last, note that we can also incorporate any of these metrics into the objective function (which already contains two metrics: κ and σ), and search for E* that performs overall the best, if so desired. We leave this investigation to future work.

5.3 Explainer “Attacking” the Model

Another concern is that the search procedure may overfit to the model. Specifically, removing a word w in a partial sentence $\tilde{x}_e^{(l)}$ drastically changes the model prediction but does not have the same effect for most other $\tilde{x}_e^{(l')}$. This makes E* assign w an

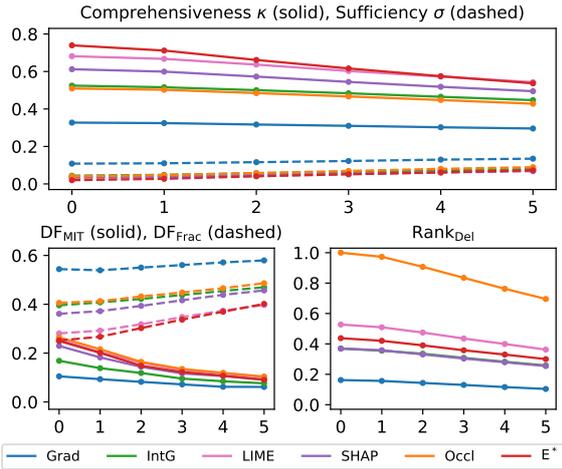

Figure 5: Metric values for explanations under different levels of perturbation represented by s on the x -axis.

overly high attribution, as w only happens to have a high impact in one particular case. By contrast, explainers like LIME and SHAP automatically avoid this issue by computing the average contribution of w on many different partial sentences.

We test this concern by locally perturbing the explanation. If E^* uses many such “adversarial attacks,” we should expect its metric values to degrade sharply under perturbation, as the high-importance words (according to E^*) will no longer be influential in different partial sentence contexts.

To perturb the explanation, we first convert each explanation e to its ranked importance version e_r using $r(\cdot)$ in Def. 4.1, which does not affect any metric as they are value-agnostic. Then we define the perturbed rank by adding to each entry of e_r an independent Gaussian noise: $e'_r = e_r + n$ with $n \sim \mathcal{N}(\mathbf{0}, s^2)$. Thus, two words x_i and x_j with $r(x_i) > r(x_j)$ have their ordering switched if $r(x_i) - r(x_j) < n(x_j) - n(x_i)$. A visualization of the switching with different s is in Fig. 12 of App. E.

Fig. 5 plots the metrics under different s values (Rank_{Ins} not shown due to its intrinsic issue discussed in App. D). Everything degrades to various extents. Although E^* degrades slightly faster than the rest on κ and DF_{Frac} (and on par on others), it still achieves best results even at $s = 4$, with many order switches (Fig. 12), and a faster degradation is reasonable anyway for metrics with better starting values (c.f. occlusion on Rank_{Del}).

The evidence suggests that there is at most a slight model overfitting phenomenon, as E^* remains comparable to other explainers under quite severe perturbation. Furthermore, we can incorporate perturbation robustness into metric solving to obtain an E^* that degrade less, similar to adver-

sarial training (Madry et al., 2018). We leave the exploration of this idea to future work.

App. F describes another assessment of model overfitting, though with a mild assumption and relying on word-level sentiment scores provided by the SST dataset. Similar conclusions are reached.

5.4 Ground Truth Recovery

For a model trained on a natural dataset, its ground truth working mechanism is rarely available – in fact, arguably the very purpose of interpretability methods is to uncover it. Thus, a series of work (e.g., Zhou et al., 2022a) proposed methods to modify the dataset such that a model trained on the new dataset has to follow a certain working mechanism to achieve high performance, which allows for evaluations against the known mechanism.

Ground Truth Definitions We construct three types of ground truths – short additions, long additions and replacements. First, we randomize the label to $\hat{y} \sim \text{Unif}\{0, 1\}$ so that the original input features are *not* predictive (Zhou et al., 2022a).

For the two addition types, a word or a sentence is inserted randomly to either the beginning or the end of the input. The inserted text is randomly chosen from the the sets in Tab. 4.

For the replacement type, each word in the input is checked against the list of replacement word sets in Tab. 5, and if the word belongs to one of the

Type	$\hat{y} = 0$	$\hat{y} = 1$
Short	terrible, awful, disaster, worst, never	excellent, great, fantastic, brilliant, enjoyable
Long	A total waste of time. Not worth the money! Is it even a real film? Overall it looks cheap.	I like this movie. This is a great movie! Such a beautiful work. Surely recommend it!

Table 4: Set of insertions for the addition type according to the new label \hat{y} . The words are comma-separated for “short”, and each line is one piece of text for “long”.

Replacement word sets	$\hat{y} = 0$	$\hat{y} = 1$
a, an, the	a	the
in, on, at	in	on
I, you	I	you
he, she	he	she
can, will, may	can	may
could, would, might	could	might
(all forms of <i>be</i>)	is	are
(all punctuation marks)	(period)	(comma)

Table 5: Replacement word sets and their target words.

Explainer	Short Addition				Long Addition				Replacement			
	Sym		Asym		Sym		Asym		Sym		Asym	
	Pr ↑	NR ↓	Pr ↑	NR ↓	Pr ↑	NR ↓	Pr ↑	NR ↓	Pr ↑	NR ↓	Pr ↑	NR ↓
Grad	0.91	0.06	0.51	0.08	0.70	0.37	0.77	0.30	0.50	0.75	0.51	0.74
IntG	0.82	0.10	0.60	0.21	0.60	0.76	0.70	0.55	0.49	0.74	0.48	0.74
LIME	1.00	0.06	1.00	0.06	0.72	0.60	0.84	0.32	0.63	0.65	0.54	0.71
SHAP	0.98	0.07	1.00	0.06	0.61	0.83	0.75	0.98	0.65	0.67	0.62	0.68
Occl	1.00	0.06	1.00	0.06	0.72	0.59	0.79	0.42	0.40	0.80	0.40	0.85
E*	1.00	0.06	1.00	0.06	0.67	0.64	0.92	0.38	0.60	0.66	0.54	0.73
Random	0.06	0.54	0.07	0.53	0.25	0.89	0.24	0.88	0.27	0.85	0.28	0.85

Table 6: Average values of precision and normalized rank of the ground truth correlated words for each explainer.

set, it is changed according to the new label \hat{y} . On average, 27% of input words are replaced.

We call these modifications symmetric since inputs corresponding to both $\hat{y} = 0$ and $\hat{y} = 1$ are modified. We also define the asymmetric modification, where only inputs with $\hat{y} = 1$ are modified, and those with $\hat{y} = 0$ are left unchanged.

Metrics We use the two metrics proposed by Bastings et al. (2022): precision and normalized rank. First, we define the ground truth correlated words. For the two addition types, they are the inserted words. In the asymmetric case, instances with $\hat{y} = 0$ does not have any words added, so we exclude them in metric value computation.² For the replacement type, they are the words that are in the replacement set (but not necessarily replaced).

Let W be the set of ground truth correlated words. Using ranked importance $r(\cdot)$ in Def. 4.1, precision and normalized rank are defined as

$$\text{Pr} = |\{w \in W : r(w) > L - |W|\}|/|W|,$$

$$\text{NR} = (L - \min\{r(w) : w \in W\} + 1)/L.$$

Precision is the fraction of ground truth words among the the top- $|W|$ ranked words, and normalized rank is the lowest rank among ground truth words, normalized by the length L of the input. Both values are in $[0, 1]$, and higher precision values and lower normalized rank values are better.

Results Tab. 6 presents the test set Pr and NR values. Many explainers including E* score perfectly on short additions, but all struggle on other types. Nonetheless, E* still ranks comparably or favorably to other methods. Its largest advantage shows on the asymmetric long addition, because this setup matches with the computation of κ and σ : E* finds the most important words to remove/add to maximally change/preserve the original prediction, and

²This also highlights an intrinsic limitation of feature attribution explanations: they cannot explain that the model predicts a class because certain features are *not* present.

those words are exactly the ground truth inserted ones. For replacement and symmetric addition, the search procedure does not “reconstruct” inputs of the other class, and E* fails to uncover the ground truth. This finding suggests a mismatch between metric computation and certain ground truth types.

Conversely, vanilla gradient performs decently on ground truth types other than short addition, yet ranks at the bottom on most quality metrics (Tab. 1 and 3), again likely due to the mismatch.

In fact, this evaluation is fundamentally different from the rest in its *non-solvability*, specifically due to its use of privileged information. To understand this point, let us first compare the evaluation of model *prediction* to that of model *explanation*, as illustrated in Fig. 6. The former runs the model on the input, receives the prediction, and compares it with the ground truth label, which is emphatically *not* available to the model under evaluation. By contrast, no such privileged information exists when computing interpretability metrics, allowing

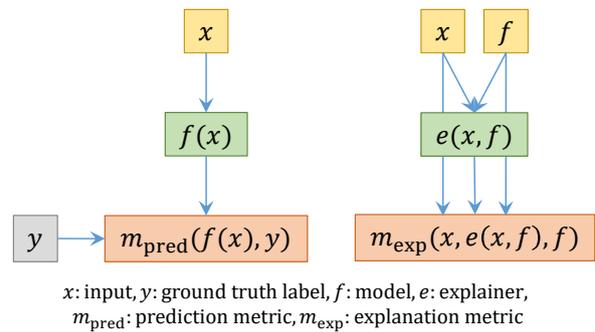

Figure 6: The complete evaluation diagrams for model predictions (left) and explanations (right). Green boxes are the model and explainer under evaluation, which have access to the information in yellow, and orange boxes are the evaluators. Notably, prediction evaluation (e.g., accuracy) uses the ground truth label y not accessible to the model, but no such privileged information is used by the interpretability evaluation.

the explainer to directly solve them. In this ground truth recovery evaluation, we employ similar privileged information (i.e., induced ground truth model working mechanism) by dataset modification and model retraining. However, as discussed by Zhou et al. (2022a), such evaluations are limited to the range of ground truths that could be induced.

6 Discussion

Definition-Evaluation Duality Our investigation demonstrates that some evaluation metrics can be used to find high-quality explanations, defined as the optimizers of the metrics. Conversely, we could also use any explanation definition d as an evaluation metric m . A very simple one would be $m(x, e) \doteq -\|e - d(x)\|$, where e is the explanation under evaluation, $d(x)$ is the “reference explanation” and $\|\cdot\|$ is a suitably chosen distance metric. It is obvious that $d(x)$ itself achieves the optimal evaluation metric value.

Therefore, in theory, there should not be a difference of using a concept as definition vs. evaluation, but in practice, we almost always see some used mainly as definitions and others as evaluations (Fig. 2). A major reason of not considering to use evaluations as definitions could be the presumed intractability of the optimization, which is experimentally refuted in this paper, as the beam search demonstrates its efficacy and efficiency.

Conversely, why do we not see more definitions (e.g., gradients and LIME) used as evaluations? Such an attempt may sound trivial yet unjustifiable at the same time: trivial because it is equivalent to claiming that the corresponding explainer definition is the best, which is in turn a seemingly unjustifiable circular logic.

More importantly, we motivate a new research direction opened up by the duality concept. Traditionally, definitions and evaluations have been considered and developed separately, but duality suggests that any interpretability concept can be used as both. Thus, we propose that we should focus on studying the *intrinsic* properties of these concepts, independent of their usage as one or another. For example, are some concepts inherently superior for model explanations than others? How can we measure the similarity between two concepts? What does the space of these concepts look like? None of them are currently answerable due to a complete lack of formalization, but research on it could lead to a much deeper understanding of local explanations.

Demonstrable Utility Given the duality, how should we evaluate explanations? Fundamentally, local explanations are used for model understanding (Zheng et al., 2022; Zhou et al., 2022b), and we advocate for evaluating *demonstrable utility*: the presence of an explanation compared to its absence, or the newly proposed explanation compared to existing ones, should lead to a measurable difference in some practically beneficial aspect.

For example, people use explanations to identify spurious correlation during development, audit fairness before deployment, and assist human decision makers during deployment. However, recent findings cast doubt on the feasibility of model explanations to support any of these use cases (Bansal et al., 2021; Jia et al., 2022; Zhou et al., 2022a).

Demonstrating such utilities would bypass discussions of solvability and directly assert their usefulness (Chen et al., 2022). The examples listed here are by no means comprehensive, and a systematic taxonomy is valuable. Furthermore, it is likely that no single explainer is a one-size-fit-all solution. More refined knowledge of the strengths and weaknesses of each method in supporting different aspects of model understanding is highly desirable.

7 Conclusion

We study the relationship between definitions and evaluations of local explanations. We identify the *solvability* property of evaluation metrics, such that for each evaluation metric, there is an explicit search procedure to find the explanation that achieves the optimal metric value. In other words, every evaluation admits a definition that *solves* it.

Compared to the current practice of defining a explainer and then evaluating it on a metric, solvability allows us to directly find the explanation that optimizes the target metric and guarantee a very favorable evaluation outcome. In this paper, we investigate the feasibility of this process. First, we propose to use beam search to find the explanation E^* that optimizes for comprehensiveness and sufficiency (DeYoung et al., 2020). Then, in a suite of evaluations, we find E^* performing comparably or favorably to existing explainers such as LIME.

Therefore, for practitioners, we recommend using the proposed explainer for computing local model explanations and provide the Python `solveX` package for easy adoption (App. A). For researchers, we propose a definition-evaluation duality inspired by solvability, which opens up many new research directions.

Limitations and Ethical Impact

The focus of our paper is to investigate the search-based explanation that explicitly optimizes a target quality metric. While the results suggest that it is comparable or favorable to existing heuristic explainers on various technical aspects, its societal properties have not been studied. For example, [Ghorbani et al. \(2019\)](#) showed that many heuristic explanations can be easily manipulated and [Slack et al. \(2020\)](#) demonstrated that discriminative models can be carefully modified such that their discrimination is hidden by heuristic explanations. It is possible that same issues exist for the search-based explanation, and thus we advise to carefully study them before deployment.

Another limitation of this approach is that E* explainer only produces rankings of feature importance, rather than numerical values of feature importance. In other words, E* does not distinguish whether one feature is only slightly or significantly more important than another. By comparison, almost all heuristic explainers output numerical values (e.g., magnitude of gradient). Other than the ease of search in the ranking space than the numerical value space, we give three additional reasons. First, the utility of actual values, beyond the induced rankings, has not been well studied in the literature. In addition, many popular explanation toolkits (e.g., [Wallace et al., 2019](#)) even defaults to top-*k* visualization. Last, popular evaluation metrics rarely consider values either, suggesting that there currently lack guiding principles and desiderata for these values. Moreover, if and when such value-aware metrics are widely adopted, we could augment our optimizer with them or incorporate them into a post-processing fix without affecting the ranking, similar to the shift operation done on Line 9 of Alg. 1.

A The Python `solvex` Package

We release the Python `solvex` package implementing explainer in a model-agnostic manner. The project website at <https://yilunzhou.github.io/solvability/> contains detailed tutorials and documentation. Here, we showcase three additional use cases of the explainer.

To explain long paragraphs, feature granularity at the level of sentences may be sufficient or even desired. `solvex` can use `spaCy`³ to split a paragraph into sentences and compute the sentence-level attribution explanation accordingly. As an explanation, Fig. 7 shows an explanation for the prediction on a test instance in the Yelp dataset (Asghar, 2016) made by the `albert-base-v2-yelp-polarity` model.

Contrary to other reviews, I have zero complaints about the service or the prices. I have been getting tire service here for the past 5 years now, and compared to my experience with places like Pep Boys, these guys are experienced and know what they're doing. Also, this is one place that I do not feel like I am being taken advantage of, just because of my gender. Other auto mechanics have been notorious for capitalizing on my ignorance of cars, and have sucked my bank account dry. But here, my service and road coverage has all been well explained - and let up to me to decide. And they just renovated the waiting room. It looks a lot better than it did in previous years.

Figure 7: A sentence-level explanation on a Yelp test instance. Red color indicates positive contribution.

This package can explain image predictions with superpixel features (similar to LIME (Ribeiro et al., 2016)). Fig. 8 shows the explanation for the top prediction (Class 232: Border Collie, a dog breed) by the ResNet-50 (He et al., 2016) trained on ImageNet (Deng et al., 2009).

Figure 8: An explanation for the top prediction (Class 232: Border Collie, a dog breed) on an image made by a ResNet-50 model trained on ImageNet. Red color indicates positive contribution.

Last, it can also explain models trained on tabular datasets with both categorical and numerical features. For a random forest model trained on the Adult dataset (Kohavi and Becker, 1996), Fig. 9 shows the attribution on each feature that contributes to the class 0 (i.e., income less than or equal to \$50K). Note that a more positive attribution value indicates that the feature (e.g. age or relationship) contributes more to the *low* income prediction.

³<https://spacy.io/>

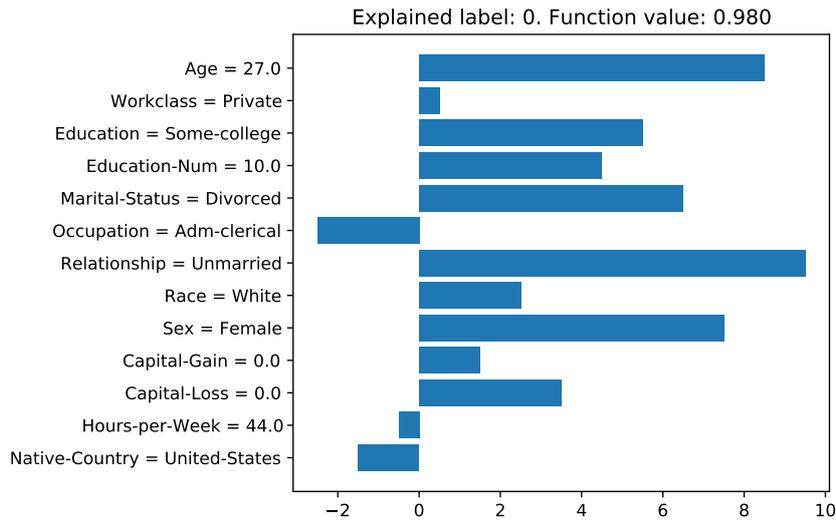

Figure 9: An explanation for the low income prediction made by a random forest model on the Adult dataset.

B The Definition-Evaluation Spectrum and Its Various Concepts

We describe the reasoning of assigning each concept to its location on the definition-evaluation spectrum (Fig. 2, reproduced as Fig. 10 below), as currently perceived by the community according to our understanding. Note that the discussion is unavoidably qualitative, but we hope that it illustrates the general idea of this spectrum.

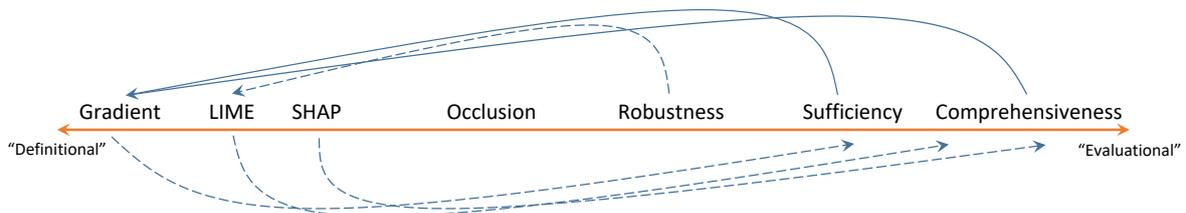

Figure 10: A definition-evaluation spectrum for various interpretability concepts, reproduced from Fig. 2.

We start on the definition side, where the gradient saliency (Simonyan et al., 2013; Li et al., 2016a) is a classic feature attribution definition but, to the best of our knowledge, has never been used in any evaluation capacity. Moving towards the evaluation side, we have LIME (Ribeiro et al., 2016), which is again used mainly to define explanations (as linear regression coefficients), but the notion of local fidelity introduced by LIME has been occasionally used to evaluate other explainers as well (Plumb et al., 2018). Similar to LIME, SHAP (Lundberg and Lee, 2017) defines explanations as those that (approximately) satisfy the Shapley axioms (Roth, 1988), which can also be used to evaluate how well a certain explanation performs with respect to these axioms (Zhang et al., 2019). Next up we have the occlusion concept, which, as seen in Sec. 2, can be used as one explainer definition, Occl (Zeiler and Fergus, 2014; Li et al., 2016b), and two (not so popular) evaluations, DF_{MIT} (Chrysostomou and Aletras, 2021) and $Rank_{Del}$ (Alvarez-Melis and Jaakkola, 2018b).

Further on the evaluation side, we now encounter concepts that are more often used for evaluations than definitions. Robustness (Ghorbani et al., 2019) evaluates the similarity between explanations among similar inputs and a higher degree of similarity is often more desirable (Alvarez-Melis and Jaakkola, 2018a). However, this robustness desideratum is incorporated explicitly into some explainers, such as via the noise aggregation in SmoothGrad (Smilkov et al., 2017). On the right-most end we have sufficiency and comprehensiveness (DeYoung et al., 2020), which evaluates whether keeping a small subset of features could lead to the original model prediction, or removing it could lead to a large drop in model prediction. They are arguably the most popular among various evaluation metrics, and have been

repeatedly proposed under different names such as the area over perturbation curve (AoPC) (Samek et al., 2016) and insertion/deletion metrics (Petsiuk et al., 2018). Using such these two ideas for definitions are relatively rare, with one notable exception of smallest sufficient/destroying regions (SSR/SDR) proposed by (Dabkowski and Gal, 2017).

Overall, it is clear that the community considers certain concepts more for definitions and others more for evaluations, which motivates the investigation for this paper and future work: can we swap the definition/evaluation roles, and if so, what are the implications?

C Additional Qualitative Examples of the E* Explanation

Fig. 11 presents more visualizations of E* explanations. These examples suggest that E* mostly focus on words that convey strong sentiments, which is a plausible working mechanism of a sentiment classifier.

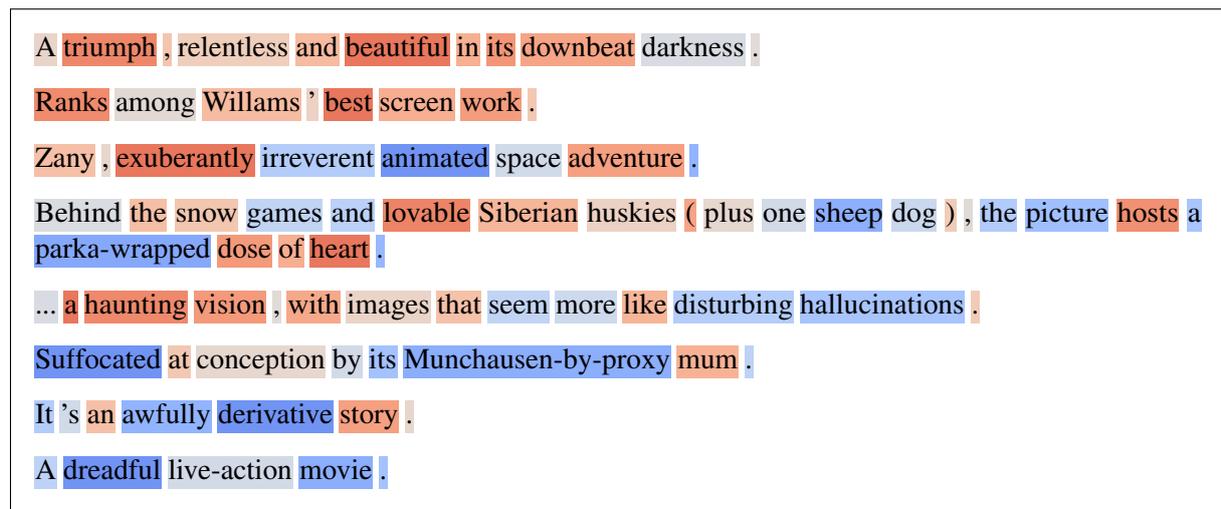

Figure 11: More E* explanations. The shade of background color represents feature importance.

D An Analysis on the Rank_{Ins} Metric

As introduced in App. 2, Rank_{Del} evaluates the monotonicity of the model prediction curve when more important features are successively inserted into an empty input. While this expectation seems reasonable, it suffers from a critical issue due to the convention in ranking features: if a feature contributes *against* the prediction, such as a word of sentiment opposite to the prediction (e.g., a positive prediction on “Other than the story plot being a bit boring, everything else is actually masterfully designed and executed.”), it should have negative attribution and the convention is to put them lower in the rank (i.e., less important) than those have zero contributions. This implementation leads to the correct interpretation of all other metric values.

However, under this convention, the first few words added to the empty input should decrease the model prediction and then increase it, leading to a U-shaped curve. In fact, it is the comprehensiveness curve shown in Fig. 4, flipped both horizontally (because features are inserted rather than removed) and vertically (because the plotted quantity is the model prediction rather than change in prediction). Thus, a deeper U-shape should be preferred, but it is less monotonic. This also explains why the random attribution baseline achieves such a high ranking correlation: as we randomly add features from the empty string to the full input, on average the curve should be a more or less monotonic interpolation between model predictions on empty and full inputs, which has better monotonicity rank correlation than the U-shape.

It is not clear how to fix the metric. Previous works that proposed (Luss et al., 2021) or used (Chan et al., 2022) this metric often ignored the issue. One work (Arya et al., 2019) filtered out all features of negative attribution values and evaluate the rank correlation only on the rest. This, however, is easily manipulatable by an adversary. Specifically, an explainer could shift all attribution values down such that only the most positive one has a non-negative value. This change results in a perfect correlation as long as

removing most positive feature induces a decrease in model prediction – an especially low requirement to satisfy. Empirically, we found that inserting features based on their (unsigned) magnitude barely affects the result either. Thus, we argue that this metric is not a good measurement of explanation quality.

E Visualization of Perturbation Effects

Fig. 12 visually presents the random perturbation, with different standard deviation s of the Gaussian noise. In each panel, the top row orders the features by their ranked importance, from least important on the left to most on the right, and the bottom row orders the features with perturbed ranked importance, with lines connecting to their original position. For example, in the top panel for $s = 1$, the perturbation swaps the relative order of the two least important features on the left.

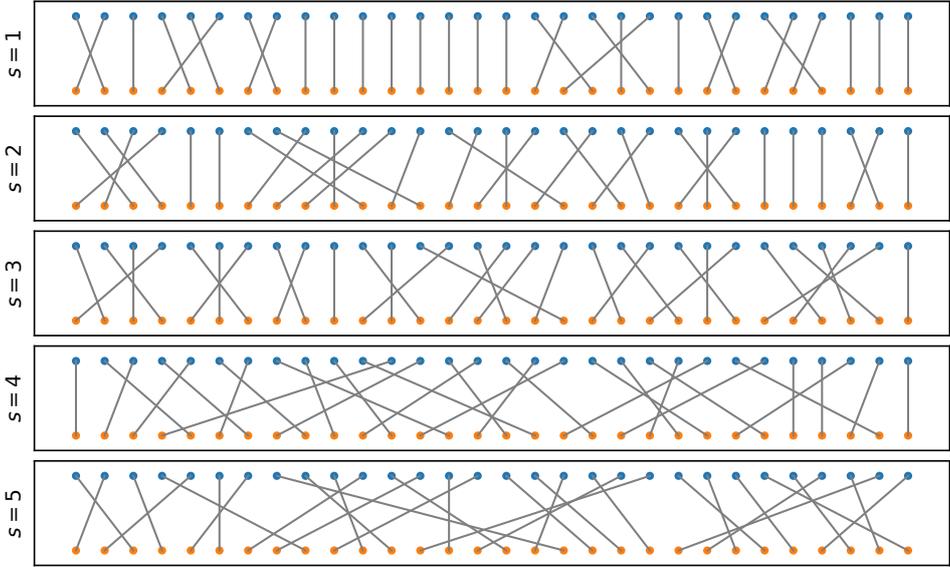

Figure 12: Visualization of rank perturbation under different values of s .

F Another Assessment on the Explainer-Attacking-Model Behavior

We describe another experiment to assess whether the explanations exploit the adversarial vulnerability of the model. While it is possible that the model could use some shortcuts (Geirhos et al., 2020), we would expect it to predominantly use sentiment-conveying words, as it achieves high accuracy and no such shortcuts are known for the dataset. In this case, we should expect an explainer that does not adversarially exploit the model to give attributions for words correlated with their sentiment values, while an explainer that attacks the model would rate words that are “adversarial bugs” to be more important.

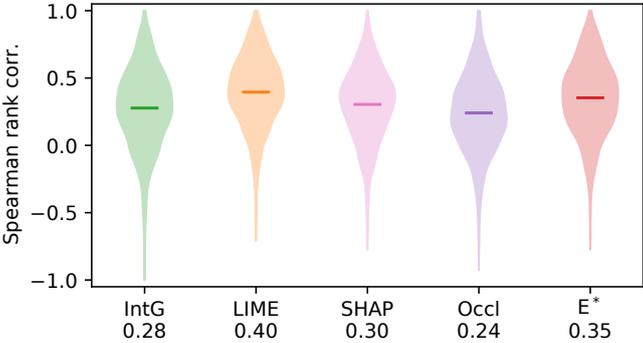

Figure 13: Spearman rank correlation coefficient between intrinsic word polarity score and attribution value.

Conveniently, the SST dataset provides human annotations of the polarity score between 0 and 1 for each word, where 0 means very negative, 1 means very positive, and 0.5 means neutral. We compute the alignment between the attribution values (for the positive class) and this score for each word. Given a sentence $x = (x_1, \dots, x_L)$ with explanation $e = (e_1, \dots, e_L)$ and word polarity score $s = (s_1, \dots, s_L)$, the alignment is defined as the Spearman rank correlation coefficient $\rho(e, s)$. Since the vanilla gradient only produces non-negative values, it is impossible to identify whether a word contributes *to* or *against* the positive class, and we exclude it from the analysis.

Fig. 13 plots the distribution of rank correlations among the test set instances, with the average shown as the bar and also annotated on the horizontal axis. Although no method achieves very high alignment, E* is the second-highest, after LIME. Thus, giving out assumption that high-polarity words are the indeed genuine signals used by the model for making predictions, we can conclude that E* does not adversarially exploit the model for its vulnerability any more severely than the heuristic explainers.

Reliable Gradient-free and Likelihood-free Prompt Tuning

Abstract

Due to privacy or commercial constraints, large pre-trained language models (PLMs) are often offered as black-box APIs. Fine-tuning such models to downstream tasks is challenging because one can neither access the model’s internal representations nor propagate gradients through it. This paper addresses these challenges by developing techniques for adapting PLMs with only API access. Building on recent work on soft prompt tuning, we develop methods to tune the soft prompts without requiring gradient computation. Further, we develop extensions that in addition to not requiring gradients also do not need to access *any* internal representation of the PLM beyond the input embeddings. Moreover, instead of learning a single prompt, our methods learn a distribution over prompts allowing us to quantify predictive uncertainty. Ours is the first work to consider uncertainty in prompts when only having API access to the PLM. Finally, through extensive experiments, we carefully vet the proposed methods and find them competitive with (and sometimes even improving on) gradient-based approaches with full access to the PLM.

1 Introduction

Pre-trained language models (PLMs) are versatile learners and demonstrate impressive few-shot capabilities (Brown et al., 2020) and promising performance (Radford et al., 2018; Devlin et al., 2018; Raffel et al., 2020; Lewis et al., 2019) on various downstream tasks such as text classification (Kowsari et al., 2019), commonsense reasoning (Zellers et al., 2018), question answering (Rajpurkar et al., 2016), and machine translation (Bahdanau et al., 2014).

The conventional approach to adapting PLMs to downstream tasks involves fine-tuning the model (Peters et al., 2018; Devlin et al., 2018). Although fine-tuning is effective, it can be challenging to do in practice. First, fine-tuning large

language models are compute and memory intensive, e.g., a large model like GPT-3 (Brown et al., 2020) contains billions of parameters. Further, it is inefficient to adapt a PLM to a large number of downstream tasks since each task would require storing a copy of model parameters.

Prompt tuning alleviates these issues by providing an efficient way to adapt a PLM to a downstream task. It only learns a small number of prompt parameters while keeping the large PLM frozen but still achieves comparable performance to fine-tuning the entire PLM (Liu et al., 2021a; Shin et al., 2020; Lester et al., 2021; Liu et al., 2021c).

Although more efficient than traditional fine-tuning, prompt tuning still requires the propagation of gradients through the entire PLM. Beyond being computationally expensive, this may not be possible due to privacy risks or legal and commercial constraints. In fact, large PLMs are often only made available in the form of black-box APIs (Brown et al., 2020). Motivated by these observations, a recent line of research (Sun et al., 2022b,a) has started exploring *gradient-free* approaches to prompt tuning. BBT (Sun et al., 2022b) optimizes continuous prompt by leveraging the derivative-free optimization algorithms, and BBTv2 (Sun et al., 2022a) improves over BBT by optimizing multiple deep prompts at various intermediate layers of PLM. Although these approaches are *gradient-free*, they still assume that intermediate layers of the model being tuned are accessible.

Moreover, when deploying an NLP model in a real-world setting, it is inevitable to encounter unexpected scenarios. For example, the test data to be predicted might originate from out-of-distribution resources (Arora et al., 2021). For the model to be useful in such scenarios, it is essential that the model is able to quantify the uncertainty associated with its predictions and that these uncertainties are well-calibrated.

To this end, here we further push the limits of *gradient-free* prompt tuning in two aspects:

- First, we develop methods that add a layer of uncertainty quantification (UQ) aimed toward more reliable prompt tuning. We show that this improves calibration and UQ performance on several tasks, including selective classification and text Out-of-Distribution (OOD) detection.
- Second, we consider a much stricter notion of black-box setting, i.e., *likelihood-free* setting, where the PLM-based API does not provide probability scores or *logits* as the output, but only the discrete outcome labels. We propose a simulation-based-inference approach that yields competitive performance in the stricter setting even compared to the SOTA prior works on the relaxed black-box setting.

2 Background

Prompt Tuning Prompting, in the simplest form, involves appending manually curated words or tokens to a text input such that the language model, conditioned on such an augmented input, generates the desired output (Liu et al., 2021a). Such curated prompts were shown to be much more efficient than fine-tuning the entire PLM (Brown et al., 2020). However, curating good prompts for a new task can be difficult without deep domain expertise (Liu et al., 2021c; Zhao et al., 2021). One solution is to search the space of discrete prompts (Shin et al., 2020; Gao et al., 2020). This search in discrete space can be a hard optimization problem. Recent works instead learn continuous or soft prompts in the form of a small number of free parameters injected into certain layers of the PLM (Li and Liang, 2021). In this paper, we work with the simpler form of continuous *prompt tuning*, where the free parameters are only injected in the embedding layer (Lester et al., 2021).

Gradient-free Prompt Tuning *Gradient-free* prompt tuning aims to learn the continuous prompt without the propagating gradients through the PLM. BBT (Sun et al., 2022b) utilizes derivative-free optimization algorithms to optimize the continuous prompt. BBTv2 (Sun et al., 2022a) extends BBT by incorporating the idea of *deep prompt tuning*, which optimizes the deep prompt injected at additional intermediate layers of the PLM. Since our goal is to treat the PLM as a black-box, deep

prompt tuning is out of the scope of this work. We instead focus on the problem setting of the original BBT (Sun et al., 2022b) that learns a single prompt at the input layer.

Beyond point-estimates of prompts Many applications demand accurate quantification of uncertainty in predictions. This can be achieved in the prompt-tuning setting by not just learning a point estimate of the prompts but also inferring a distribution over the prompts for a given downstream task. In a non-black-box setting, to infer such a distribution, we can apply classical frequentist or Bayesian approaches. Although a few recent works focus on uncertainty quantification in NLP applications (Arora et al., 2021; Xiao and Wang, 2019; De-sai and Durrett, 2020; Kumar and Sarawagi, 2019), quantifying uncertainty in prompt-tuned large language models remains a severely under explored area. Our paper is the first to explore prompt uncertainty in gradient-free settings.

Simulation-based Inference Classic approaches for statistical inference mentioned above are intractable when the likelihood function is not accessible. The problem of inferring parameters of such a black-box model, called Simulation-based Inference (SBI) (Cranmer et al., 2020), is gaining popularity. Traditional SBI approaches include Approximate Bayesian Computation (ABC) (Beaumont et al., 2002; Marjoram et al., 2003; Marin et al., 2012; Beaumont et al., 2009; Bonassi and West, 2015) and synthetic likelihood (SL) (Wood, 2010; Turner and Sederberg, 2014). More recently, the neural density estimation-based approaches utilize the powerful deep neural network density estimator to directly learn the likelihood, i.e., Sequential Neural Likelihood Estimation (SNLE) (Lueckmann et al., 2017; Greenberg et al., 2019), or the likelihood ratio, i.e., Sequential Neural Ratio Estimation (SNRE) (Papamakarios et al., 2019), or the posterior, i.e., Sequential Neural Posterior Estimation (SNPE) (Hermans et al., 2020; Durkan et al., 2020).

3 Problem Formulation

In this paper, we focus on text classification and restrict ourselves to the few-shot learning setting considered in BBT (Sun et al., 2022b). Given a dataset $\mathcal{D} = (\mathbf{X}, \mathbf{Y}) = \{(\mathbf{x}_i, y_i)\}_{i=1}^N$ and a pre-trained language model (PLM) f , we aim to adapt f to predict the label y_* for an unseen text pas-

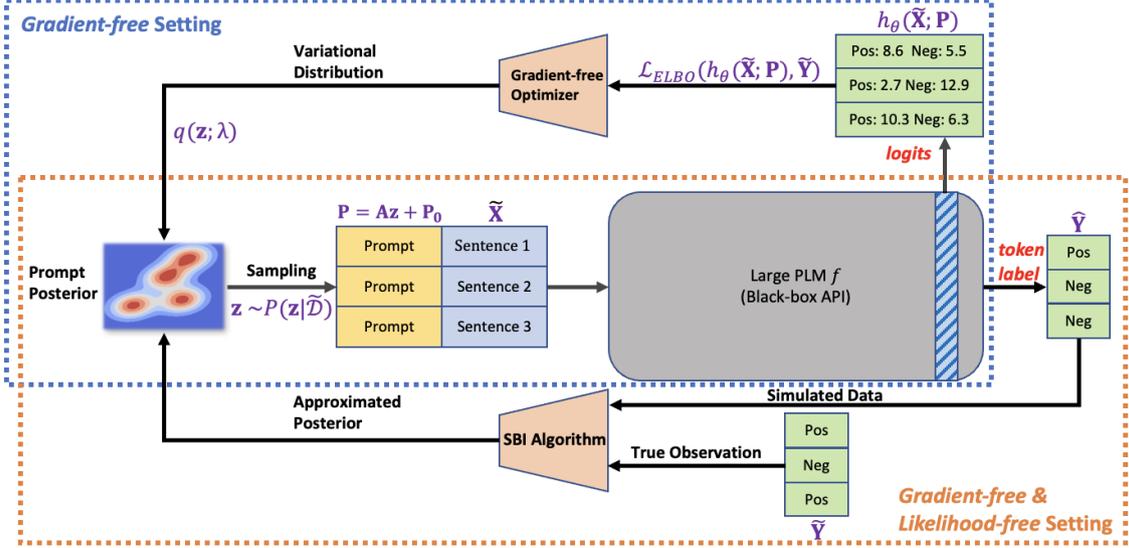

Figure 1: Our general goal is to estimate the posterior distribution of prompts. The *Gradient-free setting* uses the internal logits of PLM for optimization. Our proposed Gradient-free Variational inference approach utilizes the likelihood to compute the ELBO objective and leverage the gradient-free optimizer to optimize the variational distribution. The *Gradient-free and likelihood-free setting* can be formulated as an SBI problem, where the PLM is treated as a black-box simulator, and its output discrete outcome labels are the simulated data. The posterior samples can be efficiently approximated by the proposed ABC-SMC algorithm.

sage x_* . We formulate the classification task as a masked language modeling problem, where the input text x_i is converted into \tilde{x}_i via predefined templates, e.g., adding trigger words like “It was [MASK]”, and the labels y_i are mapped to label tokens \tilde{y}_i in the vocabulary such as “great” or “bad”. We denote this transformed dataset $\tilde{\mathcal{D}} = (\tilde{\mathbf{X}}, \tilde{\mathbf{Y}})$.

We use soft prompt tuning (Lester et al., 2021) to adapt f , i.e., we construct a continuous prompt embedding $\mathbf{P} \in \mathbb{R}^D$ and feed it along with the converted input text \tilde{x}_i to the PLM f to generate a label token, $\hat{y}_i = f(\tilde{x}_i; \mathbf{P})$, where the notation $\hat{y}_i = f(\tilde{x}_i; \mathbf{P})$ is short hand for $\hat{y}_i \sim \text{Cat}(\sigma(h_\theta(\tilde{x}_i; \mathbf{P})))$. Here, Cat denotes the Categorical distribution, σ is the softmax function, and θ represents the frozen parameters of the PLM. We use h_θ to denote all but the final layer of the PLM f . Finally, we aim to learn an optimal prompt

$$\mathbf{P}^* = \arg \min_{\mathbf{P}} - \sum_{i=1}^N \log \text{Cat}(\tilde{y}_i | \sigma(h_\theta(\tilde{x}_i; \mathbf{P}))). \quad (1)$$

This is just the standard cross-entropy loss and can be easily minimized using standard stochastic gradient based approaches provided (i) we can propagate gradients through the PLM f , and (ii) we can access the PLM’s logits, i.e., $h_\theta(\tilde{x}_i; \mathbf{P})$. The problem becomes substantially more challenging when these requirements are not satisfied.

When we are unable to propagate gradients

through f , we need to rely on *gradient-free* approaches to optimize Equation 1. Recent work (Sun et al., 2022b) has demonstrated promising gradient-free prompt tuning results by first employing a lower dimensional re-parameterization, $z \in \mathbb{R}^d$ with $d \ll D$, $\mathbf{P} = \mathbf{A}z + \mathbf{P}_0$, where $\mathbf{A} \in \mathbb{R}^{D \times d}$ is a random projection matrix and \mathbf{P}_0 is a fixed prompt embedding, and then using gradient-free evolutionary algorithms, in particular, Covariance Matrix Adaptation Evolution Strategy (CMA-ES) (Hansen and Ostermeier, 2001; Hansen et al., 2003) to optimize,

$$z^* = \arg \min_z - \sum_{i=1}^N \log \text{Cat}(\tilde{y}_i | \sigma(h_\theta(\tilde{x}_i; \mathbf{A}z + \mathbf{P}_0))) \quad (2)$$

Going forward, we also adopt this lower dimensional parameterization, but instead of learning a point estimate z^* , we learn a distribution $p(z | \tilde{\mathcal{D}})$ in a *gradient-free* setting. Similar to the point estimated variants, our algorithms to learn $p(z | \tilde{\mathcal{D}})$ also rely on CMA-ES.

Next, we consider the fully black-box setting — *likelihood-free* and *gradient-free*. Here, beyond being unable to propagate gradients through f , we are further handicapped by only observing the predicted label tokens, $\hat{y}_i = f(\tilde{x}_i; \mathbf{P})$ for each training instance \tilde{x}_i , and not the corresponding logits, i.e.,

$h_\theta(\tilde{\mathbf{x}}_i; \mathbf{P})$. In this more challenging setting we found CMA-ES based approaches to be unreliable, often getting stuck in poor optima. Instead, we found it effective to pose the *likelihood-free* and *gradient-free* prompt tuning task as a simulation-based inference (SBI) (Cranmer et al., 2020) problem. We view the PLM f as a black-box simulator that given a realization of \mathbf{z} and the text $\tilde{\mathbf{x}}_i$ produces \hat{y}_i . We then use a sequential Monte-Carlo approximate Bayesian computation (SMC-ABC) approach to infer the distribution $p(\mathbf{z}|\tilde{\mathcal{D}})$.

Finally, we use the distribution $p(\mathbf{z}|\tilde{\mathcal{D}})$ to characterize the uncertainty in predictions via the predictive distribution $p(\tilde{y}|\tilde{\mathbf{x}}, \tilde{\mathcal{D}}) = \int p(\tilde{y}|\tilde{\mathbf{x}}; \mathbf{z})p(\mathbf{z}|\tilde{\mathcal{D}})d\mathbf{z}$. We form Monte-Carlo approximations to this integral. In the *gradient-free* case, this is,

$$p(\tilde{y}|\tilde{\mathbf{x}}, \tilde{\mathcal{D}}) \approx \frac{1}{S} \sum_{s=1}^S p(\tilde{y}|\tilde{\mathbf{x}}; \mathbf{z}_s),$$

where $\mathbf{z}_s \sim p(\mathbf{z}|\tilde{\mathcal{D}})$. In the *likelihood-free* and *gradient-free* case, since we only have access to the label tokens, we approximate the predictive distribution,

$$p(\tilde{y} = c|\tilde{\mathbf{x}}, \tilde{\mathcal{D}}) \approx \frac{1}{S} \sum_{s=1}^S \mathbb{1}\{\hat{y}_s = c\}, \quad (3)$$

where $\hat{y}_s = f(\tilde{\mathbf{x}}; \mathbf{A}\mathbf{z}_s + \mathbf{P}_0)$, $\mathbf{z}_s \sim p(\mathbf{z}|\tilde{\mathcal{D}})$. In Section 5 we empirically demonstrate that by characterizing the uncertainty in \mathbf{z} through $p(\mathbf{z}|\tilde{\mathcal{D}})$ we get better calibrated predictive uncertainties, improved selective classification, and out-of-distribution detection.

4 Methods

We now describe our methods in greater detail. First, we discuss two algorithms for the *gradient-free* setting in 4.1 and 4.2. After that, we focus on addressing the *gradient-free* and *likelihood-free* setting from the SBI perspective in 4.3.

4.1 Prompt Ensembles

Deep ensembles (Lakshminarayanan et al., 2017) are a simple yet effective technique for quantifying uncertainty in deep neural network predictions. They generate a uniformly-weighted ensemble by re-training the same neural network from different random initialization. Leveraging the CMA-ES algorithm (Hansen and Ostermeier, 2001; Hansen

et al., 2003), we can adapt this idea to *gradient-free* prompt tuning.

CMA-ES is an evolutionary strategy that maintains a multivariate normal distribution $\mathcal{N}(m_t, \sigma_t^2 C_t)$ over a population of solutions. Each iteration of the algorithm involves sampling a set of possible solutions and updating the normal distribution to favor low loss solutions. To build a prompt ensemble, we run S instances of CMA-ES, each initialized with a different random initialization of the mean m_t and variance σ_t^2 and record the optimized prompt embeddings produced by each instance. This collection of S prompt embeddings $\{\mathbf{z}_s\}_{s=1}^S$ form the distribution $p(\mathbf{z}|\tilde{\mathcal{D}})$ and are used to approximate the predictive distribution via Equation 2.

4.2 Gradient-free Variational Inference

An alternative way to estimate the predictive distribution is by approximating the posterior distribution of prompt embedding $p(\mathbf{z}|\tilde{\mathcal{D}})$. Since direct computation of posterior is intractable, in our setting we resort to variational inference (VI) and approximate the posterior distribution with a tractable surrogate $q(\mathbf{z}; \boldsymbol{\lambda})$, where $\boldsymbol{\lambda}$ denotes the variational parameters. VI minimizes KL-divergence between variational distribution and true posterior distribution with respect to $\boldsymbol{\lambda}$. i.e., $\boldsymbol{\lambda}^* = \arg \min_{\boldsymbol{\lambda}} \text{KL}(q(\mathbf{z}; \boldsymbol{\lambda}) \| p(\mathbf{z}|\tilde{\mathcal{D}}))$. This is equivalent to maximizing the evidence lower bound (ELBO), i.e.,

$$\begin{aligned} \boldsymbol{\lambda}^* &= \arg \max_{\boldsymbol{\lambda}} \mathbb{E}_{q(\mathbf{z}; \boldsymbol{\lambda})} [\log p(\tilde{\mathcal{D}}|\mathbf{z})] \\ &\quad - \text{KL}(q(\mathbf{z}; \boldsymbol{\lambda}) \| p(\mathbf{z})) \end{aligned} \quad (4)$$

$$\begin{aligned} &= \arg \max_{\boldsymbol{\lambda}} \sum_{i=1}^N \mathbb{E}_{q(\mathbf{z}; \boldsymbol{\lambda})} [\log \text{Cat}(\tilde{y}_i | \sigma(h_\theta(\tilde{\mathbf{x}}_i; \mathbf{P})))] \\ &\quad - \text{KL}(q(\mathbf{z}; \boldsymbol{\lambda}) \| p(\mathbf{z})), \end{aligned} \quad (5)$$

where $\mathbf{P} = \mathbf{A}\mathbf{z} + \mathbf{P}_0$, and $p(\mathbf{z})$ denotes the prior distribution, which is assumed to be a normal distribution with zero mean and diagonal covariance matrix, i.e., $\mathcal{N}(0, \sigma \cdot \mathbf{I})$. Optimizing the ELBO objective requires taking derivative w.r.t $\boldsymbol{\lambda}$ as well as computing the gradient of log likelihood w.r.t \mathbf{z} , i.e., $\nabla_{\mathbf{z}} \mathbb{E}_{q(\mathbf{z}; \boldsymbol{\lambda})} [\log \text{Cat}(\tilde{y}_i | \sigma(h_\theta(\tilde{\mathbf{x}}_i; \mathbf{A}\mathbf{z} + \mathbf{P}_0)))]$, which causes standard variational inference algorithms to be infeasible in the *gradient-free* setting.

Instead of back-propagation, we propose a gradient-free variational inference algorithm lever-

aging the derivative-free optimizer CMA-ES. Specifically, we consider the variational distribution as a multivariate normal distribution $q(\mathbf{z}; \boldsymbol{\lambda}) = \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where we assume the covariance matrix is diagonal, i.e., $\boldsymbol{\Sigma} = \text{diag}(\boldsymbol{\alpha}) \in \mathbb{R}^{d \times d}$. The variational parameter, as the target for optimization, is the mean and diagonal elements of the covariance matrix, i.e., $\boldsymbol{\lambda} = (\boldsymbol{\mu}, \boldsymbol{\alpha}) \in \mathbb{R}^{2d}$. At each iteration of the optimization, the CMA-ES outputs a collection of candidate solutions $\{\boldsymbol{\lambda}_j\}_{j=1}^m = \{(\boldsymbol{\mu}_j, \boldsymbol{\alpha}_j)\}_{j=1}^m$. For each candidate variational parameter $\boldsymbol{\lambda}_j$, we evaluate the corresponding ELBO loss using the variational distribution $q(\mathbf{z}; \boldsymbol{\lambda}_j) = \mathcal{N}(\boldsymbol{\mu}_j, \text{diag}(\boldsymbol{\alpha}_j))$, where the expectations in Equation 5 is approximated by Monte-Carlo samples obtained from the variational distribution. Finally, the CMA-ES optimizer takes the current collection of variational parameter $\{\boldsymbol{\lambda}_j\}_{j=1}^m$ and their corresponding ELBO loss to conduct the next iteration of optimization. The schematic of the process is shown in Figure 1, and the overall algorithm is summarized as Algorithm 1 in Appendix A.

After we obtain the optimal variational parameter $\boldsymbol{\lambda}^*$ that maximizes the ELBO loss, the predictive label distribution can be estimated by taking Monte Carlo samples from the optimal variational distribution, i.e., $q(\mathbf{z}; \boldsymbol{\lambda}^*) = \mathcal{N}(\boldsymbol{\mu}^*, \boldsymbol{\Sigma}^*)$.

4.3 SBI-based Algorithm for Likelihood-free Prompt Tuning

Now, we describe our proposed approach for the *gradient-free* and *likelihood-free* case. For this problem, the most naive algorithm applicable is rejection approximation Bayesian computation (ABC) (Pritchard et al., 1999) that repeatedly samples from a prior distribution $\mathbf{z} \sim p(\mathbf{z})$ and obtains the corresponding simulated observation $\hat{\mathbf{Y}}$. The algorithm only accepts the sampled prompt embedding if the simulated observation is sufficiently close to the ground truth observation $\tilde{\mathbf{Y}}$ based on a distance function ρ and tolerance ϵ , i.e., $\rho(\hat{\mathbf{Y}}, \tilde{\mathbf{Y}}) < \epsilon$. The collection of accepted samples can be used to approximate the posterior distribution. However, rejection ABC typically suffers from poor computational efficiency, especially when ϵ is small and the dimensionality of observations is large. In preliminary experiments, we found rejection ABC to not be effective for our purposes. Instead, in this work, we adapt a more advanced technique — sequential Monte Carlo ap-

proximate Bayesian computation (ABC-SMC) algorithm (McKinley et al., 2009) to enable efficient prompt posterior inference. The core idea of ABC-SMC is to use a sequential tolerance schedule, i.e., $\epsilon_1 > \epsilon_2 > \dots > \epsilon_T$ to construct a sequence of intermediate distributions, which gradually converges to the true posterior distribution.

First, we draw prompt embedding samples from the prior $p(\mathbf{z}) = \mathcal{N}(0, \sigma \cdot \mathbf{I})$ and pass them into PLM f to receive the corresponding token label prediction $\hat{\mathbf{Y}}$ for a batch of text data $\tilde{\mathbf{X}}$. Then, we accept S samples $\{\mathbf{z}_s^{(1)}\}_{s=1}^S$ that satisfy the condition $\rho(\hat{\mathbf{Y}}, \tilde{\mathbf{Y}}) < \epsilon_1$. We use accuracy as the distance function ρ . In the next iteration, we resample embeddings from $\{\mathbf{z}_s^{(t-1)}\}_{s=1}^S$ with probability proportional to weights $w^{(t-1)}$, and perturb the sampled embeddings via a perturbation kernel to obtain a new sample, i.e., $\mathbf{z}^{(t)} \sim \mathcal{N}(\mathbf{z}^{(t-1)}, \boldsymbol{\Sigma}^{(t-1)})$. Again, we propagate these sampled embeddings through the PLM f and accept the newly proposed embeddings, $\{\mathbf{z}_s^{(t)}\}_{s=1}^S$, if $\rho(\hat{\mathbf{Y}}, \mathbf{Y}) < \epsilon_t$, where the tolerance ϵ_t is decayed by one step per iteration, i.e., $\epsilon_{t+1} = \epsilon_t - \frac{1}{N}$, where N is the total number of training data. Finally, the weights $w^{(t)}$ and the variance of the perturbation kernel are updated after each iteration (details are elaborated in Appendix B). Empirically, we find that simply using uniform weights leads to better performance (more discussion in Section 5.3). These steps are repeated for T iterations until the tolerance ϵ_T is sufficiently small. The schematic is in Figure 1 and the overall algorithm is summarized as Algorithm 1 in Appendix A.

The final collection of prompt samples $\{\mathbf{z}_s^{(T)}\}_{s=1}^S$ form an approximation to the posterior $p(\mathbf{z}|\mathcal{D})$ and we use Equation 3 to derive the approximate predictive distribution.

5 Experiment Results

In this section, we demonstrate the solid empirical performance of our proposed methods. We begin with introducing the uncertainty quantification applications and describe the experiment settings. Then, we present our main results in terms of prediction performance and UQ quality. Finally, we provide an ablation study and relevant perspectives of comparison. Detailed results and implementation steps are provided in Appendix D.

5.1 Settings

Uncertainty Quantification Applications. We assess the performance of the uncertainty quantification from three perspectives: (1) **Calibration** – the typical UQ quality metric that measures how well the model confidence aligned with the correctness of its prediction; (2) **Selective Classification** – aims to avoid the risk of wrong predictions by abstaining the prediction for samples with high uncertainty; and (3) **OOD Detection** – aims to identify the out-of-distribution data that is unobserved during the training stage. The OOD data can exhibit different forms of distribution shift, including the *covariate shift* where the OOD data distribution is different from the training samples; and the *semantic shift* where the OOD data contain unobserved class. In our experiment, we focus on two types of OOD tasks: the **Far OOD** detection task where both *covariate shift* and *semantic shift* happen simultaneously; the **Near OOD** detection task where the OOD data only contain *covariate shift*, but have the same class label words.

Benchmark. For a comprehensive comparison with BBT (Sun et al., 2022b), we mainly employ the same text classification benchmark datasets as BBT, including sentiment analysis datasets SST-

2 (Socher et al., 2013) and Yelp polarity (Zhang et al., 2015); topic classification datasets AG’s News (Zhang et al., 2015) and DBPedia (Zhang et al., 2015); paraphrase dataset MRPC (Dolan and Brockett, 2005); natural language inference (NLI) datasets SNLI (Bowman et al., 2015) and RTE (Wang et al., 2018).

Both calibration and selective classification tasks are conducted using the original test samples for each benchmark dataset. For the far OOD detection task, we create the ID/OOD dataset pairs by combining two datasets belonging to two different tasks, e.g., SST-2/RTE. For the near OOD detection task, we use IMDB (Maas et al., 2011) for the sentiment analysis task and MNLI (Williams et al., 2017) for the NLI task.

Baselines. For prediction performance, besides the SOTA *Gradient-free* prompt tuning approach BBT (Sun et al., 2022b), we also compare with other *Gradient-free* methods: (1) The naive **Manual Prompt** that uses the hand-crafted prompt templates; (2) **In-context Learning** (Brown et al., 2020); (3) Feature-based approaches (Peters et al., 2019) that trains auxiliary models on top of the PLM extracted features, including **Feature-MLP** training a MLP classifier and **Feature-BiLSTM**

training a LSTM model followed by a classifier. We include additional results of *Gradient-based* approaches: (1) **Model Tuning** that fine-tunes the entire PLM; (2) **Prompt Tuning** (Lester et al., 2021) that only trains the continuous prompt without modifying PLM; (3) **P-Tuning v2** (Liu et al., 2021b) that trains the several continuous prompts injected at different layers of PLM. For uncertainty quantification tasks, few existing prompt tuning works aim to tackle this problem, so we mainly compare with BBT to justify how we can address its limitation under the *gradient-free* setting.

Implementation Details. We follow the same experiment setting as BBT. We focus on text classification as a few-shot learning problem, motivated by the fact that labeled training data can be limited in practice. Specifically, we construct few-shot training and validation data by drawing 16 random samples for each class from the original training dataset. The prediction performance is evaluated on the original development or test set, depending on the datasets. We use the same PLM model RoBERTa_{LARGE} as the backbone model and keep the hyper-parameter same as BBT. Specifically, we set the prompt length as 50, i.e., $D = 50 \times 1024$, and the subspace dimensionality as $d = 500$. The only modification is that we adapt the normal distribution (Sun et al., 2022a) to generate the random projection matrix \mathbf{A} , instead of the uniform distribution used in BBT. For a fair comparison, we reproduce the results of BBT using the random pro-

jection generated from normal distribution. More implementation details are included in Appendix C.

Performance Metrics. For prediction performance, we evaluate the prediction accuracy on the testing dataset. For calibration performance, we adopt the expected calibration error (ECE) (Guo et al., 2017) score as the metric. For both selective classification and OOD detection tasks, we compute the area under the risk vs. rejection rate curve (AURRRC) (Franc and Prusa, 2019). The risk is defined as the portion of wrong-predicted samples among the data chosen for prediction in selective classification and the portion of OOD samples among the data identified as in-distribution in the OOD detection task. The rejection rate is defined as the portion of data that abstained from the prediction based on specific uncertainty measurement. Note that an oracle with perfect knowledge of uncertainty measurement can achieve a minimum AURRRC score. This is obtained by assigning an uncertainty score based on the oracle knowledge, i.e., whether a test sample is wrong-predicted (OOD samples) or not. We denote such minimum AURRRC score as the *lower-bound*.

Given the predictive label distribution, we utilize two uncertainty measurements, including *Entropy* of the label distribution, i.e., $\mathcal{H}\left(p(\tilde{y}|\tilde{\mathbf{x}};\tilde{\mathcal{D}})\right)$, and *MaxP*, which is defined as $\max_c p(\tilde{y} = c|\tilde{\mathbf{x}};\tilde{\mathcal{D}})$.

5.2 Results

We conduct extensive evaluations of our proposed methods under both the *Gradient-free* setting and the *Gradient-free* and *Likelihood-free* setting. The results of prediction performance are shown in Table 1. For the uncertainty quantification performance, the calibration results are shown in Table 2, the selective classification results are shown in Table 3, the Far OOD detection results are shown in Table 4 and the Near OOD detection results are shown in Table 5.

Gradient-free and Likelihood-free Setting. No existing work is trying to tackle the *Gradient-free* and *likelihood-free* prompt tuning problem. However, we still compare our proposed method with other baseline methods on different problem settings to understand how well we can achieve and the price we need to pay for such a more strict constraint. In addition, we also include the results of neural net-based approach SNPE (Hermans et al., 2020; Durkan et al., 2020) for solving the SBI problem.

As shown in Table 1, our proposed method ABC-SMC can achieve competitive prediction performance as SOTA approach BBT and even outperform the other *Gradient-free* baselines without the requirement of the model likelihood. We also observe that ABC-SMC performs better than SNPE. The possible explanation is that the density estimation model adopted by SNPE usually requires a large number of simulated samples to achieve good performance, which is hindered by the slow inference speed of large PLM.

For the uncertainty quantification tasks, ABC-SMC underperforms on calibration and selective classification tasks but can still achieve comparable performance on the two OOD detection tasks. The performance gap can possibly be mitigated if we collect more samples (by increasing K) for a more accurate estimation of the empirical label distribution, but the computational cost is the price we need to pay for the *likelihood-free* constraint.

Gradient-free Setting. By relaxing the *likelihood-free* constraint, it is observed that our proposed methods, both Gradient-free Variational Inference (denoted as ELBO) and Ensembles algorithms, achieve comparable or even better prediction performance than BBT and other *gradient-free* baselines, while outperforming BBT in terms of uncertainty quantification across all

the tasks. Such empirical observation justifies the effectiveness of leveraging Bayesian and Ensemble techniques to enable more reliable *gradient-free* prompt tuning without sacrificing the prediction performance.

5.3 Discussions

In this section, we further investigate our proposed methods by exploring the use of alternate models and the effect of using uniform weights in the SMC-ABC algorithm.

Performance on other backbone models To demonstrate that our proposed methods generalize well on other PLM backbone models, we evaluate them on BERT_{LARGE} under the both *Gradient-free* setting and *Gradient-free* and *likelihood-free* setting. The results are presented in Appendix D.1. Note that our proposed methods consistently outperform BBT in terms of both prediction and uncertainty quantification performance under the *Gradient-free* setting while achieving competitive performance with a small gap under the *Gradient-free* and *likelihood-free* setting.

Ablation study of weights in ABC-SMC In practice, we observe that the ABC-SMC algorithm suffers from weight degeneracy, with weights for certain particles approaching one and effectively causing the posterior to be approximated by a single particle. Although, this issue can be mitigated by designing better proposals, we found that the heuristic of using uniform weights instead of updating the weights at each iteration of the algorithm to be far more effective. To demonstrate the efficacy, we conduct an ablation study about the sampling weights, and the results are shown in Appendix D.2. We find that with uniform weights ABC-SMC provides both improves prediction and uncertainty quantification for our application.

6 Concluding Remarks

In this work, we explore *gradient-free* prompt tuning along two under-explored angles: quantifying uncertainty in soft prompts; and tackling a more strict *likelihood-free* setting from the SBI perspective. Our developed methods demonstrate encouraging empirical performance across multiple tasks.

Investigating more modern neural SBI methods and designing more robust methods for learning prompt posteriors are exciting directions for future research. Other perspectives on *gradient-free*

prompt tuning, such as learning natural language-like interpretable prompts, are also worthy of exploration.

7 Limitations

We explored methods for learning a distribution over prompts for tuning PLMs with only API access. We rely on approximate inference algorithms to infer these distributions. Since the true posterior is intractable, effectively evaluating the quality of the inferred approximate posteriors is challenging. Here, we use downstream metrics to compare different algorithms. However, such metrics conflate the quality of posterior approximation with predictive performance. Assessing the quality of approximate posteriors remains an open problem. Another limitation of our ABC-based approach is that it is more expensive than approaches that can exploit gradient information. Improving the computational efficiency of such approaches comprises interesting future work.

A Omitted Algorithms

The overall algorithm of Gradient-free Variational Inference and ABC-SMC are shown in Algorithm 1 and Algorithm 2, respectively.

Algorithm 1 Gradient-free Variational Inference

input Training data set $\{(\tilde{\mathbf{x}}_i, \tilde{y}_i)\}_{i=1}^N$; CMA-ES optimizer ES; Prior distribution $p(\mathbf{z})$; Number of candidate solutions m ; Total iteration T .

Initialize the initial collection of variational parameter, i.e., $\{\boldsymbol{\lambda}_j^{(0)}\}_{j=1}^m = \{(\boldsymbol{\mu}_j^{(0)}, \boldsymbol{\alpha}_j^{(0)})\}_{j=1}^m$.

for $t = 1, 2, \dots, T$ **do**

for $j = 1, 2, \dots, m$ **do**

 Generate S prompt embedding samples from the variational distribution, i.e.,

$$\{\mathbf{z}_s^{(t-1)}\}_{s=1}^S \sim \mathcal{N}(\boldsymbol{\mu}_j^{(t-1)}, \text{diag}(\boldsymbol{\alpha}_j^{(t-1)}))$$

 Evaluate the ELBO loss of j -th variational distribution i.e.,

$$\begin{aligned} \mathcal{L}_j^{(t-1)} &= \sum_{i=1}^N \sum_{s=1}^S \log \text{Cat}(\tilde{y}_i | \sigma(h_\theta(\tilde{\mathbf{x}}_i; \mathbf{A}\mathbf{z}_s^{(t-1)} + \mathbf{P}_0))) \\ &\quad - \text{KL}(q(\mathbf{z}; \boldsymbol{\lambda}_j^{(t-1)}) \| p(\mathbf{z})) \end{aligned}$$

end

 Request a new collection of variational parameter solutions, i.e.,

$$\{\boldsymbol{\lambda}_j^{(t)}\}_{j=1}^m \leftarrow \text{ES}(\{\boldsymbol{\lambda}_j^{(t-1)}\}_{j=1}^m; \{\mathcal{L}_j^{(t-1)}\}_{j=1}^m)$$

end

output Optimized collection of prompt embedding samples $\{\mathbf{z}_s^{(T)}\}_{s=1}^S$ corresponding to max ELBO loss.

B Implementation details of ABC-SMC

Updating of $w^{(t)}$ In the ABC-SMC algorithm, the sampling weights are initialized as uniform distribution at the first iteration $t = 1$ as all the samples are sampled from the prior distribution $p(\mathbf{z})$. In the later iterations, the new samples are drawing from a mixture proposal distribution consisted the previous samples and the perturbation kernel, i.e., $\sum_{s=1}^S w_s^{(t-1)} \cdot \mathcal{N}(\mathbf{z}_s^{(t-1)}, \boldsymbol{\Sigma}^{(t-1)})$. The weights are updated in an importance sampling manner as the ratio between the prior probability and the proposal probability, i.e.,

$$w_s^{(t)} = \frac{p(\mathbf{z}_s)}{\sum_{s=1}^S w_s^{(t-1)} \cdot \mathcal{N}(\mathbf{z}_s^{(t-1)}, \boldsymbol{\Sigma}^{(t-1)})}$$

Updating of $\boldsymbol{\Sigma}^{(t)}$ The covariance $\boldsymbol{\Sigma}^{(t)}$ in the perturbation kernel is a diagonal covariance matrix

Algorithm 2 ABC-SMC

input PLM f ; The fixed random projection matrix \mathbf{A} and initial prompt \mathbf{P}_0 ; Training data set $(\tilde{\mathbf{X}}, \tilde{\mathbf{Y}}) = \{(\tilde{\mathbf{x}}_i, \tilde{y}_i)\}_{i=1}^N$; Prior distribution $p(\mathbf{z})$; Initial tolerance ϵ_1 ; Distance measure function $\rho(\cdot)$; Number of samples S ; Total iteration T .

for $t = 1, 2, \dots, T$ **do**

if $t == 1$ **then**

for $s = 1, 2, \dots, S$ **do**

do

 Generate prompt embedding samples from the prior distribution, i.e., $\mathbf{z}_s^{(1)} \sim p(\mathbf{z})$;
 Obtain the corresponding prediction result $\hat{\mathbf{Y}} = f(\mathbf{A}\mathbf{z}_s^{(1)} + \mathbf{P}_0; \tilde{\mathbf{X}})$.

while $\rho(\hat{\mathbf{Y}}, \tilde{\mathbf{Y}}) > \epsilon_1$;

 Initialize the sampling probability weights $w_s^{(1)} = \frac{1}{S}$.

end

 Decay the tolerance, i.e., $\epsilon_{t+1} = \epsilon_t - \frac{1}{N}$; Initialize the perturbation kernel variance $\boldsymbol{\Sigma}^{(1)}$.

else

for $s = 1, 2, \dots, S$ **do**

do

 Draw a random sample $\mathbf{z}_s^{(t-1)}$ from $\{\mathbf{z}_s^{(t-1)}\}_{s=1}^S$ with probability $w_s^{(t-1)}$;
 Generate a new sample $\mathbf{z}_s^{(t)} \sim \mathcal{N}(\mathbf{z}_s^{(t-1)}, \boldsymbol{\Sigma}^{(t-1)})$;
 Obtain the corresponding prediction result $\hat{\mathbf{Y}} = f(\mathbf{A}\mathbf{z}_s^{(t)} + \mathbf{P}_0; \tilde{\mathbf{X}})$.

while $\rho(\hat{\mathbf{Y}}, \tilde{\mathbf{Y}}) > \epsilon_t$;

 Update the sampling probability weights $w^{(t)}$ (see Appendix B).

end

 Decay the tolerance, i.e., $\epsilon_{t+1} = \epsilon_t - \frac{1}{N}$; Update the perturbation kernel variance $\boldsymbol{\Sigma}^{(t)}$ (see Appendix B).

end

end

output Optimized collection of prompt embedding samples $\{\mathbf{z}_s^{(T)}\}_{s=1}^S$; Final sampling weights $w^{(T)}$.

$\text{diag}(\boldsymbol{\alpha}^{(t)})$, where the diagonal elements $\boldsymbol{\alpha}^{(t)}$ are updated using the weighted empirical variance of previous collection of samples, i.e.

$$\boldsymbol{\alpha}^{(t)} = \sum_{s=1}^S w_s^{(t-1)} \cdot (\mathbf{z}_s^{(t-1)} - \bar{\mathbf{z}}^{(t-1)})^2$$

Where $\bar{\mathbf{z}}^{(t-1)} = \sum_{s=1}^S w_s^{(t-1)} \cdot \mathbf{z}_s^{(t-1)}$ is the mean.

C Implementation Details

All of our experiment results are reported with means and standard deviations over three trials, each with a different random seed. The experiments are implemented in PyTorch, and each run of our proposed methods requires less than 24h of training computation time (on a single NVIDIA Tesla V100 GPU). Our proposed algorithms generate a collection of S prompt samples to estimate the predictive label distribution. We set $S = 10, 100, 100$ for Ensembles, Gradient-free Variational Inference, and ABC-SMC, respectively. The total budget for the derivative-free optimizer CMA-ES is set to be 300 with a population size of 20. We use the same prior distribution $p(z)$ for all algorithms, which is assumed to be a normal distribution with zero mean and diagonal covariance matrix, i.e., $\mathcal{N}(0, \sigma \cdot \mathbf{I})$. σ controls how concentrated the prior distribution is, and we use $\sigma = 50$ in our experiments. In ABC-SMC, the distance measure function ρ is defined as the prediction error rate, i.e., the portion of wrongly predicted data among the whole data batch. The initial tolerance ϵ_1 in ABC-SMC is initialized as the prediction error rate of an arbitrary prompt sample drawing from the prior distribution. The tolerance is decayed by one step per iteration, i.e., $\epsilon_{t+1} = \epsilon_t - \frac{1}{N}$, where N is the total number of training data.

D Additional Experiment Results

D.1 Performance on other backbone PLM

We evaluate the performance of our proposed methods on SST-2 and SNLI tasks using BERT_{LARGE} as the backbone model. We keep the hyperparameter settings the same as the original experiments. The results are shown in Table 6, 7, 8, and 9.

Table 6: **Test Performance (test acc \uparrow)**

Settings	Methods	SST-2	SNLI
Gradient-free	BBT	74.77 \pm 3.21	41.07 \pm 2.97
	Ours(ELBO)	75.38 \pm 1.74	41.20 \pm 0.39
	Ours(Ensembles)	80.05 \pm 1.79	42.64 \pm 1.96
Gradient-free & Likelihood-free	Ours(ABC-SMC)	66.40 \pm 0.46	39.00 \pm 0.22

D.2 Ablation of ABC-SMC sampling weights

We compare both the prediction and uncertainty quantification performance of our proposed ABC-SMC approaches using the updated sampling weights and the fixed uniform weights. We denote

Table 7: **Calibration Performance (ECE score \downarrow)**

Abstract

Recent years saw a dramatic increase in the popularity of online counseling services providing emergency mental health support. This paper provides a new language model for automatic detection of suicide risk in online chat sessions between help-seekers and counselors. The model adapts a hierarchical BERT language model for this task. It extends the state of the art in capturing aspects of the conversation structure in the counseling session and in integrating psychological theory into the model. We test the performance of our approach in a leading national online counseling service that operates in the Hebrew language. Our model outperformed other non-hierarchical approaches from the literature, achieving a 0.76 F2 score and 0.92 ROC-AUC. Moreover, we demonstrate our model's superiority over strong baselines even early on in the conversation, which is key for real-time detection in the field. This is a first step towards incorporating suicide predictive models in online support services and advancing NLP tools for resource-bounded languages.

1 Introduction

Suicide accounts for more than 700,000 lives lost across the world every year. It is the second leading cause of death for adolescents and adults from 15 to 29 years of age in many countries. A key effort in suicide prevention is to identify individuals at risk of suicide as early as possible (World-Health-Organization, 2021).

In the past decade, online counseling services for mental health support have become commonplace in many countries, providing chat support and guidance to at-risk individuals (see fictitious example in Figure 1). Online counseling services aim to provide mental support and address a variety of mental health crises through specialist counselors. These counselors are trained to detect suicide risk during conversations and intervene quickly as needed. These services have ex-

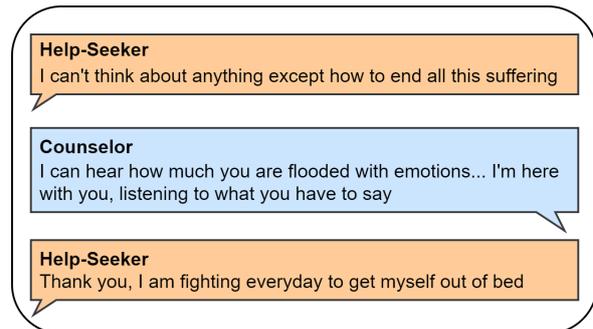

Figure 1: A fictitious example of a conversation.

perienced tremendous growth in traffic since the commencement of the COVID pandemic (Zalsman et al., 2021). Any kind of technological support to help counselors in this critical task can potentially save lives.

This paper provides a computational model for detection of suicide risk from anonymous text-based discussions between help-seekers and counselors. Our data is taken from an online counseling service in a low-resource language (Hebrew). There are several challenges towards solving suicide risk detection in our setting: State of the art pre-trained language models for suicide prevention usually focus on posts from social media which are very different in structure from online conversations between counselors and help-seekers. Existing works that do consider conversations in this domain ignore the conversation structure or are limited in the size of the conversation they consider. Also, the set of NLP resources available for low-resource languages is extremely limited when compared to English.

To address this gap, we present a hierarchical language model called SR-BERT that includes a base layer for encoding the conversation text and an additional layer for capturing aspects of conversation structure. The hierarchical structure of SR-BERT encodes each of the messages in the conversation separately and is not limited by the size

of the conversation. We hypothesized that incorporating knowledge from suicide risk theory as part of the pre-training step can improve downstream performance of the detection model. To this end, we develop a new domain knowledge-based pre-training step that embeds a Suicide Risks Factor lexicon (SRF) into SR-BERT. The SRF lexicon was created by a team of psychologists who are experts on suicide risk theory and prevention.

In empirical studies, SR-BERT significantly outperforms alternative classifiers for suicide risk (SR) detection, including the state-of-the-art (Bialer et al., 2022). We show that adding the domain-expert information to SR-BERT plays a critical part in its performance. In particular, it obtained consistently better performance than Bialer et al. (2022) when processing different portions of the conversation. These findings suggest that SR-BERT can perform well in the field when analyzing conversations in real-time.

We extend the state-of-the-art hierarchical language models to combine conversation structure and expert-based knowledge in the pretraining step. We show this approach leads to significant increases in performance for detecting suicide risk from chat conversations.

2 Related Work

This paper relates to past studies in suicide risk detection in online settings, representing domain knowledge and conversation structure in deep language models and NLP tools for low-resource languages. We expand on each of these topics in turn. For a review on using machine learning in suicide prevention, we refer the reader to Ji et al. (2021).

The majority of work using machine learning to predict suicide risk analyzes posts from social media (Coppersmith et al., 2018; Zirikly et al., 2019; Shing et al., 2018; Sawhney et al., 2018; Tadesse et al., 2019). Recent works in this social media suicide prediction space includes Cao et al. (2019) who used an LSTM with an additional attention layer to predict SR from social media posts, and Wang et al. (2021) who combined a generic BERT model with predefined rules for scoring suicide risk in social media. Additionally, Ophir et al. (2020) showed that psychological questionnaires can improve the performance of neural networks to identify at-risk individuals from Facebook posts. We significantly differ from the social media setting in our focus on conversations from online coun-

seling services, where messages are significantly longer than social media posts, and messages are part of a conversational structure and exhibit psychological dynamics. We show that capturing these aspects in the conversation model is necessary for recognizing SR in our setting.

There are few works on suicide detection in online counseling conversations, but none of these reasons about the conversation structure in the session. Most relevant to our approach is the model by Bialer et al. (2022) who combined a pre-trained language model based on BERT (Devlin et al., 2018) with a lexicon of suicide terms that were manually extracted from conversations. This model was able to represent only part of the conversation (512 tokens) and ignored the input from the counselor. Our SR-BERT model used a lexicon extracted from psychological theory, which was embedded in the pre-training process. The model significantly outperforms that of Bialer et al. (2022) on the same dataset, both for entire conversations as well as when considering early detection on parts of the conversation.

We mention two approaches for detecting SR in counseling services that did not consider early detection. Xu et al. (2021) combined a word2vec representation of suicide concepts with a bi-directional LSTM network for SR prediction in Korean online counseling service. Each side of the conversation was represented by an independent BI-LSTM. This approach used a knowledge graph to represent a psychological lexicon which may be more time-consuming for human experts to construct. Our model is shown to outperform a baseline using a similar representation (doc2vec) on our dataset. Bantilan et al. (2021) used TF-IDF embedding with XGBoost to predict SR in transcribed phone calls from an English counseling service. This model did not use a lexicon.

There is ample evidence on the benefits of incorporating domain knowledge in language models for downstream tasks (Childs and Washburn, 2019; Cao et al., 2019; Lee et al., 2020; Colon-Hernandez et al., 2021; Gaur et al., 2019). Notable examples include Gaur et al. (2019) and Wang et al. (2021) who showed that using lexicon-based features can improve machine learning prediction of suicide risk in Chinese blogs. They use lexicons to map terms from online discussions to clinically relevant sets of categories. We extend these approaches by presenting a new method for incorporating domain

knowledge in the pre-training phase of deep learning models.

In general, NLP models and solutions for low-resource languages are extremely limited. In Hebrew, two pre-trained language models were published, HeBERT (Chriqui and Yahav, 2021) and AlephBERT (Seker et al., 2022). We used AlephBERT which is freely available and was trained on a larger dataset than HeBERT and was able to outperform HeBERT on a variety of natural language tasks. We are first to use hierarchical transformer architecture to model conversation structures in a low-resource language.

3 The Sahar domain

Sahar (Hebrew acronym for Online Mental Health Support ¹) was established in 2000 and is the leading internet-based emotional support and suicide prevention organization in Israel. It provides anonymous, confidential, and free crisis support via a chat hotline (in Hebrew and in Arabic). The organization handles more than 40,000 chat sessions per year, and these numbers have increased significantly during the COVID-19 pandemic (Zalsman et al., 2021).

Sahar counselors are volunteers who receive year-round guidance and supervision from a team of mental health professionals. Shifts take place in the evening hours and are accompanied by trained therapists who monitor the conversations and provide professional support to counselors as needed. During the shifts, counselors work in a high-stress environment and usually handle multiple chat sessions in parallel at any given time. Counselors provide a written summary of each of their conversations, as well as indicate whether the conversation exhibits suicide risk.

The Sahar corpus contains more than 40,000 chat sessions (conversations) that took place over the span of five years (2017-2022). Each conversation includes the messages generated by the help-seekers and the counselors, ordered by time signatures. Table 1 presents general statistics about the dataset. We note that 39.5% of the sessions are labeled with either positive or negative SR label and 17% of these sessions are SR positive.

To validate the SR labels, a sample of 600 conversations (300 positive SR, 300 negative SR) was labeled separately by clinical psychologists with expertise in suicide theory. The Krippendorff’s α

Table 1: General statistics for Sahar corpus

Total num. of sessions	44,506
Num. of labeled sessions	17,564
SR positive label ratio	17%
Mean(Median) num. of messages	57(46)
Mean(Median) num. of turn exchanges	27(25)
Mean(Median) num. of tokens	617(566)

for inter-annotator agreement between the psychologists and the SR label in the conversation is 0.766, which is en par with other works. We note that the inconsistencies found in the samples were debated by the psychologists and resolved in the data set.

4 The SRF Psychological Lexicon

As part of our research, a team of psychology experts from a national center for suicide prevention in Israel has constructed a Suicide-Risk Factors Lexicon (SRF) in Hebrew that is based on psychological theory.

The SRF lexicon contains terms relating to personal and situational variables associated with an increase in suicidal thinking, based on valid self-report questionnaires in the psychological and psychiatric literature (Klonsky and May, 2015; Turecki and Brent, 2016; Nock et al., 2008).

Each of the 3,094 sentences in the lexicon belonged to one of 25 categories. Specifically, terms relating to depression are taken from the Patient Health Questionnaire Depression Module (PHQ-9) (Kroenke et al., 2001). Terms relating to a sense of burdensomeness are taken from the Interpersonal Needs Questionnaire (INQ) (Van Orden et al., 2012). Terms relating to a sense of hopelessness are taken from the Beck hopelessness scale (Beck et al., 1996). Terms relating to suicide behavior were taken from the Columbia questionnaire (Posner et al., 2008) which is a standard tool to measure suicide risk.

Examples of sentences for the category “perceived burdensomeness” (translated) included sentences such as “better without me”, “I am a burden”, “I spoil everything for my spouse”; and the lexicon category “explicit suicide mentions” contains phrases such as: “to die”, “to commit suicide”, “kill myself” etc.

5 The SR-BERT Language Model

Our main contribution is SR-BERT, a two-layer hierarchical language model that extends the generic DialogBERT (Gu et al., 2021) to reason about con-

¹<https://sahar.org.il>

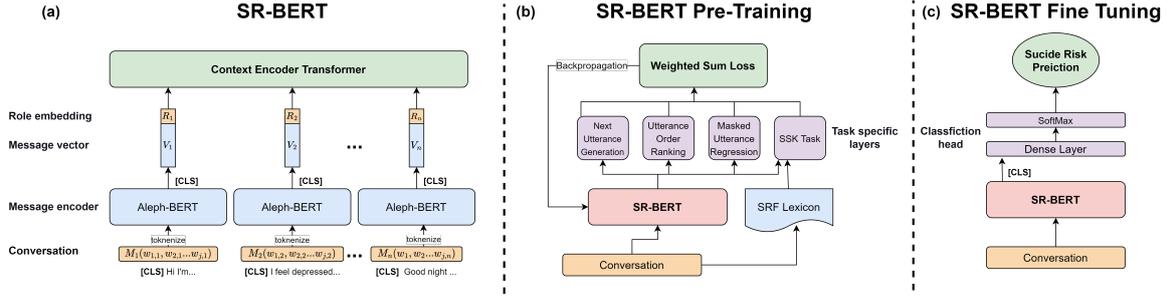

Figure 2: Model architecture. (a) SR-BERT base architecture, encoding conversation and speaker roles. (b) Pre-training procedure on 4 self-supervised tasks including psychological knowledge learning using the SRF lexicon. (c) Fine-tuning procedure learning to predict Suicide Risk (SR)

versation structure in suicide risk prediction settings and harness psychological domain knowledge. The SR-BERT architecture is shown in Figure 2(a).

The architecture is composed of two part: A transformer based layer performing message encoding, and on top of it an additional transformer layer, which captures conversation structure, named Context Encoder Transformer.

The base layer uses the AlephBERT (Seker et al., 2022) pre-trained language model to encode each message in the dialogue to a vector. The received message encoding is then combined with speaker role representation (help-seeker vs. counselor) to capture important conversation aspects such as turn-taking. The Context Encoder Transformer is a transformer based encoder applied at the message level (instead of the single token level) which transforms the series of message vectors into a context-sensitive repression of the conversation. The Context Encoder Transformer included 12 attention layers, and 12 hidden layers, each with a vector size of 780. The hidden layer size is 780 rather than 768 in AlephBert to account for the additional speaker role encoding.

The hierarchical structure of the architecture enables the model to capture multiple messages including turn exchanges and speaker roles. Furthermore, it enable the encoding of each message independently, thus avoiding the need to truncate conversations (due to AlephBert’s 512 token limit) as in past work.

5.1 Pre-training with Self Supervised Knowledge

In this section we describe the use of several pre-training tasks for adapting SR-BERT to conversation structure of online counseling, including a new pre-training task for incorporating the SRF lexicon.

This procedure uses the entire Sahar dataset, and is shown in Figure 2 (b).

The first step in this process is to represent conversations as a 25 dimension vector representing the different categories in the lexicon. For a given conversation, the value at index k is the number of sentences in the conversation with at least one occurrence in the k th lexicon category.

We also considered a reduced 5-dimension representation of conversations on the SRF lexicon space. To this end we selected the top categories using XGBoost feature selection (Chen and Guestrin, 2016) on the SR prediction task of entire conversations. We identified the top 5 categories as “self perceived burdensomeness”, “previous suicide attempt”, “loss of hope” “self injury” and “suicidal thinking”. The 5-dimension representation outperformed the 25-dimension representation on the validation set, leading us to use this representation in the subsequent pre-training phase.

The second step, called the Self Supervised Knowledge task, applies a new pre-training task for predicting Sahar conversations in the SRF representation space. For a given prefix of a conversation, we mask a message in this subset with a fixed probability of 80%. We then use SR-BERT to predict the conversation subset’s representation in the SRF space using a fully connected layer. The loss is obtained by calculating the mean squared error (MSE) between the original subset representation and the predicted (masked) representation in the SRF space. This process is repeated for increasing size of conversation prefixes, to simulate conversations of varying sizes.

In addition to the SSK task, we implemented the three pre-training tasks defined by DialogBERT(Gu et al., 2021) for capturing several aspects of the conversation structure: message-level semantics,

conversation structure, and underlying dialogue sequential order. We describe them briefly here and refer the reader to the full paper for more details.

- **Next Utterance Generation** The goal of this task is to generate the next message in the conversation when the previous messages are given. The task tries to minimize the cross-entropy loss between the predicted words and the original words of the next message.
- **Masked Utterance Regression** The goal of this task is to predict a randomly masked message in a conversation from its context. The loss is obtained by calculating the MSE between the original and the predicted message vectors.
- **Distributed Order Ranking Network** This task predicts the order index of each message from a shuffled order of a conversation. The task tries to minimize the KL divergence between the predicted order and the true order.

The calculated loss for the model propagation over the four self supervised tasks is the weighted sum of each loss function in the pre-training stage. The AdamW optimizer is employed with a linear planned warm-up technique and an initial learning rate of $5e-5$. Additionally, we use an adaptive learning-rate scheduler with 0.01 weight decay, 15,000 warm-up steps, and a batch size of 32. The model is trained for 20 epochs. All experiments are conducted on a GeForce RTX 3090 GPU using the PyTorch package.

5.2 Fine-tuning

In the fine-tuning step [Figure 2\(c\)](#), SR-BERT is adapted for the suicide risk prediction task using a standard approach ([Sun et al., 2020](#)). To this end we add a binary classification head to SR-BERT. The classification head consists of a dense layer with an output size of 2 and a softmax activation function. By maximizing the log-likelihood of the actual label, we fine-tune the Context Encoder Transformer and the classification head. We employ the AdamW optimizer with a linear planned warm-up technique and an initial learning rate of $2e-5$. Additionally, we use an adaptive learning-rate scheduler with 0.01 weight decay, and a batch size of 16. The model is trained for 10 epochs.

6 Empirical Methodology

We randomly split the labeled Sahar dataset to a train (70%) validation (15%) and test (15%) sets. These data sets were used throughout the experiments described in the following section. The validation set was used for training model hyper parameters.

We follow prior work in evaluating model performance using ROC-AUC which is widely employed in suicide detection research ([Bernert et al., 2020](#)). Additionally, we report on the F2-score ([Sokolova et al., 2006](#)) for predicting the positive SR label. This measure concentrates on reducing false negatives (rather than false positives) and is thus well suited for SR detection where missing a positive class has life threatening implications.

We compare SR-BERT with SSK to the following baseline models:

6.1 SR-BERT w.o.SSK

This model omits the SSK pre-training task from SR-BERT w. SSK. Apart from the SSK pre-training task this model is identical to SR-BERT w. SSK. including the hierarchical structure and pre-training on the other 3 tasks.

6.2 Explicit based lexicon + XGBoost

We used an XGBoost classifier that was based on an encoding of conversations over the explicit suicide related terms proposed by [Bialer et al. \(2022\)](#). This list includes 67 terms such as “commit suicide”, “cut wrists”, “wish to die” etc. We note that explicit terms carry very weak signal for SR detection.

6.3 Ensemble SI-BERT ([Bialer et al., 2022](#))

This is a non-hierarchical Hebrew language model ensembled with a classifier based on the Explicit lexicon, that represents the state of the art for SR detection. It was trained on the same dataset from the Sahar organization. To bypass BERT’s constraint of 512 tokens, Ensemble SI-BERT only utilized the help seeker text and truncated text greater than 512 tokens. We re-implemented this model with the code and parameters provided by the authors and run it on the dataset provided for this research. This is the reported state of the art for this domain in the Hebrew language.

6.4 SRF based lexicon + XGBoost

An XGBoost ([Chen and Guestrin, 2016](#)) classifier based on the 5-dimension SRF conversations rep-

Table 2: SR prediction results of compared models. Bold highlights highest value.

Model	Recall [%]	Precision [%]	ROC-AUC [%]	F2 [%]	F1 [%]
Doc2Vec+XGBoost	31.3	69.2	64.7	35.1	43.1
Explicit lexicon+XGBoost	49.2	67.1	76.9	52.3	57.7
SRF lexicon + XGBoost	55.1	67.2	76.5	57.1	60.0
Ensemble SI-BERT	60.4	70.9	91.3	62.3	65.3
SR-BERT w.o. SSK	72.9	68.4	92.1	71.9	70.6
SR-BERT w. SSK	78.3	68.9	92.1	76.2	73.3

resentation over the SRF lexicon. We note that XGBoost outperformed Random Forest and Logistic Regression as the classifier for this baseline (and for the next two baselines)

Consider for example one of the sessions which includes the statement “I am having strong stomach aches since yesterday, I want to die.”. This session includes a term from the Explicit lexicon while it is not an SR positive session.

6.5 Doc2Vec + XGBoost

An XGBoost classifier based on an encoding of each conversation to a 300-dimensional space using the Doc2Vec representation (Le and Mikolov, 2014).

7 Results

We first present the performance of the SR-BERT model in predicting SR on labeled conversations compared to the proposed baselines. Results are then reported for early SR detection, when increasing percentages of conversation information are available.

7.1 SR Detection from Complete Conversation

Table 2 compares the performance of the SR-BERT model to the baselines when predicting suicide risk from complete conversations. As seen in the table, both SR-BERT-based models (with and without SSK pre-training) outperformed the Ensemble SI-BERT model in terms of recall, F1, F2, and ROC-AUC metrics. Most notable improvement was in the recall metric where SR-BERT w.o. SSK achieved a 12.5% improvement over the Ensemble SI-BERT model, which led to a 9.6% improvement in the F2 metric. Moreover, the additional SSK pre-training improved on the SR-BERT w.o. SSK results for all metrics except the ROC-AUC score, where it hasn’t change. Ensemble SI-BERT achieved the highest precision, which was slightly

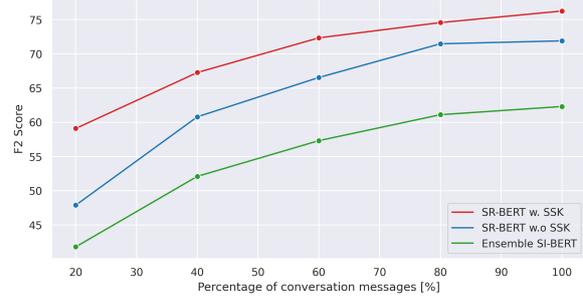

Figure 3: Classification results for early detection of top-performing SR detection approaches

better than SR-BERT w. SSK. It exhibited a substantially lower recall score, which correlates to lower F1 and F2 values.

The SRF lexicon + XGBoost based classifier was better than the Explicit lexicon + XGBoost classifier in all measures apart from ROC-AUC. We also note that the BERT based models outperformed the none BERT models on all tested metrics.

We used the McNemar paired test for labeling disagreements (Gillick and Cox, 1989) to compare between the predictions of the different models. Statistical significance with $p < 0.05$ was demonstrated for SR-BERT w. SSK vs. SR-BERT w.o. SSK and for SR-BERT w. SSK vs. Ensemble SI-BERT.

Overall SR-BERT w. SSK achieved a substantial improvement in recall and F2 compared the Ensemble SI-BERT of 17.9% and 13.9% respectively, with only a slight decrease in precision performance. This is critical in the suicide risk detection realm where recall is key to identifying help-seekers at risk and enabling targeted support.

7.2 Early SR Detection

Evaluating the ability of SR-BERT to predict SR risk from partial sessions provides an indication of its performance in real time, when only part of the session is available. To this end, Figure 3 compares the performance of the different models after

receiving the first {20, 40, 60, 80, 100} percent of messages in the session. As seen in the figure, the performance of all models improved as the sessions progressed. However, SR-BERT w. SSK model consistently outperformed the other models, followed by SR-BERT w.o. SSK. The difference in performance between SR-BERT with SSK and SR-BERT w.o. SSK was the largest at the beginning of the session and reduced as the sessions advanced. This may indicate the contribution of SR-BERT w. SSK to identify risk variables from the lexicon in early stages of the dialogue when information is lacking. In contrast, the difference in performance between SR-BERT w.o. SSK and the Ensemble SI-BERT model increases as sessions advance. This could be due to the inability of Ensemble SI-BERT to process the lengthy dialogue without having to truncate it, which may result in the loss of important information as sessions develop.

8 Conclusion and Future Work

This work has provided a new automatic approach for suicide risk detection in online conversations between help-seekers and counselors. Early detection of at-risk individuals is a key goal of suicide prevention. Our approach extends the state-of-the-art in deep language modeling by 1) incorporating domain knowledge relevant to suicide risk detection as part of the pre-training step; 2) reasoning about the structure of the conversation between help-seekers and counselors; 3) adapting to a low-resource language (Hebrew). The presented approach was able to significantly outperform the state-of-the-art approaches when detecting SR from complete conversations, as well as early detection when only part of the conversation is available. These results suggest the model may be able to support the work of counselors in real chat sessions, alerting them in real-time to at-risk individuals and enabling quick and focused responses. For future work, we intend to improve our approach by capturing more aspects of conversations, such as prosody (Wilson and Wharton, 2006; Kliper et al., 2010) as well as model the mental state dynamics of the help-seeker. We are also extending the model with explanations to be able to provide justifications for predictions made and point to key exchanges and phrases that triggered specific predictions.

9 Limitations

We note several limitations of this study.

First, our model was evaluated only in the Hebrew language. We have not directly compared SR-BERT to approaches for detecting suicidal risk in non-Hebrew domains, and note that the effectiveness of the model may vary across different languages and cultural contexts. It is difficult to make this comparison given the lack of public data sets from online counseling services.

Second, the proposed approach relies on the existence of psychological knowledge for pre-training the SR-BERT model which requires human effort. On the one hand, psychological lexicons already exist in English (Lee et al., 2020) and possibly in other languages. On the other hand, lexicons inherently suffer from limited coverage, lack of context and are expensive to maintain. Sharing domain knowledge across research tasks may go a long way to overcome these issues. We intend to make the lexicon developed for this research publicly available.

Third, the annotation of the help seekers' mental state was performed by the counselors, rather than the help seekers themselves. While the counselors underwent a thorough training process lasting several months and were monitored by certified clinical psychologists, there is still the possibility that they may have misclassified the mental state of the help seekers. This issue is prevalent in many studies that rely on observer-reported data.

Finally, the current model does not provide any explanations for its predictions, which are of high importance in order to support counselors in the field. This is essential in order to ensure that the model is not merely a means of classification but instead is able to provide valuable insights and assistance to counselors. This is a key focus of our future development plans.

10 Ethics Statement

The present study has been conducted in accordance with the highest ethical standards and has been approved by the relevant institutional review board of the participating institutions. All data utilized in this study, including the Sahar corpus of conversations between help-seekers and counselors, and the SRF psychological lexicon, have been obtained in compliance with the IRB. Specifically, the Sahar dataset has been anonymized and encrypted to protect the privacy of the participants, and all

help-seekers who have provided data for this study have given informed consent for the anonymous use of their sessions for research purposes. The counselors signed consent papers to allow the usage of their text data for the study.

It is important to note that despite the model's ability to successfully predict SR during the conversation and its demonstrated gender fairness, it is not intended to replace human volunteer counselors. We believe that human involvement is essential in providing support to help-seekers, and the role of an automated model is to serve as an aid to counselors, enhancing their ability to assess SR rather than replacing them. Our take is that in the future, when such models could be deployed in the field (after all necessary approvals and adaptations), they may only act as a "friendly parrot" on the counselors' shoulders, providing additional insights and supporting their decision-making process in the high load situations these counselors are facing on a daily basis.

Abstract

Although many large-scale knowledge bases (KBs) claim to contain multilingual information, their support for many non-English languages is often incomplete. This incompleteness gives birth to the task of cross-lingual question answering over knowledge base (xKBQA), which aims to answer questions in languages different from that of the provided KB. One of the major challenges facing xKBQA is the high cost of data annotation, leading to limited resources available for further exploration. Another challenge is mapping KB schemas and natural language expressions in the questions under cross-lingual settings. In this paper, we propose a novel approach for xKBQA in a reading comprehension paradigm. We convert KB subgraphs into passages to narrow the gap between KB schemas and questions, which enables our model to benefit from recent advances in multilingual pre-trained language models (MPLMs) and cross-lingual machine reading comprehension (xMRC). Specifically, we use MPLMs, with considerable knowledge of cross-lingual mappings, for cross-lingual reading comprehension. Existing high-quality xMRC datasets can be further utilized to finetune our model, greatly alleviating the data scarcity issue in xKBQA. Extensive experiments on two xKBQA datasets in 12 languages show that our approach outperforms various baselines and achieves strong few-shot and zero-shot performance. Our dataset and code are released for further research¹.

1 Introduction

Large-scale knowledge bases (KBs) such as Freebase (Bollacker et al., 2008) and DBpedia (Auer et al., 2007) store huge amounts of structured

Question:

谁在蜘蛛侠2中扮演玛丽简?

スパイダーマン2でメリージェーンを演じるのは誰ですか?

Qui joue Mary Jane dans Spiderman 2?

(Who plays Mary Jane in Spiderman 2?)

Knowledge Base (Subgraph):

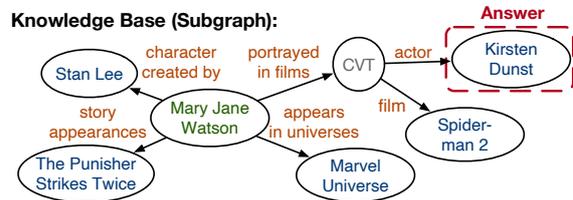

Figure 1: An example of answering questions in non-English languages over an English knowledge base.

knowledge. These KBs support a variety of natural language processing tasks, including question answering over knowledge base (KBQA), where models exploit the knowledge related to the questions and precisely identify the answers by reasoning through various KB relations. Although most large-scale KBs claim to contain multilingual information, they could not completely support non-English languages as expected. For example, Freebase has no translation for the KB relations/attributes in any non-English languages. More than half of the entities in Freebase have no Chinese translations, despite the fact that Chinese is the most spoken non-English language in the world. Therefore, these KBs could not directly support question answering in non-English languages, bringing up the problem of answering non-English questions over the KBs constructed in English.

In this work, we focus on cross-lingual KBQA (xKBQA), which aims to answer questions over a KB in another language. Figure 1 shows a KB subgraph and several factoid questions in non-English languages, which can be answered by a node in the KB subgraph. Despite considerable progress in monolingual KBQA, xKBQA receives little attention. A significant challenge in xKBQA is the

* Corresponding author.

¹<https://github.com/luciusssss/xkbqa-as-mrc>

lack of large-scale xKBQA datasets. Such datasets are quite expensive to annotate since the annotators are expected to be multilingual and have background knowledge about KBs. As a result, even the largest xKBQA dataset so far contains only a few hundred questions (Ngomo, 2018). Another challenge is that, compared to other cross-lingual tasks, the expression difference between structured KB schemas and natural language questions further hinders the learning of cross-lingual mapping.

To address these challenges, we propose to convert the KB subgraphs into natural language texts and leverage the progress in cross-lingual machine reading comprehension (xMRC) to solve the xKBQA task. Recently, there has been a series of large-scale xMRC datasets, such as MLQA (Lewis et al., 2020), MKQA (Longpre et al., 2021) and XQuAD (Artetxe et al., 2020). Multilingual pre-trained language models (MPLMs), such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), achieve competitive performance on these xMRC benchmarks. As for xKBQA, by converting KB subgraphs into natural language texts, we narrow the gap between KB schemas and natural language expressions. We then utilize the PLM-based xMRC models finetuned on xMRC datasets to learn the cross-lingual mapping efficiently, even with limited xKBQA annotations.

Specifically, we first identify the topic entity from the given question, link it to the KB, and extract its n -order neighbors to construct a KB subgraph, following traditional monolingual KBQA methods (Saxena et al., 2020; He et al., 2021). We then convert the subgraph into a question-specific passage with KB-to-text generation models, incorporating the KB triples with contextual expressions. Given the converted cross-lingual question-passage pairs, we adopt MPLMs to rank answer candidates in the passages. As a general framework, our approach can be easily applied to different languages or KBs without specialized modifications.

We empirically investigate the effectiveness of our method on two xKBQA datasets, QALD-M (Ngomo, 2018) and WebQSP-zh. QALD-M is a collection of a few hundred questions in 11 non-English languages, from a series of xKBQA evaluation campaigns. Considering its small size, we also construct a new dataset WebQSP-zh with 4,737 Chinese questions translated from WebQSP (Yih et al., 2016) by native speakers. WebQSP-zh is much larger in size and involves more natural

expressions as the annotators take into account commonsense knowledge and realistic vocabulary choices during manual translation.

Experimental results demonstrate that our method outperforms a variety of English-as-pivot baselines based on monolingual KBQA models, reaching 74.37% hits@1 on WebQSP-zh. Moreover, our method achieves strong few-shot and zero-shot performance. Using only 10% of the training data, our method performs comparably to several competitive English-as-pivot baselines trained with full training data. For the zero-shot evaluation on QALD-M, our method achieves 51.20% hits@1 on average across 11 languages.

Our main contributions are summarized as:

- We formulate xKBQA as answering questions by reading passages converted from KB subgraphs, bridging the gap between KB schemas and natural language expressions. Existing high-quality xMRC resources are further utilized to alleviate the data scarcity issue.
- We collect a large xKBQA dataset with native expressions in Chinese, i.e., WebQSP-zh. It, along with its original version, i.e., WebQSP, can be used for analyzing the gap between monolingual and cross-lingual KBQA.
- We conduct extensive experiments on two datasets with 12 languages. Our method outperforms various baselines and achieves strong few-shot and zero-shot performance.

2 Related Works

KBQA Recent efforts in KBQA generally fall into two main paradigms, either the information extraction style (Miller et al., 2016; Sun et al., 2018; Xu et al., 2019; Saxena et al., 2020; He et al., 2021; Shi et al., 2021) or the semantic parsing style (Yih et al., 2015; Lan and Jiang, 2020; Ye et al., 2022; Gu and Su, 2022). The former retrieves a set of candidate answers from KB, which are then compared with the questions in a condensed feature space. The latter manages to distill the symbolic representations or structured queries from the questions.

xKBQA Both styles of KBQA methods can be applied to xKBQA. Previous xKBQA efforts generally fall in the semantic parsing style. They rely on online translation tools (Hakimov et al., 2017) or embedding-based word-to-word translation (Zhou et al., 2021) to obtain synthetic training data. In

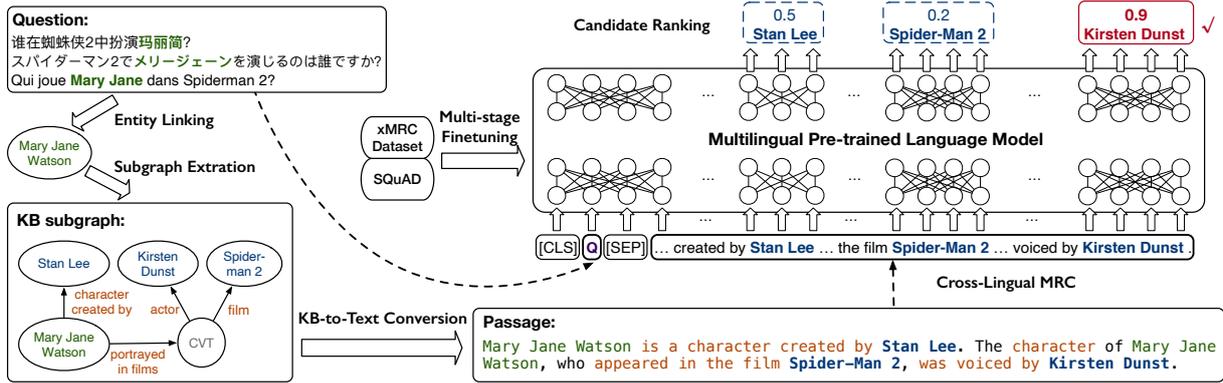

Figure 2: An illustration of our method. Given a large-scale KB in a rich-resource language such as English, to answer a question in a language with relatively fewer resources, we first extract a subgraph from KB according to entity linking results. We then convert the subgraph into a question-specific passage in natural language with KB-to-text generation models, complementing the KB triples with contextual expressions. The question and converted passage are fed into a PLM-based xMRC model, which ranks all candidate answer spans to obtain the final answer.

contrast, the information extraction based xKBQA approach is less explored. An advantage of this style of xKBQA methods is that it requires no annotation of structured queries, which is expensive to obtain for non-English languages. In this paper, we attempt to explore xKBQA approaches of the information extraction style with less reliance on machine translation tools and investigate their performance in the few-shot and zero-shot settings.

xMRC xMRC is a cross-lingual QA task receiving extensive attention recently, with considerable progress in datasets and models. There has been a stream of high-quality datasets in a wide range of languages, including MLQA (Lewis et al., 2020), MKQA (Longpre et al., 2021), XQuAD (Artetxe et al., 2020) and TyDi QA (Clark et al., 2020). Several works for xMRC adopt machine translation tools (Asai et al., 2018; Cui et al., 2019; Lee et al., 2019) or question generation systems (Riabi et al., 2021) to obtain more cross-lingual training data, while other works attempt to learn better cross-lingual mapping with MPLMs (Yuan et al., 2020; Wu et al., 2022).

KB-to-text in QA To benefit xKBQA with the progress in xMRC, we propose to convert the xKBQA task into reading comprehension. Previous works in other QA tasks attempt to convert KB triples into texts by simple concatenating heuristics (Oguz et al., 2020) or by manually-designed rules (Bian et al., 2021). Ma et al. (2022) resort to PLM-based generation models and argue that data-to-text can serve as a universal interface for open domain

QA. To the best of our knowledge, our work is the first to introduce data-to-text methods into KBQA and cross-lingual QA. Compared with Ma et al. (2022), we further address the real-world problems of complex KB structures, cross-lingual semantic gap, and data scarcity when applying data-to-text to xKBQA.

3 Methodology

We propose a novel approach to tackle xKBQA as reading comprehension. As illustrated in Figure 2, we first convert KB triples into sentences using generation models and obtain question-specific passages for reading comprehension. We then adopt MPLMs finetuned on xMRC datasets to answer cross-lingual questions according to the converted passages.

3.1 Task Formulation

In xKBQA, given a knowledge base G in language A and a question q in another language B , the model is expected to answer q by entities or literal values in G . In practice, A is often a rich-resource language such as English, and B is a language with relatively fewer resources. A knowledge base G consists of a set of knowledge triples. In a triple (h, r, t) , $h \in E$ is a head entity, $t \in E \cup L$ is a tail entity or a literal value, and $r \in R$ is the relation/predicate between h and t , where E denotes the set of all entities, L denotes the set of all literal values, and R denotes the set of all relations.

3.2 KB-to-Text Conversion

In a typical monolingual KBQA framework, one first identifies the topic entity in the question and links it to the given KB. This can be achieved by surface-level matching (Sun et al., 2018) or supervised entity linkers (Yang and Chang, 2015). In the cross-lingual setting, one can directly adopt multilingual entity linkers such as mGENRE (De Cao et al., 2022) or translate questions and KB entities into the same language for monolingual linking.

After entity linking, a KB subgraph is constructed by the neighbors within several hops around the topic entities. Based on the given question, all candidates in the subgraph are ranked to arrive at the final answers. To successfully identify from the subgraph the KB predicates leading to the answer, the KBQA models are expected to learn a mapping between KB predicates and natural language expressions in the questions. In addition to the language gap as in most cross-lingual tasks, the models have to deal with the difference in expression styles used in the KB schemas and questions.

To narrow down the gap of mapping, we propose to convert KB subgraphs to natural language passages, formulating xKBQA as an xMRC task, so that we can benefit from recent advances in xMRC. Converting KB subgraphs into natural sentences brings plausible context for candidate KB answers, facilitating the matching between questions and answers. Furthermore, with the natural language expressions of the KB subgraphs, current xMRC models can be directly adopted to solve the questions. We believe that xMRC models could benefit the xKBQA task for their strong capabilities of mapping between cross-lingual expressions. Even without annotated xKBQA data, they are able to answer a portion of xKBQA questions, utilizing their prior knowledge of the cross-lingual mapping learned from pre-training and fine-tuning on xMRC datasets.

To convert KB subgraphs into readable passages, we utilize PLM-based KB-to-text models, such as JointGT (Chen et al., 2021). A KB-to-text model converts a structured KB subgraph to natural language texts, complementing the given entities and relations with potential contextual expressions. Compared with simply concatenating the head entity, relation and tail entity of a triple, a KB-to-text model can generate more natural and coherent sentences. It also alleviates the onerous manual design of conversion rules. Moreover, the KB-to-text

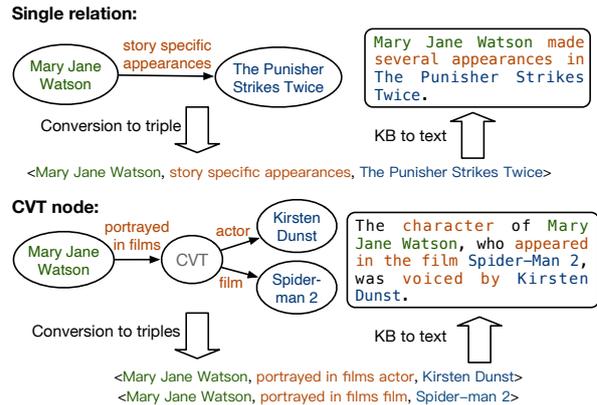

Figure 3: Examples of KB-to-text conversion for a single relation (upper) and a complex event-like fact, such as CVT nodes in Freebase (lower).

model can handle not only single-relation triples but also more complex KB structures, such as CVT nodes, which is a complex node type in Freebase referring to an event with multiple fields. Figure 3 shows examples of KB-to-text conversion for a single-relation triple and a CVT node.

After conversion, we identify the candidate answer spans from the pieces of text with fuzzy string matching tools. To form a passage, we concatenate the pieces of text, sorted by their semantic similarities to the questions.² We observe that the subgraphs around a topic entity can be very large, especially for the *hub* entities like *the USA*. Consequently, the converted passages can be very long, even up to 20k words in length. Current xMRC models struggle with such long passages. To shorten the converted passages, we fix the maximum length of the passage and discard the remaining redundant sentences.

3.3 Cross-Lingual Reading Comprehension

MPLMs are widely adopted in xMRC for their strong capabilities of understanding cross-lingual texts. They can encode different languages in a unified semantic space, relieving the reliance on translation tools. We thus use MPLMs to solve the xMRC instances converted from xKBQA.

Specifically, we concatenate the question and the converted passage as the input to the MPLMs and predict the boundary of the answer span. In the KB-to-text step, we have identified the corresponding

²Previous work shows that PLM-based MRC models are not sensitive to the order of sentences in the passage (Sugawara et al., 2020). We do not observe significant performance change after we shuffle the sentence order in the passage, which conforms to the finding by Sugawara et al. (2020).

WebQSP-zh: 安娜肯德里克出演过什么? / *What did Anna Kendrick star in?*

WebQSP-MT: 安娜肯德里克在干什么? / *What is Anna Kendrick doing?*

WebQSP: What has Anna Kendrick been in?

Freebase Predicate: film.actor.film film.performance.film

WebQSP-zh: 1945年前苏联的领导人是谁? / *Who was the leader of the former Soviet Union in 1945?*

WebQSP-MT: 1945年苏联的领导人是谁? / *Who was the leader of the Soviet Union in 1945?*

WebQSP: Who was the leader of the Soviet Union in 1945?

Freebase Predicate:

government.governmental_jurisdiction.governing_officials
government.government_position_held.office_holder

Table 1: Examples from WebQSP-zh and their corresponding questions in WebQSP. WebQSP-MT is the Chinese translation of WebQSP by Baidu Translate, a machine translation tool. The italic English texts are the literal meaning of the Chinese questions.

span in the passage for each candidate KB entity or literal value. Thus, during inference, we only need to rank the candidate answer spans. The corresponding KB entity or value for the top-ranked candidate span is selected as the final answer.

To address the data scarcity in xKBQA, we further propose to finetune the models on MRC data in multiple stages before on xKBQA data. Compared to KBQA, it is easier to acquire annotated MRC data for its straightforward annotation process without the requirement of background knowledge in KBs. Apart from large-scale English MRC datasets such as SQuAD (Rajpurkar et al., 2016), there are a series of high-quality xMRC datasets, including MLQA, MKQA and XQuAD, covering a wide range of non-English languages such as Russian, Hindi, and Dutch. In the first stage, we use large-scale English MRC datasets, e.g., SQuAD, to help MPLMs learn the language-agnostic ability to find answers from the passages. In the second stage, we finetune the models on high-quality xMRC datasets in the target language, strengthening the reading comprehension ability for the target language. In this way, the two-stage finetuning before training on xKBQA data benefits models with the rich resources in MRC and mitigate the data scarcity problem in xKBQA.

4 Experimental Setup

4.1 Datasets

We evaluate our method on two datasets, **QALD-M**, a small evaluation dataset in 11 languages, and

WebQSP-zh, a new dataset with a larger size and more realistic expressions.

QALD-M QALD-M is a series of evaluation campaigns on question answering over linked data. We use the version provided by Zhou et al. (2021) and filter the out-of-scope ones. It consists of testing questions for 11 non-English languages (fa, de, ro, it, ru, fr, nl, es, hi, pt, pt_BR) over DBPedia. The numbers of used questions for each language range from 66 to 363. We use QALD-M mainly for zero-shot evaluation. See Appendix A.1 for more details.

WebQSP-zh Considering that the size of QALD-M is small and its multilingual questions are mostly literal translations without language-dependent paraphrasing, we collect a new xKBQA dataset WebQSP-zh, with 3,098 questions for training and 1,639 questions for test.

To collect WebQSP-zh, we employ two Chinese native speakers proficient in English to manually translate all the questions in WebQSP (Yih et al., 2016), a widely-used English KBQA dataset, together with another annotator responsible for checking translation quality. To provide a more realistic benchmark for cross-lingual evaluation, the annotators are instructed to pay much attention to commonsense knowledge and natural vocabulary choices during translation. For example, in the upper example of Table 1, the phrase *be in* in the WebQSP question has multiple translations in Chinese. Based on the commonsense knowledge that *Anna Kendrick* is an actress, it is translated as *出演/star in* instead of its literal meaning *在做/be doing*. In the lower example of Table 1, the annotator chooses the Chinese word *前苏联/former Soviet Union* for translation instead of *苏联/Soviet Union* because the former is more often used by native Chinese speakers. See Appendix A.2 for more statistics, annotation details, and examples.

4.2 Baselines

Supervised A widely-adopted baseline method in cross-lingual QA tasks is translating data in non-English languages into English with machine translation tools and utilizing mono-lingual models (Asai et al., 2018; Cui et al., 2019), which we call **English-as-pivot**. For supervised experiments on WebQSP-zh, we select several competitive monolingual KBQA models for English-as-pivot evaluation. For information extraction style, we select **EmbedKGQA** (Saxena et al., 2020),

GraftNet (Sun et al., 2018), **NSM** (with its teacher-student variant, He et al., 2021), all of which require no annotation of structured KB queries, as our method does. For semantic parsing style, we select **QGG** (Lan and Jiang, 2020).³

We also provide a **Closed-book QA** baseline (Roberts et al., 2020) with generation-based MPLMs, e.g., mT5 (Xue et al., 2021). We feed the question directly into the model and expect it to output the answer based on its knowledge learned in pre-training. This method requires no external knowledge, such as KBs, and can coarsely evaluate how much parametric knowledge an MPLM may have.

Zero-shot Since the above supervised baselines are unable to answer any questions without training data, we further implement two baselines inspired from Zhou et al. (2021) for zero-shot evaluation. One is **Multilingual Semantic Matching**, which measures the similarity between questions and inferential chains with an MPLM finetuned on LC-QuAD (Trivedi et al., 2017), an English KBQA dataset. The other, based on the previous baseline, uses **Bilingual Lexicon Induction** (BLI, Lample et al., 2018) to obtain word-to-word translation in the target languages as data augmentation.

4.3 Metrics

Following previous works (Saxena et al., 2020; He et al., 2021), we use hits@1 as the evaluation metric. It is the ratio of questions whose top 1 predicted answer is in the set of golden answers.

4.4 Implementation Details

Following previous works (Sun et al., 2018; Saxena et al., 2020; He et al., 2021), we use the golden topic entities for a fair comparison with the baselines. We also discuss the effects of entity linking in Section 5.5. For KB-to-text generation, we use JointGT (Chen et al., 2021) finetuned on WebNLG (Gardent et al., 2017), a KB-to-text dataset. We use TheFuzz⁴ to identify candidate answer spans. We fix the maximum passage length to 750 words and discard the sentences with lower

³We did not include the recent semantic-parsing-style models based on Seq2Seq generation, including RnG-KBQA (Ye et al., 2022) and ArcaneQA (Gu and Su, 2022), both of which outperform QGG by 1.6% F1 on WebQSP. However, setting up an environment for them requires up to 300G memory, far exceeding our computational budgets. So we think that QGG is a suitable baseline that strikes a good balance between performance and computational resources.

⁴<https://github.com/seatgeek/thefuzz>

Model	WebQSP	WebQSP-zh
<i>English-as-pivot</i>

Table 2: Hits@1 (%) of baselines and our method on the test set of WebQSP-zh using the full training data. The “WebQSP” column shows the model performance on the test set of WebQSP after training on the original English WebQSP data. The numbers in the brackets denote the performance drop of English-as-pivot models compared to their corresponding English KBQA models on WebQSP. All models except GraftNet use golden topic entities.

semantic similarity to the questions, measured by the multilingual model of SentenceTransformers (Reimers and Gurevych, 2020). For xMRC, we experiment with mBERT and XLM-R. Before finetuning on the xMRC instances converted from xKBQA datasets, we first finetune models on SQuAD 1.1, and then on three xMRC datasets, MLQA, MKQA and XQuAD. We do not search hyperparameters for the xMRC models and adopt the default configuration used by SQuAD. For English-as-pivot baselines, we use Baidu Translate API⁵ to obtain English translations. See Appendix B for more details.

5 Results and Analyses

5.1 Supervised Setting

As shown in Table 2, we first compare our method with English-as-pivot baselines using full training data of WebQSP-zh. These baselines can benefit from the development of monolingual KBQA models and achieve over 63% hits@1 on WebQSP-zh. Suppose we have perfect translation results, the English-as-pivot baselines on the WebQSP-zh should reach the performance of monolingual models on the original English WebQSP. However, the English-as-pivot baselines on WebQSP-zh drop 1.4-3.0% hits@1 compared to their monolingual per-

Table 3: Hits@1 (%) of the baseline and our method with XLM-R-large on QALD-M under the zero-shot setting. “LC-QuAD” and “SQuAD” means using LC-QuAD and SQuAD for finetuning, respectively. “BLI” and “xMRC” means using BLI translation and xMRC datasets for finetuning, respectively. “Sing.” means using the data in the target language only while “All” means combining the data in all the languages. We do not find available xMRC datasets for Persian (fa), so the performance of “+ Sing. xMRC” on Persian is the same as that of “SQuAD”.

formance on the original WebQSP. This is because the English-as-pivot baselines are highly dependent on machine translation tools, whose outputs may contain unnatural expressions or even errors.

As for the closed-book QA baselines, mT5-large correctly outputs the answers in English for even 12.9% of the WebQSP-zh questions, without resorting to any external knowledge. This proves that MPLMs have learned a large amount of factual knowledge and strong cross-lingual capabilities, which can be properly utilized for xKBQA, as our method does.

All our models reach over 69% hits@1 on WebQSP-zh. Our two base-size models outperform EmbedKGQA by approximately 6% hits@1, an English-as-pivot baseline that utilizes RoBERTa-base and the KB embedding ComplEx (Trouillon et al., 2016). Our model with XLM-R-large outperforms all baselines, achieving 74.37% hits@1 thanks to the strong cross-lingual capability from MPLMs and rich resources in xMRC. Moreover, these results demonstrate another merit of our approach that it can directly answer non-English questions over KBs in English, reducing the reliance on machine translation systems. Although NSM-student, which does not use PLMs itself, performs better than our two base-size models, the parameters and computational complexity introduced by the translation system are much heavier than the MPLM used in our method. Furthermore, our approach demonstrates its advantage with fewer or even no training data, as we will discuss next.

5.2 Few-Shot and Zero-Shot Settings

Consider the high cost of annotating high-quality xKBQA data, we investigate the capabilities of our method under few-shot and zero-shot settings.

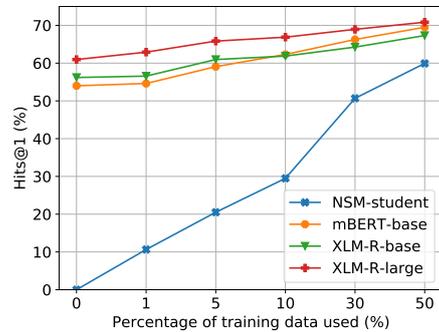

Figure 4: Few-shot and zero-shot performance of our method and NSM-student on the test set of WebQSP-zh.

Figure 4 shows the performance of our method and NSM-student on WebQSP-zh under few-shot and zero-shot settings. For NSM-student, its performance drops drastically with the decrease in training data. and it is totally incapable of zero-shot xKBQA. By contrast, when trained with half of the training data, our method still performs well, with less than 3% decrease in hits@1 compared with those trained with full data. With only 10% of the training data, i.e., 310 instances, our models reach over 62% hits@1, comparable with EmbedKGQA trained with full training data. Even under the zero-shot setting, our method can achieve 53-61% hits@1. The high performance of our method with limited training data is attributed to the KB-to-text conversion, which in turn makes it possible to benefit from the rich resources in xMRC. The MPLMs for xMRC have learned to encode different languages in the same semantic space during pre-training. After finetuning on xMRC datasets, the models can learn the ability to seek information from passages in a different language. By combining the prior knowledge of cross-lingual

mapping and reading comprehension abilities, our models can successfully answer a large portion of the xMRC-like questions converted from xKBQA.

To demonstrate that our method can generalize to different languages without specialized modifications, we test our approach on QALD-M in 11 typologically-diverse languages under the zero-shot setting. We evaluate the model on QALD-M after finetuning (1) on SQuAD only, (2) on SQuAD and xMRC datasets of a single language, and (3) on SQuAD and xMRC datasets of all the languages. As shown in Table 3, after finetuning XLM-R-large with SQuAD, our models achieve 43.9% hits@1 on average across 11 non-English languages, demonstrating our method’s strong generalization ability from English MRC datasets. After further finetuning on xMRC datasets for each language, we observe a 6.7% hits@1 boost in the average performance, showing the benefit of xMRC datasets in the absence of xKBQA data. If we combine the xMRC of all the languages for finetuning, the average hits@1 further increases slightly by 0.6%, probably due to the potential complementary effects between data in different languages. Compared with the semantic matching baseline finetuned with LC-QuAD and BLI-based translations, our best model outperforms it by 4.2% hits@1 on average. This is because the KB-to-text process of our method provides richer context than single inferential chains and the xMRC data are of higher quality than the BLI-based word-to-word translation.

5.3 Ablation Study

To evaluate the effectiveness of the designs in our approach, we conduct experiments in several ablated settings on WebQSP-zh with full xKBQA training data. We additionally conduct an ablation study with only 10% of the training to investigate what is behind the promising few-shot performance. The results are shown in Table 4.

With full training data, after we replace the PLM-based KB-to-text model with the simple heuristic of concatenating the head, predicate, and tail (w/o KB to text), the performance drops by 2.13% hits@1. Although the xMRC models can to some extent learn the mapping between questions and sentences converted by heuristics, the coherence and readability of KB-to-text generation results contribute to the final performance. Skipping the finetuning on either SQuAD (w/o SQuAD) or xMRC datasets (w/o xMRC data) leads to a performance drop,

Model	100%	10%
XLM-R-large (Ours)	74.37	67.60
- w/o KB to text	72.24 (-2.13)	65.58 (-2.02)
- w/o xMRC data	71.81 (-2.56)	65.53 (-2.07)
- w/o SQuAD	71.02 (-3.35)	65.10 (-2.50)
- w/o xMRC data, SQuAD	66.69 (-7.68)	54.79 (-12.81)

Table 4: Ablation study of our method with XLM-R-large on WebQSP-zh, using 100% or 10% of the training data (Hits@1 in percent).

showing the importance of high-quality data augmentation in absence of large-scale xKBQA data.

In the setting with 10% of the training data, both KB-to-text generation and finetuning on the MRC data contribute to the high few-shot performance, similar to the full training data setting. We observe a drastic drop of 12.81% hits@1 if the model is not finetuned on any MRC data (w/o xMRC data, SQuAD). This indicates that MRC data, no matter monolingual or cross-lingual, can greatly relieve the problem of data scarcity in xKBQA.

5.4 Error Analysis

We sample 50 error cases in WebQSP-zh and analyze their sources of error, as shown in Table 5.

34% of the errors result from the annotation of the original WebQSP dataset, where the annotated answer sets may be incomplete or incorrect. Another common source of error is the MRC model, which incorrectly answers 34% of the sampled questions. Among them, many are complex questions involving constraints or multiple relations. In the future, multi-hop MRC models can be adopted for addressing them. Besides, there are also several error cases resulting from KB-to-text generation and sentence filtering. We believe that our model will achieve better performance if each module in our framework is carefully optimized for the datasets.

5.5 Effect of Entity Linking

Entity linking (EL) is a crucial issue in KBQA, which requires linking the entity mentions in the questions to the entities in a KB. It becomes even more difficult in the cross-lingual setting. In the experiments above, we use golden entity linking results following previous works. To further investigate the effect of entity linking in xKBQA, we conduct pilot experiments with two EL methods. One is surface-level matching after translating the questions, and the other is mGENRE (De Cao

Source	Example	Explanation	%
Answer Annotation	Question: 沃尔玛经营什么产业? / <i>What industry does Walmart operate in?</i> Passage: ... The industry of Walmart is <u>Retail-Store</u> , <u>Variety Stores</u> and <u>Department Stores</u> Answer: Variety Stores Prediction: Retail-Store	The annotated answers in the original WebQSP dataset are incomplete or incorrect. In the left case, the annotated answer set fails to include two correct answers, <i>Retail-Store</i> and <i>Department Stores</i> .	34
KB-to-text Generation	Question: 凯南·鲁兹在灯红酒绿杀人夜中扮演谁? / <i>Who does Kellan Lutz play in Prom Night?</i> Passage: ... Kellan Lutz, a character in the film “Prom Night”, played with <u>Rick Leland</u> Kellan Lutz, a character in <i>Twilight</i> , played the role of <u>Emmett Cullen</u> Answer: Rick Leland Prediction: Emmett Cullen	The KB-to-text model converts a KB schema to a wrong natural language expression or omits the entities in the given triple. In the left case, the model incorrectly converts the KB schema <i>character</i> to the expression <i>play with</i> .	12
Sentence Filtering	Question: 爱德华多·包洛奇在他的工作中使用了什么材料? / <i>What Materials did Eduardo Paolozzi use in his work?</i> Passage: ... The art forms of Eduardo Paolozzi are <u>Sculpture</u> Answer: Bronze Prediction: Sculpture	The answers are missing in the passages because the model for sentence similarity calculation incorrectly filters out the sentences containing answers. In the left case, the sentence containing the answer <i>Bronze</i> is mistakenly filtered out.	20
Reading Comprehension	Question: 谁是杰拉尔德福特的副总裁? / <i>Who was the vice president of Gerald Ford?</i> Passage: ... David Gergen was appointed as the White House Communications Director by President Gerald Ford The vice president of Gerald Ford was <u>Nelson Rockefeller</u> Answer: Nelson Rockefeller Prediction: Staff Dick Cheney	The xMRC model fails to select the correct answer span. In the left case, the xMRC model incorrectly maps the word 副总裁/ <i>vice president</i> to the expression <i>White House Communications Director</i> in the passage.	34

Table 5: Examples, explanations and percentages of different sources of error in the 50 sampled WebQSP-zh question that XLM-R-large fails to answer. The underlined spans in passages are answer candidates.

et al., 2022), a cross-lingual EL tool that does not rely on machine translation tools. On the test set of WebQSP-zh, two EL methods achieve 89.1% and 76.8% recall@5, respectively. With the results from two EL methods, our xMRC model with XLM-R-large achieves 65.9% and 56.5% hits@1, respectively. The large gap compared to the results with golden topic entities indicates that more future research on cross-lingual EL is desired.

6 Conclusion

In this paper, we propose to formulate xKBQA as answering questions by reading passages, benefiting from the recent advance in xMRC. By converting KB subgraphs into passages, we narrow the gap between KB schemas and natural questions under cross-lingual settings. The cross-lingual knowledge in MPLMs and the rich resources in xMRC alleviate the problem of data scarcity in xKBQA. To facilitate the evaluation of xKBQA, we collect WebQSP-zh, a new large-scale xKBQA dataset with more natural expressions. Extensive experiments on two datasets with 12 languages show

the strong performance of our method under both supervised and zero-shot settings.

We hope that our work will inspire more efforts into xKBQA. Several promising research directions under our framework include generating better passages for KB subgraphs, supporting more types of KBQA questions, and exploring better EL strategies for xKBQA.

Limitations

We discuss the limitations of our work from the following four aspects:

First, our work mainly focuses on single-relation questions and CVT questions in KBQA. We construct a new dataset WebQSP-zh based on WebQSP, which lacks complex questions with multiple constraints or relations. Since we use a vanilla BERT-based MRC model in our framework, it has a limited capacity for solving complex KBQA questions. As future work, multi-hop MRC models can be adopted to address complex questions in cross-lingual KBQA.

Second, our method is mainly designed for

entity-centric QA. It can handle well the answer types of KB entities or attribute values in KBQA. Yet its capability on other types of answers is currently unknown. We will consider extending our method with more diverse answer types in the future.

Third, the size of retrieved KB subgraphs is constrained by the maximum input length of PLMs. This could, to some extent, lower the answer coverage of the converted passages and hurt the overall performance. In the future, Longformer-based encoders or text summarization techniques could be explored to address this limitation.

Fourth, although using existing xMRC datasets can alleviate the data scarcity problem in xKBQA, it cannot fundamentally solve the problem of insufficient and expensive cross-lingual datasets. With more powerful cross-lingual PLMs, we may reduce the reliance on xMRC data. We will explore more strategies for tackling the data scarcity problem in future work.

A Dataset Details

A.1 QALD-M

Statistic The QALD-M dataset used in our paper is based on the version released by Zhou et al. (2021), composed of questions from QALD-M 4 to QALD-M 9 in 11 non-English languages. We filter the yes/no questions, counting questions, and the questions whose answers cannot be found in the knowledge base. The sizes of testing questions for each language are shown in Table 7, ranging from 66 to 363.

Knowledge Base For QALD-M, we use the 2016-10 version of DBPedia⁶. We discard the KB triples that are unlikely to contain answers such as page IDs and revision history, and only include information about article categories and object properties. For each question, we include in the subgraph the triples where the topic entity is the head entity or the tail entity, namely its one-hop neighbors.

A.2 WebQSP-zh

Statistics The WebQSP-zh dataset proposed in our paper consists of 4,737 question-answer pairs, of which 3,098 instances are for training and the remaining 1,639 instances are for testing. The average length of questions is 12.7 characters. The average number of answers per question is 9.8.

Knowledge Base For WebQSP-zh, we use a pre-processed version of Freebase⁷. Following previous works (Sun et al., 2018; Saxena et al., 2020), we further prune it to contain only those relations that are mentioned in the dataset. For each question, we obtain the neighborhood graph within two hops of topic entities.

Annotation Details We recruited the annotators from a Chinese campus BBS, who are proficient in both Chinese and English. They are instructed to translate the questions in WebQSP into Chinese and to pay attention to commonsense knowledge and natural vocabulary choice. They are paid 3 CNY for each question annotated, which is adequate given the participants’ demographic. The annotators are informed of how the data would be used.

⁶<http://downloads.dbpedia.org/wiki-archive/downloads-2016-10.html>

⁷<https://github.com/hugochan/BAMnet>

More Examples We provide more examples from WebQSP-zh in Table 6 to show that WebQSP-zh is a more realistic benchmark for cross-lingual evaluation, incorporated with commonsense knowledge and realistic vocabulary choices.

In the first example of Table 6, based on the knowledge that Aldi is a company, the word *originate* is translated as 创建/*found* instead of its literal translation 起源/*originate*. In the second example of Table 6, the annotator uses 范德堡大学/*Vanderbilt University* instead of 范德堡/*Vanderbilt* because native Chinese speakers often call Western universities by their full names and rarely drop the word 大学/*university*.

WebQSP-zh: 阿尔迪是什么时候创建的? / *When was Aldi founded?*

WebQSP-MT: 阿尔迪是什么时候起源的? / *When did Aldi originate?*

WebQSP: When did Aldi originate?

Freebase Predicate:

business.employer.employees
business.employment_tenure.from

WebQSP-zh: 范德堡大学的吉祥物是什么? / *What is Vanderbilt University’s mascot?*

WebQSP-MT: 范德堡的吉祥物是什么? / *What is Vanderbilt’s mascot?*

WebQSP: What is Vanderbilt’s Mascot?

Freebase Predicate:

education.educational_institution.mascot

Table 6: Examples from WebQSP-zh and their corresponding questions in WebQSP. WebQSP-MT is the Chinese translation of WebQSP by the machine translation tool Baidu Translate. The italic English texts are the literal meaning of the Chinese questions.

A.3 xMRC datasets

We use three xMRC datasets for data augmentation. Their preprocessing details and statistics are as follows.

In terms of MLQA and XQuAD, we directly use the officially released data with English passages paired with non-English questions. In terms of MKQA, the passages for reading comprehension are full-length English Wikipedia articles. Since the Wikipedia articles are too long for PLM-based xMRC models to handle, we use the annotated non-tabular long answers as passages, which are generally a few hundred words long.

For each language, we combine the data from different xMRC for finetuning. Specifically, we use MLQA for zh, de, es, hi; MKQA for zh, de, es, fr, it, nl, pt, pt_BR, ru; XQuAD for de, es, hi, ro,

Language	fa	de	ro	it	ru	fr	nl	es	hi_IN	pt	pt_BR
Size	334	363	344	363	171	363	346	346	262	171	66

Table 7: The sizes of QALD-M testing questions in 11 languages used in our paper.

Language	zh	de	ro	it	ru	fr	nl	es	hi_IN	pt	pt_BR
Size	5,641	8,904	1,190	2,685	3,875	2,685	2,685	9,628	6,615	2,685	2,685

Table 8: The number of questions in the combined xMRC datasets used in our paper.

ru. The statistics of the combined xMRC data are shown in Table 8.

B Implementation Details

B.1 KB-to-Text

We use JointGT (Chen et al., 2021) based on BART-base for KB-to-text generation. It is finetuned on WebNLG with the same hyperparameters in the original paper. In sentence filtering, we use the paraphrase-multilingual-mpnet-base-v2 model in SentenceTransformers for cross-lingual semantic similarity calculation.

B.2 xMRC

Our implementation of xMRC models is based on the Transformers⁸. For the finetuning on SQuAD, we set the batch size to 12, the learning rate to 3e-5, the number of training epochs to 2, the maximum input length to 384, and the document stride to 128. For the finetuning on xMRC datasets and the data converted from xKBQA, we use the same hyperparameters as the finetuning on SQuAD. The results are from single runs. We use an NVIDIA A40 GPU for experiments. An epoch on the data converted from xKBQA takes about 9 minutes.

C Licenses of Scientific Artifacts

The licenses for each dataset used are as follows: CC BY-SA 4.0 for SQuAD, Apache-2.0 License for MKQA, CC BY-SA 4.0 for XQuAD, CC-BY-SA 3.0 for MLQA, CC-BY 4.0 for WebQSP, GPL-3.0 License for LC-QuAD, and MIT License for QALD. The licenses for each model used are as follows: Apache-2.0 License for EmbedKGQA, BSD-2-Clause License for GraftNet, and Apache-2.0 License for Transformers. No license is provided by other models.

Abstract

Visual question answering (VQA) is one of the crucial vision-and-language tasks. Yet, existing VQA research has mostly focused on the English language, due to a lack of suitable evaluation resources. Previous work on cross-lingual VQA has reported poor zero-shot transfer performance of current multilingual multimodal Transformers with large gaps to monolingual performance, without any deeper analysis. In this work, we delve deeper into the different aspects of cross-lingual VQA, aiming to understand the impact of 1) modeling methods and choices, including architecture, inductive bias, fine-tuning; 2) learning biases: including question types and modality biases in cross-lingual setups. The key results of our analysis are: **1)** We show that simple modifications to the standard training setup can substantially reduce the transfer gap to monolingual English performance, yielding +10 accuracy points over existing methods. **2)** We analyze cross-lingual VQA across different question types of varying complexity for different multilingual multimodal Transformers, and identify question types that are the most difficult to improve on. **3)** We provide an analysis of modality biases present in training data and models, revealing why zero-shot performance gaps remain for certain question types and languages.

1 Introduction

The lack of multilingual resources has hindered the development and evaluation of Visual Question Answering (VQA) methods beyond the English language until recently. A rise in interest in creating multilingual Vision-and-Language (V&L) resources has inspired more research in this area (Srinivasan et al., 2021; Su et al., 2021; Liu et al., 2021a; Pfeiffer et al., 2022; Wang et al., 2022; Bugliarello et al., 2022, *inter alia*). Large Transformer-based models pretrained on images and text in *multiple* different languages have been proven as a viable vehicle for the development of

multilingual V&L task architectures through transfer learning, but such models are still few and far between (M3P, UC2; Ni et al., 2021; Zhou et al., 2021). Large decreases in task performance between monolingual and (zero-shot) cross-lingual transfer setups have been measured and reported, among other multilingual V&L tasks, in VQA (Pfeiffer et al., 2022). Yet, the reasons for such low results in this pivotal V&L task have not been investigated in depth.

In this work, we aim to shed new light on the cross-lingual performance gap of cross-lingual VQA models from multiple angles. To the best of our knowledge, we are the first to provide a comprehensive analysis of multilingual VQA, with a focus on cross-lingual transfer.

We first assess and discuss the impact of modeling methods and choices on the final cross-lingual VQA performance, aiming to mitigate the present performance gap. This includes experimenting with diverse prediction head architectures, incorporating inductive bias by extending input signals, as well as more sophisticated fine-tuning strategies. We analyze cross-lingual VQA across different question types of varying complexity for different multilingual multimodal Transformers, and in zero-shot and few-shot scenarios.

Next, we focus on the learning biases, where we investigate whether current multilingual multimodal models suffer from the so-called unimodal bias: that is, we probe if the models truly reason over both images and questions to solve the VQA task, or if they take unimodal ‘shortcuts’ instead, exploiting spurious correlations and artifacts of data creation. Our analysis allows us to identify the most difficult question types and reveals a shortcoming of the current evaluation scheme.

We find that standard approaches from text-only cross-lingual transfer scenarios (Pires et al., 2019; Hu et al., 2020) do not leverage the full multilingual capabilities of the pretrained models; we mea-

sure the considerably worse performance of ‘standard’ fine-tuning compared to a simple modified fine-tuning regime. Interestingly, we report a discrepancy between monolingual and cross-lingual performance in the modified fine-tuning regime: while they do not have any substantial impact on the model performance in the *source* language (English), they considerably improve *cross-lingual* VQA capabilities, achieving gains of more than 10 absolute accuracy points over the baselines.

Code is available at github.com/UKPLab/eacl2023-xlingvqa.

2 Preliminaries

The VQA task is typically framed as a classification problem with a large number of classes. For instance, in the VQA task on the standard English GQA dataset (Hudson and Manning, 2019), given a pair of an image and a question, a model needs to predict a correct answer from 1,853 possible classes. GQA consists of diverse structural and semantic patterns, in which the questions are visually grounded in the image. In multilingual and cross-lingual VQA, the goal is to make similar predictions, but the questions can be posed in different *target* languages (Pfeiffer et al., 2022): e.g., the VQA task on the multilingual xGQA dataset (Pfeiffer et al., 2022) relies on the same set of 1,853 classes as English GQA.

We base all our analyses and experiments on the xGQA dataset, which is, due to its size and language coverage, arguably the most comprehensive evaluation resource for cross-lingual VQA to date. It has also been included in the multimodal multilingual evaluation benchmark IGLUE (Bugliarello et al., 2022). xGQA is the multilingual extension of the English GQA dataset (Hudson and Manning, 2019) to 7 typologically diverse languages.

In this work, we use and empirically compare two state-of-the-art pretrained multimodal multilingual Transformer architectures: **M3P** (Ni et al., 2021) and **UC2** (Zhou et al., 2021).¹ The standard cross-lingual *zero-shot* transfer setup for VQA involves fine-tuning all the weights of the pretrained model on the downstream task data in the source language only. In the *few-shot* setup, after the source-language fine-tuning, the model is additionally optimized on a handful of task-annotated examples in the target language (Pfeiffer et al., 2022).

¹For technical details of the two models, we refer the reader to their respective papers.

3 Modeling Methods

Motivation. Recent work on VQA in cross-lingual settings (Pfeiffer et al., 2022; Bugliarello et al., 2022) benchmarked standard multimodal architectures in zero-shot and few-shot transfer scenarios on the xGQA dataset, without aiming to provide a deeper understanding of the particulars of the cross-lingual VQA task. At the same time, they report large gaps of cross-lingual transfer performance when compared to monolingual English performance, suggesting that there is ample room for improvement. In this work, we aim to leverage novel insights into different aspects of the cross-lingual VQA task (e.g., analyses over different question types or classification architectures) to guide improved cross-lingual VQA methods. In particular, we assess the impact of three orthogonal directions: **1)** classification architectures (§3.1); **2)** (richer) input signals (§3.2); **3)** fine-tuning strategies (§3.3).

3.1 Classification Architecture Variants

The original work on xGQA (Pfeiffer et al., 2022) evaluated only a simple ‘shallow’ linear classification head, termed **Linear** here: the output [CLS] token of the pretrained Transformer-based model (which has cross-attended over all text and image features) is simply passed into a linear classification head. However, we hypothesize that this choice might have a substantial impact on transfer performance. Therefore, in the so-called **Deep** variant, instead of a linear classification head, we add a 2-layer transformation network (f_{trans}) with the GELU activation function (Hendrycks and Gimpel, 2016), dropout and a layer-normalization layer, before feeding the representations into a linear layer for classification. The first layer of f_{trans} uses an orthogonal initializer (Saxe et al., 2014). Unless noted otherwise, all of our following experiments are based on this ‘deeper’ architecture; we illustrate the architecture in Figure 3 in Appendix C.

3.2 Incorporating Inductive Bias into the Input Signal

A large number of output classes (see §2) potentially amplifies the difficulty of zero-shot and few-shot cross-lingual transfer due to the need of aligning contextual representations in multiple languages for multi-class classifications. Standard VQA datasets such as GQA and xGQA contain questions of five different structural types (*Verify*,

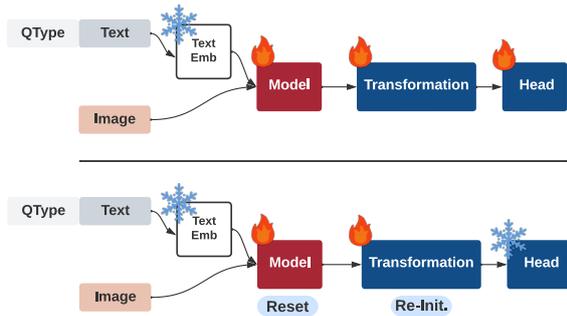

Figure 1: Self-Bootstrapping (§3.3). *Top*: Fine-tuning with frozen text embeddings (Stage 1). *Bottom*: Fine-tuning with text embeddings and classification head frozen. Other parameters are reset to their pretrained values or randomly initialized (Stage 2).

Logical, Query, Choose, Compare).² Pfeiffer et al. (2022) have demonstrated a considerable performance variation over different question types, e.g., there is a large cross-lingual performance drop especially for *Choose*-type questions.

To help alleviate this issue, we propose to feed the model with designated question-type tokens (Prager, 2006; Murdock et al., 2012) which appear in GQA and xGQA. The idea is to influence the label distribution for the VQA classification task by conditioning on a question-type token.

More concretely, we prepend a question-type token *QType* in English to the text input. We use structural question types as the question-type tokens; the text input then takes the following format: ‘[QType] : [Question]’.

As the xGQA data contains questions with binary answers (i.e. *Yes/No* questions). We anticipate that for a large fixed number of output classes, these questions should benefit the most from using the question-type tokens. The models which rely on this question-type conditioning are denoted with the superscript Q , e.g., M3P Q , see also later §3.4.

Recent work (Schick and Schütze, 2021; Li and Liang, 2021; Liu et al., 2021b; Shin et al., 2020) suggests that there exist more sophisticated prefixes/prompts and prompt-tuning methods. As our focus is not on conducting a large-scale analysis over different prompt-based conditioning, we leave this topic for future work.

²See Appendix B for example questions for each of the five question types.

3.3 Fine-Tuning Strategy

Misalignment of multilingual text embeddings (Søgaard et al., 2018; Dubossarsky et al., 2020) has been indicated by Pfeiffer et al. (2022) as one of the principal causes for reduced zero-shot performance in the cross-lingual VQA tasks. Therefore, we propose two fine-tuning strategies, tailored exactly towards mitigating such undesired shifts in the multilingual embedding space.

Freezing Text Embeddings. In the first variant, we freeze text embeddings during fine-tuning and only optimize the Transformer weights and the classification head. This should prevent misalignment of the text embedding space during fine-tuning, as only the alignments between image and text embeddings change, but not text-to-text alignments. This strategy, labeled **+FT**, is referred to as contrastive tuning by Zhai et al. (2022).

Self-Bootstrapping. Zero-shot cross-lingual transfer via standard fine-tuning is known to be sensitive to parameter initialization (Bugliarello et al., 2022). Previous work has shown that fine-tuning a classification head first, then fine-tuning the model can effectively improve the generalization of the model (Kumar et al., 2022; Yang et al., 2022). Motivated by these insights from prior research, we first train the network to learn the classification head, then reset and fine-tune the remaining model parameters. This leads to a two-stage fine-tuning process, termed *self-bootstrapping* (labeled **+SB**), illustrated in Figure 1 and outlined here:

Stage One: We fine-tune all parameters (with text embeddings frozen) on the task data.

Stage Two: We **1)** freeze the classification head (excluding the bias parameters) and text embeddings, **2)** reset the remaining parameters in the multimodal multilingual model to pretrained weights, and **3)** re-initialize the f_{trans} network (see §3.1). We then fine-tune the transformer weights on the task data.³

In order to make fair comparisons between +FT fine-tuning and self-bootstrapping, we define two extra +FT variants that match the fine-tuning budget of self-bootstrapping. In +FT_{short} we fine-tune until the budget of self-bootstrapping’s Stage 1 is matched. In +FT_{long}, we fine-tune until the total

³In our preliminary experiments, we found that self-bootstrapping-based fine-tuning still achieves better performance even if we perform Stage 1 with tunable text embeddings (i.e., standard fine-tuning). Freezing text embeddings in Stage 1 is an empirical decision, freezing them in Stage 2 is essential for self-bootstrapping to work.

training budget of self-bootstrapping is matched.

3.4 Model Configurations and Notation

Different choices across the orthogonal axes of classification architecture, input, and fine-tuning strategy give rise to a wide spectrum of *model configurations*. In particular, we can independently choose **1**) between the Linear or Deep classification architecture; **2**) whether to include the information on the question type at input (Q) or not; **3**) whether to apply standard fine-tuning from prior work (Pfeifer et al., 2022), or rely on +FT or +SB fine-tuning strategies. On top of this, we can also vary **4**) the underlying model (M3P or UC2), and **5**) the transfer scenario (zero-shot versus few-shot). For clarity of presentation, unless noted otherwise, we always assume zero-shot scenarios and Deep classification architecture. Moreover, different variants are also labeled in a systematic manner using abbreviations introduced in §3.1-§3.3: e.g., *M3P+SB* means that we apply self-bootstrapping on the underlying M3P model (with Deep architecture assumed). In another example, *UC2^Q+FT_{long}* means that we apply the *long* variant of +FT fine-tuning (see §3.3) with UC2 as the underlying model, and we condition the model on the information about question types.

4 Analysis Methods

The VQA task is inherently multimodal—a model is required to reason over both images and questions in textual form to solve the task. However, as with some unimodal text-only tasks (Gururangan et al., 2018; Poliak et al., 2018) VQA models might also be prone to ‘taking shortcuts’, that is, exploiting spurious correlations and artifacts of data creation. In other words, the VQA model could circumvent the multimodal aspect and only focus on a single modality to solve the task (Agrawal et al., 2016, 2018). Therefore, to better understand the multimodal reasoning abilities of VQA models in cross-lingual transfer, we propose several diagnostic approaches and methods that ablate the input features of the models, inspired by the diagnostic methods of Frank et al. (2021) and Shrestha et al. (2020) in monolingual setups. They should provide us with deeper insights into the inner workings of cross-lingual VQA models.

4.1 Unimodal Evaluation

The first set of analyses involves a combination of standard multimodal (MM) training with unimodal

inference/evaluation. During training, we pass both visual features and text tokens into the model. However, at inference, we provide the model with features of only one modality (Visual modality: **V** or Text: **T**). This naturally gives rise to the following two experimental setups:

MM-V: When evaluating on xGQA’s test set, we pass only a single ‘?’ as textual input to the model, while the standard visual features are used.

MM-T: At inference, we zero out all visual features (e.g., object features, spatial features), only providing the model with the total number of objects detected; the unchanged questions in the textual form are provided to the model.

4.2 Unimodal Training and Evaluation

Next, we probe purely unimodal models *trained* on a single modality (**V** or **T**): during training, the model is provided only with visual features or text tokens; at inference, we again only provide the model with unimodal features from the same modality. This creates three experimental setups:

V-V: We pass only ‘?’ as a (placeholder) textual input to the model, while the standard visual features (from the full multimodal model) are used.

T-T: All visual features are zeroed out; we only provide the number of objects detected; the unchanged questions in the textual form are provided.

T^G-T^G: We randomly sample object features from a Gaussian distribution with a mean and a standard deviation that match the actual object feature distribution for that image. Spatial features and the number of objects detected are kept as in the full MM model. The standard unchanged questions in the textual form are provided to the model.

5 Experimental Setup

Pretrained Models and Data. As introduced in §2, we 1) rely on two standard state-of-the-art multimodal multilingual transformers (M3P, UC2; Ni et al., 2021; Zhou et al., 2021) as the underlying pretrained models, and 2) conduct all evaluations on the standard monolingual English GQA dataset, and its multilingual extension: xGQA.

The GQA dataset consists of two training sets: **full** and **balanced**. The full dataset contains 113K images and 22M questions, whereas the balanced dataset consists of 1.7M data samples. The dataset also contains a balanced test-dev set with 12,578 questions and 398 images for evaluation. In xGQA, the questions are manually translated from the

Table 1: Zero-shot transfer results on xGQA. Avg. refers to the average accuracy across languages excluding English. Group G1: baselines. *: our runs of baselines trained on balanced GQA. Group G2: results using a question-type token. Group G3: results using self-bootstrapping (+SB). Group G4: combining different fine-tuning strategy with the use of question-type tokens. Best results in each column and per each pretrained model across Groups G1-G4 are shown in **bold**. Results are averaged across four random seeds.

GQA test-dev set into 7 different languages: Bengali, Chinese (simplified), German, Indonesian, Korean, Portuguese, and Russian. xGQA provides a zero-shot evaluation set and a different training/evaluation set for the few-shot setting. Please see the original paper for details.

Training Details and Hyperparameters. Following the recommendations from Bugliarello et al. (2022), we predominantly run training on the more lightweight *balanced* subset of GQA.⁴ We also define a total training budget of 6 epochs (less than 24 hours of training). For the self-bootstrapping procedure, this means the total training time (Stage 1 + Stage 2) is equal to 6 epochs. See Appendix A for further details.

6 Results and Discussion

In §6.1, we discuss the results of the different modeling approaches across the three dimensions (see

⁴Another established yet less efficient training procedure is to train on the full GQA dataset first, then further train on the balanced dataset (Li et al., 2020). This procedure can produce good results on the English evaluation dataset at the cost of a substantial increase in computation demands (~4 days on one NVIDIA V100 for one model). Furthermore, our initial experiments have indicated that training with the balanced set performs similarly to the previously reported baselines in the xGQA paper while using substantially less computing. We stress that we also further run experiments under the more demanding training regime (Li et al., 2020) with the best-performing model configuration from our experiments. For more details, we refer the reader to §7.

§3): classification architectures, input signals and fine-tuning strategies. A finer-grained analysis concerning different structural question types is provided in §6.1. Finally, in §6.2 we delve deeper into the VQA models’ susceptibility towards exploiting unimodal biases and artifacts of the VQA datasets, relying on model variants discussed in §4.

6.1 Impact of Modeling Methods

A summary of the results with a wide spectrum of possible model configurations (see §3.4) is provided in Table 1, with accuracy as the main metric.

First, an interesting trend emerges: different model configurations have *no* significant effect on performance in the source language (English), especially so for the better-performing pretrained model UC2. However, variations in different modeling choices from §3 do show *considerable* impact on cross-lingual transfer performance: we report gains by more than 16 and 13 absolute accuracy points for M3P and UC2, respectively.

Classification Architectures. Surprisingly, simply adding additional non-linear layers to the prediction head has a considerable impact on the cross-lingual transfer performance of the baseline models (especially for the M3P model) while performance in the source language stays nearly the same (Table 1, Group G1). Put simply, a deeper classification architecture seems to benefit cross-lingual

transfer performance, and the extent of its impact cannot be captured by monolingual English-only evaluation. Further, to isolate the source of these improvements, we conducted additional experiments by removing the layer normalization component from the deeper architecture. The results are provided in Table 8 in the Appendix. Another key observation is that the impact of depth is model-dependent with stronger configurations. While it yields large gains when we start from the baseline transfer models (G1), the gains from the classification architecture are less pronounced or even non-existent, e.g., for the best-performing UC2^Q + SB model variant (see Group G4): 39.87 (Deep) versus 40.89 (Linear). The gains from classification architecture remained for the M3P model variant: 36.19 (Deep) versus 18.24 (Linear).

Input Signal. The large number of output classes of GQA potentially results in a noisy distribution over the predicted labels when sentences in a different language are passed into the model. We find that including the question-type token (Q) improves the average cross-lingual zero-shot transfer accuracy by more than 10% relatively for both M3P^Q and UC2^Q (Table 1, Group G2). This modeling decision again has an inconsequential impact on the source language but suggests that the question-type token can partially mitigate the poor performance of cross-lingual transfer. A comparison of G3 versus G4 models in Table 1 demonstrates that including the question type at input yields gains of almost 6 accuracy points with M3P, and more than 3 points with UC2, with especially large gains for Bengali as the lowest-performing language.

Fine-tuning Strategy. Freezing the embeddings to mitigate a shift in the multilingual embedding space results in positive gains for cross-lingual scenarios (Table 1, Group G4). The self-bootstrapping strategy (+SB with and without Q) achieves further gains over both +FT embedding-freezing experimental setups. At the same time, it also yields much lower variance across languages (with Q). This validates that resetting parameters with self-bootstrapping positively impacts model performance, and supports our hypothesis that first fixing the classifier weights to good values leads to better performance and lower variance. Note that the average +SB results of UC2 are statistically significant against UC2^Q and UC2^Q + FT_{short} ($p < 0.05$).

Performance across Question Types. Finer-

grained results per individual question type are summarized in Figure 2, where we compare the baseline models with the best-performing variant, which utilizes the question-type at the input and the self-bootstrapping strategy. In sum, we observe gains across all structural question-types for such ^Q+SB model configurations, both for M3P and UC2. Performance on *Query* and *Choose* questions meets substantial gains, suggesting that improving the alignment between multilingual text embeddings has a positive effect on performance, especially for non-binary, free-form question-types. Complete results are available in Appendix B).

6.2 Learning Biases: Multi-Modal versus Unimodal VQA?

We use the analysis methods from §4 to determine whether the underlying models have learned to rely on a single modality to make predictions, either due to spurious correlations in the data or the model’s inability to effectively combine multi-modal features. The main results are provided in Table 2.

Unimodal Evaluation. The scores of MM-T/MM-V ablations reveal the sensitivity to missing features in each input modality at test time. We observe a drop in accuracy of more than 50% across all question types in the MM-T/MM-V experiments compared to their counterparts that assume ‘full-feature’ multi-modal input at inference. Moreover, *Verify*, *Logical* and *Compare* questions seem more dependent on text features. The results confirm that the trained model needs both modalities to achieve good cross-lingual performance, although not at equal proportions. In other words, high zero-shot transfer performance observed in our experiments are obtained by leveraging both modalities in synergy, and not by ‘taking unimodal shortcuts’ (§4).

Unimodal Training and Evaluation. V-V/T-T/T^G-T^G experiments reveal the worst-case exploitation of the data biases in modalities by the models. The results suggest that a majority of the final performance can be attained with text features in fine-tuned models for the *Logical*, *Verify*, and *Compare* question types. Therefore, the results indicate that these question types contain modality biases that can be exploited by unimodal VQA architectures. The exploitable data biases could also explain the observations from prior experiments. We suspect this could also explain the asymmetrical attention over modalities, observed by Frank et al. (2021) in monolingual multi-modal models.

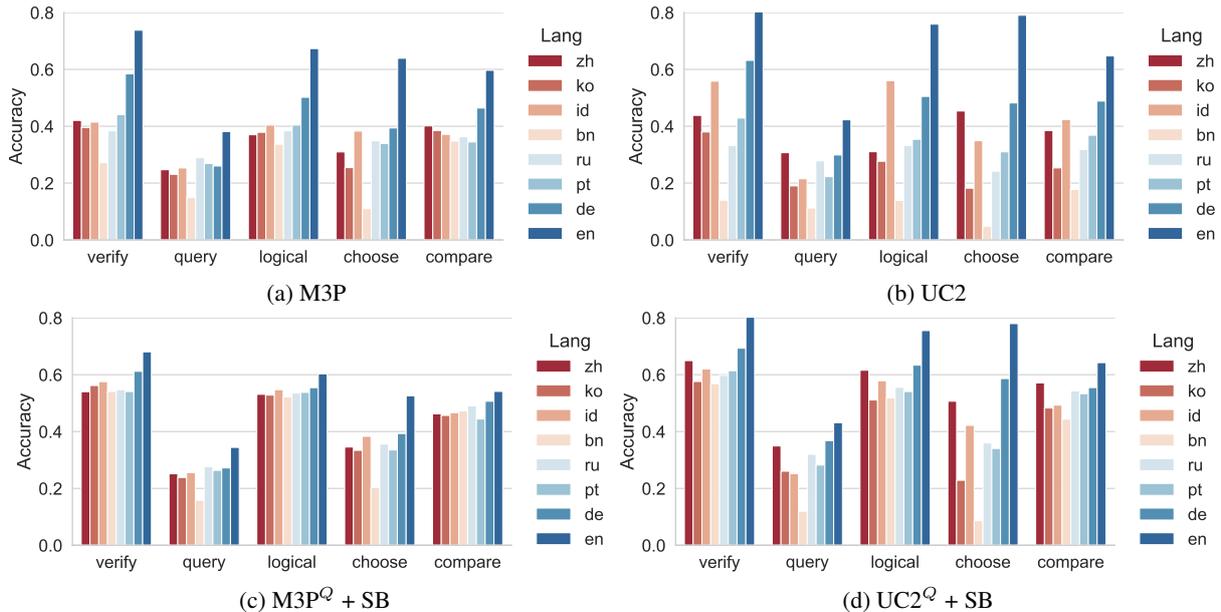

Figure 2: Zero-shot cross-lingual transfer performance across individual question types in GQA and xGQA.

Biases across Question Types.. Unimodally trained models can only attain $\sim 20\%$ (M3P) and $\sim 26\%$ (UC2) accuracy at best for the *Query* question type, with similar trends observed for *Choose*. Exposing the models to increasingly more visual features (from T-T over T^G-T^G to the full multi-model) yields significant performance gains. It thus indicates that *Query* and *Choose* questions contain fewer exploitable data biases, and additional image-text grounding could help improve predictions. Previous work in monolingual settings (Keravade et al., 2021) concludes that *Compare* and *Query* questions should be focused on for future improvements. Here, in the cross-lingual setting, we found *Query* and *Choose* questions as the most difficult questions with the largest gaps in monolingual English performance.

Table 2 also reveals that more sophisticated fine-tuning strategies such as self-bootstrapping, which prevent multilingual text embedding shifts, are an effective way to improve performance on these two (most challenging) question types.

In summary, it is crucial to conduct such finer-grained analyses across different question types in the multilingual VQA tasks, and not treat them equally with only a global accuracy metric. In particular, our results render *Query* and *Choose* question types as by far the most challenging question types for cross-lingual transfer and the types that do not suffer from exploitable data biases. Future research in multilingual VQA should put more

Table 2: Zero-shot transfer results of M3P^Q/UC2^Q trained and tested with visual features only (V-V), text features only (T-T), text features with partial visual features (T^G-T^G), as well as of M3P^Q+SB/UC2^Q+SB trained using all features, but exposed only to visual features (MM-V) or text features (MM-T) at inference (§4). The scores are averaged over all target languages in xGQA, excluding English.

emphasis on such questions, and approaches that prevent the exploitation of unimodal data biases. Future research should also look beyond the question types currently covered by xGQA, and introduce even more challenging types.

7 Additional Results

Training with Full English GQA. To validate the effectiveness of our approach in setups where more data in the source language is available, we additionally run experiments in another VQA setup: we train the best-performing method UC2^Q+SB for 5

Method	0	1	5	48
M3P	35.58	37.62	39.29	42.28
M3P + SB	33.73	35.89	39.27	42.46
M3P ^Q	33.81	35.40	37.80	41.87
M3P ^Q + SB	37.14	37.50	38.16	40.00
UC2	30.15	36.09	38.67	44.37
UC2 + SB	38.09	40.51	42.14	46.68
UC2 ^Q	37.28	39.24	40.88	45.11
UC2 ^Q + SB	39.83	42.35	43.68	46.62

Table 3: Averaged few-shot (0/1/5/48-shot) accuracy scores on xGQA (excl. English) for selected models.

epochs on the unbalanced English GQA dataset, followed by 2 epochs on the balanced dataset. Despite the fact that this variant leverages more source-language training data and consumes considerably more compute, we do not observe any gain on monolingual English performance, and observe only a small gain in the cross-lingual zero-shot setup: the accuracy score, averaged across all the target languages, increases from 39.87 to 40.51.⁵

Few-shot Experiments. Besides the zero-shot transfer scenario—which is the primary focus of this work—we also evaluate whether similar findings extend to few-shot scenarios, where a handful of annotated examples in the target language is assumed. Following the standard setup of Lauscher et al. (2020) we start from the weights of the best-performing model, already fine-tuned on English VQA data. We then further fine-tune it on the few examples in the target language. In particular, we conduct few-shot experiments with 1, 5, and 48 images.⁶ Following Pfeiffer et al. (2022) we fine-tune for 10 epochs, with a learning rate of 5e-5.

The results are summarized in Table 3 (see Table 10 in Appendix F for full results), and indicate two key findings. First, we corroborate findings from prior work, where it was shown that fine-tuning on an increasing number of shots/examples in the target language generally improves model performance. Second, although baseline models are able to recover more performance from zero-shot to few-shot setups, our best-performing configuration with UC2 still significantly outperforms the baseline. We attribute the on-par performance across M3P variants to M3P’s sensitivity to initialization and high variance. These results indicate that few-shot fine-tuning is an *additional*

⁵Table 9 in Appendix E provides per-language accuracy.

⁶We choose 1 and 5 shots because these are typical in few-shot training setups (Zhao et al., 2021). 48 shots are the maximum available training data for the few-shot evaluation.

cost-efficient approach, orthogonal to our modeling enhancements from §3, to further improve VQA model performance in the target language.

8 Related Work

Transformer-based models trained on multimodal data (Tan and Bansal, 2019; Li et al., 2020; Cho et al., 2021; Shen et al., 2022; Kamath et al., 2021, *inter alia*) have demonstrated impressive results on English-only VQA tasks. However, as training and evaluation data has previously only been available in high resource languages (Elliott et al., 2016, 2017; Barrault et al., 2018; Gao et al., 2015), progress in multilingual vision-and-language learning has not kept pace.

More comprehensive multilingual multimodal benchmarks have been developed only recently (Srinivasan et al., 2021; Su et al., 2021; Liu et al., 2021a; Pfeiffer et al., 2022; Wang et al., 2022; Bugliarello et al., 2022, *inter alia*) making it possible to evaluate multimodal models which have either been pretrained on multilingual data (Ni et al., 2021; Zhou et al., 2021) or extended to unseen languages (Liu et al., 2021a; Pfeiffer et al., 2022).

Our work complements this recent line of work by delving deeper into cross-lingual visual question answering, again highlighting the inherent difficulty of multilingual multimodal learning.

9 Conclusion

In this work, we provide an extensive analysis of the issues present in VQA-related multilingual vision-and-language learning, aiming to inspire new solutions that can improve cross-lingual VQA performance. To this end, we studied simple yet effective methods that increase previously low transfer performance and thus substantially reduce the gap to monolingual English performance. This has been achieved through more sophisticated classification architectures, fine-tuning strategies, and introducing inductive biases to input via question-type conditioning. We also conducted further analyses and empirical comparisons, including detection of unimodal biases in training and evaluation data, fine-grained analyses across different question types, and comparisons across different multilingual Transformer models and transfer scenarios. We hope that this work will spark more interest and inspire future research on cross-lingual VQA tasks in particular, as well as on multilingual multimodal learning in general.

10 Limitations

Our study focuses on the cross-lingual VQA task relying on the xGQA dataset only. xGQA contains seven typologically different languages and many low-resource languages are not included. We aim to extend this study to other low-resource languages in the future, and to other datasets that were made publicly available after the completion of this study (Changpinyo et al., 2022).

In one part of our study, we assume gold question-type information is available during training and testing. This assumption is made for analysis purposes, in practice, one could train a classifier for question-type classification first.

The proposed self-bootstrapping method requires the ability to divide training into stages and reset weights during training.

We have averaged our results over four runs. From our experiments, we noticed that both of the underlying multilingual multimodal Transformers produced high variance results. We plan to investigate the causes of the variance in detail as part of future research. Currently, we relied on one established few-shot learning paradigm, recently Schmidt et al. (2022) shows that combining English and target-language data might yield more robust transferring results, which we plan to investigate into future.

A Details of Training Setup and Hyperparameters

The hyperparameters used to train M3P and UC2 models are summarized in Table 4. We conducted all experiments with either an NVIDIA V100 or A100 GPU. The numbers of training epochs across different model configurations are summarized in Table 5. Training time for the rest of our zero-shot experiments ranges from 8 to 24 hours.

We searched over the following learning rates: $2e-5$, $5e-5$, and $1e-4$.

We note that experiments which rely on Full GQA data (*-full*) have a significantly different training budget. This setup followed the previously recommended training setup of Li et al. (2020).

We use pretrained, state-of-the-art Transformer-based M3P and UC2 models (open-sourced), which build on pre-extracted image features from pretrained object detectors. M3P was pretrained via masked language modeling, cross-lingual masked language modeling and cross-modal text-image region alignments objectives. UC2 was trained similarly to M3P with an additional auxiliary task (i.e. translation).

We extracted image features for M3P using the ResNet-101 backbone using the vqa-maskrcnn-benchmark model (Massa and Girshick, 2018) (100 bounding boxes), and we extracted image features for UC2 using the bottom-up-attention (Anderson et al., 2018) (100 bounding boxes). The feature extraction procedures are different because the pretrained M3P and UC2 use different features. For experiments, we implemented everything in PyTorch, and we utilized Hugging Face Transformers (Wolf et al., 2020) and MMT-Retrieval (Geigle et al., 2022).

Name	Value

Compare	5,89
Query	6,804
Choose	1,129

Table 6: GQA test-dev set: distribution of questions over question types.

B Structural Question Types in GQA and xGQA

There are 5 different structural question-types in GQA and, consequently, in xGQA. We used the exact lowercase name of each question type as the QType token in our experiments, namely: *verify*, *logical*, *compare*, *query*, and *choose*. The text input follows the format of: ‘[QType] : [Question]’ (see again §3.2). Some example questions for each question type are as follows:

Verify: Yes/No questions. E.g. *Do you see books near the device that looks gray? Is the bus blue?*

Logical: Questions that require logical inference. E.g. *Is there any motorcycle or ball in the scene? Does the dirt look brown and fine?*

Compare: Comparison questions between two or more objects. E.g. *Who seems to be younger, the boy or the woman?*

Query: Open questions. E.g. *What color are the pants? What is the animal that is standing on the grass called?*

Choose: Choose from two presented alternatives. E.g. *Is it red or blue? What size is the jacket, small*

Question Type	M3P	M3P + SB	M3P ^Q	M3P ^Q + SB
Verify	40.15	44.45	58.35	55.98
Logical	39.15	45.29	53.89	53.65

or large?

Verify and Logical question types are binary question types (Yes/No). The question type distribution in the test-dev set of GQA is given in Table 6, while we provide average accuracy scores overall target languages in xGQA (excluding English), with a representative set of models, in Table 7.

C Classification Architecture with and without Layer Normalization

The deeper variant of the classification architecture from §3.1 is illustrated in Figure 3. The *Multimodal Multilingual Model* block in Figure 3 denotes one of the two pretrained multimodal multilingual models used throughout the (main) paper: UC2 and M3P.

We further experimented with another variant of the architecture, where we removed the layer normalization (LayerNorm) layer. The results of this variant are available in Table 8.

In a nutshell, LayerNorm has more impact on M3P’s zero-shot transfer accuracy scores than on UC2. However, the variance of UC2 results increases with the removal of LayerNorm.

D Accuracy vs. Total Training Epochs

We conducted experiments with different total numbers of training epochs with M3P to understand the effect of the self-bootstrapping fine-tuning strategy. We experimented with the following three model configurations across different setups:

1. M3P^Q + FT: We train the M3P^Q model with text embeddings frozen for 4, 6 and 10 epochs.
2. M3P^{Q*} + FT: We initialize the M3P^Q model with fine-tuned weights (including transformation, classification head) from 1 (i.e., the variant above), and train for 4 epochs. We continue to fine-tune the model for 2 or 5 more epochs after resetting the learning rate and the optimizer.
3. M3P^Q + SB: We train the M3P^Q model with self-bootstrapping and the classification head weights from variant 1 above and do it for 4 epochs. We continue to fine-tune the model for 2 or 5 epochs.

We also run similar variants with UC2 as the underlying model with shorter training epochs. These variants are UC2^Q + FT / UC2^{Q*} + FT / UC2^Q + SB where superscripts and acronyms remain the same as the M3P variants. Results of these experiments are provided in Figure 4a (M3P) and Figure 4b (UC2).

We observe that the gains in cross-lingual transfer with +FT variants diminish or even start decreasing with the increase of training time. Similar results are observed when we reset the learning rate, weight decay and optimizer after training for 4 epochs. We also find that self-bootstrapping training continually improves the results, even with less additional total training epochs.

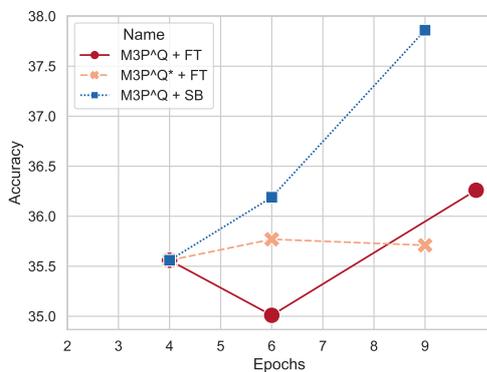

Moreover, the performance of self-bootstrapping is considerably more stable (lower variance) across random seeds, even though its classification heads are initialized from the corresponding trained weights from the M3P^Q + FT experiments.

Method	En	De	Zh	Ko	Id	Bn	Pt	Ru	Avg
M3P (Linear)	51.88 \pm 0.7	27.45 \pm 5.8	16.33 \pm 8.3	13.70 \pm 5.4	25.25 \pm 11.4	10.59 \pm 3.4	21.10 \pm 3.4	20.95 \pm 3.3	19.34

Table 9: Zero-shot results when the models are trained with Full GQA data.

(a) M3P

(b) UC2

Figure 4: Average accuracy versus total training epochs.

We also observe an increase in zero-shot transfer accuracy scores with more epochs of training in Stage 2 of self-bootstrapping. However, this results in much longer training times, which may not be realistic for academic and even some industry settings.

E Results with Full GQA Data

It is worth noting that the experiments trained with full GQA data (*-full*) have a significantly differ-

ent (and larger) training budget (see §7). We follow the previously recommended total training budget of Li et al. (2020) and combine it with our self-bootstrapping fine-tuning strategy. Table 9 shows the detailed results.

F Few-shot Experiments: Full Results

Table 10 shows the detailed results of our few-shot experiments, where the summary table is provided in the main paper: Table 3 in §7.

Bridging Argument Quality and Deliberative Quality Annotations with Adapters

Neele Falk and Gabriella Lapesa

Institute for Natural Language Processing, University of Stuttgart

{neele.falk,gabriella.lapesa}@ims.uni-stuttgart.de

Abstract

Assessing the quality of an argument is a complex, highly subjective task, influenced by heterogeneous factors (e.g., prior beliefs of the annotators, topic, domain, and application), and crucial for its impact in downstream tasks (e.g., argument retrieval or generation). Both the Argument Mining and the Social Science community have devoted plenty of attention to it, resulting in a wide variety of argument quality dimensions and a large number of annotated resources. This work aims at a better understanding of how the different aspects of argument quality relate to each other from a practical point of view. We employ adapter-fusion (Pfeiffer et al., 2021) as a multi-task learning framework which a) can improve the prediction of individual quality dimensions by injecting knowledge about related dimensions b) is efficient and modular and c) can serve as an analysis tool to investigate relations between different dimensions. We conduct experiments on 6 datasets and 20 quality dimensions. We find that the majority of the dimensions can be learned as a weighted combination of other quality aspects, and that for 8 dimensions adapter fusion improves quality prediction. Last, we show the benefits of this approach by improving the performance in an extrinsic, out-of-domain task: prediction of moderator interventions in a deliberative forum.

1 Introduction

Although people have been dealing with the art of persuasion since ancient times, there are many answers to the question of what constitutes a good argument or good argumentation, and none can be considered the best: the quality of arguments is complex, subjective and depends on the context in which the quality is assessed and on the prerequisites (attitudes and values) of the one who judges it. Despite the high complexity of this task, a considerable research effort has been done to automatically model argument quality in different contexts

(Wachsmuth et al., 2017a) due to its usefulness in downstream applications, such as automatic writing assistants (Wambsganss et al., 2020), argument extraction (Alshomary et al., 2021) and generation (Gurcke et al., 2021). Social Science offers another whole field of theories and definitions about argument quality in which the focus is usually not only on the argument itself but on the discussion between participants thus emphasizing the deliberative goal of the discourse (Gerber et al., 2018).

These two research communities, Argument Mining (AM) and Deliberative Theory (DT), have not only produced different theories of argument quality, but also a number of annotated datasets on the basis of which the models for the automatic assessment can be (or have been) trained. In both AM and DT, argument quality (AQ) and its Social Science counterpart, deliberative quality (DQ) are broken down into finer-grained dimensions. Such dimensions map, for example, whether an argument is logically constructed (micro-level), or constructive in the context of an overall discussion (macro-level). However, neither individual quality dimensions, nor an aggregated score can do justice to the complexity of this concept. Besides, a model that represents different aspects but has only been trained on one dataset will reproduce data-specific biases and may be less robust on other domains.

Multi-task learning (in this work, each quality dimension, e.g., logical cogency, clarity, persuasiveness, is a task), and the training data drawn from different datasets are a solution, as they allow to integrate the different dimensions and data sources from the two research communities. We propose to implement it using adapters (Houlsby et al., 2019), modules added between the layers of a transformer model. Differently from fine-tuning of the full model, adapters allow to use a minimal amount of parameters while still achieving good performance. Differently from standard multi-task learning, adapters do not require all the tasks to be

learnt simultaneously, but they can be learnt as specific modules that can also be combined (fused or stacked). The modular design of the adapters then allows for flexible composition of the individual quality aspects and thus can be used in various configurations; this property facilitates future research of argument quality in different domains and lends itself as tool for the investigation of the relationship between different quality dimensions, both within and across disciplines. We experiment with 6 datasets containing AQ and DQ annotations, for a total of 20 dimensions (AQ:8; DQ: 12) covering a wide range of logical, rhetorical and dialectical aspects and a variety of domains and topics. Our work proceeds in two steps.

In the first step, we employ adapter fusion to learn a target dimension as a weighted combination of single-task adapters (e.g., clarity as a combination of cogency and effectiveness). We improve the results with respect to single-task learning on 8 dimensions out of 20 in a low-resource scenario. Furthermore, fusion activation patterns provide us a tool to investigate the relationship between different quality dimensions.

In the second step, we employ quality adapters for a new task on a new dataset: predicting that a post in a deliberative forum needs moderation (Park et al., 2012). A fusion based on quality adapters is compared to baseline and full fine-tuning, outperforming both. Moreover, our analysis shows that in solving the task, the models exploit information from all major quality sub-categories. Crucially for the downstream application, casting moderation prediction as a fusion of quality adapters allows us to provide recommendation explained along specific quality dimensions (e.g., "this comment has major issues with the logical side of argumentation and it is disrespectful").

The contributions of this paper are at multiple level: a) at the level of task and methods, this is the first work which employs adapters for finer-grained AQ dimensions; b) at the conceptual/theoretical level, we make a first step in the integration of theories of AQ and DQ, bridging between the annotations produced by the two communities and proposing adapter activation as a tool to empirically compare the conceptual core shared by AQ and DQ dimensions c) at the level of application, we show that quality adapters can support the task of predicting moderation of user comments, additionally contributing a theory-based explanation layer.

2 Related Work

Argument Quality Much work on automatic modeling and annotation of argument quality (AQ) in the Argument Mining community focuses either on a specific aspect of quality (e.g. argument relevance (Wachsmuth et al., 2017b), sufficiency (Stab and Gurevych, 2017)) or a more general notion of argument quality based on human intuition (Habernal and Gurevych, 2016). Wachsmuth et al. (2017a) proposes a holistic taxonomy based on different theories of argument quality, inspired from rhetoric and linguistics, which divides AQ into three main sub-categories. The logical dimension measures whether an argument has premises and a valid conclusion (cogency) thus takes the content and structure of a single argument into account. The rhetorical dimension (effectiveness) measures the persuasiveness of the argument and takes into account *how* it is presented (style, emotional appeal). The dialectical dimension (reasonableness) plays a more important role in the context of a discourse and reflects whether an argument is valid towards a universal audience (e.g. whether the reasoning is based on values generally accepted by the society) or whether it is constructive in helping to resolve issues. Wachsmuth et al. (2017a) construct a corpus consisting of 302 arguments annotated with the three core and 15 sub-dimensions. Wachsmuth and Werner (2020) investigate which linguistic features are predictive of the fine-grained dimensions and which of the dimensions can be automatically assessed based on the textual input representations alone. The work by Fromm et al. (2022) are the first that try to combine AQ definitions from different corpora and based on different annotation schemas into one model. They investigate the generalizability of AQ when combining different sources and explore multi-task learning for assessing it in four different datasets. On top of that they investigate the relationship between AQ and other AM tasks such as evidence detection.

While most work on AQ in the Argument Mining community focuses on the logical dimension or specific aspects of persuasion, research on deliberative quality (DQ) from Social Science puts the discourse as a whole and the interaction between discourse participants into the focus. Here, argument quality (or discourse / deliberative quality) is investigated to find out which tools and solutions (e.g. moderation, platform design, structured overviews) can contribute to a more productive and

respectful public discourse. Thus, the annotated datasets from this domain complement the ones from the AM community providing many aspects of the rhetorical and dialectic dimensions.

Adapters Adapters (Houlsby et al., 2019) are a set of task-specific parameters that are introduced in every layer of a transformer (Vaswani et al., 2017) and updated for a specific task while the rest of the pre-trained language-model parameters is kept frozen. Besides being more efficient than full fine-tuning, adapters can be used as building blocks for other tasks due to their modular architecture and are therefore particularly well suited for transfer- and multi-task learning (He et al., 2021) and to inject external knowledge sources to solve downstream tasks (Lauscher et al., 2020a). Pfeiffer et al. (2021) propose to train task-specific adapters first (knowledge extraction) and combine them in a second step (knowledge composition) using self-attention to mitigate catastrophic interference, a problem which often occurs with traditional multi-task learning approaches. In their work, this approach has proven to be useful especially in low-resource settings which is often the case for complex annotations such as the AQ ones. To the best of our knowledge, our work is the first to employ adapters for AQ to conduct a systematic comparison of AQ and DQ on different data sources.

3 Datasets

For our experiments we rely on diversity, both in terms of data sets and different conceptualizations of argument quality. Therefore, we also integrate two datasets from the Social Sciences, which are not established in the argument quality community, but show a particularly large variety of dimensions. **Europolis** (Gerber et al., 2018): consists of transcriptions of a face-to-face discussion about the topic immigration, initiated by the European Union in order to enable deliberation on a European level. The spoken multi-lingual contributions have been transcribed, partially translated and annotated with five different dimensions of DQ by political scientists, each dimension between two to five labels that can be arranged on a scale from a low to a high standard of deliberative abilities. The dimensions capture the logical aspect (*justification*), rhetorical aspects (*storytelling*) and dialectic aspects (*common Good*, *interactivity* and *respect*).

THF/BK (Esau, 2022): this dataset contains comments from two online citizen dialogues on munic-

ipal issues: one on the further development of the “Tempelhofer Feld” site in Berlin and the other on the use of the former lignite area in North Rhine-Westphalia. The data was annotated by political scientists with different dimensions of DQ using a binary label for each dimension. The goal of the work was to investigate the relationship between “classic standards of deliberation”, such as rationality and constructiveness and alternative forms of deliberation, such as humor, narratives and the use of emotions. This dataset therefore offers annotations for the so far rather underexplored and more affective dimensions of argument quality, such as *positive emotions*, *narration* and *empathy*.

Kialo (Durmus et al., 2019): This dataset was created based on the online discussion platform Kialo <https://www.kialo.com> on which users engage in structured discussions about a certain statement. Users are able to rate the *impact* of an argument given its context. The dataset contains arguments about a large number of different topics together with their impact – a label which aggregates impact votes by all users. Durmus et al. (2019) and Li et al. (2020) report F-macro scores between 0.56 and 0.58 using different transformer-based models.

Grammarly Argument Quality Corpus (GAQ) (Ng et al., 2020): this dataset contains online contributions from four different domains annotated with the coarse-grained levels of the taxonomy introduced by Wachsmuth et al. (2017a) on a five-point scale. Lauscher et al. (2020b) evaluate different systems for automatic prediction of the quality scores, also experimenting with different multi-task architectures showing that multi-task learning can lead to improvements for all dimensions.

IBM-Rank-30k (Gretz et al., 2020): the largest available corpus with AQ annotations has been created based on a large quantity of binary annotations for human-generated arguments. The authors evaluate different methods of aggregating the annotations into a continuous score and conduct experiments on the automatic prediction of these scores with a Pearson correlation of around 0.48 on a test set with unseen topics. Lauscher et al. (2020b) found positive correlations between this aggregated AQ score and automatically generated scores for *cogency*, *effectiveness* and *reasonableness* on this corpus.

SwanRank (Swanson et al., 2015): as one of the first datasets with AQ annotations in the AM community this corpus contains arguments from on-

Dataset	size	genre	topics	mean length
SwanRank	5k	online discussion	gay marriage, gun control, death penalty, evolution	19
GAQ	5k	Debates, CQA, Reviews	diverse	109
IBM-Rank-30k	30k	crowd-sourced arguments	71 common controversial topics	18
Kialo	7k	argument maps	741 topics	23
Europolis	1k	face-to-face deliberation	immigration in Europe	131
THF/BK	1k	online deliberation	Redevelopment Tempelhofer Feld (THF) and lignite mining (BK)	124

Table 1: Overview of the datasets: original size, genre, topics and mean length in tokens of contributions

dimension	short description	measured	corpus
overall	general argument quality	score (1-5)	GAQ
cogency	acceptable and sufficient premises to draw a conclusion	score (1-5)	GAQ
reasonableness	contribution to resolution of issues, argument is accepted by universal audience	score (1-5)	GAQ
effectiveness	persuasion, rethorical, emotional appeal	score (1-5)	GAQ
quality	general argument quality	score (0-1)	IBM-Rank-30k
clarity	is it hard or easy to interpret the argument?	score (0-1)	Swanson
justification	rationality, providing reasons, reflection	multi-class (4)	Europolis
respect	empathy or respect towards groups (e.g. immigrants)	multi-class (3)	Europolis
storytelling	personal experience, subjective description of an event or situation	binary	Europolis
interactivity	respect towards other participants, reference to other participants arguments	multi-class (4)	Europolis
common good	taking interests of the broader community or utilitarianism based values (justice, equality) into account	multi-class (3)	Europolis
posEmotion	positive emotions are contained in the utterance	binary	THF/BK
proposal	a statement about what or how something is to be done	binary	THF/BK
narration	personal experience, subjective description of an event or situation	binary	THF/BK
reference	participant refers to another discourse participant	binary	THF/BK
argument	providing reasons and/or evidence in favor of or against a claim	binary	THF/BK
negEmotion	negative emotions are contained in the utterance	binary	THF/BK
empathy	Speaker puts himself in the perspective or emotional state of others	binary	THF/BK
Q(uestion) for justification	asks for the reasons for a statement or action	binary	THF/BK
impact	user likes / recommendations	multi-class (3)	Kialo

Table 2: Overview of the datasets with their respective argument quality dimensions

line discussion fora about four controversial topics. The corpus was annotated using crowd-sourcing on a continuous scale expressing whether an argument is easy or hard to interpret, thus reflecting the *clarity* of an argument. More recent experiments on this dataset are for example reported in Gretz et al. (2020) who experiment with fine-tuning transformer-based models after pre-training them on the IBM-Rank-30k dataset.

Table 2 shows an overview of the mentioned datasets and their corresponding quality dimensions, an example with the annotated label / score for each dimension can be found in Tables 13 to 16 in the appendix. Table 1 shows an overview of the six datasets with their respective size and number of topics. While the two datasets from Social Science offer the largest amount of different annotations they are also the smallest in size. On the other hand they consist of full discussions whereas the datasets from Argument Mining consist of single arguments without their broader context.

4 Experiment 1: Modeling AQ and DQ using adapters and adapter-fusion

In the following experiment we are interested in the relationship between different conceptualizations of AQ and DQ from a modeling perspective: does injecting knowledge about other dimensions help to improve the predictions on a target dimension? If so, which dimensions are especially helpful? To investigate this we treat each of the 20 dimensions as a task which we aim to model. We want to compare how the models perform without external information (using only a single-task adapter) with those using information about other dimensions (using multi-task learning with adapter-fusion).

4.1 Experimental setup

The input for all adapter models is the argumentative text, which consists of a sentence, a comment, or a spoken contribution, depending on the data set. We use RoBERTa (Liu et al., 2019) (`roberta-base`) as the backbone transformer model for all dimensions. Note that for each of the 20 single-task adapters we train a task-specific prediction head, depending on the underlying classifi-

cation problem (binary-, multi-class classification or regression). We pick the model with the best results on the validation set (lowest mean-squared error for the regression-, highest F1 macro for the classification tasks using class weights to counteract class imbalance).

Heuristic: how to select source tasks for adapter fusion? As the number of existing dimensions is large (20) we apply a heuristic to select different pools of source tasks for a target quality dimension. For this, we use predictions of dimension-specific adapters as proxies to uncover relationships between different quality aspects. We train an adapter for each dimension on the whole corresponding source dataset, generate predictions on all other datasets and measure pair-wise correlations across the datasets. We hypothesize that dimensions that have a clear positive or negative correlation to the target dimension will be most useful to support modeling that quality aspect, thus we add a dimension as source task if the absolute value of the correlation to the target dimension exceeds a threshold.

We sample source tasks from correlations between all 20 dimensions (*fusion corr ALL*), from correlations between dimensions from datasets with a focus on deliberation (Europol, THF/BK, Kialo: *fusion corr DQ*) and from those originating from established datasets from Argument Mining (GAQ, IBM, SwanRank: *fusion corr AQ*). We use the third quartile of the correlations of the respective dimensions as the threshold in each case (more details and correlation matrix in Appendix Section C and Figure 6). Appendix table 12 displays the output of the selection based on this heuristic. For most of the target dimensions, it indicates a fusion with between 2 and 9 source dimensions: more logical or general dimensions are more often selected (e.g. most frequent source dimension is *justification*, which gets selected for 14 target dimensions). A qualitative inspection of the suggested combinations shows that the heuristic is picking up sensible conceptual patterns. For example, for the target dimension *empathy* the candidates for fusion in the *fusion corr ALL* setup are *negEmotion*, *story* and *narration*.

For each setup we experiment whether we need to add the adapter of the target dimension as source task (*w own adapter*) as it has been done in Pfeiffer et al. (2021) or whether we can learn a target dimension as a weighted combination from

other source dimensions (*w/o own adapt.*) As the multi-tasking approach should be most helpful for low-resource scenarios, we down-sample the larger datasets (Kialo, IBM-Rank-30k, GAQ, SwanRank) to 1000 instances. We use the original train/val/test split for IBM-Rank-30k, GAQ and Kialo and create our own split for THF/BK, SwanRank and Europol. We train the fusions similar to the single-task adapters with a lower number of epochs and a smaller learning rate ($5e - 5$).¹ We train each model with 3 different seeds and report mean and standard deviation of F1 macro score and Pearson correlation in Table 11.

5 Results

Can we improve modeling AQ with adapter-fusion? Table 3 shows the results comparing single-task adapters with the fusion-based models, averaged over three seeds. We use the Almost Stochastic Order test (Del Barrio et al., 2018; Dror et al., 2019) as implemented by Ulmer et al. (2022) to identify for which dimensions multi-task learning can lead to significant improvements.²

Our results show that: a) Information about related quality dimensions can improve modeling for individual dimensions (significant improvements for 8 of 20 dimensions). These stem from 4 different datasets, so the trend holds across different datasets from both communities (AM and DT). b) For most dimensions the fusion does not lead to performance drops, which confirms the fact that adapter-fusion is more robust than traditional multi-task learning (no catastrophic forgetting / interference). The individual modules for different dimensions can thus be tried out without major disadvantages for new data sets or quality annotations. c) we gain improvements, even when the target adapter is not provided to the fusion (GAQ dimensions, *narration* and *argumentative*). Thus the target dimension can be learned as a weighted combination of source dimensions that are different. This can be especially useful when we only have little or noisy data for the target dimension available.

¹For implementation details refer to Appendix Section A.

²The test compares two score distributions by quantifying to which extend stochastic order is being violated. If the amount of violation is small enough, one model can be considered as superior (stochastically dominant) over the other.

6 Analysis: relationship between AQ and DQ dimensions

For each target dimension we analyze which adapters get activated during inference. We extract the attention scores for source dimensions for each target dimension based on the test set. Similar to Pfeiffer et al. (2021) we assume that high activations indicate more useful source tasks.

General AQ / AQ based on intuition First we compare two very general conceptualizations of general AQ: *quality* (from the IBM-rank dataset) which was trained on a wide variety of controversial topics and *clarity* with a slightly more tolerant conceptualization of quality (is the argument clear / understandable?) on 4 different topics. Both conceptualizations are rather under-specified and based on human intuition, we can thus gain insights into which dimensions play a particularly important role for the intuitive understanding of AQ. Figure 1 visualizes the most activated dimensions. For both dimensions different aspects, logical (*justification*, *cogency*) and rhetorical (*effectiveness*) are activated. Emotions play a role (high activation for *posEmotion*) and all dimensions from GAQ receive high activation indicating that they provide useful information in general. Interestingly, the adapter for *quality* (IBM) gets the most activation when modeling *clarity*, while the other way around is not the case. This may indicate that *clarity* represents a somewhat more specific conceptualization of argument quality, while *quality* reflects a more general.

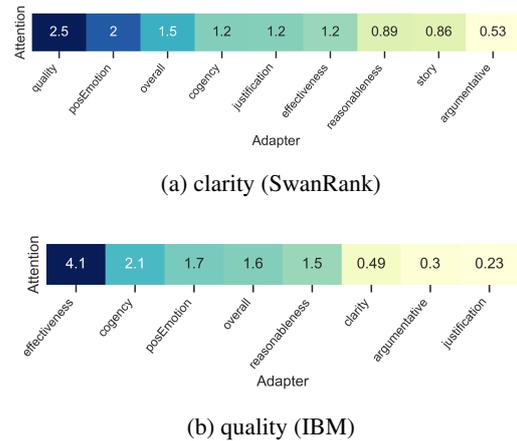

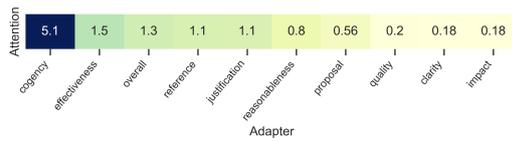

Figure 1: General conceptualizations of quality: sum of adapter activations over all layers.

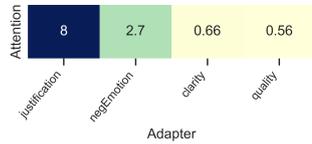

Recall also that the source corpus for *quality* is IBM rank, which covers 71 topics thus resulting in representations that are more applicable to corpora of other domains. Dialectical dimensions are less relevant, as both datasets contain single arguments without a discussion context.

Logical aspect of AQ and DQ With Figure 2 we can compare two logical conceptualizations, one from the AM community (*cogency* from GAQ) and one from the Social Science (*argumentative* from THF/BK). This allows us to explore the extent to which a similar conceptualization of logical argument quality varies between the two datasets from the different research communities.

Argumentative benefits mostly from the other logical dimension of the DQ dataset (*justification*),

(a) cogency (GAQ)

(b) argumentative (THF)

Figure 2: Logical conceptualizations of quality: sum of adapter activations over all layers.

while *cogency* benefits mostly from other dimensions from the same dataset. However *justification* also provides useful information for *cogency* hence seems to be the connecting element between the two conceptualizations. Other useful dimension from a deliberative source are *references* to other people for *cogency* and *negative emotions* for *argumentative*. Having a look at concrete correlation values reveals that the models pick up on positive and negative correlations: arguments with high cogency are less likely to focus on interaction with other people (refer to other peoples arguments) while more argumentative arguments in the THF/BK corpus express more negative sentiment.

Rhetorical aspects: narratives as alternative form of deliberation Finally, we examine a deliberative dimension that is rather rarely studied in the context of argument quality: *narration* (Figure 3). Moreover, this represents a rhetorical quality dimension, which enables us to compare how this kind of quality dimension differs from logical and general argument quality. Emotions as well as classical argumentative properties play a major role (high activation for positive, negative *Emotions* and *argumentative*), indicating that narration and argumentation are often intertwined. The high activation for *empathy* and *reference* (reference to others) illustrates perspective taking, which is characteristic for narrative. Overall, rhetorical and dialectical aspects play more of a role for this dimension.

We can summarize the following trends: either dimensions that come from similar or the same datasets or conceptually related dimensions are particularly activated. However, we also find empirical evidence that emotions play a role in modeling all

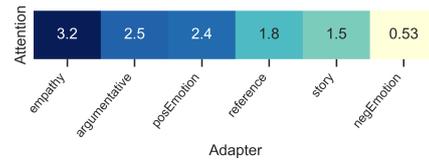

Figure 3: rhetorical conceptualization of quality – narration (THF): sum of adapter activations over all layers.

kinds of dimensions. We suspect that the relationship between emotions and AQ strongly depends on discourse/context, but further research is needed to investigate the relationships more precisely.

7 Experiment 2: predicting moderator interventions

In this experiment, we evaluate the models using a new down-stream application: we want to predict whether a comment in an online discussion should be moderated. Our hypothesis is that we can use information about different quality dimensions to solve the task. Moderation, especially in deliberative discussions such as on civic participation platforms, is a complex task that generally consists of facilitating a productive and fair discussion with respectful interaction. Since the task becomes more difficult for human moderators to perform as the number of participants and comments increases, automatic models can be useful for predicting whether a comment should be moderated. Here, the logical quality dimensions can help distinguish less argumentative from argumentative comments, the rhetorical dimensions are important for ensuring civil interaction, and the dialectical dimensions can identify valuable comments (is a solution proposed or the common good considered?).

We use the dataset from Park et al. (2012), in which the authors annotated the functions of moderation in discussions on a deliberative platform and identified ‘quality of comments’ as a common reason for intervention. The dataset was used in Falk et al. (2021), who obtained an F1 score of 0.34 using a full fine-tuning approach with roberta-base. The dataset is small and consists of 876 negative and 222 positive instances, a further motivation for a multi-task based approach. We train and test the models on the 5-fold split provided by Falk et al. (2021). As moderator interventions are the minority class we use class weights for all models. We compare the following models:

(*quality*) scores *ST*: we generate predictions for

each quality dimension and convert them into scores.³ Classifier: logistic regression.

(*quality*) *scores-MT*: similar to *quality scores* but we generated with the fusion-based adapters. Classifier: logistic regression.

model	F1 intervention	F1 macro
random baseline	0.29±0.06	0.45 ±0.04
scores-ST	0.37±0.05	0.55±0.04
scores-MT	0.38±0.04	0.54±0.04
moderation-ST	0.34±0.03	0.57±0.03
fusion-AQ	0.35±0.04	0.56±0.01
fusion-all	0.38±0.05	0.57±0.03
(Falk et al., 2021)	0.34±0.05	0.57±0.03

Table 4: F1 positive (moderator intervention) and F1 macro: average and standard deviation over 5 test sets.

moderation-ST: we train a single-task adapter on the task of moderation intervention.

fusion-AQ: we train a fusion on the task of moderation intervention using only quality adapters as input representations.

fusion-all: we train a fusion on the task of moderation intervention using all quality adapters and the adapter for moderation.

roberta-full: we report the result of Falk et al. (2021) who predict interventions on the same data split with full fine-tuning RoBERTa.

We use the same hyperparameters for the fusion and the single-task adapter as in experiment 2.

Can AQ adapters be applied to predicting moderator interventions? Table 4 shows F1 for interventions and F1 macro as average over the 5 splits. We consider F1 for interventions to be more important because it represents the minority class and only the positive instances are suggested to a human moderator for further evaluation. Figures 5 and 7 (Appendix) show the model-to-model calculated significance values for the almost stochastic order test. All models are outperforming the baseline. The single-task adapter yields similar results to full fine-tuning, the two feature-based models with the scores for the quality dimensions yield better results for interventions, indicating that the information on the quality dimensions is useful for this task. The best results are obtained with an adapter-fusion, provided that it also includes the adapter for moderation. This indicates that the information about the quality dimensions is comple-

³For dimensions based on binary classification we use the probability of the positive class, for the multi-class dimensions, we use the probability for each class (e.g. *common good* will be converted into three features: probability for class 1 ('no reference'), class 2 ('reference to own country') and class 3 ('reference to common good'))

mentary with a data and task specific representation (*moderation-ST*).

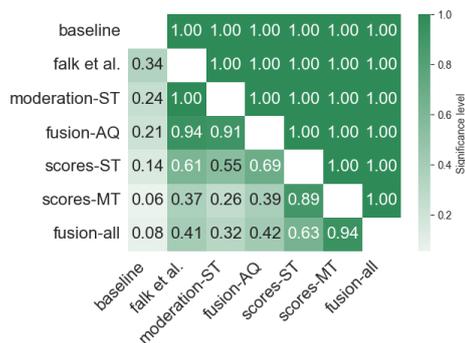

Figure 5: Almost Stochastic Order Scores (ϵ) for moderation test data for the F1 positive class, adjusted by using the Bonferroni correction. $\epsilon = 0.0$ means model in row is stochastically dominant over model in column, $\epsilon < 0.5$ denotes *almost stochastic dominance*.

Which aspects of AQ are important for predicting moderation? As discussed for the analysis of the relationship between quality dimensions in Experiment 1, an additional advantage of fusion-based models is the additional level of interpretability they provide. We investigate the relevance of each quality dimension for predicting moderation interventions using activation patterns of quality adapters. We compute the activation of each adapter of our best model (*fusion-all*) and visualize this as a heat-map (Fig. 4). The adapter for *impact* is the most activated. This is probably because this adapter is a good representation for distinguishing high vs. low quality comments, since the underlying dataset provides a high number of different topics (and thus can provide a good domain-independent representation). This is followed by dimensions that are important for a civic and appreciative interaction (*empathy* and *respect*) or for a solution-oriented discourse that considers the common good (*proposal*, *cgood*). The adapters for *argumentative* and *quality* add the more rational dimensions of two very different data sources, followed by the more affective and rhetorical dimensions (*story*, *narration*, *emotion*).

8 Conclusion

This work targeted the relationships between different aspects of argument and deliberative quality. We experimented with 6 datasets and 20 quality dimensions, employing adapters we learn modular representations of the targeted dimensions. We

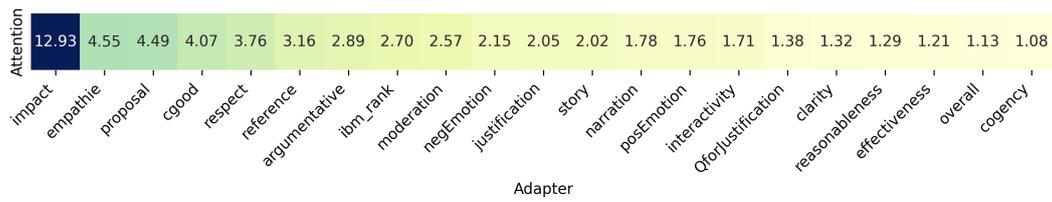

Figure 4: Predicting moderator intervention: activation for each dimension (avg. over all test instances, sum over all layers)

show that adapter fusion improves predictions in 8 dimensions out of 20. We then use the learnt adapters in the task of predicting moderator interventions - we show that information about different argument quality dimensions helps to improve the performance. Having more insights about which aspects of argument quality were activated more or less when the model that a user contribution should be moderated could help human moderators decide which aspects to focus on and information about why that model fired can increase human moderators awareness of and (ideally) confidence in automated support methods. We make models for single-task adapters and fusions and the code to train and test them available: <https://github.com/Blubberli/ArgQualityAdapters.git>.

9 Limitations

The datasets were created with very different motivations, the annotations were partly created by experts, partly via crowd-sourcing. The definitions of the different aspects of argument quality are also based on different theories or merely on human intuition. This work is only a first step to collect the existing data, to use it and to gain first insights about overlaps between relations based on empirical experiments. A deeper analysis of the underlying annotations and definitions is an urgent next step. Another limitation is that we compare the benefits of adapter-fusion to single-task adapters in a low-resource scenario. Because we are dealing with a large amount of different dimensions (20) additional experiments that compare this approach to full fine-tuning or traditional MLT-learning were not feasible in this work but can be conducted in the future, potentially on a smaller set of selected dimensions. On top of that we do not try to improve the state-of-the-art results for each quality dimension for each dataset. This is for the following reasons: the main focus of this work is to

investigate whether adapter-fusion improves the results compared to single-task adapters, not which model works best for which data set. The SOTA results for individual dimensions in our case are either not available (Social Science datasets) or based on data-specific optimizations of the hyperparameters / architectures. We focus on a variety of dimensions and datasets, especially those coming from the social sciences. In addition to the potential improvements in results through MLT with adapter-fusion, we see the advantage above all in the modular design (depending on the annotation from future datasets, dimensions can simply be added or omitted) and the insights we can gain about the contribution of individual dimensions through attention patterns. The models in this work were partially trained on small datasets. It is necessary to investigate to what extent the models are applicable to other domains. Also the influence of the topics in the discussions (topic bias) should be investigated.

Potential Negative Societal Impacts The automatic modeling of Argument Quality bears the danger that what is considered as "high quality arguments" will be closely related to what is represented as high quality in the existing datasets. This might disadvantage certain styles of argumentation but also certain opinions that are so far underrepresented in the data. It is therefore necessary to investigate how these models behave with data with such underrepresented styles and opinions and to create new datasets with AQ with greater diversity.

Acknowledgments

We would like to thank Anne Lauscher and Agnieszka Faleńska who provided valuable feedback at various points of this work. This research has been funded by Bundesministerium für Bildung und Forschung (BMBF) through the project E-DELIB (Powering up e-deliberation: towards AI-supported moderation).

Appendix

A Implementation details

For training the adapters and the adapter-fusion models we use the `adapter-transformers` library (Pfeiffer et al., 2020) with `roberta-base` as a backbone. We use the default hyperparameters (learning rate of 0.0001 which was found to work empirically best in most setups (Pfeiffer et al., 2020, 2021) and a reduction factor of 16). As a maximum sequence length we use 256 which is higher than all means of the 6 datasets. We train the adapters for a maximum of 40 epochs for classification and 25 epochs for regression and use the model with the best performance (lowest MSE or highest F1 macro) on the validation set. For the adapter-fusion we also rely on the best learning rate according to Pfeiffer et al. (2021), which is $5e-5$. We lower the maximum number of epochs (25 for classification and 15 for regression). We train all models on 3 GPUs (*NVIDIA RTX A6000, each GPU has 49GB, CUDA Version 11.7*) with a batch size of 16, each model is trained with 3 seeds (5, 42, 108) for the experiments reported in section 4. We use the the adapters of one seed (42) to generate the predictions and the single-task adapters trained with that seed for the AdapterFusion in the experiment in section 7. The largest model is the AdapterFusion with 21 adapters (all quality dimensions and moderation). The training run time for this is 15.349 samples per second and 44.282 samples per second during inference. In experiment 3, for the logistic regression classifiers, we find the best hyperparameters using grid search and 3-fold cross-validation on a separate data split (L2 penalty, class weights and $C=0.1$).

B Datasets

The tables in the end of this Appendix (Table 13 for THF/BK, Table 14 for Europolis, Table 15 for GAQ and Table 16 for SwanRank, IBM-Rank-30k and Kialo) illustrate examples of each dataset, each example exhibits a high score (or label) of a different dimension of AQ.

Parts of the transcriptions of the Europolis dataset were not in English and automatically translated using DeepL (<https://www.deepl.com/translator>). Similarly, the online-comments from THF/BK are originally German and have been automatically translated

using DeepL. Samples of the automatic translations were verified by native speakers.

Data splits for Experiment 1: Table 5 shows the amount of training / development and test data for each corpus.

	train	dev	test
THF/BK	788	198	247
Europolis	546	140	175
Kialo	650	150	200
GAQ	650	150	200
SwanRank	650	150	200
IBM-Rank-30k	650	150	200

Table 5: Amount of train, validation and test data for each dataset. The amount for *Kialo, GAQ, SwanRank, IBM-Rank-30k* has been down-sampled to 1000 instances.

Table 6 gives an overview the positive amount of instances for each quality dimension in the training data. Most of the dimensions (except argumentative) are the minority class.

dimension	relative amount in train
posEmotion	13 %
proposal	38 %
narration	31 %
reference	41 %
argumentative	75 %
negEmotion	21 %
empathy	11 %
Qjustification	20 %

split for IBM-Rank-30k (train=20974, val=3208, test=6315), GAQ (train=2746, val=1177, test=538) and Kialo (train=5170, val=1108 test=1108) and create our own split for SwanRank (train=3440, val=860, test=1075), THF/BK and Europolis (splits in Table 5).

Table 11 shows the results of each single-task adapter on the original-sized dataset. We report the mean and standard deviation across 3 seeds.

We then take the adapter for each dimension and generate predictions for all other datasets. For feasibility, we sample 3000 instances for Kialo, IBM-rank-30k and SwanRank to generate predictions on these subsets. Based on the predictions we compute the pair-wise Spearman correlations between the AQ dimensions for each dataset. For binary classes we use the probability of the positive class as a continuous score, for dimensions with 3 to 4 classes we convert the predicted class labels into scores on a linear scale, e.g. *impact* has 3 class

dimension	mean	std

Table 11: Results on the test set for each quality dimension. Performance with standard deviation, averaged over 3 seeds.

labels: low impact, medium impact, high impact which we convert into 1, 2 and 3 respectively. We compute the pair-wise correlations for each dataset (we take the gold annotations when available) and average them across datasets. Figure 6 shows the pair-wise correlations as a correlation matrix.

Next we sample source tasks for each target task based on the correlations. Taking different samples of dimensions we compute a threshold based on absolute correlation values and add a dimension as source task if the correlation to the target dimension exceeds the computed threshold. We consider the following setups:

fusion corr ALL We select the source tasks from all dimensions if the absolute correlation value is

higher than 0.24 (corresponds to the third quartile of all correlations).

fusion corr DQ We consider only source tasks from datasets with a deliberative focus (THF/BK, Europolis, Kialo). The tasks are sampled from 14 dimensions and the threshold is 0.15 (third quartile of all correlations between the 14 dimensions).

fusion corr AQ We extract the source tasks from all dimensions that stem from more general argumentative contexts (IBM-rank-30-k, GAQ, swanson). The threshold is based on the correlations between the 6 dimensions (0.54, the second quartile due to the high correlations between the GAQ dimensions).

Table 12 shows the source task dimensions for each target dimension, depending on the setup (*fusion corr ALL*, *fusion corr DQ*, *fusion corr AQ*). Each dimension is learned using between 1 and 9 other dimensions as source tasks. For *respect* there were no dimensions with a high enough correlation in any of the setups.

D Experiment 2: predicting moderator interventions.

<p>I'm a fairly tolerant human being and am in no way an advocate of the death penalty. I also understand that a short sentence and rehabilitation is also an effective form of justice in terms of re-offending in many countries. However I think there's gotta be a line drawn somewhere in which a person entirely loses their liberty and autonomy if the crime they committed was as heinous as the one committed by Mr Breivik. Also, even though I am aware that there is a good chance he will still remain behind bars for the rest of his life, the possibility that he won't baffles and worries me. Please CMV.</p>	high cogency (5)
<p>Well, this topic has raised lots of questions lately particularly in France. This is where I stand: - Wearing a burqa should be a matter of choice, just as women choose to wear anything else, regardless of any religious manifestations. - Wearing the burqa shouldn't be banned, and shouldn't be forced to women either; it should be a personal choice. - When talking about choices, it's the society that gives these choices according to what the majority thinks, hence the more civilized and democratic a society is the more choices people have. - It's basically a matter of respect, if a woman chooses to wear it then we should respect that, we can't force her not to wear it, as we can't force her to wear it: free will :) , on the other hand that woman should respect and obey all the security issues that comes along with wearing it.</p>	high effectiveness (5)
<p>The point of daylight savings is to make our numeric time cycle fit with the Sun's time cycle. In other words, standardize the time of day in which the sun is shining. This way, people and businesses can keep their operating hours steady without working in the dark, and less electricity is used. Most arguments I've heard against it pertain to the inconvenience of changing clocks and accounting for gained/lost hour, but with most clocks being digital and synced up to DST nowadays, that's becoming less and less of a problem. And besides, one day of inconvenience in exchange for a whole season of "correct" daylight seems like a pretty good deal to me.</p>	high reasonableness (5)
<p>I believe property is a social construct that is only justified through appeals to utility. In other words, any particular set of property laws are only justified insofar as they make people better off, in terms of their capabilities. Most Libertarians I've debated with either believe property rights are somehow fundamental(natural or God-given) or develop out of other moral principles, like the NAP. The first option appeals to non-existent entities. The second is circular, as what NAPer's define as aggression is violation of property rights, and violations of property rights is defined in terms of the NAP.</p>	high overall (5)

Interventional Probing in High Dimensions: An NLI Case Study

Julia Rozanova¹, Marco Valentino², Lucas Cordeiro¹, André Freitas^{1,2}

Abstract

Probing strategies have been shown to detect the presence of various linguistic features in large language models; in particular, semantic features intermediate to the “natural logic” fragment of the Natural Language Inference task (NLI). In the case of natural logic, the relation between the intermediate features and the entailment label is explicitly known: as such, this provides a ripe setting for *interventional* studies on the NLI models’ representations, allowing for stronger causal conjectures and a deeper critical analysis of interventional probing methods. In this work, we carry out new and existing representation-level interventions to investigate the effect of these semantic features on NLI classification: we perform *amnesic* probing (which removes features as directed by learned linear probes) and introduce the *mnesic* probing variation (which forgets all dimensions *except* the probe-selected ones). Furthermore, we delve into the limitations of these methods and outline some pitfalls have been obscuring the effectivity of interventional probing studies.

1 Introduction

The *probing* paradigm has emerged as a useful interpretability methodology which has been shown to have reasonable information-theoretic underpinnings (Pimentel et al., 2020; Voita and Titov, 2020; Zhu and Rudzicz, 2020), indicating whether a given feature is captured in the intermediate vector representations of neural models. It has been noted many times that this does not generally imply that the models are *using* these learnt features, and they may represent vestigial information from earlier training steps (Ravichander et al., 2021; Elazar et al., 2020).

Only through interventional analyses can we start to make claims about which modelled features are used for a given downstream task: this is the aim of works such as Elazar et al. (2020);

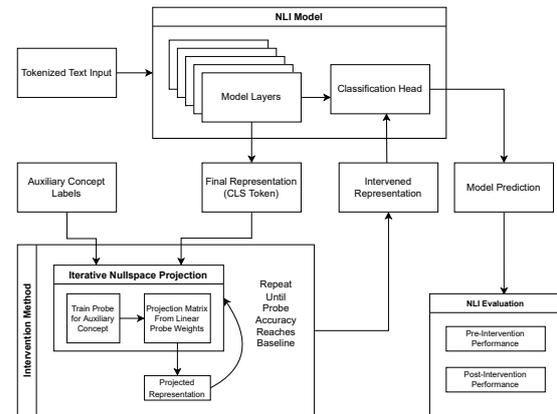

Figure 1: Workflow for interventional probing for NLP classification models: a basis for both the *amnesic* and *mnesic* intervention strategies.

Giulianelli et al. (2018) and Geiger et al. (2021). We refer to the case where the interventions are guided by trained probes as *interventional probing*.

It has been suggested in Elazar et al. (2020) (as the guidance for their *amnesic probing* methodology) that if features are strongly detected by probes, one may use debiasing methods such as *iterative nullspace projection (INLP)* (Ravfogel et al., 2020) to intervene on the corresponding vector representations and effectively “remove” the features before re-insertion into the given classifier. Investigating the effect of these intervention operations on the classifier performance could allow for stronger causal claims about the role of the probe-detected features.

In this work, we delve deeper into the amnesic probing methodology with an NLI case study and identify two key limitations. Firstly, there is an issue of dimensionality: when the number of dimensions is high and the number of auxiliary fea-

ture classes is low, it seems that amnesic probing is not sufficiently informative. In particular, we cannot rely on the same control baselines to reach the kind of conclusions discussed in (Elazar et al., 2020), as nulling out small numbers of random directions consistently has no impact on the downstream performance. Secondly, in the linguistic settings explored in Elazar et al. (2020), we do not have expectations for exactly *how* or even *if* the explored features should be affecting the downstream task. This makes it difficult to explore the effectivity of the methodology itself.

To this end, we propose the use of a controlled subset of NLI called *natural logic* (MacCartney and Manning, 2007). In this setting, the intermediate linguistic features of *context monotonicity* and *lexical relations* are already known to be highly extractable from certain NLI models’ hidden layers (Rožanova et al., 2021b), allowing us a certain amount of understanding and control of these features’ representations in the latent space. Using the deterministic and well-understood nature of the problem space where we have concrete *expectations* about the theoretical interaction between the intermediate features and the downstream label, we may critically analyse the effectivity of interventional probing.

Through the application of probe-based interventions in this setting, we show that blindly applying the amnesic probing argument structure leads to unexpected and contradictory conclusions: the two features which the final label is *known* to depend on are shown to have no influence on the final classification (both jointly and independently). This further calls into question the suitability of these methods for situations where a small number of feature label classes and high dimensionality of representations is concerned. Even more perplexingly, when we treat the NLI gold label itself as an intermediate feature which can be nulled out with INLP, we yet again observe *almost no change to the NLI performance*. As such, the feature removal strategy appears ineffective here: we attribute this to the disproportionate size of probe-selected feature subspaces to the very high-dimensional representations.

In response, we introduce and study a variation which we call *mnesic* probing, which we show to be more informative in the high-dimensional, low-class-count setting: the core idea is to *keep only* the directions identified by the iteratively trained

probes. This allows us to analyse much lower dimension subspaces, while making better use of the outputs of the INLP strategy used in amnesic probing.

We find that *mnesic probing* leads to more informative observations which are a) in line with expected behaviour for natural logic, and b) yield results which seem to better discriminate between model behaviours.

In summary, the contributions of the paper are as follows:

1. We propose the setting of *natural logic* to be ripe territory for exploration of interventional probing strategies.
2. We note two limitations of the amnesic probing methodology, demonstrating both dimensionality limitations for the control baselines 4.4 and contradictory behaviour in the NLI setting 4.2 (namely that that the expected effects of semantic features on the downstream NLI task are notably absent).
3. Building upon previous interventional methodologies, we introduce an additional *mnesic* intervention operation which uses the outputs of the INLP process in the opposite way.
4. We contrast the mnesic probing strategy with the amnesic probing results, and demonstrate it presents more informative results which are aligned with the constructed expectations in our high dimensional, low label class count setting.

2 Interventional Probing

We may summarise the general setup of interventional probing as follows: suppose we start with a classification model that may be decomposed as $f \circ g : \mathcal{X} \rightarrow \mathbb{R}^n$, where g is an encoder module which yields a representation which serves as an input to the classifier head f , and n is the number of output classes of the final classifier. We aim to intervene on the output of g and observe the change in the performance of f (usually in comparison with some kind of random control baseline intervention).

Linear probes (also known as *diagnostic classifiers*) are able to identify subspaces in which a given intermediate feature set is found to be represented. These may be used as a guide for vector-

level interventions on the representation space; we are specifically concerned with interventions which are vector *projections*. Otherwise, The exact nature of this intervention is interchangeable. We consider two projection strategies in particular: the *amnesic* intervention introduced in Elazar et al. (2020) (described further in section 2.2) and our *mnesic* variation which uses the same INLP technique (section 2.3).

2.1 What Should it Tell Us?

The interventional probing steps are performed on exactly the representation that would have been an input to the classifier head f . We may re-insert the intervened representations and re-calculate the classifier accuracy (note that the iterative projections in sections 2.2 and 2.3 maintain the original dimensionality of the vector set but reduce the *rank*).

We are looking to see if the downstream performance of the classifier f drops. If it does, the interventions have removed information that was necessary for successful classification. However, as any projection would remove some information, these results must be viewed in the context of a control intervention: if the INLP process ends up removing n directions, a sample of n randomly chosen directions is selected from the original representation, Elazar et al. (2020) argue that if the amnesic downstream performance drops significantly more than the random removal control performance, we may conclude that the features were necessary for the final downstream classification. On the other hand, if the performance does not drop at all, the features were not useful for the classifier in the first place. In the ensuing sections and results, we demonstrate that this is not necessarily a valid conclusion.

2.2 The Amnesic Intervention

We follow the procedure in (Elazar et al., 2020) (in turn based on *iterative nullspace projection* (Ravfogel et al., 2020)): given a set X of encoded representations for the textual input (with dimensions $\text{num_examples} \times \text{embedding_dimension}$), we iteratively train linear SVM classifiers according to a set of auxiliary feature labels. For each INLP step i , This yields a linear transformation $W_i X + B$, where the vectors of W_i define directions onto which the probe projects the representations for auxiliary label classification (i.e., these are the chosen directions most aligned with auxiliary class separation). For each step i , an orthogonal basis denoted R_i is found for this rowspace. The

projection to the intersection of the nullspaces is given by a matrix

$$PX = (I - (R_0 + \dots + R_n))X.$$

The matrix product PX is a matrix in the original dimensions of X , but with reduced rank by the number of iteration steps (as each projection "flattens out" the representation in these directions).

Projection to the intersection of nullspaces is thus the removal of any information pertaining to the auxiliary feature labels (or at least, the information which allows high performance for a linear probe). The training terminates these auxiliary task classifiers start consistently performing at the majority class baseline, indicating that there is no further linearly information to be extracted from the remaining representation. As such, the resulting representation is treated as an altered representation where this feature is *removed* or forgotten.

2.3 A Variation: The Mnesic Intervention

Elazar et al. (2020) perform a series of experiments on various linguistic features which had previously been shown to be well-captured in language model representations and use the amnesic probing methodology to distinguish between features that are *used* by the model and those that are not by comparing post-intervention downstream task performance to a baseline of randomly removed directions.

Rather than projecting the embedded representations to the intersection of nullspaces of the trained probes (removing the target property), we project them to the *union of the rowspaces* with the transformation:

$$\begin{aligned} (I - P)X &= (I - (I - (R_0 + \dots + R_n)))X \\ &= (R_0 + \dots + R_n)X \end{aligned}$$

This has the opposite effect: we use projection to null out *everything except* the directions identified by the probes as indicative of the target feature. As such, we "remember" only that feature rather than forgetting it.

3 Experimental Setup

In this study, we use interventional methods ¹ to study the internal behaviour of NLI models.

¹We reuse much of the code included with (Elazar et al., 2020), but we include our data and reproducible experimental code at https://github.com/juliarozanova/mnesic_probing.

We compare amnesic and mnestic variations of the INLP strategy, evaluating intermediate feature probing performance and downstream NLI performance after every step of the intervention process.

For each auxiliary feature label and model, we perform the *interventional probing* as outlined in figure 1.

3.1 Dataset

Our setting for this study is a fragment of NLI called *Natural Logic* (MacCartney and Manning, 2007). In particular, we focus on single-step natural logic inferences in which entailment examples are generated by replacing a noun phrase in a sentence with a hyponym, hypernym or unrelated noun phrase. The context of the substituted term is either *upward* or *downward* monotone, as determined by the composition of negation markers, generalized quantifiers or determiners present in the context. The entailment label of the example is a consequence of this feature and the lexical relation between the substituted terms.

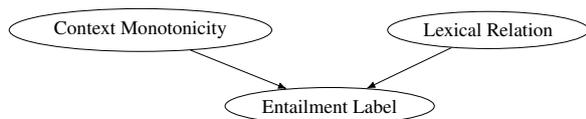

Figure 2

We use the NLI_{XY} dataset from (Rožanova et al., 2021b,a). By construction, the NLI_{XY} dataset consists of NLI examples which rely on exactly these two abstract features: context monotonicity and the lexical relation of the substituted terms.

We perform two flavours of probe-based interventions (described fully in section 2) with four feature label sets (described next).

Auxiliary Feature Labels We begin with the two relevant intermediate features (respectively, context monotonicity and lexical relation) which are already known to correlate with stronger performance on the downstream NLI_{XY} task (Rožanova et al., 2021b). We will refer to this as *single-feature* interventional probing, as the probing and intervention steps are only applied to one feature set at a time. Next, we combine the two features in a cross product, creating a new feature label set with all possible combinations of these intermediate features (in the dataset, they are completely independent variables by construction (Rožanova

et al., 2021a)). We refer to this as the *composite feature label*.

Lastly, we also consider the *entailment label* itself (the downstream task label) as an input to the interventional probing process. The latter is particularly useful as a diagnostic sanity check, and aids the critical nature of our findings.

3.2 NLI Models and Encoding

We compare a selection of BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) models trained for NLI classification. Firstly, we include a pair of models trained respectively on the MNLI (Williams et al., 2018) and SNLI (Bowman et al., 2015) benchmark datasets. In (Rožanova et al., 2021b) and (Rožanova et al., 2021a), it is shown that when `roberta-large-mnli` (a model which performs well on benchmarks but poorly on the targeted NLI_{XY} challenge set) receives additional training on the adversarial HELP dataset (Yanaka et al., 2019) it improves in NLI_{XY} performance and *begins to show high probing performance for the relevant intermediate features*, context monotonicity and lexical relations: this is the necessary precondition for doing interventional probing. We include two of their models with this property: `roberta-large-mnli-help` and `roberta-large-mnli-double-finetuning`, with the other models included for a contextual comparison.

We perform probing and intervention on the final representation that precedes the NLI classification head: in the case of BERT and RoBERTa, this is the [CLS] token of the final layer.

The initial input is a tokenized NLI example from the NLI_{XY} dataset. The findings in (Rožanova et al., 2021b) show that the intermediate feature labels (context monotonicity and lexical relations) are detectable in the concatenated tokens of the substituted noun phrases: however, for interventional purposes, we perform the probing and intervention steps on the [CLS] token which serves as an input to the NLI classifier head: we have found that the same features are detectable to a comparable standard, and this is the only position at which we are able to make a sensible intervention that would allow conclusions about the final classifier head only.

3.3 Evaluation

The significant metrics for these interventional probing paradims are the *probing accuracy* before

and after the iterative nullspace projection steps (a decline to random performance indicates the feature is being “removed” from the representation in the sense that it is no longer detectable by linear probes) and the *downstream classification accuracy* on the NLI task the model’s were trained for (in our case, we report the accuracy on the NLI_XY task).

For amnesic probing, we report the performance deltas for both the probing and downstream tasks. However, for mnesic probing, a slightly more nuanced and qualitative view is helpful: it can be assumed that eventually mnesic probing will reach comparable performance to the untouched vector representations, but we are interested in the comparative rates at which this happens. As the interventions are iterative, we may feed the intervened representations into the classifier head at *each step* of the intervention process - we use this to provide a step-wise presentation of results in linear plots in figure 5.

While the tabulated deltas in table 1 results are sufficient to present our observations on amnesic probing, for comparison we also include the step-wise graphical presentations in the appendix.

4 Results and Discussion

4.1 Single Feature Amnesic Probing

The results for the standard amnesic probing procedure are in table 1. In particular, the single feature results are in the rows with features labelled *insertion relation* and *context monotonicity*. The amnesic operation is successful - the respective probing accuracies approach and reach the majority class baseline.

We also include the step-wise plots of both probing performance and downstream NLI task performance: we single out the case of the insertion relation label in figures 3 and 4, but include the full suite of expanded plots for each feature in the appendix. The length of the iterative amnesic probing process is indicative of the number of dimensions removed to reach this baseline: it can also be considered a proxy for the strength of the feature presence in the representations, or rather, the dimension of the semantic subspace corresponding to the target features.

The second phase of this process, i.e. the resubstitution of the modified representations as inputs to the NLI classifier head, can be seen in the right hand portion of table 1, labelled *NLI-XY Perform-*

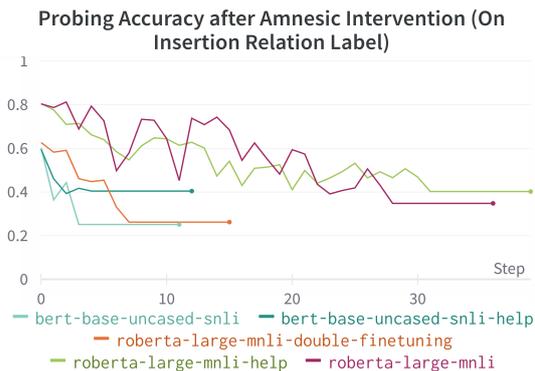

Figure 3: Step-wise probing performance throughout the amnesic probing process: a decrease towards the random baseline accuracy (roughly 0.3 for this 3-class task) indicates the feature is less and less extractable from the remaining representations as the iterative process continues.

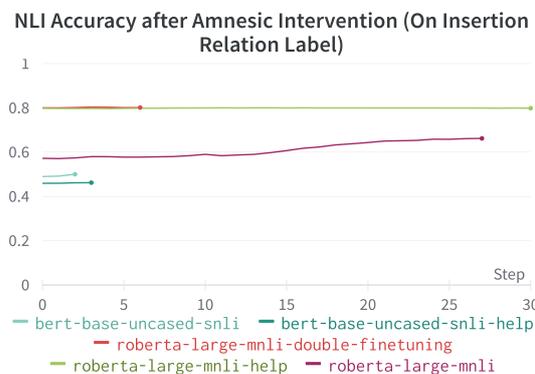

Figure 4: Downstream performance on NLI_XY after amnesic intervention (removing lexical relation information). For such an important feature to the end-task, we would expect to see a drop: but we don’t!

mance. The result is unexpected: for each of these features, *the downstream task performance appears to be unaffected after their removal*. This is surprising when the dataset is explicitly controlled to rely only on these two features.

4.2 Multi Feature Amnesic Probing

The results for the amnesic probing procedure utilizing *both* auxiliary feature label sets and the entailment gold label are in the rows of table 1 with labels *composite* and *entailment label* respectively. We observe that once again, the downstream task performance is mostly unaffected. Unlike the unexpected result in the previous section, it’s difficult to argue away the fact that this is somewhat contradictory: while single feature removal may be subject to some confounding bias, the removal of

Model	Feature	Probing Performance		NLI-XY Performance	
		Start	Intervention Δ	Start	Intervention Δ

	entailment label	42.44	-0.24	49.42	0

Table 1: Amnesic probing performance deltas across models and target feature labels: first listed is the performance on the probing task with respect to the indicated feature, and then the accuracy on the downstream NLI-XY task. We note the results pre-intervention and the ensuing change in accuracy.

both features exhausts the variables on which this classification depends. This is highly unexpected, and suggests a point of failure for the amnesic probing process. Naturally, we cannot be without doubt that despite all our best efforts to work with a controlled dataset that relies only on these two known (but still complex) features, a model may yet find unrelated heuristics to exploit that may correlate so strongly with the downstream task label that it may perform well without representing and using these intermediate features. However, we imagine this to be a rather low probability scenario to be that the model simultaneously learns such heuristics but simultaneously learn representations that create strong clusters for the known intermediate features *without using them at all*. The models which we have observed to perform more or less well on NLI-XY (such as roberta-large-mnli) are indeed estimated to be using sub-par heuristics, but this also comes with poor probing results for the intermediate features - naturally, this in itself does not imply anything conclusive, but certainly adds to our convictions.

On a separate note, it is noted in Elazar et al. (2020) that there is no control for the number of dimensions removed, while there is a clear correlation between downstream task performance and the number of label classes (and thus removed probe

directions) are in play. Our feature sets have only 2 and 3 classes respectively. In the most analogous result in (Elazar et al., 2020) where the auxiliary features had very few classes and no change on the downstream performance was observed, it was concluded that the features must have no effect on the outcome. It is very likely that *too little information* is being removed in this process to observe any impact on the downstream task performance. This could potentially be pointing to high redundancy in the representations which the amnesic intervention may struggle to remove appropriately.

4.3 Mnestic Probing

Given the possible dimensionality problem, the alternative method of *mnestic* probing seems promising: after the *mnestic* intervention, many dimensions are removed and few remain, so it appears to be a ripe setting for observing and comparing effects on downstream NLI accuracy at a finer granularity. The results for NLI-XY task accuracy after the *mnestic* probing procedure are presented as step-wise plots in figure 5. There is a clear increase in NLI performance with subsequent addition of probe-chosen directions to the representations, especially viewed in the context of section 4.4, where we compare the performance to random choices of included directions. In the latter, performance

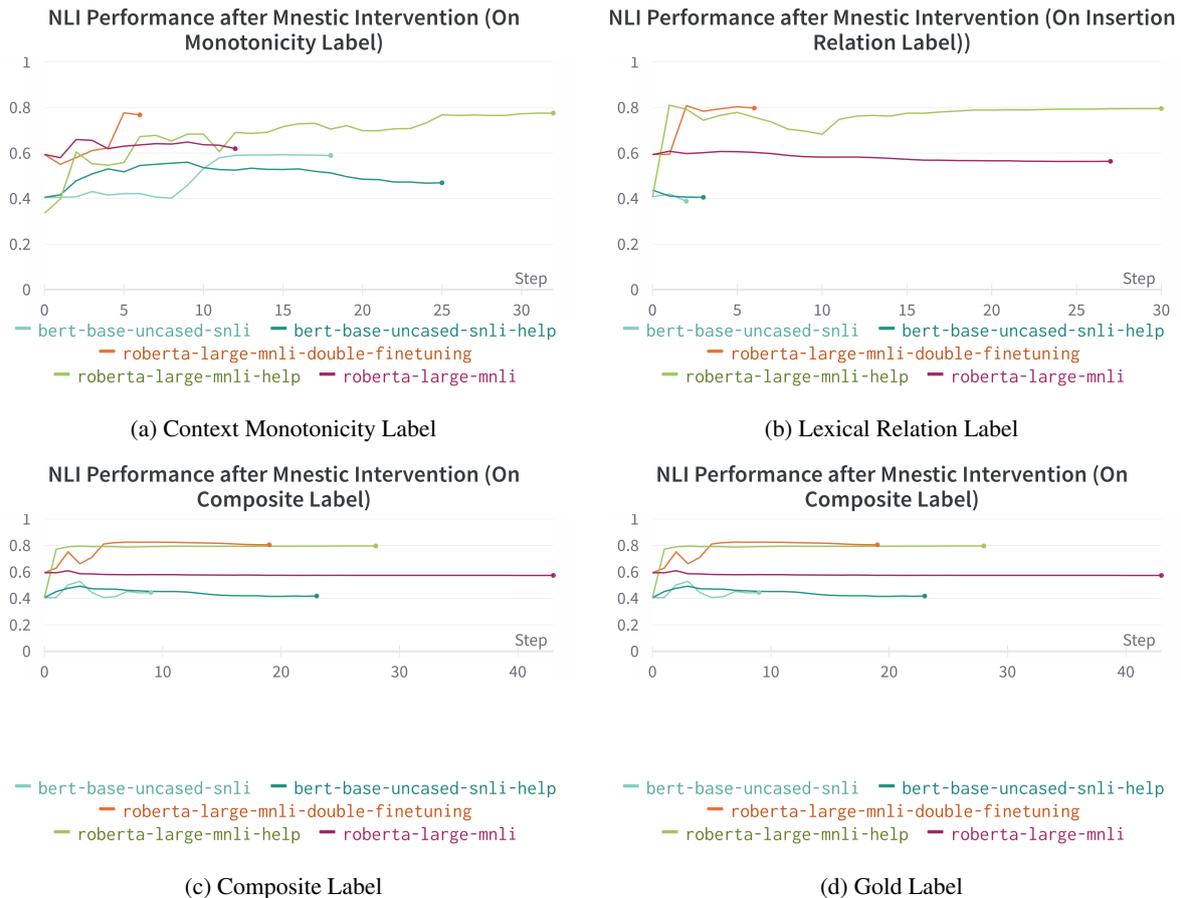

Figure 5: Downstream NLI Task Performance After Mnestic Interventions

varies randomly rather than presenting a structured increase as seen here.

We observe that the *composite* label and the gold *entailment* label are reflected in line with expectations in the mnestic probing experiments: the inclusion of the probe-selected dimensions with respect to these labels introduces a sharp and immediate increase in the NLI classifier performance. This is significantly steeper than the baseline increase observed in random addition of representation directions. Similarly, the increase is nearly as sharp for the lexical relation label. However, although an increase is observed during the iterative mnestic probing intervention for context monotonicity, this increase is not at a dramatically higher rate than adding subsequently more directions from the original representation. For monotonicity specifically, this is not enough to conclude that the feature (or at least, the corresponding probe-selected dimensions) are critical to the final classifier.

Nevertheless, we have been able to make clearer observations than were possible in the amnesic probing setting.

4.4 Control Comparison

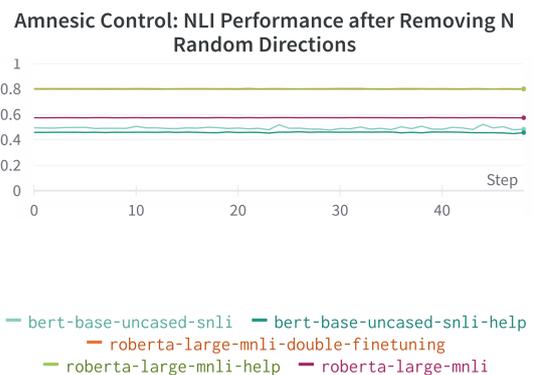

Figure 6: Amnesic control experiment: Downstream NLI accuracy upon the *removal* of n random directions of the original representation.

We contextualise all the preceding results with a set of control experiments both for amnesic (figure 6) and mnestic (figure 7) probing. Note in particular that even with very few random dimensions kept, downstream performance starts approaching comparable levels to the full representations. As

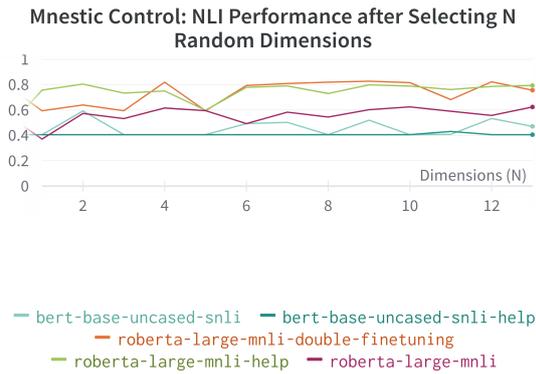

Figure 7: Mnestic control experiment: downstream NLI accuracy upon the *selection* of n random directions of the original representation.

such, a single random baseline as in Elazar et al. (2020) can be misleading: there is enough variability in the random direction results so as to allow for a false claim of feature irrelevance by simply getting lucky; as few as 3 dimensions can perform at the original model’s performance level or arbitrarily lower.

Lastly, we compare to the mnestic probing results in figure 5: with the probe-selected mnestic dimension choices, the increase in downstream performance does seem to happen faster and in a more consistent fashion, while the selection of n randomly chosen directions introduces very haphazard performance spikes. This suggests the probe-selected dimensions are consistently adding to the model’s access to the relevant information, and this may be stronger evidence for the usefulness of the examined features for the final classification.

5 Related Work

The use of probing as an interpretability strategy dates back as far as works such as Alain and Bengio (2018) and (Conneau et al., 2018), but a core set of work on the detailed development of the methodology includes Hewitt and Liang (2019); Belinkov and Glass (2019); Voita and Titov (2020); Pimentel et al. (2020). For a full survey, see Belinkov (2022).

The application of probing strategies to natural logic components has been explored in Rozanova et al. (2021b) and Geiger et al. (2020). In Rozanova et al. (2021b), probing experiments have proven effective in detecting the presence or absence of features such as *context monotonicity* and *phrase-pair relations* in the internal representations of NLI models.

Regarding interventions as interpretability tools for machine learning classifiers, there are two broad categories: those that modify the raw input (such as image or text) in a controlled way, and those that modify the hidden/latent vector representations of the data at various stages of the models’ input processing. While input-level interventions are more common as they are usually easier to control and are strongly interpretable, they don’t allow us to explore and conjecture about exact high-level representational mechanisms in the latent space. We tabulate a few relevant interventional interpretability methods in table 2. Note in particular the variation in the *generation* step for the intervened input; some use generative modelling for counterfactual examples, while we use cheaper linear probes.

The only other work in which interventional methods have been applied to natural logic is Geiger et al. (2021): a similar problem setting is considered, but at a finer granularity. Our work focuses more on the summarised abstract notion of context monotonicity as a single feature, rather than the intermediate tree nodes that determine its final monotonicity profile. The interventions used in this work are vector *interchange* interventions; partial representations from transformed inputs are used, as opposed to direct manipulations of the encoded vectors.

6 Conclusion and Future Work

Our experimental setting has shown significant limitations of amnesic probing in high-dimensional settings where there are few label classes (and consequently fewer dimension modified), even if these classes are strongly detectable. Our results point out that it is misguided to conclude that a given feature is not used when post-amnesic-intervention downstream performance fails to drop, especially in our example amnesic probing studies of a) the gold downstream feature label and b) the composite of two labels that jointly determine the entailment label. This may be due to a dimension/rank confounder variable and high redundancy of information in the representations. It remains to be checked whether high performance in the random control directions corresponds to strong alignment with these probe-selected directions: we propose an analysis of the *dot products* with the fixed set of probe-selected dimensions, which indicates a shared directionality measure (0 for orthogonal vectors and 1 for codirectional ones).

Table 2: Related Work on Latent Concept Interventions

In summary: we have introduced a modification of the amnesic probing paradigm which we call *mnesic* probing which uses the same INLP process but considers the opposite intervention: using the union of projection rowspaces to keep *only* the directions the probes have identified to be mod-elling the target information. This strategy presents results that are more aligned with theoretical expectations (in the NLI case), possibly because we are now able to make comparisons in a lower rank setting.

7 Limitations

A key limitation of the *mnesic* probing strategy is that as one reconstructs the original representation one dimension at a time, information content is naturally due to increase: as such, no *mnesic* probing result can be viewed in isolation, but should be used as a comparative study. Preferably, various randomized selections of linear subspaces with the same number of dimensions should be included as baselines input representations. Furthermore, we mention two some additional caveats: firstly, the probing strategies used here to identify the informative semantic subspaces in question are always linear; relevant information may be present non-linearly. However, as with amnesic probing, we discount any non-linearly encoded information as the final model classification layer is linear and thus cannot exploit this information. Lastly, probing for subspaces which are informative of target auxiliary features may always include correlated features in the resulting subspaces; this must always be taken into account when drawing conclusions from *mnesic*/amnesic probing.

Abstract

Answering complex reasoning questions from chart images is a challenging problem requiring a combination of natural language understanding, fine-grained perception, and analytical reasoning. Current chart based Question Answering (QA) approaches largely address structural, visual or simple data retrieval type questions with fixed-vocabulary answers and perform poorly on reasoning queries. We focus on answering realistic, complex, reasoning-based questions where the answer needs to be computed and not selected from a fixed set of choices. Our approach employs a neural semantic parser to transform Natural Language (NL) questions into SQL programs and execute them on a standardized schema populated from the extracted chart contents. In the absence of program annotations, i.e., in a weak supervision setting, we obtain initial SQL predictions from a pre-trained CodeT5 semantic parser and employ Filtered Iterative Back-Translation (FIBT) for iteratively augmenting our NL-SQL training set. The forward (neural semantic parser) and backward (language model) models are initially trained with an external NL-SQL bootstrapping data. We iteratively move towards the required NL query distribution by generating NL questions from the synthesized SQL programs using a Probabilistic Context-Free Grammar (PCFG) where the production rule probabilities are induced to be inversely proportional to the probabilities in the training data. We filter out the generated NL queries with mismatched structure and compositions. Our FIBT approach achieves State-of-the-Art (SOTA) results on reasoning-based queries in the PlotQA dataset yielding a test accuracy of 60.44%, superseding the previous baselines by a large margin.

1 Introduction

Charts and plots are compact visualization techniques capturing illustrated facts that are frequently used in scientific and financial documents for sum-

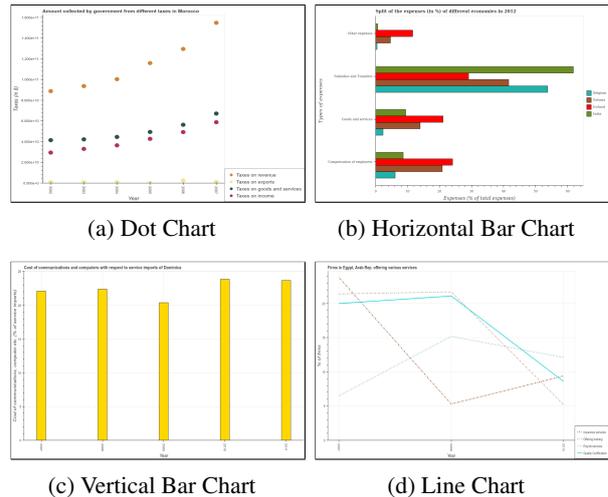

Figure 1: PlotQA Chart Types

marizing observations and drawing conclusions about the underlying data. Inferring relevant conclusions from charts entails answering complex reasoning style queries, a task which has so far proved challenging to automate. Most existing approaches and datasets for automatic QA over charts specifically focus on structural, visual, relational or simple data retrieval type queries (Chaudhry et al., 2020; Siegel et al., 2016; Kim et al., 2020). Also, as depicted in Table 1 many approaches assume either binary answers or assume the answer belongs to a fixed vocabulary.

On the other hand, for real world applications, more complex reasoning based questions have to be answered which involves a combination of perception, language understanding, and reasoning. For example, to answer the question depicted in Table 1, for the chart (d) in Figure 1, the following steps have to be followed: (i) Refer to the legend to infer that the ‘percentage of firms offering quality certification’ are depicted by the solid sky blue line, (ii) For each year value on the X-axis, retrieve the corresponding Y-values depicted by the solid sky blue line, (iii) If the value of corresponding year y is $V(y)$, then find if $\forall y_i$ and y_j , where $i \neq j$,

if $y_i > y_j$ then $V(y_i) \geq V(y_j)$, to determine if the values are monotonically increasing. In this work, we address such complex reasoning style questions on charts. These questions may also involve nested arithmetic and aggregation operations over the chart data and thus the answer is not necessarily derived from a fixed vocabulary, or extracted from the chart text. We evaluate our approach against the reasoning questions provided in the PlotQA V2 dataset (Methani et al., 2020).

We define a common schema for the data across all chart types and employ a state-of-the-art chart visual extractor to populate the schema with chart data. The PlotQA dataset does not provide any SQL program annotations for the Natural Language (NL) questions (only answers). We automatically generate SQL programs for these NL questions by using a Filtered Iterative Back-Translation (FIBT) approach (Hoang et al., 2018) and execute these programs on the extracted schema to compute the answers. We use the SPIDER (NL to SQL) dataset to train both the forward and backward models for FIBT. The NL query distribution of this dataset is different from the required PlotQA query distribution, in terms of query composition, schema (database) structure and chart domains. We build on the observations of (Guo et al., 2020), who empirically show that Iterative Back Translation (IBT) improves the performance of compositional generalization while generating logical forms from NL questions by correcting errors in the pseudo-parallel data at each iteration.

We define a Probabilistic Context-Free Grammar (PCFG), as a subset of the SQL grammar, to sample SQL programs executable on the extracted chart schema. Existing PCFG based data augmentation approaches for semantic parsing (Wang et al., 2021b), synthesize SQLs following similar compositions to that of a given query set by inducing proportional grammar probabilities. Our approach differs from these as we set the probabilities of our PCFG to be inversely proportional to the set-of programs in the training data. This results in synthesis of SQL programs that (i) were not present in the current training data and (ii) follow the program distribution of the SQL programs needed to compute the answers for the PlotQA questions. We iteratively augment the training data by generating NL questions from SQL programs. We further use denotations and a novel compositional similarity based filtration strategy for removing noisy

NL-SQL pairs. We observe that this data augmentation and filtration strategy results in improvement in the PlotQA execution accuracy for every iteration of FIBT, finally achieving State-of-the-Art performance on the reasoning-based queries for the PlotQA dataset with a 60.44% test set accuracy, superseding the previous baseline (14.82%) (Methani et al., 2020) by a large margin and even surpassing human performance. The ChartQA model (Masry et al., 2022) showed that the T5 language model offers the best overall performance for the questions in PlotQA. We demonstrate that our approach surpasses T5 for complex reasoning type of questions in PlotQA with OOV answers. The main contributions of this work are:

- To the best of our knowledge, ours is the first approach to effectively address reasoning style NL questions over charts whose answers are computed and not restricted to a fixed vocabulary.
- In absence of program annotations, we propose a weakly supervised FIBT approach for SQL synthesis with novel data augmentation and filtration strategies to adapt the Neural Parser to more closely follow target NL-Question distribution.
- Our approach allows us to achieve State-of-the-Art results on PlotQA reasoning-based questions with a 60.44% test set accuracy, superseding the previous baseline (14.82%) by a large margin and even surpassing human performance (58.70%).
- As opposed to existing end-to-end approaches (Singh and Shekhar, 2020; Kafle et al., 2020; Chaudhry et al., 2020), our approach is more interpretable as we can track reasoning patterns in the synthesized programs via the generated programs.

2 Related Work

2.1 Datasets for Chart Q&A

Chart QA datasets such as DVQA (Kafle et al., 2018) or FVQA (Kahou et al., 2017) are synthetically generated with limited variations, containing simple binary or fixed-vocabulary questions. To avoid these biases, Leaf-QA (Chaudhry et al., 2020) and PlotQA (Methani et al., 2020) datasets are constructed from open real-world sources from World Bank, Government, Global Terrorism Database, etc. Questions in these datasets are in English and are templated but paraphrased to prevent models

NL Questions	(a) Dot Chart	(b) Horizontal Bar	(c) Vertical Bar	(d) Line Chart
Structural	Is the number of dotlines equal to the number of legend labels? (Y/N)	How many groups of bars are there? (Fixed)	Does the graph contain any zero values? (Y/N)	Does the graph contain grids? (Y/N)
Retrieval	What is the amount collected as tax on revenue in 2005? (Open)	What is the label of the 4th group of bars from the top? (Chart)	What is the label or title of the Y-axis? (Chart)	What is the title of the graph? (Chart)
Reasoning	Is the difference between the amount collected as tax on goods in 2003 and 2007 greater than the difference between the amount collected as tax on exports in 2003 and 2007? (Y/N)	What is the difference between the highest and the second highest percentage of amount spent on other expenses? (Open)	Do a majority of the years between 2008 and 2011 (inclusive) have cost of communications and computer greater than 10? (Y/N)	Does the percentage of firms offering quality certification monotonically increase over the years? (Y/N)

Table 1: PlotQA Questions for Charts in Figure 1, Answer Types: Yes/No, Fixed, Chart or Open Vocabulary

Data	Images		Questions		
	Total	R*	Total	Reasoning	R*

Valid	33,650	3,110	4,360,648	3,574,081	13,740
Test	33,657	-	4,342,514	3,559,392	-
Total	224,377	16,044	28,952,641	23,727,129	82,740

Table 2: PlotQA V2 Dataset Statistics. R*: Representative images (c_{rep}) and questions (q_{rep}) used for FIBT

from memorizing the templates. Both datasets have a significant proportion of analytical reasoning queries, however the PlotQA dataset has 81.95% complex value-based queries, requiring stronger numerical and analytical reasoning capabilities (Chaudhry et al., 2020). Also 80.84% PlotQA queries have answers from an open vocabulary. Moreover, $\sim 82\%$ of questions in PlotQA are reasoning based, as opposed to the recently introduced CharQA dataset (Masry et al., 2022), which has only 43% (compositional) reasoning based questions. Since our main focus is on answering complex questions requiring numerical and analytical reasoning, we use the reasoning based questions in the extended version (V2) of the publicly available PlotQA dataset (Table 2) to evaluate our approach.

2.2 Chart Q&A Approaches

Existing end-to-end approaches use deep models to combine image and question features at various levels of granularity (Kafle et al., 2020). A recent approach (Chaudhry et al., 2020) fuses the chart entities extracted using a Masked RCNN and the NL question using spatial attention to predict the answer. (Singh and Shekhar, 2020) use a structural transformer-based learning that takes the question encoding as input and uses the feature maps of the chart’s visual elements, with its localization information used as positional encodings. These approaches provide results on previously mentioned FVQA, DVQA, and LeafQA datasets on relatively simpler queries. Recently, (Masry et al., 2022; Masry and Hoque, 2021) published benchmarks for chart QA using several end-to-end approaches including, VL-T5 (Cho et al., 2021), TAPAS (Herzig

et al., 2020) and VisionTaPas, which is an extension of TAPAS (Masry et al., 2022) and T5 (Raffel et al., 2019). TAPAS is able to address very simple aggregation type queries and cannot handle complex queries with nested aggregation and arithmetic operations and thus provides poor results on PlotQA (12.90%). T5 provides the best reported results for PlotQA V2 (56.22% test accuracy for all queries). Our proposed approach, designed for complex reasoning type of queries, surpasses their results. Unlike prior end-to-end approaches, we adopt a two staged approach, which not only provides us SOTA results, but allows for more interpretability. Along similar lines, (Methani et al., 2020; Kim et al., 2020) propose a multi-stage solution, where the chart extractions are stored in a semi-structured form, and pre-defined rule-based semantic parsing (Pasupat and Liang, 2015) converts the queries into a logical form. However, these approaches do not generalize to queries not expressible by the grammar rules defined for other datasets, leading to very low test accuracy especially for complex reasoning type of queries (14.82% for PlotQA). An elaborate listing of prior work on Table Q&A and Semantic Parsing and the comparison with our approach highlighting our novelty is in Appendix A.

3 Problem Definition

Our task is defined as follows: given a chart c and a question q on the chart, output a value a that answers the question according to the information represented in the chart. The system has access to a training set $D_{chart} = (q_{chart}, c_{chart}, a_{chart})_1^N$ of questions, charts, and answers. The charts and corresponding questions in test data do not appear during training. We assume availability of a bootstrapping dataset of $D_{tr} = (s_{tr}, q_{tr}, p_{tr})_1^M$, where s are the database schema, q are the Natural Language (NL) queries posed on the schema and p are the SQL programs corresponding to the NL queries. The domain of the charts c_{chart} can be distinct from the domain of the schema s_{tr} .

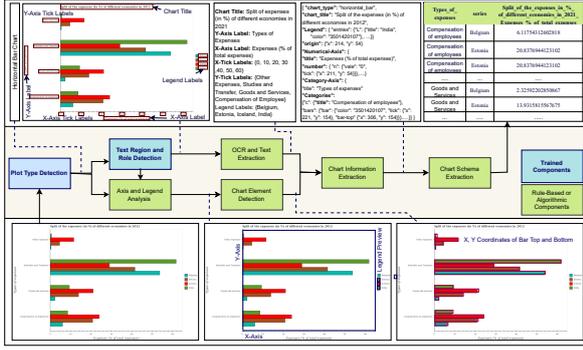

Figure 2: Chart Schema Extraction Vision Pipeline

We assume that the SQL programs p_{tr} share the primitive arithmetic, aggregation and logical operations (SUM, DIFFERENCE, RATIO, AVERAGE, MEDIAN, MAXIMUM, MINIMUM, GREATER THAN, LESS THAN) with the SQL programs required to answer the NL questions q_{chart} . However, distributions over the primitive operations and their compositions can differ.

4 Approach

We follow a two stage approach. In the first stage, we use a computer vision pipeline to extract chart and store the chart data in a format (schema) s_{chart} , common across all the chart types. In the second stage, we synthesize SQL programs for the NL questions in the dataset by using Filtered Iterative Back-Translation (FIBT). We use SQL as the target logical form for program synthesis because it’s grammar (i) is well suited to the tabular structure of our extracted data and (ii) includes the primitive operations required to be handled for the NL queries in PlotQA. Also, SQL is close to NL and easy to understand, allowing for interpretability.

4.1 Chart Schema Extraction

In the first stage, we extract chart information using the following pipeline: (i) Chart Type Detection (Trained) (ii) Text Region and Role Detection (Trained) (iii) OCR and Text Extraction (Algorithm) (iv) Axis and Legend Extraction (Rule-Based) (v) OCR and Text Extraction (Algorithm) (vi) Chart Information extraction (Algorithm).

Since the chart types have distinct visual features we fine-tune a Resnet-34 model pretrained on ImageNet to detect chart types, using chart type labels provided by PlotQA. The text present in the image is detected by employing the CRAFT model (Baek et al., 2019). However, CRAFT frequently

misses isolated characters and often yields partial detection of text regions. We propose an approach which corrects partially detected text, segments out the corrected text region and identifies text-role labels (such as chart title, legend labels, X/Y-axis, and X/Y-tick labels) for the text regions (Appendix B). We use Tesseract 4.0.0 (Smith, 2007) to extract text from the detected regions and tag them to the corresponding roles. The results of the chart element extractions and text role region extractions are described in Appendix F. We define rules to identify (i) the origin, axes and chart region from the detected chart lines by a line detection algorithm (Paliwal et al., 2021), (ii) location of the legend previews and their styles (color and pattern) using the detected legend-labels, and (iii) chart elements (bars, dots, lines) which are regions matching with each legend preview style. We extract a schema (table) from the above available chart information, by filtering noise (Appendix C) and extracting the data series elements (Appendix E).

Henceforth, we use the following nomenclature. For the horizontal-bar charts illustrated in Figure 1 (b), we refer to the X-axis as the Numerical-axis and Y-axis as the Categorical-axis. For the remaining chart types in Figure 1 viz. dot, vertical bar, and line chart, the nomenclature is reversed. We call each legend label as a series. Thus, the extracted chart information is in the form of a set-of tuples $\langle category_label, series_label, numerical_value \rangle$, with the schema (table) header being category axis label, series, and a string formed by concatenating the chart title with the numerical axis label. We store these tables s_{chart} in the SQLite3 database to facilitate the execution of synthesized SQL programs (Section 4.2) on the schema. As ‘Median’ is not an in-built aggregation operation for SQLite3, we define a stored procedure for the same.

4.2 SQL Program Synthesis

As the part of the second stage, we execute Filtered Iterative Back Translation (FIBT) (Algorithm 1), to train the neural semantic parser $M_{NL \rightarrow P}$, which is used to synthesize SQL programs for the reasoning questions in the PlotQA test set. The generated SQLs are executed on the test set chart schema s_{chart} , extracted from the corresponding chart image c_{chart} , to compute the final answer. This answer is compared with the ground truth answer a_{chart} to calculate the test accuracy.

4.2.1 Bootstrapping Data

We use SPIDER (Yu et al., 2018) augmented with a few (359) NL-SQL query pairs as the bootstrapping dataset D_{tr} to initialize the parameters of the forward $M_{NL \rightarrow P}$ and the backward $M_{P \rightarrow NL}$ models of FIBT. The augmented query pairs are defined to include the primitive operations (DIFFERENCE, RATIO, LESS THAN and MEDIAN), required by the PlotQA NL questions q_{chart} but missing in the SPIDER SQLs, leading to the bootstrapping data q_{tr} and the PlotQA questions q_{chart} sharing the same set-of primitive operations. Inclusion of such query pairs allows the models to learn these primitive operations (followed by their compositions in the subsequent FIBT iterations), which otherwise would not be possible. The query pairs are synthesized using templates. For example, the templates used to synthesize NL-SQL pairs for RATIO operation is: NL: "What is the ratio of the *numerical column name* having *categorical column* value a x to that of *categorical column* value of y ?", SQL:

```
"SELECT T1.numerical_column_name /
T2.numerical_column_name FROM
table_name T1, table_name T2 WHERE
T1.categorical_column_name =
'categorical_column_value_x' AND
T2.categorical_column_name =
'categorical_column_value_y' "
```

These queries are synthesized on a subset of SPIDER schema tables, whose structure match with our extracted chart schema. Thus in the above template, the 'numerical_column_name' is the name of a column of a table belonging to one of the SPIDER database schemas, having a numerical datatype. and 'categorical_column_name' is the column name of the same table, with text datatype with values x and y as its entries.

4.2.2 Probabilistic Context Free Grammar

We define Probabilistic Context Free Grammar (PCFG) depicted in Table 7 in the Appendix, as a subset of the SQL grammar to synthesize SQL programs: (i) to address possible compositions of primitive operations required for the PlotQA NL questions q_{chart} and (ii) executable on the schema s_{chart} . To synthesize SQL programs whose distribution match with the programs for the NL questions in the PlotQA, but are not covered by the current training data D_{tr} , we induce the probability (P_{inv}) for each of the production rules R in the

PCFG with the heuristics depicted in Equation 1.

$$P_{inv}(R) = \frac{Wt(R)}{\sum_{RHS(r)=RHS(R)} Wt(r)} \quad (1)$$

$$Wt(R) = \left(\frac{MAX_{RHS(r)=RHS(R)}(P(r))}{P(R)} \right)^{1-\alpha} \quad (2)$$

$P(R)$ gives the probability with which a rule R is triggered by the set-of SQL queries existing in the training data D_{tr} . $RHS(R)$ is the Right Hand Side of the production rule R. Thus, $RHS(r) = RHS(R)$ provides the set of all production rules which share the source node (RHS) with the rule R. α is the hyper-parameter controlling the skewedness of the distribution over the production rules. Lower the value more skewed is the distribution. For our experiments $\alpha = 0.8$.

26  end if
27 end while
```

4.2.3 Sampling Representative Questions

As depicted in Table 2, PlotQA has ~ 16.6 Million reasoning based NL questions as the part of the training data. For a more compute efficient solution, we identify representative NL questions from PlotQA for training. We randomly sample 200K NL questions from the PlotQA training set and perform the *generalize* operation to replace schema specific information in each NL question with generalized tokens and to highlight its composition or structure. We replace the schema related entity (column headings) and values (column values) in the NL questions with more generic $\langle \text{entity} \rangle$ and $\langle \text{value} \rangle$ tags using substring matching. For example, the reasoning based question, depicted in Table 1, is modified to: ‘Is the difference between $\langle \text{entity_num} \rangle$ on $\langle \text{value_series} \rangle$ in $\langle \text{value_category} \rangle$ and $\langle \text{value_category} \rangle$ greater than the difference between $\langle \text{entity_num} \rangle$ on $\langle \text{value_series} \rangle$ in $\langle \text{value_category} \rangle$ and $\langle \text{value_category} \rangle$?’, where ‘the amount collected as tax’ being a sub-string of the numerical column name of the schema, gets replaced with the generic token $\langle \text{entity_num} \rangle$ and the values of the category column, viz. ‘2003’, ‘2007’ and the series column ‘goods’ and ‘exports’ get replaced with $\langle \text{value_category} \rangle$ and $\langle \text{value_series} \rangle$, respectively. We further get the representations of these generalized NL questions using sentence-BERT (Reimers and Gurevych, 2019) and *cluster* them via DBSCAN¹ with *cosine similarity* as the similarity metric. As DBSCAN allows us to cluster data without specifying the number of clusters in advance, with *minpoints* = 15 and $\epsilon = 0.25$, we get 345 clusters for the 200K generalized NL questions. We then randomly *sample* 200 questions from each cluster to get 69K representative generalized NL questions. We fetch the corresponding original NL questions q_{rep} for these 69K questions along with their corresponding schema c_{rep} and answers a_{rep} to form a dataset of representative queries D_{rep} . A similar sampling strategy is applied on the validation split. Table 2 illustrates the statistics of the representative dataset.

4.2.4 FIBT Forward Pass

We train the forward model $M_{NL \rightarrow P}$ with the training data D_{tr} by feeding the flattened schema,

¹<https://scikit-learn.org/stable/modules/generated/sklearn.cluster.DBSCAN.html>

the table contents, the NL query with a separator token to the encoder and generate the SQL tokens at the output of the decoder in an auto-regressive fashion. The model is trained using cross entropy loss. We feed the NL queries q_{rep} from D_{rep} to $M_{NL \rightarrow P}$ to generate the corresponding SQL programs (p_{rep}). We execute these SQL programs on the corresponding extracted chart schema s_{rep} . The programs which do not execute to the ground truth denotations are filtered, and the training data D_{tr} is augmented by the remaining pairs.

4.2.5 FIBT Backward Pass

We train the backward model $M_{P \rightarrow NL}$ with the training data D_{tr} by feeding the flattened schema and the contents followed by the SQL program with a separator token to the encoder and generating the NL tokens at the output of the decoder in an auto-regressive fashion. We use p_{tr} in the training set D_{tr} , along with the SQL programs p_{filter} filtered in the prior iteration to *induce* the inverse probabilities of PCFG as explained in section 4.2.2. Here, the filtered programs are the ones whose equivalent NL questions do not match with PlotQA representative questions (explained later in this section). We sample SQL programs (p_{synth}) from the PCFG to be executed on s_{chart} and feed these synthesized SQL programs to the backward model $M_{P \rightarrow NL}$ to generate the corresponding NL questions q_{synth} . We (i) transform q_{synth} by using the *generalize* operation, explained in section 4.2.3, (ii) extract the representation for q_{synth} using sentence-BERT (Reimers and Gurevych, 2019) and (iii) compare them with the representations of generalized representative queries (q_{rep}) using *cosine similarity*. NL questions having their maximum similarity score (*max_sim*) below a *threshold* are filtered. The SQL programs corresponding to the filtered NL questions are added to p_{filter} , representing queries not matching the PlotQA questions. With this filtering, we still observe some synthetic questions with semantic noise, meaning the semantics of the NL questions q_{synth} and the corresponding SQL programs p_{synth} do not match. (Shen et al., 2019) uses phrases of NL questions to estimate the operator candidates in the corresponding programs and thus reduce the search space of the semantic parser. We use a similar technique of phrase-operator *look-up* to further filter the synthetic query pairs. Given a q_{synth}, p_{synth} pair the *look-up* operation returns ‘False’ if the pre-defined (set-of) phrase(s) in NL query (q_{synth})

NL Phrase		SQL Operator
ratio	↔	/
difference	↔	-
greater than	↔	>
less than	↔	<
total OR sum	↔	+ OR SUM
maximum OR highest	↔	MAX
minimum OR lowest	↔	MIN
average	↔	AVG
how many	↔	COUNT
median	↔	MEDIAN

Table 3: Mapping of NL Phrases and SQL Operators do(es) not match with the (set-of) operator(s) in the corresponding SQL programs (p_{synth}) and returns ‘True’ otherwise. This matching is done following the pre-defined look-up dictionary with the phrase-operator mappings between the NL questions and the SQL programs (Table 3). This filtering helps to remove the semantically incorrect NL questions (q_{synth}), which have been generated by the backward model $M_{P \rightarrow NL}$ for the synthetic SQL programs (p_{synth}). With this two level filtering, the training data D_{tr} is augmented with the remaining synthetic tuples $\langle s_{chart}, q_{synth}, p_{synth} \rangle$ and is further used to train the models in the next iteration. These added synthetic queries are closer to the PlotQA queries and thus help in adapting the models to answer PlotQA questions. For every iteration, the above defined *threshold* for similarity based query filtering is automatically set to a value for which the KL-divergence between the operator distributions of (i) PlotQA questions q_{chart} and (ii) the synthetic questions getting augmented to the training set ($q_{synth} - q_{filter}$), after filtering with the phrase-operator mappings (Table 3) is minimum. This ensures that the augmented synthetic query pairs, after filtering with the *threshold*, are closer to the required PlotQA questions.

5 Results and Discussion

CodeT5 (Wang et al., 2021c) provides the best results on the Spider dataset ² in terms of execution accuracy. For chart QA, we are more interested in correctly computing the final answer (execution accuracy) than the intermediate logical form (exact match accuracy). Thus we choose CodeT5 based neural semantic parser as our forward model ($M_{NL \rightarrow SQL}$) and CodeT5 based code summarization model ³ as the backward model ($M_{SQL \rightarrow NL}$). The number of trainable param-

eters in the CodeT5 base model are 220M. We fine-tune the models with a batch size of 48 and a learning rate of 0.0001 and gradient accumulation step of 4 using the Adam optimizer on an NVIDIA Tesla V100 32GB GPU. The average run-time for training the model differs in each iteration as the number of training samples increase with the data we augment in each iteration. However, for inference on the PlotQA V2 Test Split, with the given hyper-parameter configuration, it takes ~ 360 hours. For sampling the representative questions and SQL queries from the dataset and PCFG respectively, we use the random seed of 7. The training details of the chart extraction modules are provided in Appendix D. We use test accuracy as the evaluation metric, where for numeric answers with floating point values, we consider an answer to be correct if it is within the 5% range of the correct answer as followed by (Methani et al., 2020).

Table 4 illustrates the results of the Q&A task over reasoning based queries in the PlotQA V2 test set (~ 3.56 M NL queries on ~ 33.6 K charts). Following the benchmark approaches (Methani et al., 2020; Masry et al., 2022), we report results on PlotQA V2 test set and not the validation set. As mentioned in (Methani et al., 2020) most human errors are due to numerical precision as it is difficult to visually identify the exact value from the chart even within a 5% margin. Our weakly supervised approach surpasses the baselines (PlotQA (Methani et al., 2020) and T5 (Masry et al., 2022)) by a large margin even exceeding the human baseline. We observe improvement in test accuracy results from 39.69% to 57.45% to 60.44% in the 1st, 2nd and 3rd iterations of FIBT, respectively. This demonstrates the utility of the FIBT approach with the filtering and augmentation mechanisms used for capturing the relevant query compositions.

As per the definition provided by the authors of PlotQA, the fixed vocabulary comprises of the set of top 1000 frequently occurring answer words. Our approach yields superior performance for fixed

vocabulary (FV) and open vocabulary (OV) answers. Both FV and OV answers are numerical. Prior approach of end-to-end model predicting the final answer directly (T5 (Masry et al., 2022)) and approach which address queries with distinct answer types distinctly (PlotQA(Methani et al., 2020)), learn to distinguish the queries having YES/NO (binary) type of answers from other queries. Once this is learnt, any random guess of YES/NO as an answer to these queries would lead to a performance of 50%. On the other hand, our approach trains a single model to generate SQL programs for all queries with distinct answer types. For some cases the generated SQL program for questions with binary answers does not yield a binary result. Thus, for our approach, the random accuracy for Yes/No queries is not 50%. Moreover, the SQL programs for questions with YES/NO answers are more complex as compared to the SQL programs which leads to numerical answers (FV and OV questions) in terms of entailed compositions of primitive operations involving nesting, leading to harder synthesis. Also, our approach does not yield good performance for some of these questions with binary answers as there is no explicit mapping between the phrases in the NL query and the primitive operations involved in the SQL program. For example, for the questions: ‘Do a majority of the years between 2013 and 2010 (inclusive) have a number of secure internet servers greater than 1.16?’ or ‘Do the payments made towards primary income monotonically increase over the years?’ or ‘Is the payments made towards goods and services strictly less than the payments made towards primary income over the years?’ , the model finds it harder to learn to map the abstract phrases ‘majority of’ or ‘monotonically increasing’ or ‘strictly less than’ to a composition of primitive operations in the corresponding SQL programs as this knowledge is not explicitly provided. These are the reasons that the performance of our approach for queries with YES/NO answer type is inferior as compared to the other reasoning queries.

ChartQA (Masry et al., 2022) provides results on the complete PlotQA V2 test split (~ 4.34 M questions) for all question types including structural, data retrieval and reasoning. The test accuracy of their best performing model (T5), trained on the complete PlotQA train set (~ 20.25 M questions), end-to-end is 56.22%. For fair comparison with ChartQA (Masry et al., 2022), we train the

T5 model in an end-to-end fashion (direct answer based supervision), with 69K representative questions (0.04%) of the PlotQA training set following the same input format as in ChartQA. We test the model on reasoning based questions in PlotQA V2 test data (~ 3.56 M) to obtain the results depicted in Table 4. The T5 model can address the yes/no type of binary answers but struggles on questions with numerical answers (FV and OV). Effectively, as discussed earlier, once T5 has learnt to identify questions having binary answers, a random guess would lead to 50% accuracy. For T5, low performance on non-binary reasoning questions is expected because the end-to-end training in general struggles to perform complex reasoning in the latent space, and this is compounded by the very small amount of training data used for fair comparison. On the other hand, better performance of FV and OV answer type questions, underscores the efficacy of our approach to better handle complex numerical reasoning questions. Moreover, as we generate SQLs for NL, our approach is more interpretable, allowing users to understand the reasoning steps to get the final answer.

Apart from PlotQA (Methani et al., 2020), CharQA (Masry et al., 2022) is the only other dataset available. After thorough analysis of this dataset, we observed that the dataset contains samples with incorrect ground truth labels, spurious questions and Gold data tables with incorrect information. The details of our analysis is provided in Appendix G. Hence, we have not used CharQA (Masry et al., 2022) for benchmarking our approach.

To understand the impact of errors from vision based chart schema extraction on the downstream reasoning task, we perform an ablation to calculate the test accuracy of the reasoning task using the schema constructed with oracle extractions provided by PlotQA. We observe a 24.05% lower test accuracy with the extracted schema as compared to the oracle. We further analyze the results based on operators involved in the query. We observe that our approach works well not only for reasoning questions involving one primitive operators, but also for more complex questions involving composition of numerical operators such as (i) ‘COUNT VALUES GREATER THAN AVERAGE’ (For example, *For how many years, is the payments made towards primary income greater than the average payments made towards primary income over all*

years ?) or (ii) ‘SUM GREATER THAN MAX’ (For example, *Is the sum of the payments made towards goods and services in 2008 and 2010 greater than the maximum payments made towards primary income across all years ?*) or (iii) DIFFERENCE GREATER THAN DIFFERENCE’ (For example, reasoning type of query mentioned in Table 1 for dot charts).

We further observe that our approach does not yield good results for NL questions involving nesting in the SQL program. For example, (i) queries computing a ‘DIFFERENCE’ between the ‘MAXIMUM’ and the ‘SECOND MAXIMUM’ values of the numerical column (For example, the reasoning type of query mentioned in Table 1 for (b) Horizontal bars). In the corresponding SQL program for such questions, to compute the ‘SECOND MAXIMUM’ value requires nesting, (ii) the queries which try to find if the ‘SUM’ of two numerical values is ‘GREATER THAN’ the ‘SUM’ of other two numerical values, for ‘EVERY’ value of a non-numerical column. These NL questions demand nested SQL programs which ensure the ‘SUM GREATER THAN SUM’ criteria is true for ‘ALL DISTINCT’ values of the non-numerical column. Table 7 shows that the defined PCFG allows synthesis of nested SQL programs. We observe that as such nested SQL programs are not present in the initial training set, the strategy of inducing inverse probabilities for the PCFG facilitates synthesis of nested SQL programs in the later iterations of FIBT. However, for most of such nested SQL programs the backward model fails to generate semantically meaningful NL questions. Such noisy synthetically generated NL questions are filtered by our filtration strategy in the backward pass leading to fewer nested query samples in the training data which in turn cause low test accuracy for such questions.

6 Conclusion

We present an approach for QA on charts which addresses complex reasoning based questions that require a combination of natural language understanding, fine-grained perception, and analytical reasoning. We employ a pretrained semantic parser and FIBT we generate SQL programs for the NL questions without any program annotations. Our novel PCFG based approach helps the model to adapt to the given dataset’s query compositions and domains, unseen in the bootstrapping data. As the future work we plan to extend our approach fur-

ther to handle complex questions requiring nesting by using a hierarchical or grammar based program search technique.

7 Limitations

The focus of this paper is on complex reasoning type of questions. Our approach is not designed for structural (Table 1) or visual types of questions, pertaining to attributes of the visual elements of the plot such as color, size, spatial location. These questions are not useful for real-life applications, which require analysis on chart data to draw meaningful conclusions. Our existing approach is not designed to address such questions as the extracted schema only captures the underlying data of the chart, and not the visual entities present therein.

To have a good kick-start for the FIBT pipeline, we assume that the bootstrap SPIDER data covers the primitive SQL clauses, operators and functions required for the questions in the target dataset and there is some minimal overlap between the compositions of the SQL queries in the bootstrap SPIDER data and SQL queries required for the natural language questions in the target dataset.

In the current phrase-operator based filtering strategy only limited phrases are manually designed for the mapping of NL phrases and SQL operators (Table 3). We plan to make this approach more robust by using paraphrases or semantically similar phrases to manually designed phrases for mapping.

8 Ethical Considerations

PlotQA charts contain only factual information which is openly available in public domain and is not (i) specific to any individual or (ii) offensive. The solution provided in the paper is agnostic to the domain of the data. Like any QA task, to avoid the risks involved in critical domains such as finance, healthcare or medicine, we would have to calibrate the model or need human intervention, such that the errors are not propagated to the downstream tasks.

Appendices

A Prior work on Table Q&A and Semantic Parsing

Current approaches for table QA use an end-to-end modeling approach for either: (i) directly generating the answer (TAPAS (Herzig et al., 2020)), (ii) generate a program which produces the answer

upon execution of the generated SQL (TABERT (Yin et al., 2020) and RCI (Glass et al., 2021)) or (iii) using a Language Model pre-training strategy (neural query execution engine in TAPEX (Liu et al., 2021) using synthetic SQL programs or semantic parser trained on synthetic NL-SQL pairs generated using a Synchronous Context Free Grammar (SCFG) in GraPPa (Yu et al., 2021). These approaches are mainly designed for handling data retrieval or simple aggregation type of queries defined in WikiSQL (Zhong et al., 2017) or Wiki Table (Pasupat and Liang, 2015) datasets. The complex reasoning type queries which are part of the PlotQA dataset involve nested arithmetic operations with self-joins as well as nesting in the conditional (WHERE) clauses. (Yin et al., 2020) applied their approach on the benchmark Spider Text-to-SQL dataset (Yu et al., 2018) but their results have been eclipsed by RYANSQL (Choi et al., 2021), whose decoder is specifically designed to address nested complex queries. GraPPa (Yu et al., 2021) achieves state of the art performance on the complex spider dataset after fine-tuning with spider program (SQL) annotations.

In our scenario there are no SQL program annotations for PlotQA queries, and only the output denotations are available. Since annotating a sufficiently large number of SQL programs is a resource heavy task, semantic parsers can be trained with execution output denotations under a weak-supervision setting. These execution denotations can be used to model a reward signal in order to train the underlying semantic parser (Zhong et al., 2017; Liang et al., 2018; Hagopian et al., 2019; Agrawal et al., 2019; Agarwal et al., 2019). They can also be used to train the semantic parser with a log Multiple log Marginal Likelihood (MML) objective by using a limited number of SQL programs as latent logical forms (Wang et al., 2019; Min et al., 2019; Wang et al., 2021a). While synthesizing SQL programs, the denotations can also be used to filter candidate programs with rule-based synthesis systems (Guo and Gao, 2019; Guo et al., 2021; Wolfson et al., 2021). The reward-based approaches face issues with a large program search space and possible spurious programs. Unlike the MML approaches, we do not use any gold annotated SQL programs from the dataset under consideration (PlotQA). Most of the above weak-supervision approaches do not explicitly handle modeling or synthesizing the specific complex program compositions pertinent to

the dataset under consideration. On the other hand, our approach uses a publicly available semantic parsing dataset (Spider) as the bootstrapping data to initialize the parameters of the semantic parser, and then defines a novel PCFG-based strategy to adapt the models through FIBT to answer unseen complex reasoning queries in the PlotQA by effectively capturing the relevant query compositions.

B Text Role Region Extraction

The architecture consists a *Encoder-Decoder Module*, which the U-net (Ronneberger et al., 2015). The encoder filters out irrelevant information by squeezing the feature map to a latent space. The output of the decoder is appended along the channel dimension with the trigger patch of a text region detected by CRAFT, with highlighted patch contours and provided as an input to the *Trigger-Controller Module*, extracts features using a convolutional feature extractor followed by a Global Average Pooling (GAP) layer. The features of the trigger patch are concatenated with the extracted encoder output features and are fed to the controller module to generate dynamic kernels, which are used to generate the segmentation map (Jia et al., 2016). The dynamic kernel output is also given to a fully connected linear layer to determine the text role of the region. Thus, the trigger-controller module exploits the spatial relationships between text-roles to generate dynamic kernels and obtain text-role specific segmentation maps from the decoded image. The whole network is trained with cross entropy loss on text-role class labels and text-role segmentation map (all ground truth text-regions corresponding to that text-role). During inference, given a trigger patch for an image of a detected text-region belonging to an unknown text-role, the model provides the actual text-role classification output and the segmentation map of the text-region of that text-role. Trigger patches overlapping with detected text-role regions are removed before repeating the process for the remaining trigger patches. This process may lead to multiple segmentation maps for each text-role, over which a union operation is performed.

C Noise Correction

To handle false positive and false negative detection of Numerical-axis ticks, we find the mode (M) of differences between the (X/Y) coordinates for the consecutive ticks. We remove or add ticks where

Table 6: OCR Module Accuracy

the difference in the consecutive ticks is more or less than the mode, respectively. We add a dummy value ‘x’ for the newly added tick, if any, which is handled during correction. We replace a non-numerical tick-value detection, if any, by using M as an offset to the the neighboring tick value. To correct the tick-values not adhering to a progression followed by the majority values, we consider a tick-value as an ‘anchor’ (correct value) and calculate the other values adding and/or subtracting M from this anchor. We compute the ‘gain’ with respect to this anchor to be the intersection of the extracted values and calculated values. We repeat this process by considering distinct numerical-axis values as anchors. For the ‘anchor’ giving us the maximum ‘gain’, the corresponding calculated values are considered to be the correct set of numerical-axis tick values. Some charts (Figure 1 (a)) use scientific notation for denoting large numerical values which are converted to float values.

D Training Details for Chart Extraction Models

For the chart type classification ResNet-34 is fine-tuned for 2000 steps. We use the Adam optimizer, a learning rate of 0.0005, and a batch size of 8. The model yields 99.91% test accuracy. For text region and role detection, we use the pre-trained VGG19 and train with a batch size of 8, for 1 epoch, using the Adam optimizer with an initial learning rate of 0.0005. As the data is skewed for axes-labels, while creating training tuples, we under-sample for this text-role to avoid class imbalance.

E Data Extraction

We use interpolation and extrapolation to calculate a numerical value associated with every pixel on the numerical-axis by using numerical-axis tick coordinate pixels as reference. For every data point (pivot-point in case of dots and line charts, bar-tops in case of bars) detected we assign it: (i) a series by matching its style with the style of a legend label, (ii) a category by matching its co-

ordinate with the category tick, and (iii) a value of the pixel on the numerical axis whose coordinate matches with it. Thus, we extract the data in the form of a set-of tuples $\langle category_label, series_label, numerical_value \rangle$. For the category for which no pivot point or bar is detected for a series due to VED errors, we consider its value to be zero. We finally define a tabular schema with the column names as category axis label (category column), series (series column), and a string formed by concatenating the chart title with the numerical axis label (numerical column). All the spaces in the column names are replaced by underscores to make them SQL compatible. We insert the extracted tuples as rows in the tabular schema. The generic schema obtained for the chart in Figure 1(b) is shown in Figure 2. Charts containing only one series have a schema with only category and numerical columns.

Improvements over FIBT Iterations The generated SQL programs for the NL queries requiring certain compositions of primitive operations got corrected after the iterations of back-translation. For example, the required composition of the NL query ‘In how many years, is the amount spent in making social contributions greater than the average amount spent in making social contributions taken over all years?’ is ‘Count Greater Than Average’. After the first iteration the generated SQL program for this query is “Select t1.social_contributions > t2.social_contributions from table_data t1, table_data t2 where t1.year = ‘2010’ and t2.year = ‘2010’ “, which got corrected to “select count(*) from table_data where social_contributions > (select avg (social_contributions) from table_data)”, after the second iteration. This improvement is because of the data augmented by PCFG-based synthetic queries, which contained these SQL queries having compositions not present in the original bootstrapping data (details in Section 4.3). Some additional improvements over the iterations are because of the coverage of the additional (chart) domains, which

are not present in the initial bootstrapping data (having queries covering the SPIDER database domains), but got covered in the PCFG based synthetically generated queries on the PlotQA chart schema, addressing the domain shift.

F Results of Plot Extraction

For plot extractions we prefer mAP @0.90 IOU over mAP @0.75 and mAP@0.50 IOU as the evaluation metric as we require precise fine-grained extractions else the resulting data errors will propagate to the downstream QA task. For OCR we use accuracy (1 - Word Error Rate (WER)) as the evaluation metric. Table 5 illustrates the SOA results on plot extraction by our approach. We have state-of-the-art results with for Chart Extraction yielding 94.92% mAP @0.90 IOU when trained with all PlotQA (157K) images, beating the baseline (Ganguly et al., 2020) by 1.48%. mAP @0.90 IOU. The extraction of dot/line regions is challenging because of their small size, sparse distribution and

eclipsed or intersected dots/lines of distinct series. Table 6 depicts the SOA results of the OCR module. The PlotQA Oracle refers to the results with the OCR model applied to the ground truth text-regions. Our predicted text-detections followed by OCR outperform both the baselines from PlotQA (Methani et al., 2020), yielding State-of-the-Art results.

G ChartQA Dataset Analysis

After thorough analysis of CharQA (Masry et al., 2022) dataset, because of the following observations we have not used it for benchmarking: (i) Samples with incorrect Ground Truth (GT) labels: Few examples: (a) for the question ‘*In what year did Nicaragua have the highest risk score of money laundering and terrorist financing?*’ on the chart ‘two_col_102453.png’, the actual answer is ‘2020’, and the provided GT is ‘2015’, (b) for the question ‘*What’s the ratio of the lowest value of green bars and blue bars?*’ on the chart ‘1392.png’, the

actual answer is '2.41' and the GT is '1.216', (c) For the question 'In republicans what is the difference between the more likely and less likely?' on the chart '9987.png' the ground truth label is '21', where as based on the question the ground truth label should be '-21'. (ii) Samples with spurious questions: The contents of the question are not relevant to the data present in the chart. Few examples: (a) For the question '*What was the third most popular brand on Foursquare?*' on the chart 'two_col_80744.png', 'Foursquare' is itself an individual brand depicted in the chart and no other information about Foursquare is provided. and the GT is 'MTV' which in itself is a separate brand and not related to Foursquare. (b) the question '*How many people checked in to New Delhi on Facebook between June and August 2017?*' posed on chart 'two_col_5556.png' has some terms such as Facebook or specified Month/Year which are not present in the chart, (iii) Gold data tables⁴ with incorrect information: Gold data tables crawled through web source 'PEW'⁵ have incorrect information, which leads to predicted answers. In the test set 310 (20.54%) samples have all the data values to be zeros and others ('4931.png', '2721.png', '11627839005738.png') have floating point errors. For example, the Gold data tables for charts '4931.png', '2721.png', '11627839005738.png' are spurious. Due to this incorrect Gold Table contents even though the GT labels corresponding to the question to these charts is correct, with incorrect data points, the resulting answer does not match the label. Due to the above listed observations, we have not used this dataset for the benchmarking purpose.

Exploiting Language Characteristics for Legal Domain-Specific Language Model Pretraining

Inderjeet Nair and Natwar Modani

Adobe Research, India

{inair, nmodani}@adobe.com

Abstract

Pretraining large language models has resulted in tremendous performance improvement for many natural language processing (NLP) tasks. While for non-domain specific tasks, such models can be used directly, a common strategy to achieve better performance for specific domains involves pretraining these language models over domain specific data using objectives like Masked Language Modelling (MLM), Autoregressive Language Modelling, etc. While such pretraining addresses the change in vocabulary and style of language for the domain, it is otherwise a domain agnostic approach. In this work, we investigate the effect of incorporating pretraining objectives that explicitly tries to exploit the domain specific language characteristics in addition to such MLM based pretraining. Particularly, we examine two distinct characteristics associated with the legal domain and propose pretraining objectives modelling these characteristics. The proposed objectives target improvement of token-level feature representation, as well as aim to incorporate sentence level semantics. We demonstrate superiority in the performance of the models pretrained using our objectives against those trained using domain-agnostic objectives over several legal downstream tasks.

1 Introduction

Pre-trained language models exhibit superior performance in several NLP tasks. Most of the prominent language models optimized over Masked language modelling with BERT-like (Devlin et al., 2019; Liu et al., 2019b; He et al., 2020) architecture using large unlabelled corpus to achieve state of the art results across many NLP tasks. While the sentence-level tasks like paraphrase detection (El Desouki and Gomaa, 2019) and sentiment analysis (Zhang et al., 2018) benchmarks the capability of the model in effectively modeling the holistic representation of the sentence(s), the token-level tasks like named entity recognition (Li et al.,

2020) attempted to assess the quality of contextualized token embeddings furnished by the models. However, direct application of these models to domain-specific downstream tasks yields sub-optimal performance (Lee et al., 2020), perhaps due to change in vocabulary and style of language.

To overcome this limitation, most commonly used approach involves pre-training a language model over domain specific corpora. For instance, PubMedBERT (Gu et al., 2021) and LEGALBERT (Chalkidis et al., 2020) achieved state-of-the-art results for the biomedical and legal domain specific tasks respectively by pre-training over domain specific corpus using a domain agnostic objective. In this paper, we argue that the performance of these models can be further improved by employing pre-training objectives that exploit the language characteristics of the domain. We examine two distinct language characteristics of the legal domain, propose pre-training objectives and finally demonstrate superior performance over domain-specific NLP tasks. Legal domain departs from the generic corpora in terms of specialized vocabulary, particularly formal syntax, domain-specific knowledge semantics, etc. to the extent that it can be classified as a distinct "sub-language" (Tiersma, 1999; Williams, 2007), which may be addressed by MLM based pretraining. In this paper, we study the following additional domain characteristics and formulate closely aligned objectives in addition to domain agnostic objectives like MLM:

1. **Templatized language:** Legal documents consist of clauses that are often derived from reusable text fragments with placeholders. The placeholders are substituted with appropriate replacements for specific documents. We include a pre-training objective for this characteristic by optimizing the model to distinguish the substitutions from the rest of the text. Since, there is no labelled dataset that provides such information, we also outline the

process to approximately label the data-points with placeholder spans.

2. **Availability of Soft Labels:** Contracts and legally enforceable documents can be segmented into clauses which are sections defining terms and conditions and important provisions. Clauses can be categorized into distinct types based on the aspect they address, which (the categorization) may sometimes be available as a heading/title associated with the clauses. This categorization enables us to define semantic relations between clauses. For instance, clauses having same type are closer in meaning as compared to different typed clauses. This fact is instrumental in formulating an objective to obtain semantically aware holistic representation.

We leverage these two characteristics to design a pre-training strategy, and experimentally show that a language model pretrained using our strategy outperforms domain-specific language model which is trained only on domain-agnostic objectives, such as Masked Language Modelling.

The rest of the paper is organized as follows. In Section 2, we discuss some prominent frameworks that provisions domain specific pre-trained models and survey important works in the legal AI. In Section 3, we elucidate the details for the aforementioned legal domain characteristics and describe the objective formulation and dataset curation strategy. In Section 4 discusses the training. In Section 5, we briefly describe the baseline models used to compare the performance with our pre-trained model for several legal domain tasks, and discuss the results. Finally, in Section 6, we conclude by explaining the implications of our work and discuss its natural extensions.

2 Related Works

2.1 Prominent domain adaptation pretraining approaches:

Pretrained language models trained over non-domain specific data such as transformers (Vaswani et al., 2017), BERT (Devlin et al., 2019) and its variants (Liu et al., 2019b; He et al., 2020) has resulted in state-of-the-arts results for several non-domain specific natural language processing downstream tasks. Owing to their success, a prominent approach to achieve superior results in domain-specific NLP tasks involves training these models

over domain-specific corpora. For instance, to improve the performance of the models in biomedical downstream tasks, BIOBERT (Lee et al., 2020), Clinical BERT (Alsentzer et al., 2019), Clinical BIOBERT (Alsentzer et al., 2019) and PubMedBERT (Gu et al., 2021) were pretrained over speciality corpora closely associated with the biomedical domain using the MLM objective. Recently, (Chalkidis et al., 2020) proposed LEGAL-BERT, a language model pretrained using MLM over domain specific corpora, to achieve state-of-the-art performance for several legal downstream tasks. Most of these methods focus on choosing appropriate corpora for MLM pretraining and the selection of optimal hyperparameters in contrast to the approach taken in this work. Here, we propose a new direction to adapt a pretrained language model by utilizing language characteristics. In particular, by studying the language characteristics of the legal domain, we propose pretraining objectives that explicitly tries to learn these characteristics. While there are other approaches that adapts the language model to domain-specific tasks (Rietzler et al., 2020; Han and Eisenstein, 2019; Gururangan et al., 2020), our work mainly tries to address the problem of pretraining a language model for a particular domain.

2.2 Legal Artificial Intelligence (AI)

Legal AI refers to the application of AI/NLP techniques to solve several tasks in the legal domain (Zhong et al., 2020). Due to the distinct language characteristics of the legal domain, many legal domain-specific tasks requires the expertise of legal practitioners for solving them. Furthermore, the complexity of the associated tasks requires a significant time commitment even for experienced legal professionals. Thus, this motivated the development of legal AI to reduce the tedium in understanding and solving these legal tasks.

In the legal AI, task-specific methods and datasets were proposed for the following tasks: Legal Judgement Prediction (Aletras et al., 2016), Legal Entity Recognition and Classification (Cardellino et al., 2017), Legal Question Answering (Kim and Goebel, 2017), Automated Legal Review (Hendrycks et al., 2021), Legal Text Classification (Chalkidis et al., 2021), etc. Instead on improving task-specific solution approaches, our objective is to make improvements for several downstream tasks. The objective of this work in very

similar to that of (Chalkidis et al., 2020), however, our solution approach is very different.

3 Domain Specific Objectives

We now describe the legal domain characteristics which we will use for formulating the objectives. For each of the two objectives, we also describe the associated dataset used for training. We get different pretrained language model variants by incorporating various subsets of the following objectives while pretraining.

The process of coming up with the right set of domain specific language characteristics requires significant exposure to the domain. The authors have been investigating several legal domain natural language processing tasks, and have been interviewing several practitioners for an extended period of time. The insights are a result of reading many legal domain documents and the interactions with domain experts. For one to extend our ideas in other domains, we expect them to require similar long exposure to the domain in question and opportunities to interact with domain experts. While we believe that the two characteristics identified in this work are not unique only to the legal domain, one will need to carefully evaluate whether the same characteristics apply to their chosen domain as well.

3.1 Legal Domain as a Templating Language

Contracts include clauses which often use a standardized language with some placeholders which are substituted with appropriate values (e.g., names, dates, amounts, locations, etc) for specific contracts (Figure 1). These standardized fragments with placeholders are referred to as templates (Niemeyer and Knudsen, 2005) in software engineering parlance. We refer to the tokens in the template-generated clauses that remain common across contract documents as **static** tokens and the values filled into the placeholders as **dynamic** tokens.

We propose a pre-training objective that aims to detect the **dynamic** tokens/spans from text fragments in the legal documents. Using this objective, the language model can generate holistic representation for a text-fragment cognizant of the tokens forming the dynamic part and the tokens forming the static part. This can also result in better contextualized token representation for the task of named-entity recognition or other entity level tasks.

In these Terms the following words shall have the following meanings:
"Goods" means those goods, products and/or services to be supplied and delivered by Vendor to Purchaser as described in the relevant Order.
"Purchaser" The person, company, firm, partnership or such other legal entity that places an order for Goods with Vendor and includes Purchaser's divisions, subsidiaries and affiliates.
"Vendor" means **Russel Metals Inc.** and its divisions, subsidiaries and affiliates.

In these Terms the following words shall have the following meanings:
"Goods" means those goods, products and/or services to be supplied and delivered by Vendor to Purchaser as described in the relevant Order.
"Purchaser" The person, company, firm, partnership or such other legal entity that places an order for Goods with Vendor and includes Purchaser's divisions, subsidiaries and affiliates.
"Vendor" means **AJ Forsyth** and its divisions, subsidiaries and affiliates.

Figure 1: Clauses generated from same template: The above example is believed to be generated from a standardized clause template with a placeholder in place of the text in yellow highlight. Moreover the substituted text is observed to have close correspondence with organization named-entity.

3.1.1 Dataset

One of the challenges in utilizing this characteristic in the pre-training objective is the lack of any labelled dataset with such kind of information. To overcome this limitation, we propose a dataset curation strategy that provides data points with dynamic spans. The corpus to be labelled was formed by collecting all the clauses present in the LEDGAR dataset (Tuggener et al., 2020), which consists of over 700,000 provisions in contracts.

The data curation strategy mainly consists of two steps: a) **Grouping** clauses that have very high lexical similarity which are believed to be generated from a single underlying template, b) **Contrasting** data points in a pairwise fashion for every group to differentiate the dynamic part from the static using *google-diff-match-patch*¹. Figure 3 illustrates the pipeline employed for annotating the dataset. Note that, while the contrasting tokens belong to *the dynamic part of the underlying text* (if the grouping was correct), there is inconclusive evidence for the rest of the tokens for considering them as *static* (For instance, Fig 2). This is due to the fact that some values can coincidentally be same for different instances of same clause, e.g.,

¹<https://github.com/google/diff-match-patch>

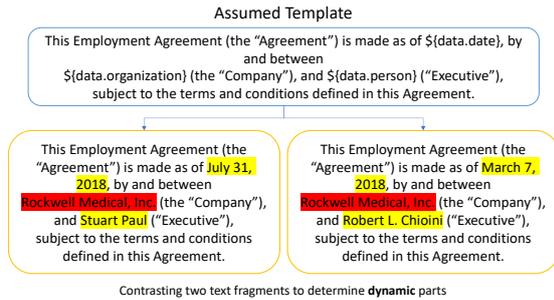

Figure 2: Limitation of the contrasting step: The two text fragments below belong to the same cluster and are believed to be generated from the template shown in the left. However, the process of contrasting annotates only some of the dynamic parts (highlighted in yellow) and misses out some (highlighted in red). Thus, the rest of the text should not be regarded as static in its entirety.

hiring date for two individuals can be the same, and therefore would not be marked as dynamic token by this strategy.

3.1.2 Objective Formulation

After applying the labelling strategy explained in the previous section, we obtain a token-wise labelled dataset $\mathcal{L} = \{(X_i, Y_i)\}_{i=1}^M$. A datapoint in \mathcal{L} is a tuple (X_i, Y_i) , where X_i represents a text-fragment as a sequence of tokens it contains ($X_i = [x_{ik}]_{k=1}^{|X_i|}$) and Y_i is the corresponding sequence of binary labels assigned to each token in X_i in the same order ($Y_i = [y_{ik}]_{k=1}^{|Y_i|}$ where $y_{ik} \in \{0, 1\}$), i.e. $y_{ik} = 1$ implies that x_{ik} belongs to the dynamic part and $y_{ik} = 0$ implies that the corresponding token can belong to any part.

Given such labelled dataset, we wish to train the language model \mathcal{M} such that $\mathcal{M}_{\text{dyn}}(X_i, x_{ik})$ provides us with the likelihood of x_{ik} being dynamic. The subscript ‘dyn’ denotes the addition of task-specific overhead architecture for detecting **dynamic** spans. We cannot directly apply binary cross entropy objective over the token-level predictions as the negative labels in our case does not imply that the corresponding tokens *are* static. To overcome this obstacle, we use the framework of positive-unlabelled (PU) (Peng et al., 2019) learning where all the tokens associated with a positive label are regarded as dynamic and rest, associated with a negative label, are regarded as unlabelled. Under this framework, all the positively labelled tokens are collected with their parent text-fragment to form the set $\mathcal{X}_p = \{(X_i, x_i)\}_{i=1}^{n_p}$ where x_i represents a positively labelled token present in the text fragment X_i . This is also repeated for the neg-

atively labelled datapoints to form the unlabelled set $\mathcal{X}_u = \{(X_i, x_i)\}_{i=1}^{n_u}$. PU learning optimizes the model parameters for the detection of dynamic parts by minimizing the following objective:

$$\begin{aligned} \mathcal{L}_{PU}(\mathcal{M}_{\text{dyn}}, \mathcal{X}_p, \mathcal{X}_u) = & \frac{1}{n_u} \sum_{(X_u, x_u) \in \mathcal{X}_u} l(\mathcal{M}_{\text{dyn}}(X_u, x_u), 0) \\ & + \frac{\pi_p}{n_p} \sum_{(X_p, x_p) \in \mathcal{X}_p} (l(\mathcal{M}_{\text{dyn}}(X_p, x_p), 1) - l(\mathcal{M}_{\text{dyn}}(X_p, x_p), 0)) \end{aligned} \quad (1)$$

where l is a positive-valued loss function that penalizes the distance between its arguments and $\pi_p \in [0, 1]$ is a hyperparameter. The above objective is derived from the following two terms: a term that incentivizes positively labeled instances to be classified as dynamic and a term that penalizes the unlabeled instances based on the assumption that the probability of being dynamic is equal to π_p Peng et al.. This implicitly assumes that the positive and unlabeled datapoints are sampled from the same distribution and the probability of a positive datapoint being labeled is independent of its input features. In contrast to the binary cross entropy objective, PU learning accounts for the possibility that some of the elements of \mathcal{X}_u can be *dynamic*.

3.2 Soft Semantic Labels for Clauses

The legal essence of many contractual documents and agreements is formed by concatenating clauses which are crucial for defining terms and conditions and important provisions. These clauses can often be categorized which can be used to optimize the model to provide semantic-aware representation scheme, and sometimes, such categorization is available as a label/title with the clause text. Formally, we want to train the language model to learn a representation scheme that maps same category clauses from the data manifold onto metrically closer points in the mapped space. We believe that by infusing the ability to generate semantic-aware representation within model, the language model may offer better performance on sentence-level tasks.

3.2.1 Dataset

We used the LEDGAR Corpus (Tuggener et al., 2020) which is a collection of labelled legal clauses and provisions. This corpus was crawled from the contracts present in the website of U.S. Securities and Exchange Commission (SEC)². While this dataset contains many clause instances with multiple labels, we retain only those clauses from this

²<https://www.sec.gov/>

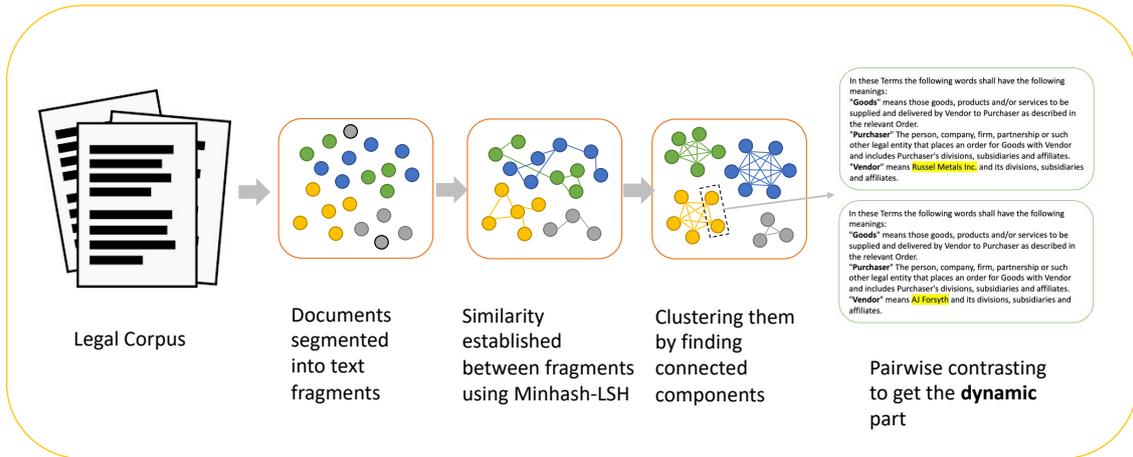

Figure 3: **Pipeline for dataset creation for dynamic part identification:** The clauses extracted from the LEDGAR corpus were originally obtained by segmenting legal documents into fragments. As clauses having fairly repetitive lexical structure are believed to be generated from the same template, the fragments are clustered using Minhash-LSH (Broder, 1997; Indyk et al., 1997), followed by finding the connected components. Finally, each pair in a cluster is contrasted to annotate what is dynamic among them.

corpus which are associated with a single label (roughly 83% of the dataset).

3.2.2 Objective Formulation

Given a language model \mathcal{M} , \mathcal{M}_{rep} denotes task specific adaptation of the original language model to generate representation for a given sentence. We formulate our requirement as a task of metric learning where the goal is to learn a function $\mathcal{M}_{\text{rep}}(\cdot) : \mathcal{X} \rightarrow \mathbb{R}^d$ that maps semantically closer input datapoints onto metrically closer points in \mathbb{R}^d . Here, \mathcal{X} denotes the domain of input clauses / provisions. Under the triplet-loss formulation, every instance in the training dataset is a triplet (x_a, x_p, x_n) where the model tries to make the distance between the representations of x_a (*anchor*) and x_p (*positive*) smaller than that between x_a and x_n (*negative*) by atleast a margin m . Mathematically, the loss function l_{tri} is defined as follows:

$$l_{\text{tri}}(x_a, x_p, x_n) = [m + D(\mathcal{M}_{\text{rep}}(x_a), \mathcal{M}_{\text{rep}}(x_p)) - D(\mathcal{M}_{\text{rep}}(x_a), \mathcal{M}_{\text{rep}}(x_n))]_+ \quad (2)$$

In the above equation, $D(\cdot, \cdot) : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ denotes a metric function measuring distances in the mapped space.

4 Training Details

We tune the parameters of our model using the algorithm employed for multi-task learning (Liu et al., 2019a). This framework optimizes the language model over multiple tasks. The language model is

shared across different tasks by employing same encoder with shared parameters for all the task-specific overhead architectures. In each iteration of mini-batch gradient descent optimization, a task is randomly selected and corresponding task-specific mini-batch of data is sampled to apply single step of gradient descent using the task-specific objective. We curated the dataset for MLM pretraining by extracting text fragments from the SEC corpus as curated by Chalkidis et al., utilizing newline character (`\n`) as the delimiter. In our ablation studies to understand the impact of various terms in the pretraining objective on downstream performance, we utilized a randomly selected subset of 40,000 text fragments to quickly assess the importance of each of the terms. Thereafter, we also evaluate the performance of our model when a significantly larger corpora is provided for MLM.

In this paper, the parameters of the shared language model are initialized using the weights of LEGAL-BERT (12-layer, 768-hidden, 12-heads, 110M parameters)³, a domain-specific language model pre-trained using MLM. Thereafter, we investigate the performance of the model variants listed in Table 1 by comparing against LEGAL-BERT. We do not assess the performance of non-domain specific models such as BERT (Devlin et al., 2019) as the superiority of LEGAL-BERT over BERT was demonstrated in (Chalkidis et al., 2020) for some of the legal downstream tasks.

³Distributed under CC BY-SA 4.0

Table 1: Model variants to be assessed in various legal downstream tasks (on top of LEGAL-BERT). Legal Corpus for MLM was collected by randomly sampling 40,000 text fragments from the SEC corpus.

Model name	Description of Additional Pre-training
LB-PU	Dynamic span recognition using PU
LB-BC	Binary classification to identify dynamic tokens
LB-MLM	MLM over legal corpus
LB-PU-MLM	Multi-task training for PU and MLM over legal corpus
LB-TRI	Representation learning task using triplet margin loss
LB-TRI-MLM	Multi-task training for triplet margin loss and MLM over legal corpus
LB-PU-TRI	Multi-task training for PU and triplet margin loss
LB-PU-TRI-MLM	Multi-task training for PU, triplet margin loss and MLM over legal corpus

Table 2: Comparison between PU learning and Binary Classification for token-level tasks in terms of F_1 -Scores (DPI: Dynamic Part Identification)

Model name	CUAD-NER	DPI
LEGAL-BERT	0.7040	0.7107
LB-PU	0.7355	0.7507
LB-BC	0.7221	0.6835

We used a 8 GPU A10G instance for training the models. While it took 32 hours to pretrain the model with best hyperparameter settings when only 40,000 datapoints for MLM is used, the model instance pretrained over the total SEC corpus (Chalkidis et al., 2020) consumed 800 hours. HuggingFace Transformers (Wolf et al., 2020) was used for both pretraining and experimental analysis.

5 Results and Discussion

We begin this section by validating the choice of using PU learning for dynamic part detection instead of binary token classification objective. In the subsequent subsection, we describe various legal downstream tasks and their associated data to be used in comparing the performance of the models in Table 1. As our models are derived from LEGAL-BERT, it is used as a baseline in our empirical analysis and we demonstrate the improvement of our model over it for several downstream tasks.

5.1 PU learning Versus Binary classification

5.1.1 Impact on downstream performance

In this subsection, we compare the performance of the model additionally pretrained using PU learning (LB-PU) and binary classification (LB-BC) for named entity recognition (NER) and dynamic part identification (DPI).

We use the NER adaptation of the Contract Un-

derstanding Atticus Dataset (CUAD) (Hendrycks et al., 2021). CUAD labels the *contracting-party* associated with each contract. This is used for constructing a NER dataset with *contracting-party* span annotations for each datapoint. This dataset consists of 16,636 training, 2,000 validation and a 10,000 testing samples.

As the dataset curated for pretraining the language model for dynamic part identification was approximately labeled, we manually annotated few text fragments by specifying the dynamic spans using the definition in section 3.1. This manual annotation furnished 132 training instances, 32 development instances and 50 testing instances. The performance was reported by computing the F_1 -Score between the inferred spans and the ground truth dynamic spans.

The results shown in Table 2 justifies the utilization of PU learning objective. Our hypothesis that training the model to identify dynamic spans will improve its ability in recognizing named entities has been validated by the improvement in NER performance achieved through the use of the PU learning objective. This is further validated in the subsequent section through an examination of the feature representations generated by the model trained with/without PU learning. For the subsequent analysis, we disregard any models trained using binary classification objective owing to the results shown in the table. The decrease in the performance from LEGAL-BERT to LB-BC for NER and DPI stems from the fact that a subset of negatively labelled tokens in some instances are labelled as dynamic for other instances. This confuses the model in learning correct characteristics associated with these tokens, resulting in poor token-level representation.

Table 3: Performance for various legal domain task given in terms of F_1 -Scores for CUAD-NER and DPI tasks, mean of F_1 -Scores for MULTI-EURLEX tasks for Level 1, 2 and 3, and soft F_1 -Score for Contract-Discovery task (Averaged for 5 runs).

Model name	CUAD-NER	DPI	MULTI-EURLEX	Contract-Discovery
LEGAL-BERT	0.7040	0.7107	0.7535	0.4591
LB-MLM	0.7344	0.7098	0.7525	0.4367
LB-PU	0.7355	0.7507	0.7488	0.0394
LB-PU-MLM	0.7427	0.7509	0.7451	0.1701
LB-TRI	0.7325	0.7380	0.7566	0.4979
LB-TRI-MLM	0.7462	0.7091	0.7567	0.5051
LB-PU-TRI	0.7320	0.7454	0.7513	0.5032
LB-PU-TRI-MLM	0.7479	0.7628	0.7574	0.5119

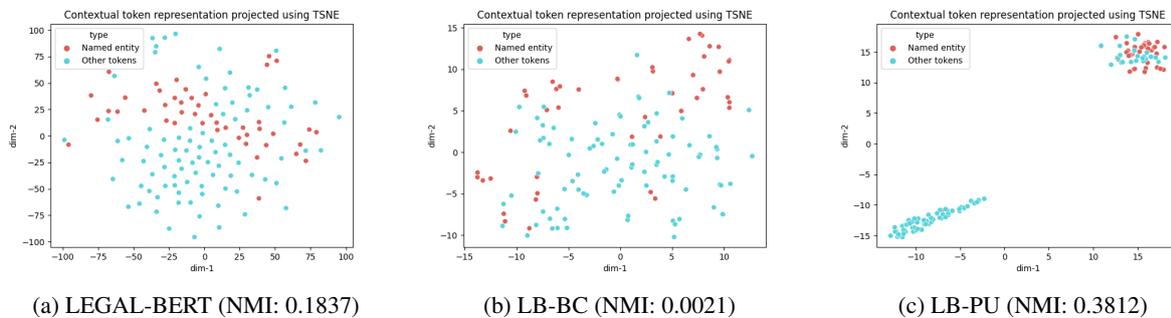

Figure 4: t-SNE projections of the contextualized embeddings obtained from different representation schemes. LB-PU visually performs the best in terms of segregating the named entities from the rest of the tokens.

5.1.2 Better feature representation for extracting named entities

We provide a qualitative justification for PU learning leading to better representation for extracting named entities in this subsection. In this assessment, we extract 30 text sentences from the **CUAD-NER** dataset that contain at least one named entity within it and compute the contextualized embeddings for the tokens in it using LEGAL-BERT, LB-BC and LB-PU. Thereafter, these embeddings are mapped to two dimensional manifold using t-SNE (Van der Maaten and Hinton, 2008) algorithm. Note that, we compute the embeddings using different representation schemes without fine-tuning on **CUAD-NER** to understand the impact of our token-level objective for distinguishing named entities from the rest of the tokens.

From Figure 4, we observe that the embeddings of the named entities and other tokens are not very well separated for LEGAL-BERT and LB-BC. On the other hand, LB-PU leads to much better segre-

gation despite not being explicitly trained for the task of named entity recognition. This can be attributed to the observation that the dynamic part of a legal text fragment corresponds to a named entity most of the times. Since, LB-PU is explicitly pretrained for the task of dynamic part detection, it furnishes suitable representation scheme for segregating named entities. While LB-BC is trained for this task, it yields suboptimal representation scheme as it does not consider the possibility that some of the unlabelled tokens may be dynamic.

5.2 Results in various downstream tasks

Apart from **CUAD-NER** and **DPI** introduced in sec 5.1.1, we consider following additional tasks to compare the performance of different models:

1. **MULTI-EURLEX** (Chalkidis et al., 2021): This dataset is meant to assess the performance in the task of Large-Scale Multi-Label Text Classification (LSMTC). The datapoints in this dataset are curated from European leg-

islative documents (EUR-LEX) and the labels derived from EUROVOC, a set of 4.3K European vocabulary labels. This dataset includes a total of 65K datapoints with the train-test-validation split of 55K-5K-5K respectively and involves fine-grained categorization of the label-set into 8 levels based on their hierarchy. We compute the performance of the model variants for 'level 1' (21 labels), 'level 2' (127 labels) and 'level 3' (567) (but report only the mean of these due to space constraint) as the other levels are not publicly available.

2. **Contract-Discovery** (Borchmann et al., 2020): This dataset is used to measure the performance of a model in semantic retrieval, where the task is to retrieve a span from a target document given a few examples (1 to 5) of similar clauses. The dataset uses about 600 target documents and is divided into 2 splits: development and test. Each of these splits consists of 5000 datapoints. The performance is evaluated by computing soft F_1 metric (Graliński et al., 2019) on the character-level inferred spans, which rewards proportionally to the extent of overlap between predicted and ground truth character spans. To solve this problem, we use the unsupervised method proposed by the authors of this task (Borchmann et al., 2020).

We can see from the Table 3 that the model pretrained using domain specific objectives achieves better performance than LEGAL-BERT for all the tasks. The models pretrained using only PU (LB-PU and LB-PU-MLM) only improves the performance for token-level tasks like CUAD-NER and DPI and achieves poor performance for other tasks. As these models only involve objectives at the token level, they offer inferior representations at the level of sentences / text-fragments as compared to other models which explains the poor performance in tasks like MULTI-EURLEX and Contract-Discovery. A similar effect is also observed for LB-MLM, where the model exhibits superior performance for some of the token-level tasks but exhibits poor performance for sentence level objective when compared against LEGAL-BERT as it does not involve any objective at the level of sentences. The models trained using triplet objective only (LB-TRI and LB-TRI-MLM) achieves better performance than LEGAL-BERT for all the tasks. This justifies the inclusion of the

objective for learning semantic-aware representation scheme. We also observe that, inclusion of MLM for the model variants almost always improves the downstream performance. This indicates the usefulness of having domain-agnostic objective like MLM in the overall objective. The model pretrained using all the objectives (LB-PU-TRI-MLM) achieves best / competitive performance for most of the tasks. It is noteworthy that even though the objective of PU learning has no direct relation to tasks such as Contract-discovery and MULTI-EURLEX, the inclusion of PU learning in combination with Triplet loss and MLM leads to further improvement in the model's effectiveness in those tasks.

These results also emphasize the importance of MLM apart from the domain-specific objectives. Here, the pretraining over MLM was performed over a dataset with about 40,000 text fragments. We believe that the performance of these models can be significantly improved by including a sufficiently larger dataset for MLM pretraining which is validated in the next subsection.

5.3 Performance when the size of MLM corpora is varied

In this section, we assess the performance of our model trained using the three objectives (PU + TRI + MLM) when the number of datapoints in the MLM corpus is varied. While the experiment performed in the previous subsection comprised of only 40,000 text fragments, this analysis assesses the model performance when the number of text fragments is varied from 1% to 100% of the total SEC corpus (Chalkidis et al., 2020).

The results shown in Table 4 clearly demonstrate that the downstream performance improves with the number of datapoints in the MLM corpus. Note that, **the pretraining corpus for LEGAL-BERT already comprises of the SEC corpus used in our analysis**. This fact also confirms the importance of involving the two objectives along with MLM for getting improved performance.

6 Conclusion

In this paper, we demonstrated a novel approach to enhance the performance of domain-specific language model across several specialty downstream tasks by exploiting the language characteristics. The objectives presented in this paper may not be applicable to all domains, which is a limitation

Table 4: Performance for various legal domain task given in terms of F_1 -Scores for CUAD-NER and DPI tasks, mean of F_1 -Scores for MULTI-EURLEX tasks for Level 1, 2 and 3, and soft F_1 -Score for Contract-Discovery task when the number of datapoints in the MLM corpus is varied.

Number of training datapoints for MLM	Fraction of the overall SEC corpus	CUAD-NER	DPI	MULTI-EURLEX	Contract-Discovery
40,000	5.56×10^{-4}	0.7479	0.7628	0.7574	0.5119
720,000	0.01	0.7483	0.7651	0.7546	0.5210
7,200,000	0.10	0.7518	0.7662	0.7547	0.5145

of our work, but the idea of formulating objectives for learning domain-specific characteristics can be applied to other specialty domains (biomedical, programming languages, etc.). Future work might involve studying other characteristics of the legal domain and understanding their impact in downstream performance. We justified the positive impact of such pretraining across several downstream tasks by conducting extensive quantitative analysis.

We conclude this section by enumerating the natural extensions of this work for future:

1. In this work, we emphasized on two characteristics in the legal domain. However, the legal domain consists of several other domain-specific characteristics. For instance, the content in a legal agreement can be structured into different parts (preamble, recitals, list of clauses, etc) and the impact of involving a pre-training objective to infer the structure of a legal document on several tasks is yet to be understood. Thus, one line of future work may involve exhaustive study of language characteristics and understanding their influence in downstream tasks.
2. In the future, we plan to study the applicability of the introduced characteristics in other domains, such as programming languages where text fragments can be classified into categories like function blocks, variable declaration, etc. and contain both static and dynamic elements that can be templated. This study may provide a thorough evaluation of the cross-domain applicability of these characteristics, including the assessment of their impact on downstream performance and the ease of curating relevant data. We would like to also

motivate the researchers in applying the principle introduced in this paper for other domains (biomedical, finance, etc.). This necessitates careful investigation in order to extract domain-specific characteristics, as well as a mechanism for training the language model to understand these characteristics.

7 Limitations

We now discuss the limitations of our work. The first limitation (or requirement) is need for significant computational power. As we showed in Section 5.3 of our paper, when the corpus size for MLM training is increased from 0.0556% to 100% of the SEC corpus, while the performance improved by about 1% on multiple tasks, the computational requirement went up from 32 hours (on a 8 GPU A10G instance) to 800 hours.

Secondly, we had built our model on top of a domain specific pre-trained language model (which had used only MLM objective on a domain specific corpus). In theory, since we do include MLM as one of the objectives, we should be able to get comparable performance with or without domain specific pretrained language model. However, due to significant cost involved, we did not train a model starting from general domain language model (e.g., BERT or RoBERTa) to compare its performance against model built on top of domain specific pre-trained language model. Therefore, we cannot make a claim if our proposed method would result in comparable performance improvement for the domains where such pre-trained models are not available.

Third, our method relies on identifying the domain specific characteristics and building objective functions suitable to exploit them. This requires building domain expertise and/or collaborat-

ing with domain experts. Since this process cannot be automated, it requires additional cost and human effort. Also, good automated data curation strategies may or may not be feasible for other domain specific characteristics, limiting using usefulness for training large language models.

Finally, we have only experimented with English language corpus. While the data curation strategy we used should be applicable in most other languages also for legal domain, the static/dynamic token classification task particularly may depend on grammatical rules for sentence construction, which may not be similar in all languages.

However, we believe that despite these limitations, our work points to possibility of improved performance of language models by using domain specific characteristics (beyond MLM based pre-training), which should open doors for more such explorations and significant advances in the state of art.

Global Constraints with Prompting for Zero-Shot Event Argument Classification

Zizheng Lin¹, Hongming Zhang² & Yangqiu Song¹

Abstract

Determining the role of event arguments is a crucial subtask of event extraction. Most previous supervised models leverage costly annotations, which is not practical for open-domain applications. In this work, we propose to use global constraints with prompting to effectively tackle event argument classification without any annotation and task-specific training. Specifically, given an event and its associated passage, the model first creates several new passages by prefix prompts and cloze prompts, where prefix prompts indicate event type and trigger span, and cloze prompts connect each candidate role with the target argument span. Then, a pre-trained language model scores the new passages, making the initial prediction. Our novel prompt templates can easily adapt to all events and argument types without manual effort. Next, the model regularizes the prediction by global constraints exploiting cross-task, cross-argument, and cross-event relations. Extensive experiments demonstrate our model’s effectiveness: it outperforms the best zero-shot baselines by 12.5% and 10.9% F1 on ACE and ERE with given argument spans and by 4.3% and 3.3% F1, respectively, without given argument spans. We have made our code publicly available.¹

1 Introduction

Event Argument Classification² (EAC), finding the roles of event arguments, is an important and challenging event extraction sub-task. As shown in Figure 1, a “Transfer-Money” event whose trigger is “acquiring” has several argument spans (e.g., “Daily Planet”). By determining the role of these arguments (e.g., “Daily Planet” as “Beneficiary”), we

¹<https://github.com/HKUST-KnowComp/Constraints-with-Prompting-for-Zero-Shot-EAC>

²We focus on event argument because existing zero-shot trigger extraction models like Zhang et al. (2021) are already strong enough, but the arguments remain a challenge. Our argument identification approach is described in Section 3.1.

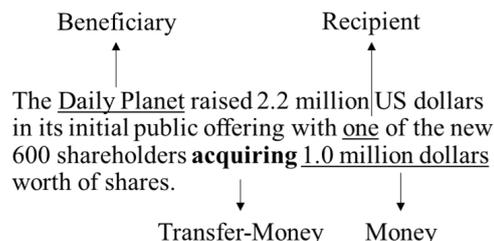

Figure 1: An example of EAC. The trigger is in **bold face**. Arguments are underlined and connected to their roles by arrows.

can obtain a better understanding of the event, thus benefiting related applications like stock price prediction (Ding et al., 2015) and biomedical research (Zhao et al., 2021).

Many previous EAC works require numerous annotations to train their models (Lin et al., 2020; Hsu et al., 2022; Liu et al., 2022), which is not only costly as the annotations are labor-intensive but also difficult to be generalized to datasets of novel domains. Accordingly, some EAC models adopt a few-shot learning paradigm (Ma et al., 2022; Hsu et al., 2022). However, they are sensitive to the few-shot example selection and they still require costly task-specific training, which hinders their real-life deployment. There have been some zero-shot EAC models based on transfer learning (Huang et al., 2018), or label semantics (Zhang et al., 2021; Wang et al., 2022), or prompt learning (Liu et al., 2020; Lyu et al., 2021; Huang et al., 2022; Mehta et al., 2022). However, these models’ corresponding limitations impede their real-life deployment. The model based on transfer learning can be ineffective when new event types are very different from the observed one. As for models using label semantics, they require a laborious preparation process and have unsatisfactory performance. Regarding models adopting prompt learning, they need tedious prompt design customized to every new type of events and arguments, and their performance is

also limited.

To address the aforementioned issues, we propose an approach using global constraints with prompting to tackle zero-shot EAC. Global constraints can be viewed as a type of supervision signal from domain knowledge, which is crucial for zero-shot EAC since supervision from annotations is inaccessible. Moreover, our model’s constraints module provides abundant global insights across tasks, arguments, and events. Prompting can also be regarded as a supervision signal as it induces abundant knowledge from Pre-Trained Language Models (PTLM). Unlike previous zero-shot EAC works, which need a tedious prompt design for every new type of events and arguments, the novel prompt templates of our model’s prompting module can be easily adapted to all possible types of events and arguments in a fully automatic way. Specifically, given an event and its passage, our model first adds prefix prompt, cloze prompt, and candidate roles into the passage, which creates a set of new passages. The Prefix prompt describes the event type and trigger span. Cloze prompt connects each candidate to the target argument span. Afterwards, our model adopts a PTLM to compute the language modeling loss for each of the new passages, whose negative value would be the respective prompting score. The role with the highest prompting score is the initial prediction. Then, our model uses global constraints to regularize the initial prediction. The global constraints are based on the domain knowledge of the following relations: (1) cross-task relation, where our model additionally performs another one or more classification task on target argument span, and our model’s predictions on EAC and other task(s) should be consistent; (2) cross-argument relation, where arguments of one event should collectively abide by certain constraint(s); (3) cross-event relation, where some argument playing a certain role in one event should play a typical role in another related event.

We conduct comprehensive experiments to demonstrate the effectiveness of our model. Particularly, our approach surpasses all zero-shot baselines by at least 12.5% and 10.9% F1 on ACE and ERE, respectively. When argument spans are not given, our model outperforms the best zero-shot baseline by 4.3% and 3.3% F1 on ACE and ERE, respectively. Besides that, we also conduct experiments to show that both the prompting and constraints modules contribute to the final success.

2 Methodology

We first present an overview of our approach. Then we introduce the details by describing its prompting module and global constraints regularization module. We follow (Liu et al., 2021) to name a prompt inserted before input text as *prefix prompt*, and a prompt with slot(s) to fill in and insert in the middle of input text as *cloze prompt*.

2.1 Overview

As shown in Figure 2, given a passage with a target argument span, our model infers the target’s role without annotation and task-specific training. Our model has two modules. The first module is the prompting module that creates and scores several new passages. During creation, the model adds prefix prompt, cloze prompt, and candidate roles into the passage, where the prefix prompt contains information about event type and trigger, and the cloze prompt joins each candidate with a target argument span.³ Afterwards, the model uses a PTLM to score the new passages. Our novel prompt templates can easily adapt to all possible events and arguments without manual work. Initial prediction is the role with the best prompting scores. The second module is the global constraints regularization module, where the model regularizes the prediction by three types of global constraints: cross-task constraint, cross-argument constraint, and cross-event constraint. All global constraints are based on event-related domain knowledge about inter-task, inter-argument, and inter-event relations.

2.2 Prompting Module

In this section, we describe the prompting module in detail. Given a passage, we first add a prefix prompt containing information about the event type and trigger span to the beginning. Such a prompt can guide a PTLM to: (1) accurately capture the input text’s perspective related to the event; (2) have a clear awareness of the trigger. Based on the definitions of events and triggers (Grishman et al., 2005), we create the following prefix prompt: “**This is a [] event whose occurrence is most clearly expressed by []**.” where the first and second pairs of square brackets are the placeholders of event type and trigger span respectively. We also con-

³Since we focus on event argument classification, we assume that the event types and trigger spans are given. The settings without given argument spans will be discussed in Section 3.1.

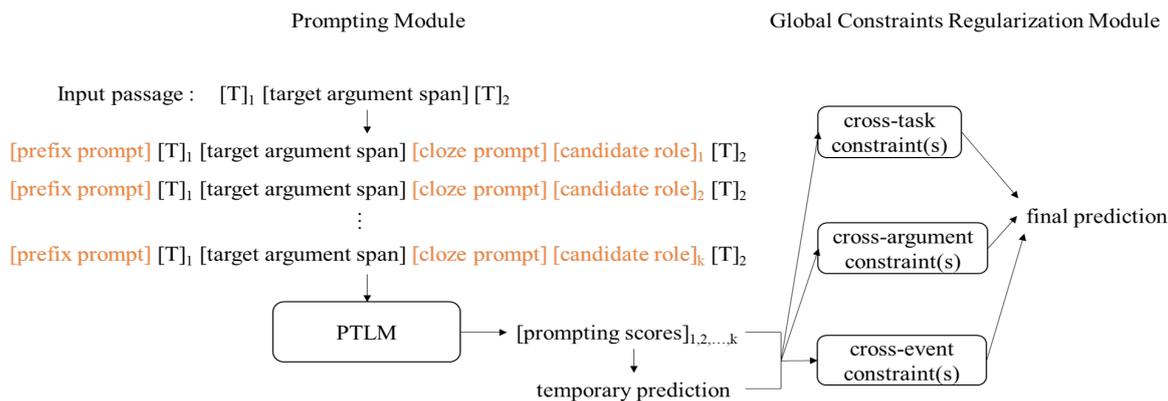

Figure 2: Model overview using prediction for one argument span as an example. $[T]_1$ and $[T]_2$ are the parts of the input passage before and after the span, respectively. k is the number of candidate roles of the event type.

ducted some experiments comparing different prefix prompts in Section A, and the results showed that the prefix above is the most effective.

Second, for each candidate role, the module inserts the cloze prompt behind the target argument span, and the role fills the prompt’s slot. The cloze prompt adopts the hypernym extraction pattern “**M and any other []**” (Dai et al., 2021), where “M” denotes the argument span and the square bracket is the placeholder of the candidate role. We did not try other hypernym extraction patterns as (Dai et al., 2021) had shown that our pattern is the most effective. The motivation for adopting the hypernym extraction pattern for cloze prompt is that, to some extent a role can be regarded as a context-specific hypernym of the respective argument span of the associated event (e.g., “Beneficiary” can be seen as a context-specific hypernym of “Daily Planet” of the Transfer-Money event described by the example in Figure 1). Hence, such a prompt induces the linguistic and commonsense knowledge stored in PTLM to help identify which candidate role is the most reasonable.

After adding the previous two types of prompts, we get several new passages. For instance, suppose the passage is “In Baghdad, a bomb was fired at 17 people.” whose event type is “Conflict:Attack”, trigger is “fired”, target argument span is “bomb”, and candidate roles are {“Attacker”, “Instrument”, “Place”, “Time”, “Target”}. The created passages would be: (1) “*This is a Attack event whose occurrence is most clearly expressed by “fired.”* In Baghdad, a bomb *and any other attacker* was fired at 17 people.”; (2) “*This is a Attack ... “fired.” ... bomb and any other instrument* was ...”; and simi-

lar text for other roles.⁴

For each new passage, we apply a PTLM to compute the language modeling loss. The negative value of the loss would be the prompting score of the respective passage, where a higher value indicates higher plausibility according to the PTLM. **Since our model’s prompt templates are independent of event type and argument role, their adaptation to any new type of events and arguments is trivial and fully automatic.** Hence, our prompting method is more scalable and generalizable than those of previous zero-shot EAC models, since, for every new type of events and arguments they need to design a customized prompt. For instance, for every type of events/arguments, Lyu et al. (2021) manually design a unique prompt as text entailment/question answering template. The initial prediction would be the role with the highest prompting score. Since the steps of obtaining scores for each candidate role are independent of other candidate roles, we implement the steps of different candidate roles in parallel. Such a parallel implementation significantly improves our model’s efficiency.

2.3 Global Constraints Regularization Module

This module regularizes the prediction by the following three types of global constraints.⁵

Cross-task constraint exploits the label dependency between EAC and auxiliary task(s) so that

⁴We only use the subtype of all events following the pre-processing done by (Lin et al., 2020)

⁵We designed 14 global constraints in total and we used preliminary experiments to choose the three most effective ones. In the preliminary experiments, we randomly sample 1k instances covering all trigger and argument types. We then evaluate each constraint on the sampled subset.

our model can get global information from the auxiliary task(s) about event arguments. We use **Event Argument Entity Typing (EAET)** as the auxiliary task. The task aims to classify an argument into its context-dependent entity type (e.g., PER). **As specified in ACE2005 ontology, an argument of a certain role in an event can only be one of several respective entity types (e.g., an argument of “Attack” role in a Conflict:Attack event can only be “ORG,” “PER,” or “GPE”).** Based on this domain knowledge, we design the cross-task constraint as follows: (1) For each input passage, our model performs prompting for EAET, where the prompting is the same as in Section 2.2 except that candidate entity types replace the candidate roles in cloze prompt.; (2) After obtaining the scores and prediction of EAET, the model check the consistency between the predictions of EAC and EAET; (3) If the consistency is violated and the score of EAC’s predicted role is lower, then discard the current role, use the role with the highest score in the remaining ones, and check the consistency again; (4) The constraint ends when the labels of two tasks are consistent. An example illustrating this type of constraint is shown in Figure 3.

Cross-argument constraint is based on domain knowledge about relationships between arguments within an event. Specifically, our model constrains the number of particular arguments for some or all events. For instance, it is very unlikely that an event mentioned is associated with multiple “Time” arguments. Such constraints offer a global understanding of event arguments to our model. The cross-argument constraint we adopt is **“A Personnel:End-POSITION event has at most one Position argument.”** Given a Personnel:End-POSITION event, our model first checks the number of “Position” argument. If the number is more than one, then our model will first collect the arguments whose roles are “Position” and remove the one with the highest score among these arguments. Then for each remaining argument, our model would change the role to its candidate with the second highest score. An example illustrating this type of constraint is shown in Figure 4.

Cross-event constraint regularizes predicted roles of arguments shared by related events. A model with such a constraint can have global insights into event arguments, because while they are making inferences for the arguments of one event, they are aware of the information of other

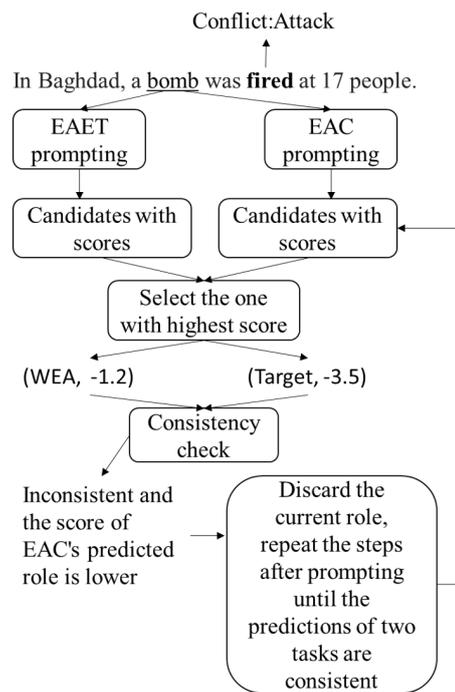

Figure 3: An Example of cross-task constraint. The text in **bold face** is the trigger, underlined text is target argument span, and a tuple denotes a predicted label with its prompting score (e.g., “(Target, -3.5)” denotes the predicted label “Target” with its prompting score“-3.5”). Similar notations are adopted in all remaining figures.

related event(s) and cross-event relations. The cross-event constraint we adopt is **“If a Life:Injure event and a Conflict:Attack event share arguments, then Injure.Place is the same as Attack.Place, Injure.Victim is the same as Attack.Target, Injure.Instrument is the same as Attack.Instrument, Injure.Time is the same as Attack.Time, Injure.Agent is the same as Attack.Attacker”**. Given a passage containing an Injure and an Attack event sharing arguments, the model imposes the constraint by checking the consistency between the respective roles of each shared argument as specified in the constraint. Any inconsistency would be fixed by changing the role with a lower prompting score to the new one satisfying the consistency. An example illustrating this type of constraint is shown in Figure 5.

Our constraint modeling method can be easily generalized to other datasets/ontologies by simply using the knowledge about corresponding cross-task, cross-argument, and cross-event relations to design new constraints. The design processes are not costly as we could easily find such knowledge

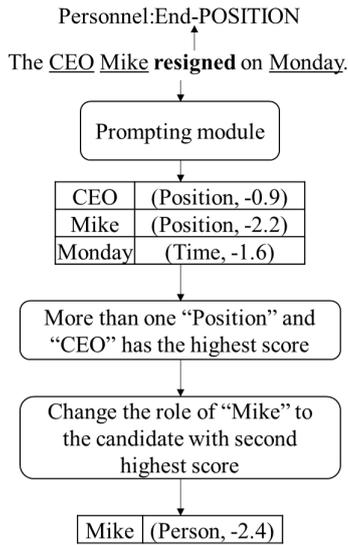

Figure 4: An Example of cross-argument constraint.

from the guidelines of the target dataset.

3 Experiments

We first present the experimental settings, baselines used for comparison, and some implementation details. Next, we show and analyze the experiment results. Then we present a detailed analysis of the prompting module and global constraints regularization module. Finally, we conduct an error analysis.

3.1 Settings

We use ACE (2005-E⁺)⁶ (Doddington et al., 2004; Lin et al., 2020) and ERE(-EN) (Song et al., 2015) as datasets. In total, ACE has 33 event types and 22 roles, whereas ERE has 38 event types and 21 roles. We pre-process all events to keep only the event subtypes whenever applicable, as done in (Lin et al., 2020). Following the pre-processing in (Zhang et al., 2021), for each dataset, we merge all splits into one test set since our approach is zero-shot. When argument spans are not given, we pipeline our model with an argument identification module adapted from (Lyu et al., 2021). Specifically, we replace the QA model in (Lyu et al., 2021) with a more powerful PTLM with a span classification head on top, and the whole model has been fined-tuned for extractive QA tasks. Then for a passage, we prompt each role using the new QA model as in (Lyu et al., 2021). We collect the prompt results for all roles (ignoring the “None” result) as

⁶<https://www ldc.upenn.edu/collaborations/past-projects/ace>

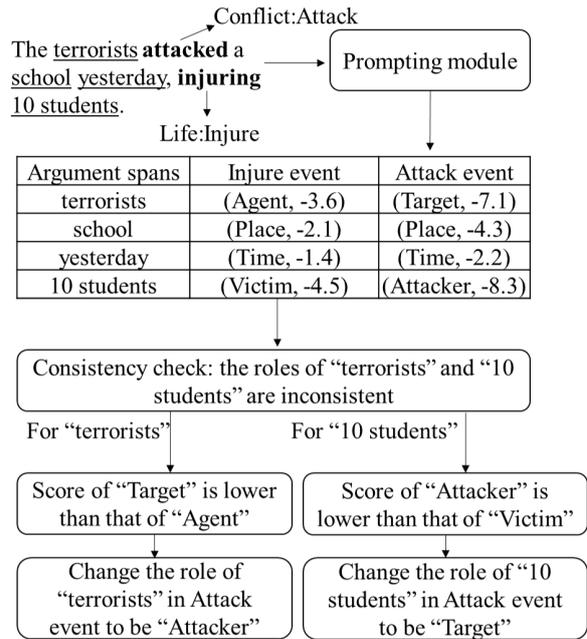

Figure 5: An Example of cross-event constraint.

candidate spans for the passage. We use the F1 score for evaluation following (Ji and Grishman, 2008), where argument spans are evaluated on the head level when not given. Regarding PTLMs, We use GPT-J (6B) (Wang and Komatsuzaki, 2021) instances from Huggingface (Wolf et al., 2020), where an instance for causal language modeling is used for prompting, and an instance for QA is used for argument identification. In all the following sections except Section 3.2, we conduct experiments on ACE, assuming that argument spans are given.

3.2 Main Results

We report the main results comparing our models with three previous powerful zero-shot models (Liu et al., 2020; Lyu et al., 2021; Zhang et al., 2021). Moreover, we also report the results of a SOTA supervised model (Hsu et al., 2022). We obtain the results of all compared methods from our own experiments to ensure a fair comparison on the same datasets and same settings. From Table 1, we have the following observations:

- Our model achieves superior performance on both datasets under both settings compared with all zero-shot baselines. Specifically, our model surpasses the best zero-shot baselines (Zhang et al., 2021) by 12.5% and 10.9% on ACE and ERE, respectively. Without argument spans, our model outperforms the respective best zero-shot baselines (Lyu et al.,

Model	ACE		ERE	
	argument span given	argument span not given	argument span given	argument span not given
(Hsu et al., 2022) (supervised)	79.3	71.8	79.8	72.5
(Liu et al., 2020)	46.1	24.2	40.9	22.8
(Lyu et al., 2021)	47.8	26.9	44.5	26.3
(Zhang et al., 2021)	53.6	23.5	51.9	20.2
Ours	66.1	31.2	62.8	29.6

Table 1: Performance of supervised model, zero-shot baselines, and our model. The best scores among the ones of zero-shot methods are in bold font.

2021) by 4.3% and 3.3% on ACE and ERE, respectively, which is also a noticeable gap. Such large performance improvements can be attributed to the following: (1) the prefix prompt guides the PTLM to effectively capture input’s event-related perspective and trigger; (2) the cloze prompt leverages linguistic and commonsense knowledge stored in PTLM to improve its contextual understanding of event arguments; (3) the global constraints regularization incorporate global information and domain knowledge in inference. In Section 3.3, we compare the effects of using different PTLMs like BERT in the prompting module, and the results show that our model consistently outperforms previous zero-shot models, as shown in Table 1 and Figure 6.

- Compared with the supervised SOTA model (Hsu et al., 2022), there is still a significant gap between our model’s performance and that it. Specifically, (Hsu et al., 2022) outperforms our model by 13.2% and 17.0% on ACE and ERE, respectively. When argument spans are not provided, (Hsu et al., 2022) outruns our model by 40.6% and 42.9% on ACE and ERE, respectively. We can see that the advantage of supervised SOTA over our zero-shot method is much more distinct when argument spans are not given in advance. This is probably because our zero-shot argument identification module described in Section 3.1 is not powerful enough, which causes severe error propagation to our EAC model.

3.3 Analysis of Prompting Module

We conduct experiments to examine the effects of different configurations of prefix prompt templates. Specifically, we compare our model’s complete prefix prompt with the following configurations: (1) removing event type information from the prefix; (2) removing trigger information from the prefix;

Configurations	F1	Δ
complete prefix prompt	66.1	-
w/o event type	64.4	-1.7
w/o trigger	64.9	-1.2
w/o prefix prompt	62.8	-3.3

Table 2: Results of using different configurations of prefix prompt.

(3) removing the whole prefix. For instance, suppose the passage is “In Baghdad, a bomb was fired at 17 people.” mentioned in Section 2.2, the prefix in configuration (1) would be “**This event’s occurrence is most clearly expressed by ‘fired’.**”, the prefix in configuration (2) would be “**This is a Attack event.**”, and in configuration (3) there would be no prefix. The corresponding results are shown in Table 2, where we have the following observations. First, removing either event type or trigger from the prefix prompt will cause a performance drop, which indicates that both kinds of information have contributions to the prompting process. Second, event type plays a more significant role than trigger does in prefix prompt, and the joint effect of them is greater than the sum of their respective effects.

In addition, we examine the effects of using different PTLMs in the prompting module. We compare the following PTLMs with GPT-J (6B): BERT (large, uncased) (Devlin et al., 2019), RoBERTa (large) (Liu et al., 2019), BART (large) (Lewis et al., 2020), GPT-2 (xl) (Radford et al., 2019), T5 (11B) (Raffel et al., 2020). The results are shown in Figure 6, where we have the following observations. First, the instance using GPT-J has the best performance, surpassing other instances by 4.2% to 7.9%. This shows that GPT-J has a better ability to understand events and their associated arguments compared to other PTLMs. Second, as PTLMs are listed in ascending order based on their numbers of

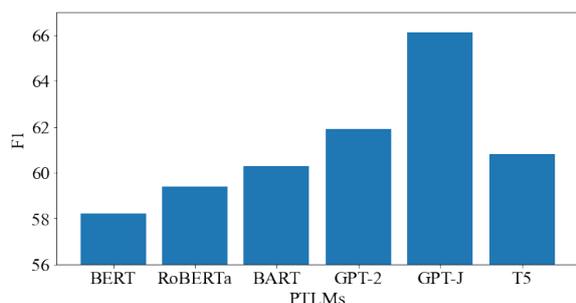

Figure 6: Comparison between the performance of using different PTLMs in prompting module.

parameters, we can see that for the first five models, the performance increases as the sizes of PTLMs become larger, which is consistent with the widely accepted notion that the larger model has a better capability of solving language tasks. However, the instance using the largest PTLM, T5 (11B), has a worse performance than GPT-2 and GPT-J. This is probably because autoregressive language modeling is more suitable for capturing information related to event arguments than mask language modeling is.

3.4 Analysis of Global Constraints Regularization Module

We conduct experiments to study the individual effect of each global constraint on the overall performance. The results are shown in Table 3, where we have the following observations. First, every

Model	F1	Δ
Full model	66.1	-
w/o cross-task constraint	60.5	-5.6
w/o cross-argument constraint	64.8	-1.3
w/o cross-event constraint	63.6	-2.5

Table 3: Results of using different configurations of global constraints.

global constraint used by our model is beneficial to overall performance, which demonstrates that exploiting the domain knowledge about cross-task, cross-argument, and cross-event relations indeed provides our model with global understanding of event arguments. Second, the contribution of cross-task constraint is the most significant, which suggests that the global insights from the entity typing tasks are more effective in improving our model’s reasoning ability about event arguments. Third, the cross-argument constraint is less effective than the

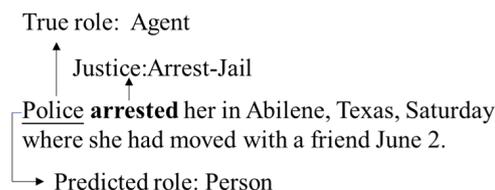

Figure 7: An Example of the wrong prediction caused by too general argument roles. The text in **bold face** denotes trigger and the underlined text denotes target argument span.

other constraints, which shows that the global insights provided by the cross-argument constraint is less informative than those provided by the other constraints.

Apart from the three global constraints described above, we have designed another 11 global constraints, which rely on cross-argument or cross-event relations. We add each of them into our model to check their respective effects on the overall performance. The results of three of them are in Table 4, whereas the results of all of them are in Section B. From the results, we can find that each of these constraints either brings minor improvement or even has a negative influence on the overall performance. Hence, we do not incorporate these constraints in our model to maintain our model’s efficiency and effectiveness.

3.5 Error Analysis

We manually checked 100 wrong predictions of our model and found that most of the errors are caused by too general roles of some event types. Specifically, some roles’ linguistic meanings are so general that a model, not knowing their detailed event-type-dependent semantics, tends to assign them to some arguments which should have been assigned other roles. An example is shown in Figure 7. The example describes a Justice:Arrest-Jail event, which is associated with the following roles: “Person,” “Agent,” “Crime,” “Time,” and “Place.” “Person” refers to the person who is jailed or arrested, whereas “Agent” refers to the jailer or the arresting agent. In the example, the argument span’s true role should be “Agent” according to the detailed event-type-dependent semantics of “Person” and “Agent.” However, our approach is zero-shot and directly models all role labels as natural language words, without incorporating the detailed event-type-dependent semantics of those roles, which are too general (e.g., “Person”). Therefore, our model assigns “Person” to “Police” since it is reasonable

Global constraint	Effect on overall performance
There is at most one Time-Arg in each event.	0.4
A TRANSPORT event has at most one ORIGIN argument.	-0.1
If an Arrest-Jail event and a Charge-Indict event share arguments, Arrest-Jail.Person is the same as Charge-Indict.Defendant, they share the same Crime argument.	0.3

Table 4: Results of three other global constraints. Results of all other global constraints are in Section B

from the perspectives of linguistic and common-sense knowledge, and “Person” is much more common than “Agent” in the pre-training corpus of the PTLM in the prompting module, which makes it have much higher likelihood in the language modeling process. Incorporating event-type-dependent semantics of the roles which are too general into our model is left as future work.

4 Related Work

In this section, we introduce related works about constraint modeling, event extractions, and prompt-based Information Extraction (IE).

4.1 Constraint Modeling

Constraint modeling, as an important technique in machine learning and NLP, aims to improve a model’s performance by incorporating domain knowledge as constraints (Ganchev et al., 2010; Chang et al., 2012, 2013; Deutsch et al., 2019; Chang et al., 2008, 2010; Graça et al., 2010). One of the most significant advantages of constrained modeling is that it enables a model to capture the expressive and complex dependency structure in structured prediction problems like EAC (Chang et al., 2012). Especially in zero-shot scenarios, constrained modeling can provide useful indirect supervision to a model, which further boosts performance (Ganchev et al., 2010). Some previous works have adopted constraints based on event-related domain knowledge to classify event arguments (Lin et al., 2020; Zhang et al., 2021). However, their constraints either require labor-intensive annotations (Lin et al., 2020) or consider limited global information (e.g., cross-event relations) (Zhang et al., 2021). In this paper, our model uses global constraints to regularize prediction by incorporating global insights from cross-task, cross-argument, and cross-event relations.

4.2 Event Extraction

Event extraction is a fundamental information extraction task (Sundheim, 1992; Grishman and Sundheim, 1996; Riloff, 1996; Grishman et al., 2005; Chen et al., 2021; Du and Cardie, 2020; Liu et al., 2020), which can be further divided into four sub-tasks: trigger identification, trigger classification, argument identification, and argument classification. Traditional efforts mostly focus on the supervised setting (Ji and Grishman, 2008; Liao and Grishman, 2010; Liu et al., 2016; Chen et al., 2015; Nguyen et al., 2016; Liu et al., 2018; Zhang et al., 2019; Wadden et al., 2019; Lin et al., 2020). However, these works could suffer from the huge burden of human annotation. In this work, we focus on the argument classification task and propose a model using prompting and global constraints, without annotation and task-specific training.

4.3 Prompt-based IE

With the fast development of large PTLMs like T5 (Raffel et al., 2020), GPT-3 (Brown et al., 2020), and Pathway Language models (Chowdhery et al., 2022), the prompt-based method has been an efficient tool of applying those giant models into downstream NLP tasks (Liu et al., 2021). IE is not an exception. People have been using leverage prompts and giant models to solve IE tasks like named entity recognition (Cui et al., 2021), semantic parsing (Shin et al., 2021), and relations extraction (Chen et al., 2022; Han et al., 2021) in a zero-shot or few-shot way. However, previous prompting methods for IE need a tedious prompt design for every new type of events and arguments. In contrast, our model’s prompt templates can be adapted to all possible types of events and arguments in a fully automatic way.

5 Conclusion

We propose a zero-shot EAC model using global constraints with prompting. Compared with previ-

ous works, our model does not require any annotation or manual prompt design, and our constraint modeling method can be easily adapted to any other datasets. Hence, our model can be easily generalized to any open-world event ontologies. Experiments on two standard event extraction datasets demonstrate our model’s effectiveness.

6 Limitations

Our work has the following limitations. One limitation is that our model is not aware of the detailed event-type-dependent semantics of those roles which are too general, as discussed in Section 3.5. In the future, we will work on enabling our model to capture the event-type-dependent semantics of the roles which are too general. Another limitation is that our model’s performance is still unsatisfactory compared with SOTA supervised model when argument spans are not given, as discussed in Section 3.2. In the future, we will work on designing a more powerful zero-shot event argument identification module for our model, so that we can obtain satisfactory zero-shot EAC performance even when argument spans are not given.

A Comparison between Different Prefix Prompts

In this section, we conduct experiments on ACE-2005 dataset to compare the effectiveness of using different prefix prompts in our models. We compare the following prefix prompts with the one discussed in Section 2.2: (1) “**This is a [] event whose trigger is "[]".**”; (2) “**The event type is [], and its occurrence is most clearly expressed by "[]".**”; (3) “**The event type is [] and the trigger is "[]".**”. The results are shown in Table 5, where “Prefix (0)” refers to the prefix prompt discussed in Section 2.2, whereas “Prefix (1)” refers to the first prefix prompt described in this section, and so on. From the table we can see that the prefix

Prefix Prompt	F1
Prefix (0)	66.1
Prefix (1)	65.2
Prefix (2)	65.6
Prefix (3)	63.0

Table 5: Performance of different prefix prompts.

prompt described in Section 2.2 is the most effective one, which might be due to the fact that the prefix prompt not only is based on the definitions of events and triggers (Grishman et al., 2005), but also has a natural and smooth expression.

B Results of all Other Global Constraints

In this section, we present the results of all other global constraints. The results are shown in Table 6.

Global constraint	Effect on overall performance
There is at most one Time-Arg in each event.	0.4
There is at most one Place-Arg in each event.	0.1
A TRANSPORT event has at most one Destination argument.	-0.2
A TRANSPORT event has at most one ORIGIN argument.	-0.1
A START-POSITION event has at most one Person argument.	0.2
A START-POSITION event has at most one Entity argument.	-0.1
A START-POSITION event has at most one Position argument.	0.1
A End-POSITION event has at most one Person argument.	-0.2
If a Start-Position event and an End-Position event share arguments, then Start-Position.Person is the same as End-Position.Person, and Start-Position.Entity is the same as End-Position.Entity, Start-Position.Position is the same as End-Position.Position.	0.1
If an Arrest-Jail event and a Charge-Indict event share arguments, Arrest-Jail.Person is the same as Charge-Indict.Defendant, they share the same Crime argument.	0.3
If a Die event and an Attack event share arguments, then Die.Place is the same as Attack.Place, Die.Victim is the same as Attack.Target, Die.Instrument is the same as Attack.Instrument, Die.Time is the same as Attack.Time, Die.Agent is the same as Attack.Attacker.	-0.2

Abstract

Driven by encouraging results on a wide range of tasks, the field of NLP is experiencing an accelerated race to develop bigger language models. This race for bigger models has also underscored the need to continue the pursuit of practical distillation approaches that can leverage the knowledge acquired by these big models in a compute-efficient manner. Having this goal in mind, we build on recent work to propose a hallucination-free framework for sequence tagging that is especially suited for distillation. We show empirical results of new state-of-the-art performance across multiple sequence labelling datasets and validate the usefulness of this framework for distilling a large model in a few-shot learning scenario.

1 Introduction

Sequence labelling (SL) can be defined as the task of assigning a label to a span in the input text. Some examples of SL tasks are: i) named entity recognition (NER), where these labelled spans refer to people, places, or organizations, and ii) slot-filling, where these spans or slots of interest refer to attributes relevant to complete a user command, such as *song name* and *playlist* in a dialogue system. In general, these spans vary semantically depending on the domain of the task.

Despite the strong trend in NLP to explore the use of large language models (LLMs) there is still limited work evaluating prompting and decoding mechanisms for SL tasks. In this paper we propose and evaluate a new inference approach for SL that addresses two practical constraints:

- **Data scarcity:** The lack of vast amounts of annotated, and sometimes even the lack of unlabelled data, in the domain/language of interest.

- **Restricted computing resources at inference time:** LLMs are very effective, but deploying them to production-level environments is expensive, especially in contexts with latency constraints, such as in a live dialogue system.

Data scarcity leads us to consider high-performing encoder-decoder based LLMs. We address deployment concerns by considering distillation of such models into much smaller SL architectures, for instance Bi-Directional Long Short Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) units, through the use of both labelled and unlabelled data.

A standard distillation approach, knowledge distillation (KD) (Hinton et al., 2015), requires access to the probability that the teacher network assigns to each of the possible output tags. This probability distribution is typically unavailable at inference time for LLMs; thus, distillation of encoder-decoder models needs to resort to pseudo-labels:¹ the student is trained on the one-hot labels that the teacher assigns to examples in an unlabelled dataset. This prevents the student model from learning those relationships among the probabilities of the incorrect classes that the teacher has learned. Similar arguments apply to decoder-only models.

In this paper, we propose **SenT'**, a simple modification of the *Simplified Inside Sentinel+Tag* (**SenT**) format by Raman et al. (2022). We combine our target sequence format with a scoring mechanism for decoding, which we collectively call **SenTScore**. This combination results in an effective framework that allows us to employ a language model to perform sequence labelling and knowledge distillation. We show that **SenTScore** is an hallucination-free

¹In this paper, we refer to distillation with pseudo-labels as the process by which a student model is trained on the one-hot labels (and only those labels) generated by a teacher model on an unlabeled dataset. We wish to distinguish this from KD, in which the probability distribution over labels is also used. See also Shleifer and Rush (2020).

Table 1: An example of how an original input text (from the SNIPS dataset) is transformed into the SenT' input for the model, and the format for the expected output. We use the explicit form of the special token strings used by T5. The addition of the extra token at the end of the input differentiates SenT' from SenT. Notice the modified BIO scheme (sBIO) that we use in our experiments: a unique I tag is used for each of the output tags; so if the original tag set is T , the tags generated by the model are $\bar{T} \equiv T \cup \{I, O\}$.

decoding scheme, and that even with smaller models it outperforms the original **SenT** format across a variety of standard SL datasets.

Our proposed **SenTScore** method defines a sequence of scores over the output tags that can be aligned with those generated by the sequence tagging student network, making KD possible. We find an advantage in terms of performance in using KD as opposed to just pseudo-labels as a distillation objective, especially for smaller distillation datasets.

In sum, our contributions are:

- A new, hallucination-free, inference algorithm for sequence labelling with encoder-decoder (and possibly decoder only) transformer models, **SenTScore**, that achieves new state-of-the-art results on multiple English datasets.
- Empirical evidence showing an advantage of **SenTScore** when distilling into a smaller student model. This approach is particularly promising in the few-shot setting, which makes it even more appealing and practical.

2 Related work

Using LLMs to perform sequence tagging is discussed by Athiwaratkun et al. (2020); Yan et al. (2021); Paolini et al. (2021); Qin and Joty (2021); Xue et al. (2022) and Raman et al. (2022). While these previous works have minor differences in the prompting format of the models, all but the last one include input tokens as part of the target sequence. Different from our work, all previous models are prone to hallucinate.

Distillation refers to training a small student model from scratch using supervision from a large pretrained model (Bucilua et al., 2006; Hinton et al., 2015). Distillation of transformer-based models for different NLP tasks is typically discussed in the context of encoder-only models (e.g. Tang et al.,

2019; Mukherjee and Hassan Awadallah, 2020; Jiao et al., 2020), with a few exceptions looking at distillation of decoder-only models (e.g. Artetxe et al., 2021).

In this paper we will discuss two approaches to distillation: *pseudo-labels* and *knowledge distillation* (KD). In the first approach the student model is trained on the hard labels generated by the teacher on some (unlabelled) dataset. In the second approach additional soft information provided by the teacher is used: typically the probability distribution the teacher assigns to the labels.

In the context of sequence labelling, using pseudo-labels allows us to perform distillation on any teacher-student architecture pair. KD, on the other hand, requires access to the teacher's probability distribution over the output tags. These are not usually available in language models for which the output distribution is over the whole vocabulary of tokens. We are not aware of other works which modify the decoder inference algorithm to generate such probabilities. However, there is recent work distilling internal representations of the teacher model, with the most closely related work to us being Mukherjee and Hassan Awadallah (2020). In that work the authors distill a multilingual encoder-only model into a BiLSTM architecture using a two-stage training process. This two-stage process, however, assumes a large unlabelled set for distilling internal model representations, embedding space, and teacher logits, and another significant amount of labelled data for directly training the student model using cross-entropy loss.

3 Datasets

We select seven English datasets that have been used in recent work on slot labelling: ATIS (Hemphill et al., 1990), SNIPS (Coucke et al., 2018), MIT corpora (Movie, MovieTrivia, and

Restaurant)², and the English parts of mTOP (Li et al., 2021) and of mTOD (Schuster et al., 2019). Some statistics about the datasets are shown in Table 2. Some of these datasets (ATIS, SNIPS, mTOP, and mTOD) come from dialogue-related tasks, while the MIT ones have been used for NER.

We use the original training, development, and test sets of the SNIPS, mTOP, and mTOD datasets. For the ATIS dataset we use the splits established in the literature by Goo et al. (2018), in which a part of the original training set is used as the dev set. Similarly, we follow Raman et al. (2022)³ to obtain a dev set out of the original training set for each of the MIT datasets.

We notice that all datasets, with the exception of MovieTrivia, contain some duplicates. Among these, all apart from Restaurant contain examples in the test set that are also duplicated in the train and dev sets. This happens for fewer than 30 instances, with the exception of mTOD, where more than 20% of the test set examples are also found in the train and dev sets. How these duplicates are handled varies across the literature; we do not remove duplicates from the datasets used in our main results.

However, for mTOD, we also obtained results on a version of the dataset that was deduplicated as follows: If an example is duplicated, we retain it in the highest priority (defined below) split and removed from the others. To ensure the test set is as close as possible to the original test set, we order the splits in ascending order of priority as follows: test, dev, and train. We found that the F1 scores on the deduped mTOD dataset are within 0.5 points those on the original mTOD dataset across all experiments; as such, we do not report the deduped results in the following sections.

In addition to covering different domains, there are noticeable differences across the datasets in terms of the number of tags and the number of labelled examples for evaluation and testing, as can be seen in Table 2. This set of seven datasets allows us to gather robust empirical evidence for the proposed work that we present in what follows.

4 Score-based sequence labelling

Using LLMs for sequence tagging requires reframing the problem as a sequence-to-sequence task. In

Table 2: Number of examples per partition and number of unique tags in the SL datasets we used.

Raman et al. (2022), the strategy that proved the most effective, at least when applied to the mT5 encoder-decoder architecture, was the *Simplified Inside Sentinel+Tag* (**SenT** in this paper). In this format (see Table 1), the original text is first tokenized according to some pretokenization strategy (whitespace splitting for all the datasets considered), and each of the tokens is prepended with one of the extra token strings provided by mT5 (the *sentinel* tokens). The resulting concatenation is then tokenized using the mT5 tokenizer and fed to the encoder-decoder model. The output that the decoder is expected to generate is the same input sequence of special token strings, which are now alternated with the tags corresponding to the original tokens.

Given the set T of string labels to be used to annotate a span of text, the scheme used to associate tags across tokens is a modification of the standard BIO scheme: we use $t \in T$ for any token that starts a labelled span, a single tag I for each token that *continues* a labelled span, and O to tag tokens that do not belong to labelled spans. We refer to this scheme as *Simplified Inside BIO* (sBIO), and we indicate with $\bar{T} \equiv T \cup \{I, O\}$ the tag set associated to it.

Raman et al. (2022) argue that the success of SenT can be attributed to two factors: 1) on the one hand, the use of sentinel tokens mimics the denoising objective that is used to pretrain mT5; 2) on the other hand, when compared to other decoding strategies, SenT does not require the decoder to copy parts of the input sentences and also produces shorter outputs. Both these facts supposedly make the task easier to learn and reduce the number of errors from the decoder (*hallucinations*, as they are often referred to in the literature).

We remark however that any output format among those described in the literature can be made completely free of hallucinations by constraining

decoding (either greedy or beam search based) through a finite state machine enforcing the desired output format (see for instance De Cao et al., 2020). In what follows we describe our proposed decoding approach that builds on this previous work.

4.1 SenTScore

Regardless of possible constraints imposed during generation, both **SenT** and the other algorithms described in Raman et al. (2022) use the decoder autoregressively at inference time to generate the target sequence. Since generation proceeds token by token and the textual representation of a tag is a variable length sequence of tokens, it is nontrivial to extract the scores and probabilities that the model assigns to individual tags.

We propose a different approach to inference, one in which the decoder is used to score sequences of tags. For this purpose, we consider a sequence tagging task with a label set T , and the associated sBIO tag set \bar{T} . Given an input sentence S , we use a pre-tokenizer (such as whitespace splitting) to turn S into a sequence of token strings $x_1 \dots x_L$, of size L . The SenT format is obtained by interleaving these tokens with special token strings to obtain the input string $S_{\text{in}} = s_0 x_1 s_1 \dots x_L$. We use juxtaposition to indicate string concatenation. In what follows, we will work with **SenT'**, a modification of SenT in which an additional special token is appended at the end, $S_{\text{in}} \leftarrow S_{\text{in}} s_L$. The reason for doing this will become clear in what follows.

The valid output strings that can be generated by the decoder are the $|\bar{T}|^L$ sequences of the form $S_{\text{out}} = s_0 t_1 s_1 \dots t_L s_L \in \mathcal{O}$ where $t \in \bar{T} \equiv T \cup \{I, O\}$ consistent with the sBIO scheme convention. The encoder-decoder model can be used to calculate the log-likelihood of each of such strings $\log \mathcal{L}_\theta(S_{\text{out}}; S_{\text{in}})$, where θ represents the model parameters, and the best output will be:

$$S_{\text{out}}^* = \arg \max_{S \in \mathcal{O}} \log \mathcal{L}(S; S_{\text{in}})$$

Exact inference is infeasible but can be approximated using beam search as described in Algorithm 1. The outputs of the algorithm are the top-K output strings and the score distribution associated with each of the output tags. As is evident from Table 1, it is simple to map back the final output string S^* to the sequence of output tags and labelled spans.

At decoding time the output string is initialized with the first sentinel token s_0 . At the i -th step,

Algorithm 1 SenTScore beam search

Require: Encoder-decoder parameters θ , input S_{in} with L tokens, sBIO tag set \bar{T} , beam size K

Ensure: Approximate top- K output sequences $\mathcal{B}_{\text{text}}$ and their sBIO tag scores, $\mathcal{B}_{\text{scores}}$

```

 $\mathcal{B}_{\text{text}} \leftarrow [s_0]_{i=1 \dots K}$ 
 $\mathcal{B}_{\text{scores}} \leftarrow [[]]_{i=1 \dots K}$ 
for  $i = 1$  to  $L$  do
   $\mathcal{H} \leftarrow [z t s_i]_{z \in \mathcal{B}_{\text{text}}, t \in \bar{T}}$   $\triangleright$  Generate hypotheses
   $\mathcal{S} \leftarrow [\log \mathcal{L}_\theta(h; S_{\text{in}})]_{h \in \mathcal{H}}$   $\triangleright$  Score hypotheses
   $\Pi \leftarrow \text{K-argsort } \mathcal{S}$   $\triangleright$  top-K args
   $\mathcal{B}_{\text{text}} \leftarrow \text{TAKE}(\mathcal{H}; \Pi)$   $\triangleright$  Update text beam
   $\tilde{\mathcal{S}} \leftarrow \text{RESHAPE}(\mathcal{S}; K, |\bar{T}|)$   $\triangleright$  Reshape scores
  for  $k = 0$  to  $K - 1$  do  $\triangleright$  Update score beam
     $\tilde{k} \leftarrow \Pi[k] \bmod K$ 
     $\mathcal{B}_{\text{scores}}[k] \leftarrow \text{APPEND}(\mathcal{B}_{\text{scores}}[\tilde{k}]; \mathcal{S}[\tilde{k}])$ 
  end for
end for
return  $\mathcal{B}_{\text{text}}, \mathcal{B}_{\text{scores}}$ 

```

SenTScore uses the model likelihood to score each of the $|\bar{T}|$ possible continuations of the output sequence

$$t s_i \text{ with } t \in \bar{T}, \quad (1)$$

picks the highest scoring one, and keeps track of the score distribution. s_i in Eq. 1, the *next* sentinel token, plays the crucial role of an EOS token at each step. This is needed to normalize the probability distribution: the likelihood of the string $s_0 t_1 \dots s_{k-1} t'_k$ is always bounded by that of the string $s_0 t_1 \dots s_{k-1} t_k$ if t is a prefix of t' , and we would never predict t' as a continuation of $s_0 t_1 \dots s_{k-1}$. This explains why we prefer using **SenT'** over **SenT**.

Finally, while **SenTScore** changes the inference algorithm, the finetuning objective we use throughout is still the original language modelling one.

4.2 Distillation

The main advantage of **SenTScore** is in the distillation setting. At each inference step, the algorithm assigns a likelihood to each sBIO tag. This distribution can be used to train the student network by aligning it to the teacher's pre-softmax logits, in a standard knowledge distillation setup.

In detail, given an input sequence S_{in} , let $(\mathbf{y}_i^*)_{i=1 \dots L}$ be the sequence of sBIO output tags (as $|\bar{T}|$ -dimensional one-hot vectors) as inferred by the teacher model, and let $(\mathbf{u}_i^*)_{i=1 \dots L}$ (also $|\bar{T}|$ -dim. vectors) be the associated sequence of log-likelihoods. We indicate with \mathbf{p}_i^* the probability obtained by softmaxing \mathbf{u}_i^* and by \mathbf{q}_i the output of the softmax layer from the student. The contribution of each of the tags to the distillation objective

that we use to train the student sequence tagger is

$$-\sum_k (y_i^*)_k \log (p_i^*)_k + \lambda_{KL} KL(\mathbf{p}_i^* || \mathbf{q}_i). \quad (2)$$

The first term is the standard cross-entropy contribution from the pseudo-labels, while the second is the knowledge distillation term, implemented with a KL divergence with λ_{KL} its associated positive weight.

We stress that we are allowed to write the second term only because **SentScore** provides us with the tag scores. This is not the case for any of the formats proposed in [Raman et al. \(2022\)](#) or, as far as we know, elsewhere.⁴

5 Experimental settings

We evaluate the models by computing the **F1** score on the test set of each dataset. **F1** is calculated following the CoNLL convention as defined by [Tjong Kim Sang and De Meulder \(2003\)](#), where an entity is considered correct iff the entity is predicted exactly as it appears in the gold data. We show micro-averaged **F1** scores.

The first set of experiments we performed are intended to investigate whether our proposed **SentScore** approach is competitive with respect to recent results on the same datasets (Table 3). Our **SentScore** model is a pretrained T5-base model (220M parameters) finetuned on each of the datasets.⁵ We trained each model for 20 epochs, with patience 5, learning rate of 10^{-3} , and batch size 32. We also want to know how the proposed framework compares against the following strong baselines:

BiLSTM: Our first baseline is a BiLSTM tagger ([Lample et al., 2016](#)).⁶ The BiLSTM has a hidden dimension of size 200. Its input is the concatenation of 100d pretrained GloVe6B embeddings ([Pennington et al., 2014](#)) from [StanfordNLP](#) with the 50d hidden state of a custom character BiLSTM. We trained each model for 100 epochs, with patience 25, learning rate of 10^{-3} , and batch size 16.

BERT: We finetune a pretrained BERT-base cased

⁴Strictly speaking the student defines $p(\cdot | t_1^* \dots t_{i-1}^*; S_{in})$ (star means predicted) while \mathbf{q}_i corresponds to $p(s_0 t_1^* \dots t_{i-1}^* s_{i-1} \cdot | S_{in})$. This discrepancy is resolved by the invariance of the softmax under constant shifts of its arguments.

⁵All our results are in the greedy setting. We find very small differences in performance by using beam search, while inference time grows considerably.

⁶We do not include a CRF layer.

model ([Devlin et al., 2019](#)) (110M parameters) for the SL task and report results for each of the seven datasets. While we consider BERT a baseline model, we note that this pretrained architecture continues to show good performance across a wide range of NLP tasks, and for models in this size range BERT is still a reasonable choice. In preliminary experiments we compared results from the case and uncased versions of BERT and we found negligible differences. We decided to use the cased version for all experiments reported here. We trained each model for 30 epochs, with patience 10, learning rate of 5×10^{-5} , and batch size 64.

SentT’: The pretrained model is the same as that used for **SentScore**. The goal of this baseline is to assess improvements attributed to our proposed decoding mechanism. This model is also the closest model to prior SOTA. The main difference between our results and those in [Raman et al. \(2022\)](#) is the pretrained model. They used a multilingual T5 model ([Xue et al., 2021](#)) with 580M parameters, whereas we use a smaller monolingual version ([Raffel et al., 2020](#)).

All the above models were trained with the AdamW optimizer ([Loshchilov and Hutter, 2017](#)). The best checkpoint for each training job was selected based on highest micro-F1 score on the validation set. All pretrained transformer models are downloaded from [Huggingface](#).

5.1 Distillation experiment

We apply **SentScore** and the loss function described in Section 4.2, to distill a finetuned T5 model into a BiLSTM architecture to perform sequence tagging. To mimic a low-resource setting, we randomly downsample the train/dev splits of all the datasets. We consider two sets of sizes for these gold train/dev splits: a 100/50 split and a 300/150 one. In both settings the remainder of the original training set is used for the distillation component using pseudo-labels.

We then finetune T5 using the **SentT’** format on each of these two gold splits. The resulting model is used as the teacher in a distillation setting in which the student is a BiLSTM. The BiLSTM student is trained on the full training set by using the downsampled gold labels, but pseudo-labels and scores generated by the T5 teacher using **SentScore** with $K = 1$ in the rest of the training data. We use a temperature parameter τ to rescale the distribution **SentScore** defines over \bar{T} . We use $\tau = 10$ in all the distillation experiments.

Table 4: Distillation results and comparisons with baselines. The distillation results use the full objective function in Eq. 2 with $\lambda_{KL} = 1$.

The training schedule we follow is the same we use to train the BiLSTM baseline model, with the only exception that the best checkpoint is selected on the reduced dev set.

6 Results

The comparisons between baselines, SenT', and **SenTScore** are shown in Table 3. **SenTScore** is used with a $K = 1$ beam size. Larger beams result in very similar performance and a considerable slowdown of inference time. **SenTScore** consistently outperforms SenT' with constrained decoding, and all other baselines. Our intuition is that one advantage of **SenTScore** comes from the fact that decoding happens tag-wise as opposed to token-wise (as in pure beam search). The last column of Table 3 shows the performance of the SenT implementation of [Raman et al. \(2022\)](#). **Perfect** scores are also reported for completeness. They are evaluated at the sentence level and correspond to the fraction of perfectly predicted examples. However these results are not directly comparable: [Raman et al. \(2022\)](#) use a different and larger model (mT5-base with 580M parameters) and different optimization details. Nevertheless **SenTScore** achieves bet-

ter performance in a majority of cases.

6.1 Distillation results

Tables 4a and 4b show the result of the distillation experiments with 100/50 and 300/150 train/dev gold splits, respectively. While a BiLSTM tagger trained on the gold data significantly underperforms a finetuned T5-base model, once the BiLSTM is distilled on the silver data generated using SenTScore, it outperforms even the original teacher model. We notice that the difference between student and teacher decreases for larger gold set size, suggesting that the effect is related to regularization properties of the distillation process. A similar phenomenon has been observed elsewhere, for instance in [Furlanello et al. \(2018\)](#) albeit with teacher and student sharing the same architecture.

In order to isolate the benefits of training the teacher model using KD as opposed to just pseudo-labels, we perform a set of ablation studies. For each dataset, we distill a BiLSTM student on a training set $\mathcal{T} = \mathcal{G} \cup \mathcal{S}$, where \mathcal{G} is the original gold set and \mathcal{S} is a random sample from the complement of \mathcal{G} . We choose $|\mathcal{S}| = 0, 250, 500$. The student is distilled using Eq. 2 with two choices of the loss

Table 6: Distillation experiments with varying silver dataset size and ablation of the KD term in Eq. 2. The gold data split is the same as in Table 4b, with a train/dev size given by 300/150. All experimental details are common with Table 5.

multipliers: $\lambda_{KL} = 1$ and $\lambda_{KL} = 0$. The first setting is the same used in Tables 4a and 4b, while the second drops the KD loss and only keeps the pseudo-labels for distillation. Whenever pseudo-labels and scores are used, they are generated by the SenTScore algorithm.

The results are shown in Tables 5 and 6. We see a consistent trend in which KD outperforms training the student using only pseudo-labels. This in particular motivates SenTScore as an inference algorithm. The results also show that for our choice of teacher and student architectures, and datasets, the gap between KD and pseudo-labels is reduced when more silver data are used. Figure 1 further explores the relationship between amount of pseudo-labeled data and gains from KD with $|\mathcal{S}| = 0, 250, 500, 2000$. The trend with more pseudo-labeled data remains unchanged.

7 Limitations and future work

A reasonable critique to our focus on real-world constraints is the simple fact the datasets we are using are not real-world ones. From noise to tokenization choices, many issues arise when considering datasets outside of the academic domain. However,

we believe our methods are simple enough to be applicable to real-world scenarios and our results to be independent of these various subtleties.

Some issues that could be addressed in future work have to do with the exploration of even larger models and different architectures such as decoder-only ones (Radford et al., 2018, 2019; Brown et al., 2020; Zhang et al., 2022; Chowdhery et al., 2022; Black et al., 2021). We note, however, that in all our experiments we finetune all the weights of the pretrained models we use. When using extremely large models this becomes impractical. Recent work (Turc et al., 2019) suggests that KD with compact encoder-only student models, such as BERT, is a promising avenue for further research. Exploring the pure few-shot scenario, or only finetuning a subnetwork, for instance by using adapters à la Hously et al., 2019, would be also interesting.

8 Conclusion

Real-time systems need to find a trade-off between performances and computing resources, the latter constraint coming either from budget or some other service requirement. Such trade-offs become particularly evident with large pretrained transformer

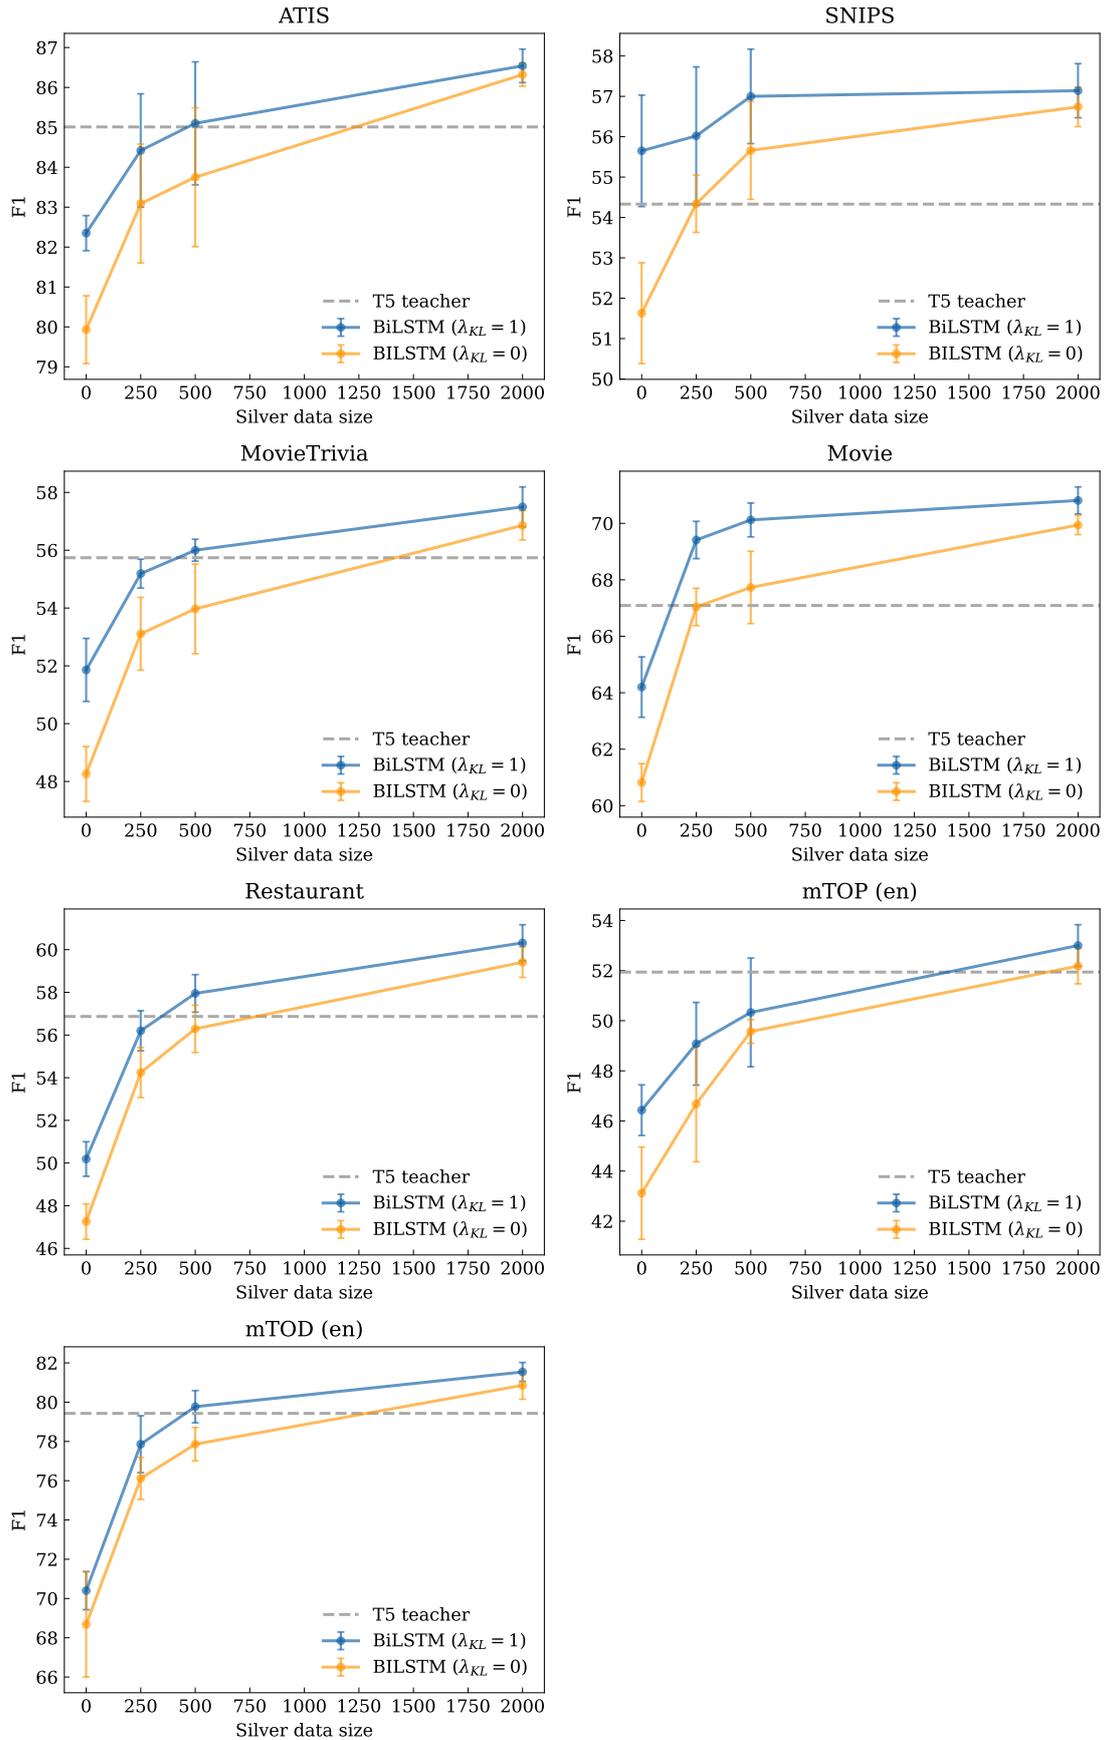

Figure 1: A graphical representation of the distillation results in Table 4a (100/50 gold train/dev split) as a function of the size of the silver dataset. Knowledge distillation using SenTScore generated scores outperforms pseudo-labels.

models, which achieve SOTA results on many NLP tasks at the cost of being extremely hard and expensive to deploy in a real-world setting.

The standard solution for this is distillation. In this paper we have revisited these issues for the SL task, which is often the first crucial step in many real-world NLP pipelines. We propose a new inference algorithm, SenTScore, that allows us to leverage the performance of arbitrarily large encoder-decoder transformer architectures by distilling them into simpler sequence taggers using KD as opposed to just pseudo-labelling.

Ethical considerations

The intended use of our proposed approach is related to sequence labelling tasks where there are latency constraints and limited labelled data available. While it is not impossible to identify potential misuses of this technology, it is not immediately clear what those malicious uses would be. On the contrary, this paper contributes to the body of work investigating efficient solutions for deployment of live systems.

Computing infrastructure and computational budget

All of our experiments were run on single V100 GPU machines with 32GB. The most expensive experiments relate to finetuning a model, including best checkpoint selection. In this case, the running time is directly related to the dataset size. For the experiments using the full train/dev set, running time varies from 45 minutes (mATIS corpus) to a few hours (mTOD corpus) for a T5-base model. Training a model takes, on average, around 4 iterations per second with batch size 32. For the generation of pseudo-labels, we did not implement batch processing and it takes around 0.15 seconds to annotate each sample.

Predicting Desirable Revisions of Evidence and Reasoning in Argumentative Writing

Tazin Afrin and Diane Litman
University of Pittsburgh
Pittsburgh, Pennsylvania 15260
{taa74, dlitman}@pitt.edu

Abstract

We develop models to classify desirable evidence and desirable reasoning revisions in student argumentative writing. We explore two ways to improve classifier performance – using the essay context of the revision, and using the feedback students received before the revision. We perform both intrinsic and extrinsic evaluation for each of our models and report a qualitative analysis. Our results show that while a model using feedback information improves over a baseline model, models utilizing context – either alone or with feedback – are the most successful in identifying desirable revisions.

1 Introduction

Successful essay writing by students typically involves multiple rounds of revision and assistance from teachers, peers, or automated writing evaluation (AWE) systems. Natural language processing (NLP) has become a key component of AWE systems, with NLP being used to assess the content and structure of student writing and to automatically provide formative feedback (Beigman Klebanov and Madnani, 2020; Zhang et al., 2016; Writing Mentor, 2016; Wang et al., 2020). While some students produce revised texts that are in line with the feedback automatically generated by a system or provided by other humans, other students either ignore the feedback or are unsuccessful in their feedback implementation attempts (Wang et al., 2020). Hence, analyzing student revisions in terms of their *desirability for improving essay quality* is important. The development of AWE systems that leverage NLP to analyze a revision’s alignment to feedback messages is one approach to convey to students a sense of a good revision direction.

Our research focuses on the *automatic classification of desirable and undesirable revisions of evidence use and reasoning*¹ in argumentative writ-

¹Such revisions of text *content* are generally considered most important in revising (Faigley and Witte, 1981).

ing. Argumentative writing is a skill that students need to develop to be strong writers and learners. By evidence use, we refer to examples and details that students use to support an argument. By reasoning, we refer to how evidence is explained and linked to an overall argument. Desirable revisions (e.g., add relevant evidence) are student revisions that have hypothesized utility in improving an essay in response to feedback (e.g., add more evidence), while undesirable revisions (e.g., add irrelevant evidence) do not have such hypothesized utility.

Table 1 shows example desirable and undesirable revisions of evidence and reasoning from original to revised drafts of an essay aligned at the sentence-level. In response to the feedback shown at the top of Table 1, the student adds both reasoning and evidence. Sentences 3, 5, and 9 are added desirable reasoning, desirable evidence, and undesirable reasoning respectively. The student also modified fluency in other sentences which is not shown here. Sentences 1, 4, and 7 are identical in both drafts.

In this paper, we first describe the labeling of desirable and undesirable revisions in three existing corpora of evidence and reasoning revisions. We then describe a baseline model and enhanced models using context and feedback information to predict revision desirability. Finally, we present results from intrinsic and extrinsic evaluations to demonstrate the utility of our enhanced models.

2 Related Work

NLP research on revision analysis primarily focuses on two domains: Wikipedia and academic writing. Studies in Wikipedia revisions focused on error correction, paraphrase or vandalism detection (Daxenberger and Gurevych, 2012), factual versus fluency edits (Bronner and Monz, 2012), semantic edit intention (Yang et al., 2017), etc. In academic writing, revision studies have instead focused on defining revisions purpose tailored to argumentative writing (Zhang and Litman, 2015;

Feedback message: "...Explain how the evidence helps to make your point... ... Tie the evidence not only to the point you are making within a paragraph, but to your overall argument..."			
	Original Draft	Revised Draft	Revision
1.	The author convinced me by saying in the passage that, "The plan is to get people out of poverty, assure them access to health care and help them stabilize the economy and quality of life in their communities."	The author convinced me by saying in the passage that, "The plan is to get people out of poverty, assure them access to health care and help them stabilize the economy and quality of life in their communities."	No-change
2.		...	
3.		They can do that by assuring that the people of Sauri, Kenya have food, water, liter, and a place to stay.	Added Desirable Reasoning
4.	Also, in paragraph 3 it says, "The goals are supposed to be met by 2025; some other targets are set for 2035."	Also, in paragraph 3 it says, "The goals are supposed to be met by 2025; some other targets are set for 2035."	No-change
5.		If the plans are going to be achieved in 2025 than their plans will be achieved in only 7 more years which would be in our life time.	Added Desirable Evidence
6.	
7.	Since so many people weren't fighting against poverty in 2010 people were being sent to the hospital and not even being treated cause they didn't have the money so, so many people died.	Since so many people weren't fighting against poverty in 2010 people were being sent to the hospital and not even being treated cause they didn't have the money so, so many people died.	No-change
8.	
9.		The kids and their families didn't have the money but but this supports my evidence by talking about how the kids don't go to school it's because them and their family are in poverty.	Added Undesirable Reasoning

Table 1: Example of revisions extracted from an essay from our elementary-school dataset.

Kashefi et al., 2022) and understanding the pattern of revisions (Afrin and Litman, 2019; Shibani et al., 2018). Exploring the pattern of iterative revision have also been studied in scientific writing (Du et al., 2022). While there have been some attempts at defining revisions in terms of their *quality* (e.g., vagueness of Wikipedia edits (Debnath and Roth, 2021), statement strength in scientific writing (Tan and Lee, 2014), quality of claims in online debate (Skitalinskaya et al., 2021), and improvement in argumentative writing (Afrin and Litman, 2018)), they fail to incorporate feedback students were provided. Afrin et al. (2020) is the first study that touched on student revisions in terms of their utility in improving the essay with respect to automated feedback messages. However,

their framework was applied to one dataset and they did not investigate state-of-the-art models for automatic classification. In this work, we focus on a simplified binary classification task to distinguish between desirable and undesirable revisions in student argumentative writing, and particularly explore the utility of two predictors of revision desirability - *context and feedback*. We also apply our model on *multiple student corpora*.

Previous revision classification approaches either do not create contextual features (Daxenberger and Gurevych, 2013; Zhang and Litman, 2015), or the context features represent only shallow information such as 'location' (Zhang and Litman, 2015). Zhang and Litman (2016) incorporated context by using cohesion blocks focusing on adjacent sen-

Datasets	#Students	Grade Level	Feedback Source	Essay Drafts Used	Essay Score Range	Improvement Score Range
Elementary	143	5 th & 6 th	AWE	1 and 2	[1, 4]	[0, 3]
High-school	47	12 th	peer	1 and 2	[0, 5]	[-2, +3]
College	60	college	X	2 and 3	[15, 33]	-1, +1

Table 2: Comparison of datasets used in this study (X = Not available).

Data	Example Feedback
Elementary (AWE generated)	Explain the evidence: Tell your reader why you included each piece of evidence. Explain how the evidence helps to make your point. Explain how the evidence connects to the main idea & elaborate: Tie the evidence not only to the point you are making within a paragraph, but to your overall argument. Elaborate. Give a detailed and clear explanation of how the evidence supports your argument.
High-school (peer feedback)	for the spendthrifts and the hoarders, you used a good example for spendthrifts but im confused on where you example for hoarding is. if it is mike tyson, i think you should include more detail about that. your fifth circle could use more detail as to what exactly made him hate man, because im confused about the story.

Table 3: Examples of feedback messages from elementary and high-school data.

tences of the target revision, and sequence labeling to utilize the interdependent revisions. Inspired by this work, we propose a new approach to extract longer context information.

Prior studies of revision quality in writing have not considered feedback students receive before revision when defining an annotation scheme (Tan and Lee, 2014; Afrin and Litman, 2018), or have not explored the benefit of using feedback during classification (Afrin et al., 2020). We leverage both pre-defined AWE feedback messages and free form peer feedback in identifying desirable revisions.

Previous studies have explored revision generation for argument writing task (Ito et al., 2019) and paraphrase generation tasks (Mu and Lim, 2022). However, state-of-the-art language models are not leveraged for revision classification task. The pre-trained Bidirectional Encoder Representations from Transformer (BERT) (Devlin et al., 2019) model has shown to be effective in various NLP models including sentence classification and sentence-pair classification. BERT has also produced excellent results in various argument mining tasks (Chakrabarty et al., 2019; Reimers et al., 2019; Ghosh et al., 2021). In this work, we leverage the standard pre-trained BERT model (bert-based-uncased) (Devlin et al., 2019) to create the model for our revision classification task.

3 Data and Resources

Our data consists of three corpora of paired drafts of argumentative essays, written in response to a prompt and revised in response to feedback. A comparison of the data is shown in Table 2. The diversity of the corpora along multiple dimensions helps ensure the utility of our proposed models.

The *elementary* school students wrote Draft1 about an article on a project in Kenya, then received AWE system feedback focused on students’ use of text evidence and reasoning (selected based on automatic scoring). An example of the feedback messages is shown in Table 3. All essay pairs were later graded on a scale from 0 to 3 to indicate improvement from Draft1 to Draft2 in line with the feedback ($\kappa = 0.77$) (Wang et al., 2020).

The *high-school* students wrote Draft1 in response to a prompt about Dante’s *Inferno* (Zhang and Litman, 2015), then received peer feedback along 6 rubric dimensions (e.g., evidence, organization, etc.). We only utilize feedback about evidence in this work (shown in Table 3), because it is closely related to the revisions we are considering. Drafts 1 and 2 of each high-school essay were separately graded by expert graders. We create an improvement score for each essay pair, calculated as the difference of the holistic score between drafts.

The *college* essays were written by 60 students on technology proliferation (Zhang et al., 2017). Students received general feedback after Draft1,

	Desirable Evidence	Undesirable Evidence	Desirable Reasoning	Undesirable Reasoning
Elementary	Relevant	Irrelevant+Repeat +Non-Text-Based + Minimal	LCE + Para- phrase	Not-LCE + Generic + Commentary + Minimal
High-school College			LCE	Paraphrase+ Not-LCE+ Generic + Commentary+ Minimal

Table 4: Desirable and Undesirable revision mapping.

then revised to create Draft2, then revised again without any further textual² feedback to create Draft3. Drafts 2 and 3 were later graded by experts based on a rubric. We create a binary improvement score for each essay pair, calculated as 1 if Draft3 improved compared to Draft2, -1 otherwise.

For all corpora, sentences from the two drafts were aligned manually based on semantic similarity. Aligned sentences represent one of four operations between drafts – no change, modification, sentence deleted from Draft1, sentence added to Draft2. Each pair of changed aligned sentences was then extracted as a *revision* (rows 3, 5 and 9 in Table 1) and annotated for its *purpose* (revise reasoning, evidence, and reasoning in rows 3, 5 and 9, respectively). Kappa of the purpose annotation was 0.753 (Afrin et al., 2020). From among the full set of annotations, we only use evidence and reasoning revisions for the current study because they are the most frequent for elementary and high-school data³. Due to low frequency of evidence revisions, we only use reasoning revisions for college data.

Finally, to understand how students revise evidence and reasoning, whether their revisions were desirable, and whether desirable revisions relate to measures of essay improvement, we then applied the evidence and reasoning revision categorization scheme developed in (Afrin et al., 2020). In this scheme, revisions related to evidence are characterized by five codes – Relevant, Irrelevant, Repeat evidence, Non-text based, and Minimal. Reasoning revisions are characterized by six codes – Linked claim-evidence (LCE), Not LCE, Paraphrase evidence, Generic, Commentary, and Minimal. The annotation was done by an expert familiar with the coding scheme (Cohen’s kappa in a previous study was 0.833 for evidence and 0.719 for reasoning).

²Feedback was given using AWE interface visualizations.

³1475 revisions were extracted from elementary-school data. Other 700 revisions (claim, word-usage, grammar mistakes, etc.) are not considered due to low frequency. 1269 revisions were extracted from high-school data. Other 772 revisions are not considered due to low frequency.

Labeling Desirable Revisions. In this paper, we abstract the evidence and reasoning revision annotations described above into two new categories - *desirable* revision and *undesirable* revision. The mapping is shown in Table 4. Desirable revisions are those that have hypothesized utility in improving the essay after revision, and are encouraged by the writing task. Given a different writing task with different feedback messages, different categories may be desirable in improving the essay quality. For our corpus, relevant evidences are desirable because they support a claim in the essay. All the other categories of evidence revisions are combined as undesirable. For reasoning revisions, LCE and paraphrase reasoning are combined as desirable for the elementary-school data⁴. On the other hand, only LCE is a desirable reasoning revision for the high-school and college data. The rest of the reasoning revisions are combined as undesirable. Table 5 shows the number of desirable and undesirable revisions for each corpus⁵. We did not combine evidence and reasoning revisions, because the schema to label each is different.

Extracting Context. We use two methods to extract context of the target revision, *simple context* (SC) and *longer context* (LC). Following Zhang and Litman (2016), we only focus on the sentences before and after the target revision to extract simple context. For example, simple context for the 3rd revision in Table 1 consists of sentence 2 and 4 from the revised draft. For longer context, we introduce a new method that considers all the sentences that are revised around the target sentence until we find a sentence that is not changed. This makes sure that the context window will have text extracted from both drafts. For example in Table 1, sentence 3 will not have any context from Draft1 using the simple context method. But with longer context, sentences 1 to 4 from the original draft will be considered as context1 from Draft1; sentences 1 to 4

⁴Paraphrase is encouraged by the writing task.

⁵See Appendix A for more data distributions.

Table 5: Statistics for number of revisions in each corpus. Average number of revisions over 10-fold cross-validation is shown after data augmentation (N = #Student).

from revised draft will be considered as context2 from Draft2. The length of the context will vary depending on the number of revisions within the window. For example, context1 for sentence 3 consists of 2 sentences from Draft1 (1 and 4, 2 was added) while sentence 5 had 3 (4, 6, and 7).

4 Predicting Revision Desirability

In this section, we describe the models for automatically classifying desirable revisions. First, we describe a data augmentation process to increase the training data. Then we describe a model to identify revision desirability, and extend it to use context and the feedback information. We setup our models to answer the following research questions:

RQ1: Is the context of the revision predictive of revision desirability?

RQ2: Is the feedback received before revising the essay predictive of revision desirability?

RQ3: Do the context and feedback together boost the identification of desirable revision?

4.1 Data Augmentation

Our limited amount of revision data is not suitable to experiment with various state-of-the-art machine learning and deep learning models. To generate more training examples, we use a customized version of the synonym replacement (SR) data augmentation strategy – randomly pick a word from the sentence and replace it with a synonym (Wei and Zou, 2019). For each sentence, we replaced one random word with its synonyms but did not consider multiple words at the same time to preserve the hand-annotated revision categories. We ignored stop words, selected words that are more than length of 5 characters, and used maximum 5 synonyms per word to limit the number of data generated. The synonyms are extracted from the Synset from WordNet lexical database from Natural Language Toolkit (NLTK) in Python (Bird et al.,

2009), e.g., the word ‘achieve’ in sentence 5 of Table 1 can be replaced by ‘accomplish’. Then the augmented new revision is added as a training instance. The last three columns in Table 5 show the average number of revisions after augmentation.

4.2 Models

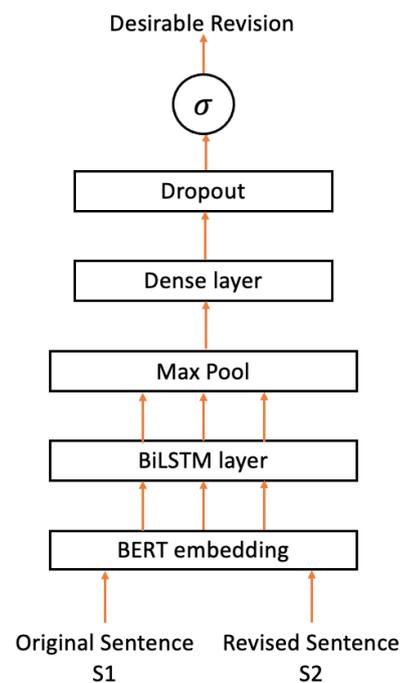

Figure 1: Our model M architecture.

Figure 1 shows the neural network model used in this study (**Model M**). We used the pre-trained ‘bert-based-uncased’ from Keras Huggingface Library (Devlin et al., 2019; Wolf et al., 2020) and encode our revision sentence pair using BERT encoder. After encoding, we use a BiLSTM layer and a Dense layer to build our neural network model using the Keras library (Chollet et al., 2015). This architecture allows easy incorporation of context and feedback as direct inputs, as discussed below.

Bidirectional Long Short Term Memory networks (BiLSTM) has been used in revision classification (Anthonio and Roth, 2020) in addition to various sentence-pair modeling and sentence classification tasks (Vlad et al., 2019; He and Lin, 2016) etc. Vlad et al. (2019) used a BERT-BiLSTM capsule model with additional dense layers with dropout. Following these works, we add a BiLSTM layer after extracting the embedding from BERT to process the input sequences.⁶ We used a dropout and recurrent dropout rate of 0.1. To down-sample the output representation from the BiLSTM, we take the maximum value over the time dimension using the GlobalMaxPool1D (Chollet et al., 2015).

To improve performance while still keeping the model simple, we add a dense layer after BiLSTM with ‘relu’ as the activation function (Javid et al., 2021). In order to make the model robust to overfitting, we add a dropout layer with rate 0.2. The output is then passed to the final output dense layer with 1 neuron. Since this is a binary classification task, we use ‘Sigmoid’ as the activation function.

We tune the model using Adam optimizer with learning rate $\{1e^{-3}, 1e^{-4}, 1e^{-5}\}$ and batch size $\{16, 32, 64\}$ using a validation set of 2000 instances extracted from the elementary evidence augmented data. Finally, we select the learning rate at $1e^{-3}$ and batch size 16, and apply the same to all data. The hidden layer size is set to 64. There were 434,817 trainable parameters in the model.

Context Model. In this model, in addition to the revision we also provide the context1 from Draft1 and context2 from Draft2 as input to the model to answer **RQ1**. Since BERT cannot handle more than 512 tokens and our context can be long in some cases, we did not concatenate contexts from two drafts before encoding. First, we encode each context from each draft using the BERT encoder and extract the embedding. Then the context1 and context2 embeddings are concatenated with the revision input in the order of [revision pair, context1, context2]. Then the concatenated embedding is sent to the BiLSTM layer. There is no change in the following layers. When the context is longer than 512 tokens, it is truncated from the end.⁷

Feedback Model. To answer **RQ2**, we use feed-

back information to predict revision desirability. We first concatenate all the sentences from the feedback messages. Then we encode the whole feedback message using BERT encoder and extract the embedding. The embedding is then concatenated with the input revision from the baseline model in the order of [revision pair, feedback] and sent to the BiLSTM layer. Feedback messages longer than 512 tokens are truncated from the end.⁸

Context & Feedback Model. We also experiment with context and feedback together to answer **RQ3**. We encode context and feedback as we did in the previous models. The embeddings are then concatenated in the order [revision pair, context1, context2, feedback] and sent to the BiLSTM layer.

Baseline Model. We compare our models with a simple model used in prior work that uses logistic regression (LogR) (Afrin et al., 2020) using GloVe word2vec (Pennington et al., 2014) features for revision classification.

5 Results and Evaluation

5.1 Intrinsic Evaluation

In our intrinsic evaluation (see Table 6), we compare whether context and/or feedback model performance improves over the proposed model **M** in terms of average unweighted F1-score⁹, over 10-folds of cross-validation. Without augmentation, our model does not learn at all from the very small amount of data, hence we only report results using augmented data. Augmentation is done at each fold on the training instances. Test instances are kept original, no augmentation applied. We ran the model 10 epochs for each fold.

First, we compare model **M** and its extensions with the LogR baseline. We see that **M** improved over LogR for all cases except high-school evidence classification. Similarly, **M** plus context and/or feedback improved over LogR in all cases except with feedback for high-school evidence.

To answer **RQ1**, we look at the results of the context model and see that our proposed longer context representation (**LC**) always improved over **M** (no context), which is not true for simple context (**SC**). For elementary data, **LC** performed better than **SC**, while for high-school data, **SC** performed better than **LC**. Recall that for high-school data, we did not truncate any context, which means students did

⁶We also experimented with simpler neural nets (e.g., no BiLSTM layer) as our core proposed model, but they did not perform better than model **M**.

⁷No truncation was needed for high-school data. For elementary school, about 9% and 4% contexts were deleted for evidence and reasoning, respectively.

⁸No truncation was needed for elementary data. For high-school, feedback messages were truncated for 55% of students.

⁹See Appendix A for more results.

	Elementary		High-school		College
Model	Evidence	Reasoning	Evidence	Reasoning	Reasoning
LogR	0.469	0.537	0.470	0.495	0.462
M	0.569	0.597	0.446	0.649	0.613
+SC	0.548	0.611	0.489	0.679	0.545
+LC	0.574	0.627	0.474	0.665	0.634
+F	0.570	0.639	0.452	0.652	–
+LC&F	0.587	0.649	0.521	0.664	–

Table 6: Intrinsic evaluation: average unweighted f1-score over 10-fold cross-validation. Best are marked bold.

not make multiple consecutive revisions frequently. This could explain why **SC** was better for high-school data. For college data, **SC** did not improve over **M**, but **LC** showed the best performance.

To answer **RQ2**, the results of the feedback model (**F**) in Table 6 show that while **F** did improve over **M** for each task, in most cases the increase is low. Desirable reasoning classification for elementary-school data had the most benefit using the feedback. This could be because every elementary-school student was specifically asked to provide more details or explain their evidence. For high-school data, although **F** improved over **M**, it did not improve over LogR for evidence.¹⁰

To answer **RQ3**, we only consider longer context and feedback messages (**LC&F**). As shown in Table 6, the **LC&F** model always improved model **M**'s performance and has the best performance except high-school reasoning revision. This indicates that feedback messages were most helpful when combined with the context, especially for elementary-school reasoning revisions where the performance increased more than 0.05 points. This could be because students did not receive feedback at sentence-level; instead, the feedback is usually about specific areas of the essay or about the argumentative structure of the essay. Hence, when combined with the context, it helps the model to capture a better picture.

5.2 Extrinsic Evaluation

To confirm that revision desirability is indeed related to the essay improvement scores described in Section 3, we calculated the Pearson correlation between the frequency of desirable and undesirable revisions (gold annotations) to improvement score. For extrinsic evaluation, we then replicate the correlation calculation for the predicted labels to see if the frequency of predicted desirable revisions are

¹⁰No feedback available for college data Draft2 and Draft3.

still correlated to the essay improvement. Table 7 shows the gold and predicted correlations.

Model **M** showed to be consistent with Gold annotations for elementary reasoning and high-school evidence prediction. **M** also showed higher correlation than LogR when it is consistent with Gold.

Overall, the number of desirable revisions predicted by **LC** showed the highest R values. While we do not expect the models to have higher correlations than the gold annotations, **LC** did in one case (desirable reasoning prediction for high-school data). Gold annotations did not show significant negative correlations to undesirable revisions. This is because the scoring rubrics typically did not penalize for revisions that did not improve the essay, as long as revising didn't make the essay worse. **LC** also did not show any significant correlation to undesirable revisions. Unexpectedly, **SC** did in one case (undesirable reasoning for high-school).

Model **F** similarly yielded significant positive correlation with desirable revisions and had higher correlations than model **M**. In most cases Model **F** is consistent with Gold annotations, except for undesirable reasoning revisions for high-school data.

Model **LC&F** also showed higher significant correlation for the predicted labels compared to Model **M**. However, unlike the intrinsic evaluation it does not show us the best performance.

Unfortunately, we did not see any significant correlation for the college data. But in most cases, desirable revisions showed positive sign, while undesirable revisions showed negative sign.

6 Qualitative Analysis

In order to better understand the model predictions, in Table 8 we compare gold and predicted labels for a few example revisions. The first example (taken from Table 1) is predicted as desirable whenever longer context information was available. Otherwise, it is wrongly predicted as undesirable. Look-

	Elementary (N=143)				High-school (N=47)				College (N=60)	
	Evidence		Reasoning		Evidence		Reasoning		Reasoning	
	D	U	D	U	D	U	D	U	D	U

Table 7: Extrinsic evaluation: significant correlations using predicted desirability that are consistent with using gold labels are marked bold (* $p < .05$, $N = \#Students$, D: Desirable, U: Undesirable).

Original Draft	Revised Draft	Gold	M	+SC	+LC	+F	+LC&F
	They can do that by assuring that the people of Sauri, Kenya have food, water, liter, and a place to stay.	D R	U	U	D	U	D
We think \$5 dollars isn't that much money but they live in poverty.	We think \$5 dollars isn't that much money but they live in situations where \$5 is a weeks worth of money.	D E	D	U	U	D	U
	They had water, food, electricity, supplies, medicine, and simple things.	U E	D	U	U	D	U

Table 8: Revision examples with gold and predicted labels. D: Desirable, U: Undesirable, E: Evidence, R: Reasoning

ing at this revision (sentence 3) and its context from Table 1, we can see that sentence 3 mentions about the ‘people’, ‘food, water, liter, and a place to stay’. The context mention ‘people’, ‘health care’ and ‘quality of life’. We think those phrases helped the context model to identify this example as desirable. However, although feedback messages asked to ‘explain the evidence’, the feedback model was not successful in identifying this as desirable.

The second example is a desirable evidence predicted as undesirable by context and desirable by the feedback model. The AWE feedback asked the student to use more evidence and add details. We think the feedback model tied the extra information in the modified sentence to what was asked for.

The last example is an undesirable evidence predicted correctly only by the models using context information. Although the example text resembles a desirable evidence, it is actually undesirable because it was repeated. Obviously, the model needed context to identify that it is a repeated evidence.

7 Conclusion

In this study, we presented new models for the automatic identification of desirable revisions in three corpora of argumentative writing varying in writer’s level of expertise, source of feedback, and grading rubrics. We presented a new method of extracting context from essay revisions. Using intrinsic and extrinsic evaluation we showed that models using the context information performed best in identifying desirable revisions. We also studied the use of feedback messages received by students to predict desirable revisions. To the best of our knowledge this is the first model to use feedback information to analyze student revision. Our experiments showed that feedback information also helped improve classifier performance, particularly when used with context. We have released the college data annotated with revision desirability. It can be downloaded from this link: <https://petal-cs-pitt.github.io/data.html>. The code is also available from here: <https://github.com/tazin-afrin/desirable-revision-classification>

Acknowledgements

The research reported here was supported, in whole or in part, by the National Science Foundation (NSF) grant 1735752 and 2202347 to the University of Pittsburgh. We would like to thank the anonymous reviewers for taking the time to review our paper and provide us with detailed feedback. We would also like to thank the members of the PETAL lab for their valuable feedback. The opinions expressed are those of the authors and do not represent the views of the Institute.

Discussion of Limitations

Our use of both context and feedback could be enhanced in future work. First, we sometimes needed to truncate context or feedback from the end, which may remove useful information. In the future, we plan to use other transformer architectures capable of handling longer sequences (e.g., Longformer (Beltagy et al., 2020)). Second, while our proposed method of extracting longer context enables the use of variable length context windows, our method does not guarantee that the context will include the major claim. Since evidence and reasoning are most effective when used to support a claim, their revision desirability might depend on the essay's claim. Third, since the feedback received by students was largely framed at the essay-level, we did not attempt to connect the messages with specific sentence revisions. Such modeling could potentially improve feedback performance.

Additional limitations include that our classifier input was based on perfect alignment of the sentences in the essay drafts and used gold evidence and reasoning revision purpose labels. An end-to-end system would have lower performance due to errors propagated from alignment and purpose classification. Our data is also limited in that essays are all of an argumentative writing style and annotated for only two types of content revisions. Also, the corpus is small. Although, we used simple augmentation to generate enough data to experiment with complex learning models, in the future we plan to explore other options for data augmentation. We also would like to use similar argumentative essays to fine-tune the BERT architecture.

Ethical Considerations

All corpora were collected under protocols approved by an institutional review board, including

that the data is not publicly available, except the college data. While the breach of private student information from the elementary and high school data will thus not pose any ethical concern, other researchers can not replicate our results for those data. However, since the college data with its purpose annotations was already made available by the original researchers, our new desirability annotations can be released upon acceptance of this study. The claims of the paper match the experimental results and the results can be hypothesized to generalize. In the future, the proposed models may be incorporated into AWE systems for student writers. While identifying and providing feedback on revision desirability will be helpful to students in improving their writing, there is the risk that the system might sometimes provide poor advice based on incorrect model classifications. Since the dataset is still fairly small after data augmentation, it is possible that the model may learn biased representation of the revisions (e.g., always predict longer revisions with more information as desirable).

Abstract

Discourse processing suffers from data sparsity, especially for dialogues. As a result, we explore approaches to build discourse structures for dialogues, based on attention matrices from Pre-trained Language Models (PLMs). We investigate multiple tasks for fine-tuning and show that the dialogue-tailored Sentence Ordering task performs best. To locate and exploit discourse information in PLMs, we propose an unsupervised and a semi-supervised method. Our proposals thereby achieve encouraging results on the STAC corpus, with F₁ scores of 57.2 and 59.3 for the unsupervised and semi-supervised methods, respectively. When restricted to projective trees, our scores improved to 63.3 and 68.1.

1 Introduction

In recent years, the availability of accurate transcription methods and the increase in online communication have led to a vast rise in dialogue data, necessitating the development of automatic analysis systems. For example, summarization of meetings or exchanges with customer service agents could be used to enhance collaborations or analyze customers issues (Li et al., 2019; Feng et al., 2021); machine reading comprehension in the form of question-answering could improve dialogue agents' performance and help knowledge graph construction (He et al., 2021; Li et al., 2021). However, simple surface-level features are oftentimes not sufficient to extract valuable information from conversations (Qin et al., 2017). Rather, we need to understand the semantic and pragmatic relationships organizing the dialogue, for example through the use of discourse information.

Along this line, several discourse frameworks have been proposed, underlying a variety of annotation projects. For dialogues, data has been primarily annotated within the Segmented Discourse Representation Theory (SDRT) (Asher et al., 2003).

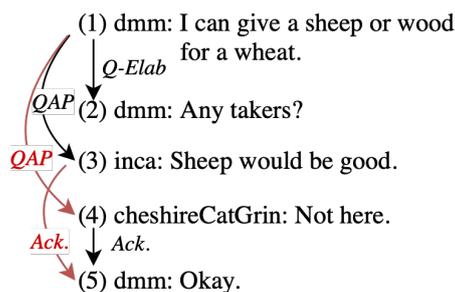

Figure 1: Excerpt of dependency structures in file *s2-leagueM-game4*, STAC. Red links are non-projective.

Discourse structures are thereby represented as dependency graphs with arcs linking spans of text and labeled with semantico-pragmatic relations (e.g. *Acknowledgment* (Ack) or *Question-Answer Pair* (QAP)). Figure 1 shows an example from the Strategic Conversations corpus (STAC) (Asher et al., 2016). Discourse processing refers to the retrieval of the inherit structure of coherent text, and is often separated into three tasks: EDU segmentation, structure building (or attachment), and relation prediction. In this work, we focus on the automatic extraction of (naked) structures without discourse relations. This serves as a first critical step in creating a full discourse parser. It is important to note that naked structures have already been shown to be valuable features for specific tasks. Louis et al. (2010) mentioned that they are the most reliable indicator of importance in content selection. Xu et al. (2020); Xiao et al. (2020) on summarization, and Jia et al. (2020) on thread extraction, also demonstrated the advantages of naked structures.

Data sparsity has always been an issue for discourse parsing both in monologues and dialogues: the largest and most commonly used corpus annotated under the Rhetorical Structure Theory, the RST-DT (Carlson et al., 2001) contains 21, 789 discourse units. In comparison, the largest dialogue discourse dataset (STAC) only contains 10, 678

units. Restricted to domain and size, the performance of supervised discourse parsers is still low, especially for dialogues, with at best 73.8% F_1 for the naked structure on STAC (Wang et al., 2021). As a result, several transfer learning approaches have been proposed, mainly focused on monologues. Previous work demonstrate that discourse information can be extracted from auxiliary tasks like sentiment analysis (Huber and Carenini, 2020) and summarization (Xiao et al., 2021), or represented in language models (Koto et al., 2021) and further enhanced by fine-tuning tasks (Huber and Carenini, 2022). Inspired by the latter approaches, we are pioneering in addressing this issue for dialogues and introducing effective semi-supervised and unsupervised strategies to uncover discourse information in large pre-trained language models (PLMs). We find, however, that the monologue-inspired fine-tuning tasks are not performing well when applied to dialogues. Dialogues are generally less structured, interspersed with more informal linguistic usage (Sacks et al., 1978), and have structural particularities (Asher et al., 2016). Thus, we propose a new Sentence Ordering (SO) fine-tuning task tailored to dialogues. Building on the proposal in Barzilay and Lapata (2008), we propose crucial, dialogue-specific extensions with several novel shuffling strategies to enhance the pair-wise, inter-speech block, and inter-speaker discourse information in PLMs, and demonstrate its effectiveness over other fine-tuning tasks.

In addition, a key issue in using PLMs to extract document-level discourse information is how to choose the best attention head. We hypothesize that the location of discourse information in the network may vary, possibly influenced by the length and complexity of the dialogues. Therefore, we investigate methods that enables us to evaluate each attention head individually, in both unsupervised and semi-supervised settings. We introduce a new metric called “Dependency Attention Support” (DAS), which measures the level of support for the dependency trees generated by a specific self-attention head, allowing us to select the optimal head without any need for supervision. We also propose a semi-supervised approach where a small validation set is used to choose the best head.

Experimental results on the STAC dataset reveal that our unsupervised and semi-supervised methods outperform the strong LAST baseline (F_1 56.8%, Sec. 4), delivering substantial gains on the com-

plete STAC dataset (F_1 59.3%, Sec. 5.2) and show further improvements on the tree-structured subset (F_1 68.1%, Sec. 6.3).

To summarize, our contributions in this work are: (1) Discourse information detection in pre-trained and sentence ordering fine-tuned LMs; (2) Unsupervised and semi-supervised methods for discourse structure extraction from the attention matrices in PLMs; (3) Detailed quantitative and qualitative analysis of the extracted discourse structures.

2 Related Work

Discourse structures for complete documents have been mainly annotated within the Segmented Discourse Representation Theory (SDRT) (Asher et al., 2003) or the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), with the latter leading to the largest corpora and many discourse parsers for monologues, while SDRT is the main theory for dialogue corpora, i.e., STAC (Asher et al., 2016) and Molweni (Li et al., 2020). In SDRT, discourse structures are dependency graphs with possibly non-projective links (see Figure 1) compared to constituent trees structures in RST. Early approaches to discourse parsing on STAC used varied decoding strategies, such as Maximum Spanning Tree algorithm (Muller et al., 2012; Li et al., 2014; Afantenos et al., 2012) or Integer Linear Programming (Perret et al., 2016). Shi and Huang (2019) first proposed a neural architecture based on hierarchical Gated Recurrent Unit (GRU) and reported 73.2% F_1 on STAC for naked structures. Recently, Wang et al. (2021) adopted Graph Neural Networks (GNNs) and reported marginal improvements on the same test set (73.8% F_1).

Data sparsity being the issue, a new trend towards semi-supervised and unsupervised discourse parsing has emerged, almost exclusively for monologues. Huber and Carenini (2019, 2020) leveraged sentiment information and showed promising results in cross-domain setting with the annotation of a silver-standard labeled corpus. Xiao et al. (2021) extracted discourse trees from neural summarizers and confirmed the existence of discourse information in self-attention matrices. Another line of work proposed to enlarge training data with a combination of several parsing models, as done in Jiang et al. (2016); Kobayashi et al. (2021); Nishida and Matsumoto (2022). In a fully unsupervised setting, Kobayashi et al. (2019) used similarity and dissimilarity scores for discourse tree creation, a

method that can not be directly used for discourse graphs though. As for dialogues, transfer learning approaches are rare. [Badene et al. \(2019a,b\)](#) investigated a weak supervision paradigm where expert-composed heuristics, combined to a generative model, are applied to unseen data. Their method, however, requires domain-dependent annotation and a relatively large validation set for rule verification. Another study by [Liu and Chen \(2021\)](#) focused on cross-domain transfer using STAC (conversation during online game) and Molwani (Ubuntu forum chat logs). They applied simple adaptation strategies (mainly lexical information) on a SOTA discourse parser and showed improvement compared to bare transfer: trained on Molwani and tested on STAC F_1 increased from 42.5% to 50.5%. Yet, their model failed to surpass simple baselines. Very recently, [Nishida and Matsumoto \(2022\)](#) investigated bootstrapping methods to adapt BERT-based parsers to out-of-domain data with some success. In comparison to all this previous work, to the best of our knowledge, we are the first to propose a fully unsupervised method and its extension to a semi-supervised setting.

As pre-trained language models such as BERT ([Devlin et al., 2019](#)), BART ([Lewis et al., 2020](#)) or GPT-2 ([Radford et al., 2019](#)) are becoming dominant in the field, *BERTology* research has gained much attention as an attempt to understand what kind of information these models capture. Probing tasks, for instance, can provide fine-grained analysis, but most of them only focus on sentence-level syntactic tasks ([Jawahar et al., 2019](#); [Hewitt and Manning, 2019](#); [Mareček and Rosa, 2019](#); [Kim et al., 2019](#); [Jiang et al., 2020](#)). As for discourse, [Zhu et al. \(2020\)](#) and [Koto et al. \(2021\)](#) applied probing tasks and showed that BERT and BART encoders capture more discourse information than other models, like GPT-2. Very recently, [Huber and Carenini \(2022\)](#) introduced a novel way to encode long documents and explored the effect of different fine-tuning tasks on PLMs, confirming that pre-trained and fine-tuned PLMs both can capture discourse information. Inspired by these studies on monologues, we explore the use of PLMs to extract discourse structures in dialogues.

3 Method: from Attention to Discourse

3.1 Problem Formulation and Simplifications

Given a dialogue D with n *Elementary Discourse Units* (EDUs) $\{e_1, e_2, e_3, \dots, e_n\}$, which are the

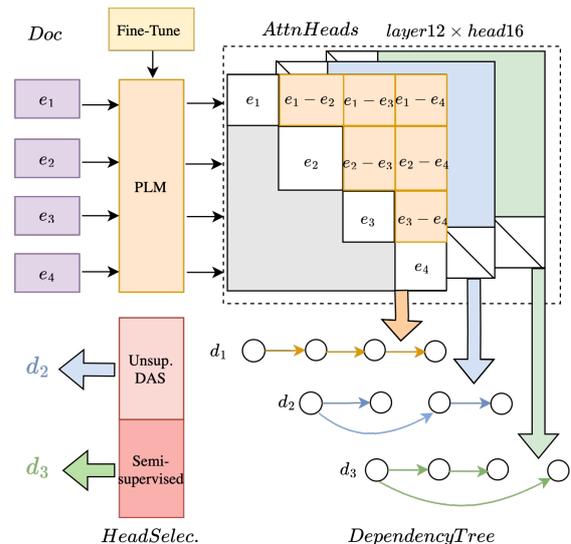

Figure 2: Pipeline for discourse structure extraction.

minimal spans of text (mostly clauses, at most a sentence) to be linked by discourse relations, the goal is to extract a Directed Acyclic Graph (DAG) connecting the n EDUs that best represents its SDRT discourse structure from attention matrices in PLMs¹ (see Figure 2 for an overview of the process). In our proposal, we make a few simplifications, partially adopted from previous work. We do not deal with SDRT *Complex Discourse Units* (CDUs) following [Muller et al. \(2012\)](#) and [Afanenos et al. \(2015\)](#), and do not tackle relation type assignment. Furthermore, similar to [Shi and Huang \(2019\)](#), our solution can only generate discourse trees. Extending our algorithm to non-projective trees ($\approx 6\%$ of edges are non-projectives in tree-like examples) and graphs ($\approx 5\%$ of nodes with multiple incoming arcs) is left as future work.

3.2 Which kinds of PLMs to use?

We explore both vanilla and fine-tuned PLMs, as they were both shown to contain discourse information for monologues ([Huber and Carenini, 2022](#)).

Pre-Trained Models: We select BART ([Lewis et al., 2020](#)), not only because its encoder has been shown to effectively capture discourse information, but also because it dominated other alternatives in preliminary experiments, including DialoGPT ([Zhang et al., 2020](#)) and DialogLM ([Zhong et al., 2022](#)) - language models pre-trained with conversational data².

¹For more details on extracting discourse information from attention mechanisms see [Liu and Lapata \(2018\)](#).

²See Appendix E for additional results with other PLMs.

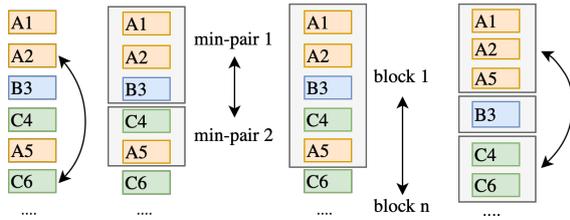

Figure 3: Shuffling strategies (left to right: partial, minimal-pair, block, speaker-turn) on a sequence of utterances 1 to 6, with A, B, C as the speakers.

Fine-Tuning Tasks: We fine-tune BART on three discourse-related tasks:

(1) **Summarization:** we use BART fine-tuned on the popular CNN-DailyMail (CNN-DM) news corpus (Nallapati et al., 2016), as well as on the SAMSum dialogue corpus (Gliwa et al., 2019).

(2) **Question Answering:** we use BART fine-tuned on the latest version of the Stanford Question Answering Dataset (SQuAD 2.0) (Rajpurkar et al., 2018).

(3) **Sentence Ordering:** we fine-tune BART on the Sentence Ordering task – reordering a set of shuffled sentences to their original order. We use an in-domain and an out-of-domain dialogue datasets (Sec. 4) for this task. Since fully random shuffling showed very limited improvements, we considered additional strategies to support a more gradual training tailored to dialogues. Specifically, as shown in Figure 3, we explore: (a) *partial-shuf*: randomly picking 3 utterances in a dialogue (or 2 utterances if the dialogue is shorter than 4) and shuffling them while maintaining the surrounding context. (b) *minimal-pair-shuf*: shuffling minimal pairs, comprising of a pair of speech turns from 2 different speakers with at least 2 utterances. A speech turn marks the start of a new speaker’s turn in the dialogue. (c) *block-shuf*: shuffling a block containing multiple speech turns. We divide one dialogue into $[2, 5]$ blocks based on the number of utterances³ and shuffle between blocks. (d) *speaker-turn-shuf*: grouping all speech productions of one speaker together. The sorting task consists of ordering speech turns from different speakers’ production. We evenly combine all permutations mentioned above to create our **mixed-shuf** data set and conduct the SO task.

³Block size is designed to be as twice or 3 times bigger than “min-pair”, we thus set criteria aiming to have ≈ 6 EDUs per block: $|utt.| < 12 : b = 2$, $|utt.| \in [12, 22] : b = 3$, $|utt.| \in [22, 33] : b = 4$, $|utt.| \geq 33 : b = 5$.

Choice of Attention Matrix: The BART model contains three kinds of attention matrices: encoder, decoder and cross attention. We use the encoder attention in this work, since it has been shown to capture most discourse information (Koto et al., 2021) and outperformed the other alternatives in preliminary experiments on a validation set.

3.3 How to derive trees from attention heads?

Given an attention matrix $A^t \in \mathbb{R}^{k \times k}$ where k is the number of tokens in the input dialogue, we derive the matrix $A^{edu} \in \mathbb{R}^{n \times n}$, with n the number of EDUs, by computing $A^{edu}(i, j)$ as the average of the submatrix of A^t corresponding to all the tokens of EDUs e_i and e_j , respectively. As a result, A^{edu} captures how much EDU e_i depends on EDU e_j and can be used to generate a tree connecting all EDUs by maximizing their dependency strength. Concretely, we find a Maximum Spanning Tree (MST) in the fully-connected dependency graph A^{edu} using the Eisner algorithm (Eisner, 1996). Conveniently, since an utterance cannot be anaphorically and rhetorically dependent on following utterances in a dialogue, as they are previously unknown (Afantenos et al., 2012), we can further simplify the inference by applying the following hard constraint to remove all backward links from the attention matrix A^{edu} : $a_{ij} = 0$, if $i > j$.

3.4 How to find the best heads?

Xiao et al. (2021) and Huber and Carenini (2022) showed that discourse information is not evenly distributed between heads and layers. However, they do not provide a strategy to select the head(s) containing most discourse information. Here, we propose two effective selection methods: fully unsupervised or semi-supervised.

3.4.1 Unsupervised Best Head(s) Selection

Dependency Attention Support Measure (DAS): Loosely inspired by the confidence measure in Nishida and Matsumoto (2022), where the authors define the confidence of a teacher model based on predictive probabilities of the decisions made, we propose a DAS metric measuring the degree of support for the maximum spanning (dependency) tree (MST) from the attention matrix. Formally, given a dialogue g with n EDUs, we first derive the EDU matrix A^{edu} from its attention matrix A^g (see Sec. 3.3). We then build the MST T^g by selecting $n - 1$ attention links l_{ij} from A^{edu} based on the tree generation algorithm. DAS measures the strength

of all those connections by computing the average score of all the selected links:

$$DAS(T^g) = \frac{1}{n-1} \sum_{i=1}^n \sum_{j=1}^n Sel(A^g, i, j) \quad (1)$$

with $Sel(A^g, i, j) = A_{ij}^g$, if $l_{ij} \in T^g$, 0 otherwise. Note that DAS can be easily adapted for a general graph by removing the restriction to $n - 1$ arcs.

Selection Strategy: With DAS, we can now compute the degree of support from each attention head h on each single example g for the generated tree $DAS(T_h^g)$. We therefore propose two strategies to select attention heads based on the DAS measure, leveraging either global or local support. The **global** support strategy selects the head with highest averaged DAS score over all the data examples:

$$H_{global} = \arg \max_h \sum_{g=1}^M DAS(T_h^g) \quad (2)$$

where M is the number of examples. In this way, we select the head that has a generally good performance on the target dataset.

The second strategy is more adaptive to each document, by only focusing on the **local** support. It does not select one specific head for the whole dataset, but instead selects the head/tree with the highest support for each single example g , i.e.,

$$H_{local}^g = \arg \max_h DAS(T_h^g) \quad (3)$$

3.4.2 Semi-Supervised Best Head(s) Selection

We also propose best heads selection using a few annotated examples. In conformity with real-world situations where labeled data is scarce, we sample three small subsets with $\{10, 30, 50\}$ data points (i.e., dialogues) from the validation set. We examine every attention matrix individually, resulting in $12 \text{ layers} \times 16 \text{ heads}$ candidate matrices for each dialogue. Then, the head with the highest micro- F_1 score on the validation set is selected to derive trees in the test set. We also consider layer-wise aggregation, with details in Appendix A.

4 Experimental Setup

Datasets: We evaluate our approach on predicting discourse dependency structures using the STAC corpus (Asher et al., 2016), a multi-party dialogue dataset annotated in the SDRT framework. For the summarization and question-answering

Dataset	#Doc	#Utt/doc	#Tok/doc	#Spk/doc	Domain
DailyDialog	13,118	13	119	2	Daily
STAC	1,161	11	50	3	Game

Table 1: Key statistics of datasets. Utt = sentences in DD or EDUs in STAC; Tok = tokens; Spk = speakers.

fine-tuning tasks, we use publicly available HuggingFace models (Wolf et al., 2020) (see Appendix F). For the novel sentence ordering task, we train BART model on the STAC corpus and the DailyDialog corpus (Li et al., 2017). The key statistics for STAC and DailyDialog can be found in Table 1. These datasets are split into train, validation, and test sets at 82%, 9%, 9% and 85%, 8%, 8% respectively. The Molweni corpus (Li et al., 2020) is not included in our experiments due to quality issues, as detailed in Appendix B.

Baselines: We compare against the simple yet strong unsupervised LAST baseline (Schegloff, 2007), attaching every EDU to the previous one. Furthermore, to assess the gap between our approach and supervised dialogue discourse parsers, we compare with the Deep Sequential model by Shi and Huang (2019) and the Structure Self-Aware (SSA) model by Wang et al. (2021).

Metrics: We report the micro- F_1 and the Unlabeled Attachment Score (UAS) for the generated naked dependency structures.

Implementation Details: We base our work on the transformer implementations from the HuggingFace library (Wolf et al., 2020) and follow the *text-to-marker* framework proposed in Chowdhury et al. (2021) for the SO fine-tuning procedure. We use the original separation of train, validation, and test sets; set the learning rate to $5e - 6$; use a batch size of 2 for DailyDialog and 4 for STAC, and train for 7 epochs. All other hyper-parameters are set following Chowdhury et al. (2021). We do not do any hyper-parameter tuning. We omit 5 documents in DailyDialog during training since the documents lengths exceed the token limit. We replace speaker names with markers (e.g. Sam \rightarrow "spk1"), following the preprocessing pipeline for dialogue utterances in PLMs.

5 Results

5.1 Results with Unsupervised Head Selection

Results using our novel unsupervised DAS method on STAC are shown in Table 2 for both the global

(H_g) and local (H_l) head selection strategies. These are compared to: (1) the unsupervised LAST baseline (at the top), which only predicts local attachments between adjacent EDUs. LAST is considered a strong baseline in discourse parsing (Muller et al., 2012), but has the obvious disadvantage of completely missing long-distance dependencies which may be critical in downstream tasks. (2) The supervised Deep Sequential parser by Shi and Huang (2019) and Structure Self-Aware model by Wang et al. (2021) (center of the table), both trained on STAC, reaching resp. 71.4%⁴ and 73.8% in F_1 .

In the last sub-table we show unsupervised scores from pre-trained and fine-tuned LMs on three auxiliary tasks: summarization, question-answering and sentence ordering (SO) with the mixed shuffling strategy. We present the global head (H_g) and local heads (H_l) performances selected by the DAS score (see section 3.4.1). The best possible scores using an oracle head selector (H_{ora}) are presented for reference.

Comparing the values in the bottom sub-table, we find that the pre-trained BART model underperforms LAST (56.8), with global head and local heads achieving similar performance (56.6 and 56.4 resp.). Noticeably, models fine-tuned on the summarization task (“+CNN”, “+SAMSum”) and question-answering (“+SQuAD2”) only add marginal improvements compared to BART. In the last two lines of the sub-table, we explore our novel sentence ordering fine-tuned BART models. We find that the BART+SO approach surpasses LAST when using local heads (57.1 and 57.2 for DailyDialog and STAC resp.). As commonly the case, the intra-domain training performs best, which is further strengthened in this case due to the special vocabulary in STAC. Importantly, our PLM-based unsupervised parser can capture some long-distance dependencies compared to LAST (Section 6.2). Additional analysis regarding the chosen heads is in Section 6.1.

5.2 Results with Semi-Sup. Head Selection

While the unsupervised strategy only delivered minimal improvements over the strong LAST baseline, Table 3 shows that if a few annotated examples are provided, it is possible to achieve substantial gains. In particular, we report results on the vanilla BART model, as well as BART model fine-

⁴We re-train the model, scores are slightly different due to different train-test splits, as in Wang et al. (2021).

Model			
<i>Unsupervised Baseline</i>

Semi-sup 10	57.0 _{0.012}	57.2 _{0.012}	57.1 _{0.026}
Semi-sup 30	57.3 _{0.005}	57.3 _{0.013}	59.2 _{0.009}
Semi-sup 50	57.4_{0.004}	57.7_{0.005}	59.3_{0.007}

Table 3: Micro- F_1 on STAC from BART and SO fine-tuned BART with unsupervised and semi-supervised approaches. Semi-supervised scores are averaged from 10 random runs. Subscription is standard deviation.

tuned on DailyDialog (“+SO-DD”) and STAC itself (“+SO-STAC”). We execute 10 runs for each semi-supervised setting ([10, 30, 50]) and report average scores and the standard deviation.

The oracle heads (i.e., H_{ora}) achieve superior performance compared to LAST. Furthermore, using a small scale validation set (50 examples) to select the best attention head remarkably improves the F_1 score from 56.8% (LAST) to 59.3% (+SO-STAC). F_1 improvements across increasingly large validation-set sizes are consistent, accompanied by smaller standard deviations, as would be expected. The semi-supervised results are very encouraging: with 30 annotated examples, we already reach a performance close to the oracle result, and with more examples we can further reduce the gap.

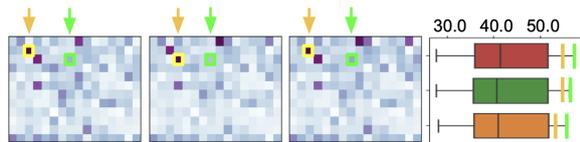

Figure 4: Heatmaps: DAS score matrices (layers: top to bottom=12 to 1, heads: left to right=1 to 16) for BART, BART+SO-DD, BART+SO-STAC. Darker purple=higher DAS score.

Boxplot: Head-aggregated UAS scores for model BART (orange), BART+SO-DD (green) and BART+SO-STAC (red). Light green=head with highest UAS. Yellow=head with highest DAS score.

6 Analysis

6.1 Effectiveness of DAS

We now take a closer look at the performance degradation of our unsupervised approach based on DAS in comparison to the upper-bound defined by the performance of the oracle-picked head. To this end, Figure 4 shows the DAS score matrices (left) for three models with the oracle heads and DAS selected heads highlighted in green and yellow, respectively. These scores correspond to the global support strategy (i.e., H_g). It becomes clear that the oracle heads do not align with the DAS selected heads. Making a comparison between models, we find that discourse information is consistently located in deeper layers, with the oracle heads (light green) consistently situated in the same head for all three models. It is important to note that this information cannot be determined beforehand and can only be uncovered through a thorough examination of all attention heads.

While not aligning with the oracle, the top performing DAS heads (in yellow) are among the top 10% best heads in all three models, as shown in the box-plot on the right. Hence, we confirm that the DAS method is a reasonable approximation to find discourse intense self-attention heads among the 12×16 attention matrices.

6.2 Document and Arc Lengths

The inherent drawback of the simple, yet effective LAST baseline is its inability to predict indirect arcs. To test if our approach can reasonably predict distant arcs of different length in the dependency trees, we analyze our results in regards to the arc lengths. Additionally, since longer documents tend to contain more distant arcs, we also examine the performance across different document lengths.

Arc Distance: To examine the extracted discourse structures for data sub-sets with specific arc lengths, we present the UAS score plotted against different arc lengths on the left side in Figure 5. Our analysis thereby shows that direct arcs achieve high UAS score ($> 80\%$), independent of the model used. We further observe that the performance drops considerably for arcs of distance two and onwards, with almost all models failing to predict arcs longer than 6. BART+SO-STAC model correctly captures an arc of distance 13. Note that the presence for long-distance arcs (≥ 6) is limited, accounting for less than 5% of all arcs.

We further analyze the precision and recall scores when separating dependency links into *direct* (adjacent forward arcs) and *indirect* (all other non-adjacent arcs), following Xiao et al. (2021). For direct arcs, all models perform reasonably well (see Figure 6 at the bottom). The precision is higher ($\approx +6\%$ among all three BART models) and recall is lower than the baseline (100%), indicating that our models predict less direct arcs but more precisely. For indirect arcs (top in Figure 6), the best model is BART+SO-STAC (20% recall, 44% precision), closely followed by original BART (20% recall, 41% precision). In contrast, the LAST baseline model completely fails in this scenario (0 precision and recall).

Document Length: Longer documents tend to be more difficult to process because of the growing number of possible discourse parse trees. Hence, we analyze the UAS performance of documents in regards to their length, here defined as the number of EDUs. Results are presented on the right side in Figure 5, comparing the UAS scores for the three selected models and LAST for different document lengths. We split the document length range into 5 even buckets between the shortest (2 EDUs) and longest (37 EDUs) document, resulting in 60, 25, 16, 4 and 4 examples per bucket.

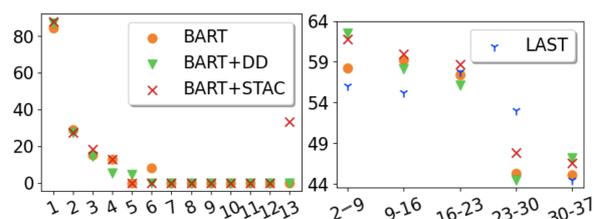

Figure 5: Left: UAS and arcs' distance. x axis: arc distance. Right: averaged UAS for different length of document. x axis: #EDUs in a document. y axis: UAS.

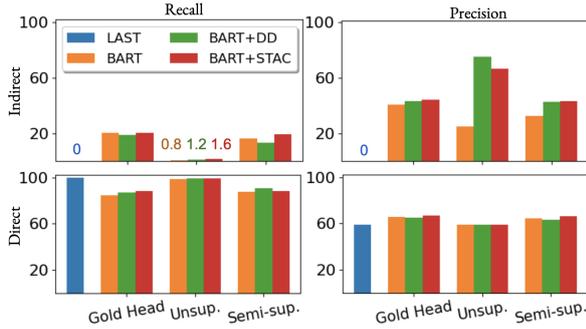

Figure 6: Comparison of recall (left) and precision (right) scores of indirect (top) and direct (bottom) links in LAST, BART, and SO fine-tuned BART models.

	#Doc	#EDUs		#Arcs	
		Single-in	Multi-in	Proj.	N-proj.
(1) Non-Tree	48	706	79	575	170
(2) Tree	61	444	0	348	35
- Proj. tree	48	314	0	266	0

Table 4: STAC test set ground-truth tree and non-tree statistics. “Single-in” and “multi-in” means EDU with single or multiple incoming arcs.

For documents with less than 23 EDUs, all fine-tuned models perform better than LAST, with BART fine-tuned on STAC reaching the best result. We note that PLMs exhibit an increased capability to predict distant arcs in longer documents. However, in the range of [23, 30], the PLMs are inclined to predict a greater number of false positive distant arcs, leading to under-performance compared to the LAST baseline. As a result, we see that longer documents (≥ 23) are indeed more difficult to predict, with even the performance of our best model (BART+STAC) strongly decreasing.

6.3 Projective Trees Examination

Given the fact that our method only extracts projective tree structures, we now conduct an additional analysis, exclusively examining the subset of STAC containing projective trees, on which our method could in theory achieve perfect accuracy.

Table 4 gives some statistics for this subset (“proj. tree”). For the 48 projective tree examples, the document length decreases from an average of 11 to 7 EDUs, however, still contains $\approx 40\%$ indirect arcs, keeping the task difficulty comparable. The scores for the extracted structures are presented in Table 5. As shown, all three unsupervised models outperform LAST. The best model is still BART fine-tuned on STAC, followed by the inter-domain

Train on \rightarrow	BART	+ SO-DD	+ SO-STAC
Test with \downarrow	F ₁	F ₁	F ₁
LAST BSL	62.0	62.0	62.0
H _{ora}	64.8	67.4	68.6
Unsup H _g	<u>62.5</u>	62.5	62.1
Unsup H _t	62.1	<u>62.9</u>	<u>63.3</u>
Semi-sup 10	54.6 _{0.058}	59.2 _{0.047}	61.6 _{0.056}
Semi-sup 30	60.3 _{0.047}	60.3 _{0.044}	65.6 _{0.043}
Semi-sup 50	64.8_{0.000}	66.3_{0.023}	68.1_{0.014}

Table 5: Micro-F₁ scores on STAC projective tree subset with BART and SO fine-tuned BART models.

	Avg.branch	Avg.height	%leaf	Norm. arc
GT	1.67	3.96	0.46	0.43
BART	1.20	5.31	0.31	0.34
+SO-DD	1.32 _{0.014}	5.31 _{0.146}	0.32 _{0.019}	0.37 _{0.003}
+SO-STAC	1.27 _{0.076}	5.28 _{0.052}	0.32 _{0.011}	0.35 _{0.015}

Table 6: Statistics for gold and extracted projective trees in BART and fine-tuned BART models.

fine-tuned +SO-DD and BART models. Using the semi-supervised approach, we see further improvement with the F₁ score reaching 68% (+6% than LAST). Degradation for direct and indirect edges’ precision and recall scores see Appendix C.

Following Ferracane et al. (2019), we analyze key properties of the 48 gold trees compared to our extracted structures using the semi-supervised method. To test the stability of the derived trees, we use three different seeds to generate the shuffled datasets to fine-tune BART. Table 6 presents the averaged scores and the standard deviation of the trees. In essence, while the extracted trees are generally “thinner” and “taller” than gold trees and contain slightly less branches, they are well aligned with gold discourse structures and do not contain “vacuous” trees, where all nodes are linked to one of the first two EDUs. Further qualitative analysis of inferred structures is presented in Appendix D. Tellingly, on two STAC examples our model succeeds in predicting $> 82\%$ of projective arcs, some of which span across 4 EDUs. This is encouraging, providing anecdotal evidence that our method is suitable to extract reasonable discourse structures.

6.4 Performance with Predicted EDUs

Following previous work, all our experiments have started with gold-standard EDU annotations. However, this would not be possible in a deployed dis-

Gold #	Predicted #	Precision %	Recall %	F ₁ %
1155	1081	96.0	93.4	94.8

Table 7: EDU segmentation results on STAC test set using DisCoDisCo model (Gessler et al., 2021), which is re-trained on 50 random dialogues from the validation set. Scores are averaged over three runs.

	LAST	Unsupervised			Semi-supervised		
		H _g	H _l	H _{ora}	semi-10	semi-30	semi-50
Gold	56.8	56.7	57.2	59.5	57.4 _{0.004}	57.7 _{0.005}	59.3_{0.007}
Pred	48.9	50.8	51.1	52.6	50.6 _{0.020}	52.1 _{0.007}	52.2_{0.004}

Table 8: Gold EDUs and predicted EDUs parsing results with BART+SO-STAC model. Scores for predicted EDUs are averaged over three runs.

course parser for dialogues. To assess the performance of such system, we conduct additional experiments in which we first perform EDU segmentation and then feed the predicted EDUs to our methods.

To perform EDU segmentation, we employ the DisCoDisCo model (Gessler et al., 2021), pre-trained on a random sample of 50 dialogues from the STAC validation set. We repeat this process three times to accommodate instability. Our results, as shown in Table 7, align with those previously reported in Gessler et al. (2021) (94.9), with an F-score of 94.8. In the pre-training phase, we utilize all 12 hand-crafted features⁵, and opt for treebanked data for enhanced performance (94.9 compared to 91.9 for plain text data). The treebanked data is obtained using the Stanza Toolkit (Qi et al., 2020).

For evaluation, we adapt the discourse analysis pipeline proposed by Joty et al. (2015). The results are shown in Table 8, comparing the predicted and gold EDUs. The best head (i.e., H_{ora}) performance decreases by ≈ 7 points, from 59.5 to 52.6, as well as unsupervised and semi-supervised results. Despite the drop, our unsupervised and semi-supervised models still outperform the LAST baseline. A similar loss of ≈ 6 points is also observed for RST-style parsing in monologues, as reported in Nguyen et al. (2021).

7 Conclusion

In this study, we explore approaches to build naked discourse structures from PLMs attention matrices to tackle the extreme data sparsity issue in dialogues. We show sentence ordering to be the best

⁵Such as POS tag, UD deprel, sentence length, etc..

fine-tuning task and our unsupervised and semi-supervised methods for selecting the best attention head outperform a strong baseline, delivering substantial gains especially on tree structures. Interestingly, discourse is consistently captured in deeper PLMs layers, and more accurately for shorter links.

In the near future, we intend to explore graph-like structures from attention matrices, for instance, by extending treelike structures with additional arcs of high DAS score and applying linguistically motivated constraints, as in Perret et al. (2016). We would also like to expand shuffling strategies for sentence ordering and to explore other auxiliary tasks. In the long term, our goal is to infer full discourse structures by incorporating the prediction of rhetorical relation types, all while remaining within unsupervised or semi-supervised settings.

Limitations

Similarly to previous work, we have focused on generating only projective tree structures. This not only covers the large majority of the links ($\approx 94\%$), but it can also provide the backbone for accurately inferring the remaining non-projective links in future work. We focus on the naked structure, as it is a significant first step and a requirement to further predict relations for discourse parsing.

We decided to run our experiments on the only existing high quality corpus, i.e., STAC. In essence, we traded-off generalizability for soundness of the results. A second corpus we considered, Molweni, had to be excluded due to serious quality issues.

Lastly, since we work with large language models and investigate every single attention head, computational efficiency is a concern. We used a 4-core GPU machine with the highest VRAM at 11MiB. The calculation for one discourse tree on one head was approximately 0.75 seconds (in STAC the averaged dialogue length is 11 EDUs), which quickly summed up to 4.5 hours with only 100 data points for 192 candidate trees in one LM. When dealing with much longer documents, for example AMI and conversational section in GUM (in average > 200 utterances/dialogue), our estimation shows that one dialogue takes up to ≈ 2 minutes, which means 6.5 hours for 192 candidate trees. Even though we use parallel computation, the exhaustive “head” computation results in a tremendous increase in time and running storage. One possibility is to investigate only those “discourse-rich” heads, mainly in the deeper layers, for future work.

Ethical Considerations

We carefully select the dialogue corpora used in this paper to control for potential biases, hate-speech and inappropriate language by using human annotated corpora and professionally curated resources. Further, we consider the privacy of dialogue partners in the selected datasets by replacing names with generic user tokens.

Since we are investigating the nature of the discourse structures captured in large PLMs, our work can be seen as making these models more transparent. This will hopefully contribute to avoid unintended negative effects, when the growing number of NLP applications relying on PLMs are deployed in practical settings.

In terms of environmental cost, the experiments described in the paper make use of RTX 2080 Ti GPUs for tree extraction and A100 GPUs for BART fine-tuning. We used up to 4 GPUs for the parallel computation. The experiments on corpus STAC took up to 1.2 hours for one language model, and we tested a dozen models. We note that while our work is based on exhaustive research on all the attention heads in PLMs to obtain valuable insights, future work will be able to focus more on discourse-rich heads, which can help to avoid the quadratic growth of computation time for longer documents.

A Semi-sup. Layer-Wise Results

We consider both **layer-wise** attention matrices - averaging 16 attention heads for every layer which gives 12 candidate layers -, and **head-wise** attention matrices - taking each attention matrix individually which results in 192 candidate matrices. Here we show results completed with layer-wise matrices for the whole test set and tree-like examples in Table 9 and Table 10.

B Molweni Corpus Quality Investigation

Molweni (Li et al., 2020) is a corpus derived from Ubuntu Chat Corpus (Lowe et al., 2015). It contains 10,000 short dialogues between 8 to 15 utterances, annotated in SDRT framework.

Considering the complexity of Ubuntu chat logs (multiple speakers, entangled discussion with various topics), we first conduct an examination of the corpus. Disappointingly, we found heavy repetition within sequential documents and inconsistency in discourse annotation among the same utterances. We thus decide not to include it in this work.

...					
105	500	4787	284	4503	606
-	-	100%	5.9%	100%	13.5%

Table 11: Quantitative resume of link and relation inconsistency in Molweni test set. “Theor =arc”: number of arcs between the same utterances, *a priori* should be linked in the same way; “Theor =rel”: number of relations between the linked utterances.

Clusters: Among 500 dialogues in discourse augmented test set, we found 105 “clusters”. One cluster groups all the documents with only one or two different utterances. For instance, document id 10 and 11 are in the same cluster since only the second utterance is different (Figure 10). A similar situation is attested in the documents {1, 2, 3}, {7, 8, 9}, {19, 20, 21}, to name a few.

Annotation Inconsistency: A closer examination of the annotation in similar examples reveals inconsistency for both discourse links and rhetorical relations. Precisely, we investigate every *document pair* (two documents in the same cluster) in all 105 clusters in the test set. A visualization of inconsistency for documents 10 and 11 is shown in Figure 10: apart from EDU₂, we expect the same links and relations among other EDUs. However, we observe one link inconsistency (in red) and two relation inconsistencies (in blue). In total, we find 6% of link errors (#Err arc) within the same EDUs and 14% of relation errors (#Err rel) in the test set⁶. The scores are shown in Table 11.

The Ubuntu Chat Corpus contains long dialogues with entangled discussion. A pre-processing had been made to generate shorter dialogues. While these slightly different short dialogues could be interesting for other dialogue studies in the field. Our focus on the discourse structure request more various data points and most importantly, the coherent discourse annotation.

C Precision and Recall Scores for Direct and Indirect Arcs in STAC Tree Set

To compare the performance of the whole test set and tree-structured subset, we present the recall and

⁶For validation and train sets we find similar error rates.

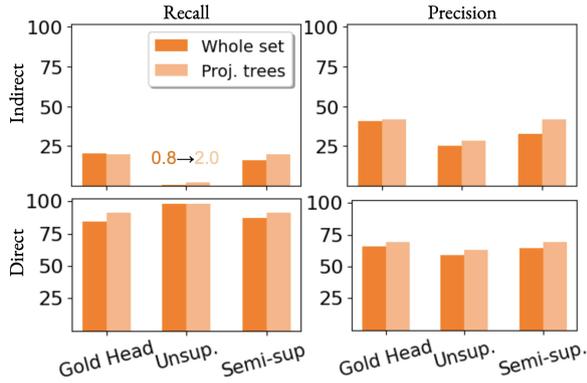

Figure 7: Recall and precision metrics in whole test set (darker color) vs. projective tree subset (brighter color), with BART model.

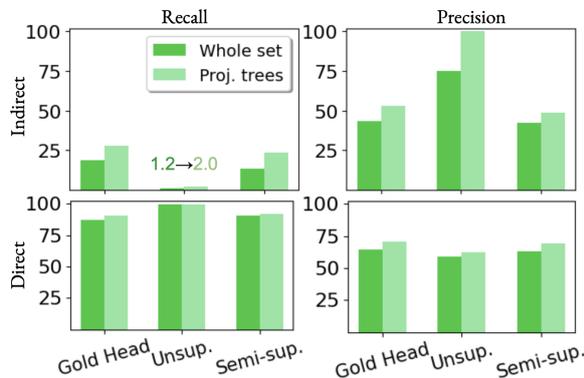

Figure 8: Recall and precision metrics in whole test set (darker color) vs. projective tree subset (brighter color), with BART+SO-DD model.

precision scores of BART (Fig. 7), BART+SO-DD (Fig. 8), and BART+SO-STAC (Fig. 9) separately.

D Qualitative Analysis in STAC

We show a few concrete tree examples: 3 well predicted (Figure 11, 12, 13), 3 badly predicted (Figure 14, 15, 16), and 2 random examples (Figure 17, 18). Some patterns observed from badly predicted structures: (1) chain-style prediction: as shown in Figure 15 and 18 where only adjacent EDUs are linked together; (2) inaccurate indirect arc prediction: especially for long documents such as the one in Figure 16.

E Results with other PLMs

We test with RoBERTa (Liu et al., 2019), DialoGPT (Zhang et al., 2020), and DialogLED (DialogLM with Longformer) (Zhong et al., 2022) to see how different language models encode discourse information. As shown in Table 12, the most discourse-rich head in RoBERTa slightly under-

Abstract

Contrastive pre-training on distant supervision has shown remarkable effectiveness in improving supervised relation extraction tasks. However, the existing methods ignore the intrinsic noise of distant supervision during the pre-training stage. In this paper, we propose a weighted contrastive learning method by leveraging the supervised data to estimate the reliability of pre-training instances and explicitly reduce the effect of noise. Experimental results on three supervised datasets demonstrate the advantages of our proposed weighted contrastive learning approach compared to two state-of-the-art non-weighted baselines. Our code and models are available at: <https://github.com/YukinoWan/WCL>.

1 Introduction

Relation extraction (RE) is the task of identifying the relationship between entities mentioned in the text, which can benefit many downstream tasks such as question answering and knowledge base population. Since most of the existing RE models (Zhang et al., 2020; Zeng et al., 2020; Lin et al., 2020; Wang and Lu, 2020; Zhong and Chen, 2021) are trained on the labeled data, the amount of training data limits the performance of supervised RE systems. To tackle this problem, recent work leverage semi-supervised distant supervision (DS) (Mintz et al., 2009; Lin et al., 2016; Vashishth et al., 2018; Chen et al., 2021) approach to generate abundant training data by aligning knowledge bases (KBs) and raw corpora. However, distantly supervised relation extraction (DSRE) inevitably suffers from wrong labeling noise. Introducing a robust framework that utilizes both the abundant but noisy data from DS and the scarce but accurate data from human annotations becomes a new research line to improve RE systems.

Recent works (Baldini Soares et al., 2019; Ormándi et al., 2021; Peng et al., 2020) propose a

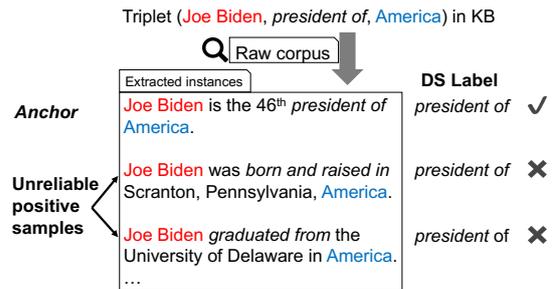

Figure 1: An example of unreliable positive samples caused by DS noise.

two-stage RE framework that they first design a RE-oriented task to pre-train BERT on DS data and then fine-tune on human-annotated (HA) datasets. Peng et al. (2020) use Wikipedia articles as the corpus and Wikidata as the KB in the pre-training stage to construct the DS data, and they introduce a contrastive learning-based method to pre-train BERT on the generated DS data. Given an anchor instance with a specific relation in the DS data, their contrastive learning method randomly selects one positive sample holding the same relation and maximizes the similarity between the anchor and positive sample. Meanwhile, their method randomly selects multiple negative samples holding different relations from the anchor and minimizes the similarity between the anchor and negative samples. The results show that their RE-oriented pre-training can effectively improve the final performance of the RE task on various target datasets.

However, in their pre-training stage, they ignore the intrinsic wrong labeling noise in the generated DS data. Since their method relies on the DS-labeled relation types to sample positive and negative instances, the noisy labeling problem leads to unreliable samples in Figure 1, potentially limiting the pre-training stage’s effectiveness. To better utilize DS data, we propose a novel weighted contrastive learning framework to both use the abundant DS data and tackle the inevitable DS noise.

First, we train a relation classifier on the HA dataset and leverage the classifier to predict the relation type of instances in the DS data. Then for each DS instance, based on the output of the classifier, we can compute the confidence score to measure the reliability of its labeled relation type. Finally, we introduce weights based on computed confidence scores into the contrastive learning loss to focus more on reliable instances while less on noisy ones.

Besides, distant supervision relies on the existing KBs to align raw corpora. To alleviate the need for KBs, we propose a new strategy to extract a triplet set from the HA dataset for generating DS data. We also include a KB-derived DS dataset in our experiments to show that our proposal can still work well for regular DS.

In conclusion, we propose a weighted contrastive pre-training approach for supervised relation extraction and introduce its details in Section 2. Then we perform the experiments on three datasets to compare our proposed method with existing baselines in Section 3.

2 Proposed Method

2.1 Overview

We show the overview of our proposal in Figure 2. We start by generating the DS data relying on the HA dataset. Then in the first stage, we introduce a weighted contrastive learning method by leveraging the HA data to estimate the reliability of DS instances for contrastive pre-training. In the second stage, we further fine-tune our pre-trained model on the HA dataset.

2.2 Distantly Supervised Dataset Construction

Since DS uses existing knowledge bases to generate training data, in the case that we have no proper existing KBs in some domains but only the annotated dataset, we first extract all entities based on each sentence, and if any two of them are labeled a relation type, they will generate a triplet with a particular relation. Otherwise, they will still generate a triplet but labeled NA (no relation). After constructing the KB, we can extract sentences containing two entities of each triplet from raw corpora. To balance the number of sentences extracted by each triplet, we also add an upper bound 100 to the number of extracted sentences.

2.3 Two-stage RE Framework

Instance representation In our pre-training stage, we use BERT to obtain the representation for each input instance. For the input format, we follow PURE (Zhong and Chen, 2021) by adding extra special markers to mark the beginning and the end of two entities. For example, given an instance x : “*Joe Biden is the president of America.*”, the input sequence is “[CLS] [H_CLS] *Joe Biden* [H_SEP] *is the president of* [T_CLS] *America* [T_SEP]. [SEP]”. Denote the k -th output vector of the BERT encoder as h_k . Assuming i and j are the indices of two beginning entity markers [H_CLS] and [T_CLS], we define the instance representation as:

$$\mathbf{x} = h_i \oplus h_j \quad (1)$$

where \oplus stands for concatenation. Then we use the instance representation for further reliability estimation and the weighted contrastive learning in the pre-training stage.

Reliability estimation With the instance representation, we first fine-tune BERT on the HA dataset as a supervised RE task. Then with the trained relation classifier \mathcal{F} , we can make predictions on each instance in the DS data. Given an input instance x with DS labeled relation r , we can derive the confidence score c to estimate its reliability by:

$$c = \frac{\exp(\mathcal{F}(\mathbf{x}, r))}{\sum_{r' \in R} \exp(\mathcal{F}(\mathbf{x}, r'))} \quad (2)$$

where R is the set of all relation classes, and $\mathcal{F}(\mathbf{x}, r)$ computes the output of our relation classifier on the labeled class r . Through this approach, we can estimate the reliability of the labeled relation for each DS instance by its corresponding confidence score.

Stage 1: DS weighted contrastive pre-training

Contrastive learning aims at maximizing the similarity between a given instance and its positive samples while minimizing the similarity between the given instance and its negative samples. As for existing work, Peng et al. (2020) focuses on the relationship level that DS instances labeled the same relation are positive samples while DS instances labeled different relations are negative samples. The latest DSRE work (Chen et al., 2021) augments the anchor as a positive sample to avoid the effect of DS noise. Both works do not explicitly address the problem of unreliable positive and negative samples.

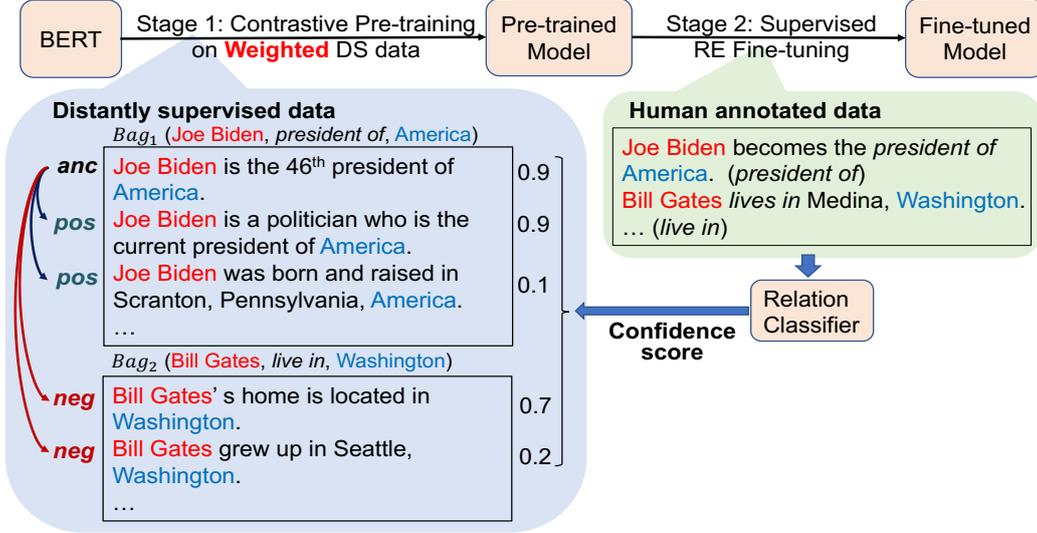

Figure 2: Overview of our proposed method.

In our work, we introduce a robust weighted contrastive learning (WCL) method with the help of reliability estimations for each instance. Given a batch input with multiple bags: ($Batch = \{B_i\}_{i=1}^G$) where G is the number of bags in one batch, and the labeled relational triplets are different from each other. Each bag B is constructed by a certain relational triplet (e_1, r, e_2) with all instances x inside satisfying this triplet. Moreover, each instance comes along with a confidence score c estimating its reliability: $B_i = \{x_j, c_j\}_{j=1}^{N_i}$, where N_i denotes the size of bag B_i . Then the weighted contrastive learning loss of an anchor instance x_j in the bag B_i is:

$$\mathcal{L}_{WCL}^{(ij)} = -\log \left\{ \sum_{k=1}^{N_i} c_j c_k e^{\cos(\mathbf{x}_j, \mathbf{x}_k)/T} / \left(\sum_{k=1}^{N_i} c_j c_k e^{\cos(\mathbf{x}_j, \mathbf{x}_k)/T} + \sum_{r_m \neq r_j} c_j c_m e^{\cos(\mathbf{x}_j, \mathbf{x}_m)/T} \right) \right\} \quad (3)$$

where $\cos(\cdot)$ denotes the cosine similarity between two instance representations, \mathbf{x}_k denotes the representation of a positive instance sampled from the same bag, and $r_m \neq r_j$ denotes that negative samples x_m are selected from all instances in the batch that is labeled a different relation from x_j . We follow (Khosla et al., 2020) to incorporate multiple positive instances sampled from the same bag. T denotes a scaling temperature.

With the help of confidence scores, the model will focus on more reliable instances while ignoring unreliable instances, which keep pace with our goal

to utilize reliable DS data.

Besides, to inherit the ability of language understanding from BERT and avoid catastrophic forgetting, we also adopt the masked language modeling (MLM) objective from BERT.

Eventually, we define our final pre-training loss:

$$\mathcal{L} = \mathcal{L}_{WCL} + \mathcal{L}_{MLM} \quad (4)$$

Stage 2: Supervised relation extraction We then fine-tune the pre-trained model on HA datasets with state-of-the-art (SOTA) methods. For i2b2 2010VA, we follow BLUEBERT (Peng et al., 2019) by treating the relation extraction task as a sentence classification and replacing two named entities in the sentence with predefined tags. For the other two datasets, we follow the encoding method of PURE (Zhong and Chen, 2021) as introduced at the beginning of Section 2.3.

3 Experiments

3.1 Setup

HA and DS datasets We evaluate our approach on three HA relation extraction datasets: i2b2 2010VA, ACE05, and Wiki20m. Table 2 shows the statistics of each dataset. The i2b2 2010VA is a medical domain RE dataset, while the other two datasets are collected from general domains. We generate the DS data for i2b2 2010VA and ACE05 from corresponding raw corpora. Meanwhile, Wiki20m is a regular KB-based distantly supervised RE dataset containing both DS data and

ing (CIL) (Chen et al., 2021) in pre-training.

Implementation details To further confirm the effectiveness of our proposal, we also conduct the experiments in the low-resource setting by randomly selecting 25% of the full HA data to construct the DS data for pre-training and finally fine-tune on this 25% HA data. Refer to Appendix A for other implementation details.

3.2 Main Results

Table 1 compares our model to other baselines. From the results, we can observe that: (1) For both the i2b2 2010VA and the Wiki20m, all two-stage models outperform the FT baseline, which indicates the effectiveness of our strategy to construct DS data from HA datasets, especially in the low-resource setting. (2) For both the i2b2 2010VA and the Wiki20m, our proposed model achieves the best F1 scores over all baselines. This improvement shows that it is worth estimating the reliability of each DS instance with the help of HA datasets in our weighted contrastive pre-training. (3) For the ACE05, the pre-training methods cannot outperform the FT baseline. To analyze this problem, we perform extra experiments on ACE05 in Section 3.3.

Besides, we also compare performances on the development set of two datasets as shown in Table 4, the experiment results emphasize the consistent improvement of our proposed methods.

3.3 Further Analysis

We find that ACE05 contains many pronoun entities, for example, "*He lives in America.*". As pronoun entities such as "*He*" naturally come along with much more severe noise in DS, we also conduct extra experiments by removing sentences containing pronoun entities in ACE05 and the corresponding DS data to confirm the effect of pronouns.

After removing pronoun entities in ACE05, as shown in Table 5, our model outperforms all baselines, including FT, which indicates that pronoun entities bring mishandled noise in the pre-training stage and limit the effect of our DS data construction approach.

4 Conclusions

We introduce a weighted contrastive pre-training method by leveraging the HA dataset to estimate the reliability of instances in the abundant DS data. To alleviate the need for KBs, we also propose to construct DS data based on the triplets derived from the HA dataset for pre-training. Experimental results demonstrate that our proposed method outperforms SOTA work on target HA datasets.

Limitations

In this paper, we propose a weighted contrastive pre-training approach for supervised relation extraction.

While our approach is simple and effective, one limitation is that the reliability estimation requires a certain amount of annotated data. Under certain settings such as few-shot learning, large-scale labeled data may not be available, and the reliability of DS data could be estimated in an unsupervised manner based on similarity-based metrics, which we leave as future work.

Another limitation is that the distant supervision of ACE05 contains additional noise caused by pronoun entities. In Section 3.3, we do the investigation by temporally removing them. In future work, we assume more strict DS extraction criteria (e.g. only entity pairs located in the same clause) might reduce the production of such noise and alleviate this situation.

A Implementation Details

During the construction of DS data, we use the preprocessing tool NLTK to split raw corpora into sentences.

Hyperparameter	Range	Best
Bag size	2-8	4
Batch size	8-32	16
Temperature	0.05-1.0	0.2

Table 6: Hyperparameter optimization.

We use *bert-base-uncased* (Devlin et al., 2019) as the base encoders for ACE05, ACE05 (no pronouns), and Wiki20m, for a fair comparison with previous works. We also use *bluebert* (Peng et al., 2019) as the base encoder for i2b2 2010VA since the SOTA performance is achieved based on this effective medical domain BERT.

For baseline models, we modify their official implementations to fit our experiments and follow the model settings in their papers. For our proposed method, the primary hyperparameters in the experiments are batch size, bag size, and contrastive learning temperature that directly influence the weighted contrastive learning loss, and we show our searching ranges and best values in Table 6.

We used 8 NVIDIA A100 for pre-training and 2 NVIDIA RTX3090 for fine-tuning.

CK-Transformer: Commonsense Knowledge Enhanced Transformers for Referring Expression Comprehension

Abstract

The task of multimodal referring expression comprehension (REC), aiming at localizing an image region described by a natural language expression, has recently received increasing attention within the research community. In this paper, we specifically focus on referring expression comprehension with commonsense knowledge (KB-Ref), a task which typically requires reasoning beyond spatial, visual or semantic information. We propose a novel framework for Commonsense Knowledge Enhanced Transformers (CK-Transformer) which effectively integrates commonsense knowledge into the representations of objects in an image, facilitating identification of the target objects referred to by the expressions. We conduct extensive experiments on several benchmarks for the task of KB-Ref. Our results show that the proposed CK-Transformer achieves a new state of the art, with an absolute improvement of 3.14% accuracy over the existing state of the art¹.

1 Introduction

Referring expression comprehension (REC) aims at locating a target object/region in an image given a natural language expression as input. The nature of the task requires multi-modal reasoning and joint visual and language understanding. In the past few years, several REC tasks and datasets have been proposed, such as RefCOCO (Yu et al., 2016), RefCOCOg (Mao et al., 2016) and RefCOCO+ (Yu et al., 2016) (RefCOCOs). These ‘conventional’ REC tasks typically focus on identifying an object based on visual or spatial information of the object, such as its colour, shape, location, etc.; therefore primarily evaluating a model’s reasoning abilities over visual attributes and spatial relationships.

In practice, however, people often describe an object using non-visual or spatial information – consider, for example, the sentence (expression) “Give

¹The code will be available in <https://github.com/FightingFighting/CK-Transformer>

me something soft but rich in starch to eat” (Wang et al., 2020). Such instances require reasoning beyond spatial and visual attributes, and need to be interpreted with respect to the common sense knowledge (fact) embedded in the expressions, such as knowledge about which kind of objects are edible, soft and rich in starch in the given image. Recently, Wang et al. (2020) proposed a new dataset, KB-Ref, to evaluate the reasoning ability of a model over not only visual and spatial features but also commonsense knowledge. The dataset is devised such that at least one piece of fact from a knowledge base (KB) is required for a target object (referred to by an expression) to be identified.

Therefore, searching for appropriate facts from a KB is also crucial part in KB-Ref. In contrast to the only existing work (Wang et al., 2020), in which for each object candidate, the top-K facts with the highest cosine similarity between the averaged Word2Vec (Mikolov et al., 2013) embedding of the fact and the given expression are maintained, our framework focuses on multi-modal embedding and reasoning simultaneously over both the expression and the image to identify the top-K facts. Multi-modal features encode richer information helping to improve reasoning over varying (semantic) contexts and identification of relevant facts; for example, the above example of expression can be answered with the object “banana” in an image (or, equivalently, with the object “mashed potato” in another image).

In this paper, we propose a novel multi-modal framework for KB-Ref – Commonsense Knowledge Enhanced Transformers (CK-Transformer, CK-T for short) – that integrates (top-K) facts into all object candidates in an image for better identification of the target object. Specifically, our contributions are four-fold: 1) We propose the CK-T (see Figure 1) that effectively integrates diverse input from different modalities: vision, referring expressions and facts; 2) To the best of our knowledge,

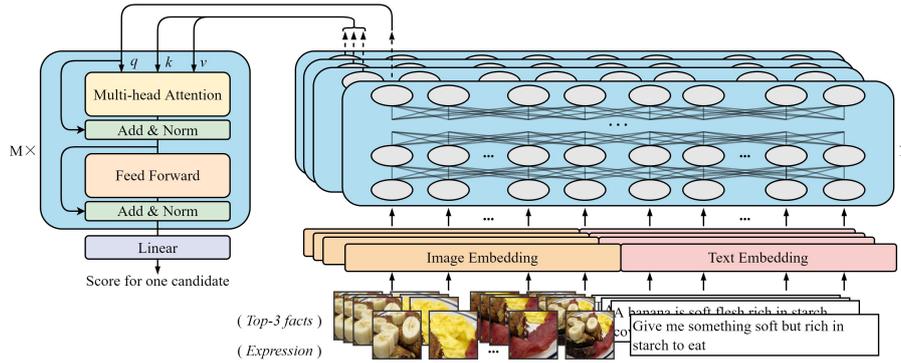

Figure 1: CK-Transformer. For each candidate (the first one in the figure), given an expression, a set of visual region candidates and top-K facts ($K=3$ in the figure), the model first encodes the expression and all top-K facts into corresponding multi-modal features, then fuses these features and maps them into a matching score for the candidate.

our approach is the first that introduces visual information into the identification of (top-K) relevant facts; 3) Our approach achieves a new state of the art using only top-3 facts per (candidate) object, which is furthermore substantially more efficient compared to existing work utilizing as much as top-50 facts; 4) We introduce facts into ‘conventional’ REC tasks, leading to improved performance.

2 Related Work

Referring expression comprehension with commonsense knowledge Different from conventional REC tasks (see Appendix A for details), KB-Ref focuses on querying objects given an expression that requires commonsense knowledge reasoning. The authors benchmarked a baseline model, ECIFA, for integration of facts, expression and image, and selects the target object by comparing the match scores between the image features and corresponding top-K fact features for all object candidates in the image (Wang et al., 2020). In our framework, we select top-K facts for each candidate by comparing the cosine similarity between the fact and expression embedding, where the embeddings are generated from a multi-modal encoder rather than a text encoder used in the ECIFA model.

Pre-trained vision–language encoders Several pre-trained multi-modal encoders (Su et al., 2019; Li et al., 2019; Chen et al., 2020; Tan and Bansal, 2019) have been proposed, achieving state-of-the-art results on vision–language tasks. Currently, UNITER (Chen et al., 2020) as one of powerful pre-trained encoders achieves the best performance on REC tasks (RefCOCOs). In this paper, we adapt UNITER such that it is used as a multi-modal en-

coder in fact search and as part of the CK-T.

3 Methodology

We formulate KB-Ref as a classification problem based on an image I consisting of a set of candidates (image regions) $I = \{c_j\}_{j=1}^n$ obtained from either ground-truth labels or predictions of a pre-trained object detector. Specifically, given an expression e , an image I and a KB, we first search for top-K facts $F_i^K = \{f_j\}_{j=1}^k$ from the KB for each candidate c_i , and then feed e , I , and F_i^K (the selected facts over I) into our CK-T simultaneously to predict the target object over all candidates.

3.1 Image-based fact search

For each candidate c_i in a given image, we retrieve all the facts from the KB (see Appendix D for details on the KB used in our framework) according to its category (e.g., a candidate object may belong to category ‘car’). Then, we calculate the cosine similarity between the facts and the given expression, where the similarities are obtained from a similarity extractor which we train by adapting UNITER. Specifically, given image–expression and image–fact pairs as input, we extract expression and fact features respectively from the position of the cross-modality output of UNITER (corresponding to the input of [CLS] token, see Appendix B for details), and then calculate the cosine similarity between the two. During training, inspired by Devlin et al. (2018), we replace 50% of ground-truth facts with random facts from the KB (with a similarity of 0), to help the model better distinguish useful facts from non-useful ones. Finally, we maintain top-K facts F_i^K with higher similarities to the expression

for each candidate c_i .

3.2 Commonsense Knowledge Enhanced Transformer

The CK-T consists of a bi-modal encoder (see 3.2.1) and a fact-aware classifier (see 3.2.2).

3.2.1 Bi-modal encoder

The bi-modal encoder (initialized by UNITER-base with N=12 layers (Chen et al., 2020)) integrates two modalities: image and text (e or f_i). Specifically, after generating the input embedding E_{Inp} consisting of image and text embedding (same with UNITER, see Appendix C for details), for each candidate c_i , we extract the expression-aware and fact-aware object features respectively (f_i^e and f_i^f) from the position of the visual output corresponding to c_i in the same encoder, based on the input of all candidates I , and e or f_i .

3.2.2 Fact-aware classifier

The fact-aware classifier is composed of multi-head attention layers and fully connected layers. For each candidate c_i , f_i^e and F_i^f (all K fact-aware object features for c_i) are fed into the integrator simultaneously (*Key* and *Value* are from F_i^f , and *Query* is from f_i^e), and fused into one three-source object features f_i^t (image, expression and top-K facts).

Finally, f_i^t is mapped into a match score s_i for c_i by a linear layer, and the optimization objective is to minimize the cross-entropy loss over all scores $\{s_j\}_{j=1}^n$ corresponding to all candidates I .

4 Results

We compare our CK-T to existing approaches on KB-Ref task without and with facts. Then we explore the importance of introducing visual information for fact search. Furthermore, we introduce facts into the traditional RefCOCO dataset, which was collected from MSCOCO (Lin et al., 2014) but differs in the types of expressions and object candidate settings. We extract image region features using an off-the-shelf detector, Faster R-CNN with ResNet-101 (Ren et al., 2015), based on bounding boxes (bbxes) (ground-truth labels or predicted results from the detector). See Appendix D and E for details about these datasets and experiment setting². Through parameter search on K and M (see Figure 3 and 4 in Appendix F), we keep M = 2 Fact-aware classifier blocks and top-3 facts for each candidate.

Model	Accuracy (%)	
	Val	Test
CMN (Hu et al., 2017)	41.28	40.03
SLR (Yu et al., 2017)	44.03	42.92
VC (Niu et al., 2019)	44.63	43.59
LGARNs (Wang et al., 2019)	45.11	44.27
MAttNet (Yu et al., 2018)	46.86	46.03
ECIFA-nf (Wang et al., 2020)	37.95	35.16
CK-T-nf (Ours)	58.02	57.53
ECIFA (Wang et al., 2020)	59.45	58.97
MAtt+E (Wang et al., 2020)	64.08	63.57
CK-T-Word2Vec	60.40	61.39
CK-T-Uw/oImage	64.44	64.78
CK-T (Ours)	65.62	66.71
Human	–	90.31

Table 1: Accuracy on KB-Ref dataset without and with facts (top and bottom part, respectively) using ground-truth bounding boxes and object categories.

Ground-truth bounding boxes and categories

By following Wang et al. (2020), we report our results on KB-Ref without and with facts. As can be seen in Table 1 (top), CK-T-nf, a version of CK-T without facts³, achieves an accuracy of 57.53% on the test set, outperforming existing approaches that do not utilize facts by approximately 11% – 22%. At the bottom part of the table we can see that our fact-enhanced CK-T model achieves the highest accuracy (66.71%) on the test set, which is 7.74% higher than that of ECIFA (a baseline model proposed by Wang et al. (2020)), and 3.14% higher than MAtt+E⁴. It is worth noting that both ECIFA and MAtt+E incorporate the top-50 facts for each candidate, which is considerably higher compared to top-3 facts in our CK-T. We surmise this is due to the fact that our fact search approach utilizes multi-modal fact and expression embeddings.

Predicted bounding boxes and categories To facilitate a fair comparison with ECIFA-d (Wang et al., 2020), we also use the maximum 10 detected bboxes for each image (CK-T-m10). As can be seen in Table 2, CK-T-m10 achieves an accuracy which is $\approx 5\%$ higher than that of ECIFA-d on the test set. CK-T-m100, a variant using at most 100 detected bboxes achieves a substantial improvement

²Including the efficiency discussion about our model

³all word tokens in fact sentences are replaced with only one [MASK] token.

⁴Wang et al. (2020) introduces their facts fusion module –Episodic Memory Module (E)–into MAttNet model (MAtt) (Yu et al., 2018) widely used for conventional REC.

Model	Accuracy (%)	
	Val	Test
ECIFA-d (Wang et al., 2020)	24.11	23.82
CK-T-m10 (Ours)	28.33	28.71
CK-T-m100 (Ours)	35.66	35.96

Table 2: Accuracy on KB-Ref using predicted bbxes and object categories.

with $\approx 7\%$, compared with CK-T-m10. This difference is primarily due to the increase in the number of correctly detected bbxes and predicted categories. Specifically, we find that with the top-100 bbxes, the number of samples containing the target bbxes rises from 18,901 to 31,653, while among these target bbxes, the number of correctly predicted categories grows from 11,324 to 15,928, out of a total of 43,284 samples in the KB-Ref dataset. This can also explain the dramatic decline on the accuracy between CK-T and CK-T-m10.

Incorporating image features into fact search

We experiment with various approaches to fact search and evaluate their effectiveness on KB-Ref (Table 1). We first utilize top-k facts searched in (Wang et al., 2020), where they use a pre-trained Word2Vec (Skip-Gram) (Mikolov et al., 2013) for searching facts (CK-T-Word2Vec). Then, we also selected facts from similarity predictors based on only text as input (CK-T-Uw/oImage)⁵, instead of image-text pairs in CK-T. As shown in Table 1, both CK-T-Uw/oImage and CK-T achieve better accuracy on the test set compared to CK-T-Word2Vec. Compared to CK-T-Uw/oImage, CK-T achieves around 2% higher accuracy. This is primarily due to the additional visual information used during fact search (see Appendix I for the examples of the selected facts by these fact search methods).

Introducing facts in traditional REC tasks

We incorporate facts from the KB used in KB-Ref into the tasks of RefCOCOs using CK-T. Table 3 shows the results comparison based on the ground-truth bbxes and categories (discussion about the detected results can be seen in Appendix G). Compared with U_{REC} ⁶, the model introducing facts achieves better or equal accuracy on all RefCOCOs tasks, where RefCOCOg is improved more than RefCOCO and

⁵Inspired by Frank et al. (2021), we replace all object candidate feature with the average of all image region features.

⁶Chen et al. (2020) achieve state-of-the-art results on RefCOCOs by finetuning UNITER. (We re-finetune the model for fair comparison and conduct McNemar Test)

Task	Accuracy (%)		
	U_{REC}	Intro Facts	
Ref-COCO	Val	90.98	91.43
	Test A	91.50	92.09
	Test B	90.89	90.95
Ref-COCO+	Val	83.23	83.45
	Test A	85.09	85.49
	Test B	79.08	79.08
Ref-COCOg	Val	86.23	87.21
	Test	85.79	87.59

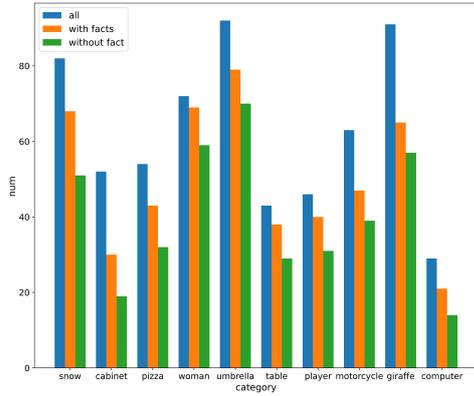

Table 3: Introducing facts into RefCOCO, RefCOCO+ and RefCOCOg. RefCOCO and RefCOCO+ have two different test sets, Test A and Test B, containing multiple persons and multiple objects in images respectively.

RefCOCO+. This is because RefCOCOg has less same-category object candidates in an image compared to RefCOCO and RefCOCO+ (an average of 1.63 and 3.9 per image, respectively) (Yu et al., 2016), and thus the retrieved facts integrated into different candidates are diversified (we first retrieve facts using the category), which contributes to distinguishing between candidates. This difference can also be proved in McNemar Test, where we find the change in the proportion of errors is statistically significant after introducing facts as compared to before on RefCOCOg ($p\text{-value} = 1.19e-08 < \alpha = 0.05$), while the similar proportions are found on RefCOCO and RefCOCO+ (see Appendix H for details about McNemar Test). The overall impact of commonsense knowledge in traditional REC is, however, not substantial. This is primarily due to much smaller number (78) of categories among the candidates in RefCOCOs, compared to 1805 in the KB-Ref (Wang et al., 2020). This limits the variety of selected facts, therefore impacting the extent to which commonsense knowledge is useful.

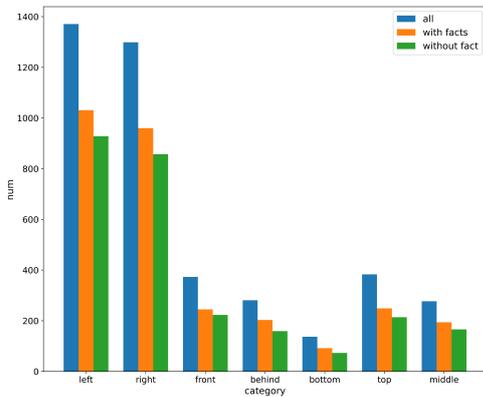

5 Analysis

To investigate in what cases commonsense knowledge helps, we conduct a fine-grained analysis of model performance on the test set of KB-Ref. Specifically, we compare the samples predicted by model with and without facts (CK-T and CK-T-nf) on three aspects: object categories, spatial relationships and the size of the bounding box.

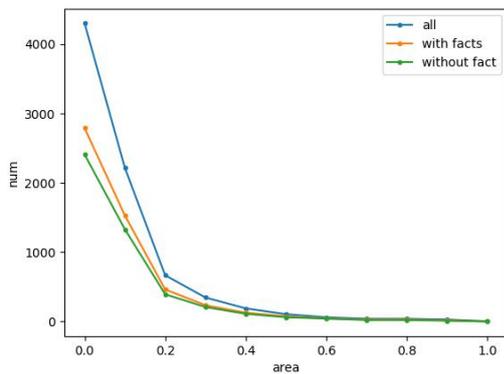

Object categories The test set contains 1502 categories and CK-T outperforms CK-T-nf on 1347 categories. Top 10 categories for which most improvement is observed are shown in Figure 2(a).

(a) Top 10 categories showing most improvement after introducing facts.

(b) The analysis of spatial relationships.

(c) The analysis of different bounding box sizes.

Figure 2: Fine-grained analysis. *all*: the total number of samples in the test set; *with fact*: the number of test samples that CK-T predicts correctly; *without fact*: the number of test samples that CK-T-nf predicts correctly.

In case of the 155 categories that do not show improvement, we find that the average number of samples per category is 6.68, making the results less reliable.

Spatial relationships We then investigate to what extent solving the REC task with and without facts relies on spatial reasoning, and whether there are particular spatial relationships between objects for which the use of facts is most crucial. Similar to the works of (Kazemzadeh et al., 2014; Johnson et al., 2017), we focus on the following spatial relationships: *left*, *right*, *front*, *behind*, *bottom*, *top*, *middle*. As shown in Figure 2(b), the model with facts (CK-T) outperforms that without facts (CK-T-nf) on all spatial relationships.

The size of the bounding box We then investigate the role of facts when identifying objects of different sizes, using the size of their bounding box as a proxy. We use the normalized area of the bounding box as the metric of bboxes size. As shown in Figure 2(c), the facts improve model performance on all bounding box sizes.

6 Conclusion

In this paper, we proposed CK-Transformer, which effectively integrates commonsense knowledge and the expression into the representations of the corresponding visual objects for multi-modal reasoning on KB-Ref. Our CK-Transformer achieves a new state-of-the-art performance on KB-Ref using only top-3 most relevant facts. We also demonstrated that visual information is beneficial for fact search. Finally, we show that commonsense knowledge improves conventional REC tasks across three different datasets.

7 Limitations

The computational requirements of our model are affected by the number of facts. Specifically, we train our CK-Transformer for 10000 steps with a batch size of 64 on one Titan RTX GPU, which takes 2.5, 3, 3.5, 7 days with the number of facts: 3, 5, 10, 20 respectively. The CK-Transformer processes 3.8, 2.8, 2.1, 0.7 samples on average per second at training time and 8.3, 7.3, 6.6, 1.1 samples per second at test time, with these amounts of facts. The computational requirements of our models are thus substantial, and future work should consider improving computational efficiency and thus reducing environmental impact.

A Referring expression comprehension

Early approaches to REC use joint embedding of image and language by combination of Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs), and predict the target object that has the maximum probability given an input expression and an image (Mao et al., 2016; Hu et al., 2016; Zhang et al., 2018). In order to model different types of information encoded in input expression (subject appearance, location, and relationship to other objects), subsequent work used modular (attention) networks, to “match” the input to corresponding regions in the image, predicting as the target the region with the highest matched score (Hu et al., 2017; Yu et al., 2018).

B UNITER

UNITER is trained using four pre-training tasks, Masked Language Modeling (MLM), Masked Region Modeling (MRM), Image–Text Matching (ITM), and Word–Region Alignment (WRA), on four large-scale image–text datasets, COCO (Lin et al., 2014), Visual Genome (Krishna et al., 2016), Conceptual Captions (Sharma et al., 2018), and SBU Captions (Ordonez et al., 2011). This enables UNITER to capture fine-grained alignments between images and language. The architecture of UNITER is similar to BERT (Devlin et al., 2018) apart from the input and the output. Specifically, the input consists of an image (a set of visual region candidates), a sentence and [CLS] token, and they respectively lead to different outputs, i.e. vision output, language output and cross-modality output on the top of UNITER.

C Input embedding

Same with UNITER, we extract the input embeddings E_{Inp} consisting of an image and a text embedding corresponding to the object candidate I and text (an expression e or a fact f_i) respectively.

Image embedding The image embedding E_I is computed by summing three types of embeddings: visual feature embedding, visual geometry embedding and modality segment embedding. We first extract the visual features $V = \{v_1, v_2, \dots, v_n\}$ for all candidates using Faster R-CNN (pooled RoI features), and build a geometry feature $G = \{g_1, g_2, \dots, g_n\}$ for all candidates, where g_i is a 7-dimensional vector consisting of the geometry information of the bounding box corresponding to

candidate c_i , namely normalized top, left, bottom, right coordinates, width, height, and area, denoted by $g_i = [x1, y1, x2, y2, w, h, w * h]$. Visual feature embeddings and visual geometry embeddings are generated by mapping the visual features and the geometry features into the same vector space through a fully connection layer fc :

$$E_I = LN(fc(V) + fc(G) + M_I) \quad (1)$$

where LN is the layer normalization layer and M_I is the modality segment embedding for the image input (like segment embedding for two sentence in BERT model).

Text embedding Similarly, the text embedding E_T is computed based on three different types of embeddings: token embedding, position embedding and modality embedding (Normally there is a fourth embedding, sentence segment embedding similarly to BERT, but, in our task, both expressions and facts consist of one sentence only and so only the first sentence segment embedding is used). Similar to BERT (Devlin et al., 2018), the text $W = \{w_1, w_2, \dots, w_u\}$ is first tokenized by WordPieces (Wu et al., 2016), which are then built into token embeddings $T = \{t_1, t_2, \dots, t_v\}$ and position embeddings $P = \{p_1, p_2, \dots, p_v\}$ according to their position in the text sequence.

$$E_T = LN(T + P + M_T) \quad (2)$$

where M_T is the modality segment embedding for the text input.

Input embedding The final input embedding E_{Inp} is computed by concatenating image embedding E_I and text embedding E_T :

$$E_{Inp} = [E_I, E_T] \quad (3)$$

D Datasets

We use the KB-Ref dataset (Wang et al., 2020) aiming at evaluating the task of referring expression comprehension based on commonsense knowledge. KB-Ref consists of 43,284 expressions for 1,805 object categories on 16,917 images, as well as a knowledge base of key–value (category–fact) pairs collected from three common knowledge resources: Wikipedia, ConceptNet (Speer et al., 2017) and WebChild (Tandon et al., 2017)). KB-Ref is split into a training set (31,284 expressions with 9,925 images), a validation set (4,000 expressions with

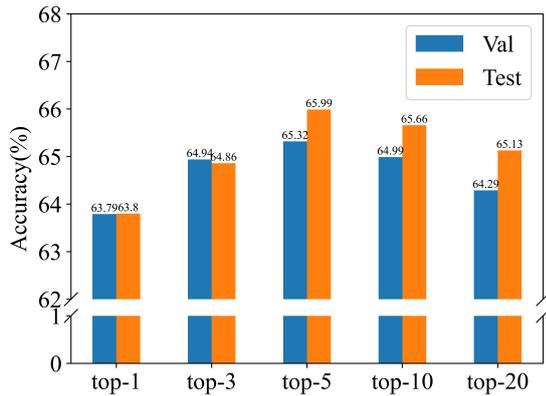

Figure 3: Accuracy across a varying number of facts (top-K).

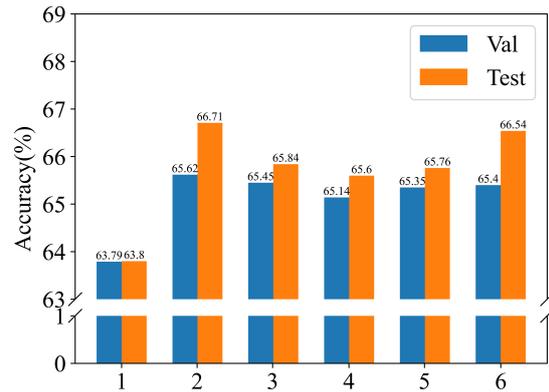

Figure 4: Accuracy across a varying number of fact-aware classifier block (M).

2,290 images) and a test set (8,000 expressions with 4,702 images).

We furthermore introduce commonsense knowledge into traditional tasks/datasets of referring expression comprehension, namely RefCOCO, RefCOCOg and RefCOCO+⁷. The datasets are devised from the MSCOCO image dataset (Lin et al., 2014) but differ in the types of expressions and object candidate settings. Specifically, RefCOCO+ does not allow the use of absolute location words in the expressions, and most expressions focus on the appearance of the objects. The expressions in RefCOCOg are longer and contain more descriptive words. RefCOCO and RefCOCO+ contain more objects of the same category within an image.

E Experimental settings

We extract image region features using Faster R-CNN with ResNet-101 (Ren et al., 2015) which was pre-trained on Visual Genome (Krishna et al., 2016) using object and attribute annotations (Anderson et al., 2018). For bounding box detection, we keep the bounding boxes with at least 0.2 confidence score indicating the extent of detection. In the CK-T, the hidden layer dimension is 768 and the number of multi-head attention heads is 12. The models are trained using Adamw (Loshchilov and Hutter, 2017) with a learning rate of $6e^{-5}$ and a batch size of 64 on Titan RTX GPUs. Our CK-Transformer has 120M parameters in total where fact-aware classifier has 34M and bi-modal encoder has 86M. As for UNITER model, we use same setting with *UNITER-base*, except for using Nvidia

⁷following Apache License 2.0

Apex⁸ for speeding up training. The efficiency of our model is effected by the number of facts. Specifically, we train our CK-Transformer 10000 steps and a batch per step, which takes 2.5, 3, 3.5, 7 days with the number of facts: 3, 5, 10, 20 respectively. The CK-Transformer trains 3.8, 2.8, 2.1, 0.7 sample in average per second and tests 8.3, 7.3, 6.6, 1.1 sample per second.

F Impact of CK-T structure

We explore the impact in performance on KB-Ref as we vary the number of top-K facts (K) and fact-aware classifier block (M) on the development set. We first keep the number of the fact-aware classifier block constant and set it to 1 to experiment with different values for K from 1 to 20. As shown in Figure 3, as K increases, performance starts to improve with a peak at K=5 before starting to gradually decrease performance.

In the second experiment, we keep K constant and set it to 3 and explore the effect of varying values for M. We observe that the highest accuracy is achieved with with top-3 facts and 2 integrator layers as shown in Figure 4.

G Introducing facts in traditional REC tasks based on detection

The results of introducing facts in traditional REC tasks based on detected bbxes and categories are shown in Table 4. Compared to result based on ground-truth bbxes and categories (Table 3), the improvement on models based on detection is less or even worse than the models without facts.

⁸<https://github.com/NVIDIA/apex>

Task		Accuracy (%)	
		U_{REC}	Intro Facts
Ref-COCO	Val ^d	81.15	81.06
	Test A ^d	86.85	86.87
	Test B ^d	74.48	73.97
Ref-COCO+	Val ^d	74.74	74.68
	Test A ^d	81.05	80.70
	Test B ^d	65.88	66.07
Ref-COCOG	Val ^d	74.49	74.69
	Test ^d	75.24	74.86

Table 4: Introducing facts into RefCOCO, RefCOCO+ and RefCOCOG based on detection (*d*).

Task		McNemar Test
		(<i>p</i> -value)
RefCOCO	Test A	0.049
	Test B	0.905
RefCOCO+	Test A	0.297
	Test B	0.966
RefCOCOG	Test	$1.19e-08$

Table 5: The McNemar Test between models before and after introducing facts on the tasks of RefCOCOs.

H McNemar Test

We also report the statistical significance for accuracy (shown in Table 3) on the tasks of RefCOCOs. Specifically, we conduct the McNemar Test between models before and after introducing facts, on the test set of RefCOCO, RefCOCO+ and RefCOCOG, respectively. As shown in Table 5, as for Test set on RefCOCOG and Test A on RefCOCO p -value = $1.19e-08$ and p -value = 0.049 (< 0.05) respectively, which means the proportion of errors is statistically significantly different after introducing facts as compared to before. However, the change in the proportion of errors after introducing facts on other tasks (Test B on RefCOCO, Test A and Test B on RefCOCO+) is not statistically significant. This is reasonable, as the error from detection will affect the fact search (we first retrieve facts using the category) and thus more error information is introduced into CK-Transformer, which make the performance worse.

I Example searched fact using different methods

As shown in Figure 5, there are several facts which are selected from three different fact search methods: CK-Transformer, CK-T-Uw/oImage and CK-

T-Word2Vec. As we can see in the Table, normally the facts of CK-Transformer model (green) is the best relevant with the referring expression (blue) and the facts in CK-T-Word2Vec model is the worst relevant with the expression.

Abstract

Transcript segmentation is the task of dividing a single continuous transcript into multiple segments. While document segmentation is a popular task, transcript segmentation has significant challenges due to the relatively noisy and sporadic nature of data. We propose pre-training strategies to address these challenges. The strategies are based on “Next Conversation Prediction” (NCP) with the underlying idea of pretraining a model to identify consecutive conversations. We further introduce “Advanced NCP” to make the pretraining task more relevant to the downstream task of segmentation break prediction while being significantly easier. Finally we introduce a curriculum to Advanced NCP (Curricular NCP) based on the similarity between pretraining and downstream task samples. Curricular NCP applied to a state-of-the-art model for text segmentation outperforms prior results. We also show that our pre-training strategies make the model robust to speech recognition errors commonly found in automatically generated transcripts.

1 Introduction

Text segmentation is the task of identifying segment breaks to organize a continuous text into semantically independent segments. Prior research in text segmentation has largely focused on segmenting documents such as Wikipedia articles (document segmentation) (Lukasik et al., 2020; Zhang et al., 2019; Badjatiya et al., 2018; Koshorek et al., 2018) or dialogues such as chat or text messages (dialogue segmentation) (Hsueh et al., 2006; Arguello and Rosé, 2006; Xia et al., 2022; Xing and Carenini, 2021). In this paper we address text segmentation of transcripts (transcript segmentation). Figure 1 shows examples of segments in transcript data. Transcript segmentation can help summarize long videos, podcasts or meetings by segmenting and summarizing the transcript such as “Video

chapters” in YouTube videos or “Outline Generation” (Zhang et al., 2019) from documents.

However, only few works have addressed segmentation of transcripts (Midei and Mandic, 2019; Jing et al., 2021; Gruenstein et al., 2008). As shown in Figure 1, transcripts consist of a mix of short sentences, utterances, interjections and long form document style answers. Unlike Wikipedia articles or chat, the sporadic and non uniform flow of text in transcripts makes annotation of segment breaks hard even for humans (Gruenstein et al., 2008). Furthermore, transcripts often involve Automatic Speech Recognition errors such as insertions, deletions, replacement and lack of proper punctuation which add to the challenges. As a result of these challenges, most labeled transcript segmentation datasets are small in size making it difficult for models to be trained on them.

To address this issue, we propose pretraining strategies that can be useful in resource constrained

settings where huge labeled datasets are not available. Our first strategy is Next Conversation Prediction (NCP). In this strategy, pairs of conversations are classified into 1 or 0 based on whether they contiguously in the transcript or not. We hypothesize that the effectiveness of this pretraining task relies on its similarity and relevance to the segmentation task. Our second strategy, Advanced Next Conversation Prediction (Advanced NCP), introduces conditions on the NCP pretraining data to increase the relevance of the pretraining strategy to the segmentation task. Our third strategy is Curricular NCP where we pretrain the model in two distinct phases based on which pretraining samples are closest to the task of transcript segmentation.

Our experiments show that the application of the proposed pretraining strategies on multiple segmentation architectures outperforms their corresponding non pretrained versions. Also, NCP does not rely on segmentation labels. We show that it is a strong unsupervised approach that outperforms state-of-the-art unsupervised model for transcript segmentation. Finally, we observe that the pretraining strategies makes the model more robust to noise and better at predicting highly segmented regions of a transcript.

Our contributions are:

- Propose a pretraining strategy based on Next Conversation Prediction for transcript segmentation. We show that it also acts as a strong unsupervised approach for this task.
- Propose Advanced NCP and Curricular NCP pretraining strategies based on similarity and relevance of pretraining samples to segmentation task.
- Provide a new state-of-the-art in transcript segmentation.
- Evaluate robustness of proposed pretraining strategies to noisy training data.
- We perform additional analysis to investigate the errors made by the pretrained models.

2 Related Work

Text segmentation has been addressed in both unsupervised (Solbiati et al., 2021; Glavaš et al., 2016) and supervised manner (Midei and Mandic, 2019; Lukasik et al., 2020; Koshorek et al., 2018; Badjatiya et al., 2018) with early works focusing on unsupervised techniques (Hearst, 1997; Choi, 2000; Utiyama and Isahara, 2001; Eisenstein, 2009). However, since the definition of a segment,

could be highly domain and data dependant, supervised learning is desirable.

Koshorek and Cohen (2017) and Koshorek et al. (2018) use LSTMs to identify if a sentence ends a segment or not. Similarly, Li et al. (2018) use GRUs and pointer-generator networks for this task. These works in segmentation propose a hierarchical approach, where the sentences are encoded into a fixed size representation followed by mapping the representations to a sequence of binary labels whether the current segment is ending at this sentence or not. Badjatiya et al. (2018) use attention based CNN-LSTMs and phrase the task differently by providing inputs of a median sentence and its right and left context to identify segment breaks. Lukasik et al. (2020) simplify the new paradigm for this task by using the left and right contexts with respect to an end of a sentence as input. They were also the first to use large pretrained language models for this task. They establish a new SOTA in text segmentation. Hence, we use their model as the base model in our pretraining experiments.

Very few works have focused on transcript segmentation. Midei and Mandic (2019) provide a podcast dataset for research in this domain and propose an LSTM and Universal Sentence Encoder (Cer et al., 2018) based sequence labeling model. Jing et al. (2021) identify introductions in podcast transcripts using BERT (Devlin et al., 2019). Solbiati et al. (2021) propose an unsupervised technique for meeting transcript segmentation. They use large language model representations including Sentence BERT (Reimers and Gurevych, 2019) and BERT to compute cosine similarity between subsequent conversations and estimate segment breaks. We present a new pretraining strategy aimed towards addressing transcript segmentation but not specific to any one model architecture. Our work is also related to Curriculum Learning (Bengio et al., 2009). It has gained popularity among NLP tasks such as Sentiment Analysis (Cirik et al., 2016) Question Answering (Sachan and Xing, 2016), NLG (Liu et al., 2018) and the GLUE benchmark (Xu et al., 2020). More recently, some works have used curriculum learning in the pretraining process of large language models. Wang et al. (2020) propose curriculum learning for pretraining the encoder of their speech translation system on multiple speech based tasks of varying difficulty. Nagatsuka et al. (2021) gradually introduce longer samples to BERT's pretraining to observe performance improvements in

Figure 2: Advanced Next Conversation Prediction (NCP) pretraining strategy illustrated with roles of the coefficients in controlling pretraining task difficulty and similarity to the downstream task.

resource poor settings. In our curriculum learning setting, we order pretraining samples based on their similarity to the downstream segmentation task.

3 Text segmentation as a binary classification task

There are two major ways supervised text segmentation has been addressed in the past. First, by phrasing it as a sequence labeling problem, where each sentence has a label indicating if it ends the segment or not (Midei and Mandic, 2019; Lukasik et al., 2020; Koshorek et al., 2018). As a result an entire transcript forms a single training instance consisting of a sequence of binary labels.

Second, by phrasing text segmentation as a binary classification task where we provide left context and right context around a sentence end and predict if the two contexts belong to the same segment or not. In particular, the input in this task is two text segments - left context (l) and right context (r) of the end of a sentence, each T tokens in length. The output in this task is 0 - if l and r belong to two different segments (segment break) and 1 if l and r belong to the same segment (not a segment break). In this setting, the number of instances is proportional to the number of segments. Lukasik et al. (2020) note in their experiments that the second setting outperforms the first on transcript segmentation. We follow the second setting and refer to it as the segmentation task in the rest of this paper.

4 Curricular Next Conversation Prediction

In this section, we explain the proposed pretraining strategy. First, we explain our basic pretraining strategy - Next Conversation Prediction (NCP). Then, we present improvements on this strategy

to make the pretraining task easier and more relevant to the transcript segmentation task (Advanced NCP). Finally, we introduce curriculum learning to our pretraining strategy (Curricular NCP) that presents the pretraining instances in an order that is more helpful for the segmentation task.

4.1 Next Conversation Prediction

Next Conversation Prediction is the backbone of our proposed pretraining strategies. Large language models such as BERT have gained recent success on the segmentation task (Lukasik et al., 2020). One of the pretraining tasks in BERT is NSP (Next Sentence Prediction). In NSP, a sentence pair is provided as input and the model predicts if the sentences occurred consecutively in their original corpora. We hypothesize that BERT’s success in text segmentation might be attributed to the NSP pretraining’s similarity to the segmentation task.

Motivated by NSP, we propose a pretraining strategy based on Next Conversation Prediction (NCP) for the task of transcript segmentation. In NCP, we address a binary classification task. The input is a pair of transcript contexts and the output is a label indicating whether the contexts are adjacent or not. Specifically, the input consists of the left (l) and right (r) contexts of a sentence end (T tokens each). The output is 1 if the two contexts are adjacent and 0 otherwise. Note that NCP does not use any information about segment break labels and so can potentially be used on transcripts dataset without segment break annotations.

NCP has two major advantages over NSP. First, NCP has longer contexts making the model learn information from a wide range of sentences varying in content and style. Second, NCP as pretraining task makes the pretraining step similar to the seg-

mentation task in terms of the structures of input and output.

4.2 Advanced Next Conversation Prediction

The predictive difficulty of the negative samples (label 0) in NCP depends on the distance between the left and right contexts, l and r , in the transcript. A greater distance between the contexts makes the NCP task easier but more different from, and hence potentially less useful for, the segmentation task. Similarly, the difficulty of the positive samples (label 1) depends on how semantically similar the contexts are to each other. Positive samples with highly semantically similar contexts will be easy to identify. To control the difficulty of the NCP samples, we introduce the following conditions on the positive and negative samples of the pretraining data respectively.

$$Sim(l, r) \geq s \text{ for label 1} \quad (1)$$

$$Dist(l, r) = d \text{ for label 0} \quad (2)$$

where $Sim()$ is a semantic similarity function¹ quantifying similarity between l and r , and s is the similarity coefficient. $Dist()$ is the distance between l and r in terms of number of sentences between them and d is the distance coefficient. Figure 2 illustrates the Advanced NCP.

In vanilla NCP, by default, the distance between non consecutive contexts is greater than 1 and there is no semantic similarity filter ($s = 0$). Increasing s will make the pretraining task easier as the positive samples (label 1) have the additional constraint of being semantically similar. However, increasing s too much can filter out too much pretraining data. Similarly, decreasing d will make the task harder but more relevant to the segmentation task.

4.3 Curricular Next Conversation Prediction

Curriculum learning (Bengio et al., 2009) proposes that models observing training samples in an increasing order of difficulty have an advantage over models observing samples in an otherwise random order. Motivated by this, we introduce a curriculum to Advanced NCP pretraining. The pretraining samples from Advanced NCP are divided into two distinct sets - “similar” to downstream task (or “harder” since, in general, segmentation is a harder task than NCP) and “dissimilar” to the segmentation task (or “easier”). In order to estimate the

¹We use Sentence BERT (Reimers and Gurevych, 2019) to compute representations of l and r , followed by cosine similarity for $Sim()$

similarity or dissimilarity of the NCP pretraining samples to the segmentation task, we use a classification model trained for the segmentation task and use it to predict labels for the pretraining instances. We refer to this as the “Auxiliary model” and classify a pretraining sample as “similar” if the Auxiliary model correctly predicts its label and vice versa. In the spirit of curriculum learning, we divide the pretraining into two steps. First training on the “dissimilar” or “easy” (from the perspective of segmentation) samples followed by the “similar” or “hard” samples. This order makes sure that the model has smoother transition between the two tasks that are semantically close but different. Figure 6 illustrates the Curricular NCP process. Table 4 shows examples of Dissimilar NCP and Similar NCP from the SliceCast-Podcast dataset. All the examples are labeled 0 in their respective tasks.

While the Auxiliary Model can be any classification model trained on the segmentation task dataset, we use a model that is additionally pretrained on Advanced NCP data. The Auxiliary model is tested on Advanced NCP samples. While these samples were used during the pretraining of the Auxiliary model, after finetuning on the segmentation task model might not predict the same labels it observed during the pretraining. In our experiments with the SliceCast-Podcast dataset (described in Section 5.1) we indeed observe that 64.4% samples are miss-classified (hence, “dissimilar”) and 35.6% are correctly classified (hence, “similar”).

5 Experimental details

In this section, we describe the dataset, the base model upon which our pretraining is tested, the implementational details, metrics and baselines.

5.1 Dataset

We use the SliceCast-Podcast (Midei and Mandic, 2019) dataset for our experiments. This dataset has 46 podcast transcripts and a total of 643 segments. On average, each transcript has 12.4 segments, though there could be high variation in number of segments as the standard deviation is 4.1. We consider 416 segments for training and 181 segments for testing purposes. While creating training data for the pretraining and the segmentation task, positive and negative samples are sampled equally. For this, in the segmentation task we randomly down sample samples labeled 1. Figure 1 shows examples of segment breaks from this dataset.

5.2 Base Binary Classification Model

We use BERT as the base classification model in the Auxiliary model. Across all classification tasks - Advanced NCP, Curricular NCP and the Segmentation task, the input is provided by concatenating l and r contexts with the token “[SEP]”. Hence the input is “ l [SEP] r ”. T , the maximum input size of l and r individually is 150^2 . The output is taken from the first position (“[CLS]”) and a binary cross entropy layer is attached to enable binary classification.

Lukasik et al. (2020) propose Cross Segment BERT, for the transcript segmentation task. We use this as the base segmentation model for transcript segmentation after finetuning it on the data described in Section 5.1.

5.3 Coefficient details for Advanced NCP

The two coefficients explained in Section 4.2 control difficulty of the Advanced NCP task and hence its relevance to the pretraining task. We experimented with various values of s and d in the Advanced NCP task. Following which, we measure performance of the these pretrained models (with different values of s and d) on a balanced Advanced NCP test data. The accuracy results are reported in Fig. 3a. A darker shade of green indicates better performance. As we can see, in general, Advanced NCP performance (accuracy) increases as the coefficients increase, making the positive and negative samples easier to identify. However, large values of s results in filtering out too many positive samples and hence the size of the training dataset leading to a decreasing in performance.

The aforementioned Advanced NCP pretrained models are then fine-tuned on the segmentation task. All the models are finetuned on the dataset described in Section 5.1. For model comparison we use the F1 of the the segment break class (0) on a held out set of containing 61 segments. Results of the finetuned models are illustrated in Figure 3b. Comparing Figures 3a and 3b we can observe that while a low performance on the Advanced NCP task also corresponds to a low performance on the segmentation task, the converse is not true. At high coefficient values, especially the distance coefficient d , the pretraining task is too distinct from the segmentation task leading to low efficacy of the pretraining strategy.

²Original Cross Segment BERT (Lukasik et al., 2020) used 125 in most of their experiments. We follow a similar setting

Models	F1 (↑)	Pk (↓)	WDiff (↓)
S-BERT	4.1	50.5	65.1
CSB	17.5	42.5	37.3
Adv. NCP + CSB	22.1**	37.2**	36.2**
Curr. NCP + CSB	22.6*	35.6**	37.5**

Table 1: Evaluation results for S-BERT (Solbiati et al., 2021), CSB (Lukasik et al., 2020) and CSB pretrained with the proposed strategies. WDiff refers to WindowDiff. Pretrained models significantly outperform CSB in all metrics. Introduction of curriculum to Advanced NCP also shows improvement. * and ** denote the difference is significant with $p < 0.03$ and $p < 0.06$ via t-test.

Models	F1-0 (↑)	Pk (↓)	WDiff (↓)
Hier.	19.9	39.2	37.1
Adv. NCP + Hier.	20.6	38.5	36.2
Curr. NCP + Hier.	20.3	37.4	36.6

Table 2: Performance of the Hierarchical (Hier.) model (Lukasik et al., 2020) before and after pretraining with Advanced NCP (Adv. NCP + Hier.) and Curricular NCP (Curr. NCP + Hier.). Application of pretraining on Hierarchical shows improvement.

Using these two figures, we find the ideal coefficients such that the Advanced NCP strategy is sufficiently easy but relevant to the downstream task concurrently. We choose $d = 200$ and $s = 0.7$.

5.4 Metrics

In line with previous works (Midei and Mandic, 2019; Lukasik et al., 2020; Solbiati et al., 2021), we use F1 score and Pk score (Beeferman et al., 1999) for evaluating text segmentation models. The scores are calculated by using the model to predict existence of segment break after each sentence end in the test set and then comparing ground truth segment break predictions and predicted segment breaks. F1 score of the label 0 is considered. This score is a strict measure as it rewards the model only if the predicted segment breaks and ground truth segment breaks exactly align. Pk score is less harsh. Pk score is calculated by using a sliding window such that predicted segment breaks near ground truth are penalised less than predictions that are far away³. One criticism of the Pk score is that it favours models that make fewer segment break predictions. To address this Pevzner and Hearst (2002) proposed WindowDiff to account for the number of segment break predictions as well. For WindowDiff and Pk, we consider size of sliding window to be half of the average segment length in number of sentences, as is the standard practice.

0.6	0.001	0.11	0.11	0.14	0.1
0.7	0.001	0	0.17	0.24	0.09
0.8	0.02	0.12	0.18	0.18	0.11
0.9	0.03	0.04	0.06	0	0.09

(b) Segmentation task performance in F1 score of the 0 label across different Advanced NCP pretraining.

Figure 3: Performance of Advanced NCP pretraining and Segmentation task with varying coefficients d and s . As we can observe higher pretraining task performance does not necessarily imply higher downstream task performance.

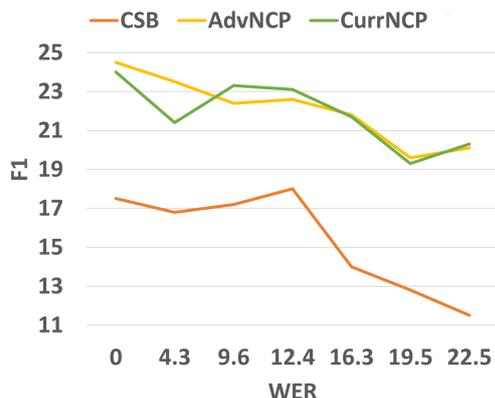

Figure 4: Performance with respect to change in transcription errors (WER). x -axis is represents different WER rates and y -axis represents the F1 scores. Proposed pretraining strategies makes the CSB model more robust to transcription errors.

For both Pk and WindowDiff, lower scores indicate better performance.

5.5 Baselines

S-BERT We compare the supervised techniques (pretrained and non pretrained) against this Sentence BERT based unsupervised transcript segmentation baseline (Solbiati et al., 2021) to show the motivation for this task to be addressed in a supervised setting.

Cross Segment BERT (CSB) This is a BERT model for the segmentation task without any proposed pretraining. The model is based on Lukasik et al. (2020), originally proposed for document segmentation where left and right contexts are concatenated with a separator and provided to the BERT model for binary classification. CSB formed a state-of-the-art in text segmentation. Hence, we apply our pretraining strategies on this model.

6 Results and Discussions

6.1 Pretraining on Cross Segment BERT

Table 1 presents the results of application of the proposed pretraining strategies - Advanced NCP and Curricular NCP on CSB (Advanced NCP + CSB and Curricular NCP + CSB respectively). We

also compare with S-BERT, the unsupervised baseline.

Challenges of an unsupervised setting The unsupervised baseline, S-BERT, vastly underperforms all other models (supervised) on all metrics (row 1 and other rows). This is because the definition of a segment could be data and domain specific. In such a case, deriving its interpretation from a supervised data becomes imperative. Hence, despite the difficulty of annotation, supervised approaches are favoured.

Improvement due to proposed pretraining By comparing pretrained models with CSB (row 2 and rows 3,4), we see that pretrained models outperform across all metrics indicating their effectiveness. We also outperform the transcript segmentation baseline proposed by Midei and Mandic (2019). However, we do not apply our pretraining strategy to it since it adopts a sequence labeling paradigm, and adapting proposed pretraining strategies for such models is left for future work.

By comparing Advanced NCP and Curricular NCP (row 3 and row 4), we see that proposing a curriculum to the pretraining leads to better F1 and Pk scores. We give two major reasons for this improvement - First, our ordering of pretraining samples in Curricular NCP is relevant to the segmentation task. Prior research in curriculum learning show such sample orderings are more effective than arbitrary sample orderings such as sentence length for sentiment analysis (Rao et al., 2020). Second, the transcript segmentation data is small in size and previous works note the efficacy of curriculum learning in resource poor settings (Cirik et al., 2016; Nagatsuka et al., 2021).

6.2 Pretraining on Sequence Labeling

To further observe efficacy of the proposed pretraining approaches, we apply them on a sequence labeling approach. We use a model based on Hierarchical BERT model from Lukasik et al. (2020) which is compatible with our pretraining task. In

this "Hierarchical" baseline- first, the left and the right context pairs are obtained by taking $T = 150$ tokens of left and right context around each sentence end. Next, CSB model is used to obtain representations for context pairs. Hence, each transcript is converted to sequence of context pair representations. Finally, this sequence of context pair representations is then input to an LSTM (50 units) in a one-to-one sequence labelling setting to output an equally long sequence of 1s and 0s. Similar to segmentation in the binary classification setting (explained in Section 3), 0 indicates a segment break and 1 indicates absence of a segment break. In this hierarchical baseline, we swap the CSB model with Advanced NCP + CSB model to obtain Advanced NCP + Hierarchical model and using a similar process we obtain Curricular NCP + Hierarchical.

The performances of all models are reported in Table 2. By comparing the pretrained models (Advanced NCP + Hierarchical and Curricular NCP + Hierarchical) to the model without pretraining (Hierarchical), we observe an improvement. The performance increment between vanilla and pretrained models, has diminished slightly in this sequence labelling setting as compared to CSB as based model setting. This is possibly because the Hierarchical model, involves more parameters (LSTM units) that have not been updated during our pretraining steps as opposed to the CSB model, where all parameters were involved in the pretraining. Regardless, pretraining leads to an improvement across all metrics. This is consistent with Table 1, showing that proposed pretraining methods have merits across the downstream model architecture (CSB or Hierarchical).

6.3 Utility in an unsupervised setting

To further understand the relationship between the pretraining and the segmentation task, we do cross domain testing. Here, we use an NCP pretrained model (prior to finetuning) to make predictions on the segmentation test data. Since NCP does not use any segmentation information, this method is unsupervised in segmentation prediction. We also make predictions on Curricular NCP pretraining test data using the segmentation model ("Pretraining Test Data").

Results of this experiment are tabulated in Table 3. For the pretraining test data, we use accuracy for performance comparison. WindowDiff is used for the segmentation test data. Comparing the perfor-

Models	Pretraining	Segmentation
	Test Data (\uparrow)	Test Data (\downarrow)
S-BERT	55.8	65.1
NCP	69.3	61.5
CSB	61.8	37.3
Curr. NCP + CSB	66.4	37.5

Table 3: Results of the cross domain testing experiment. We report accuracy for the pretraining task and WindowDiff for the segmentation task. NCP does not use any segment information and outperforms S-BERT in segmentation, thereby forming a strong unsupervised approach.

mances of S-BERT and NCP on the segmentation task, we observe that NCP outperforms S-BERT. This shows that the proposed pretraining approximates the segmentation task and gives the necessary domain knowledge to perform well even in an unsupervised setting. Next we compare the performances of the models trained for segmentation task (Curricular NCP + CSB and CSB) with the performance of NCP. We can see that Curr NCP +CSB and CSB are performing better than NCP on segmentation task but not on pretraining task. This shows that is a significant difference between the two tasks.

6.4 Robustness

Since, automatically generated transcripts tend to be noisy, in this section we measure the robustness of proposed pretraining strategies to noise in training data. In this experiment, we synthesize noise in the training samples using Easy Data Augmentation (EDA) (Wei and Zou, 2019). EDA introduces noise to transcript samples by four operations - synonym replacement, random insertion, random swap, and random deletion. EDA also provides a temperature variable to control how intensely these operations are applied. By increasing the temperature in some of these operations, we obtain six SliceCast-Podcast variants with increasing WER rates (4.33%, 9.60%, 12.42%, 16.33%, 19.51% and 22.53%) with respect to the original dataset. Only random insertion, swap, and deletion are used for introducing noise. Note that the test data is not changed across these variants. Figure 4 shows the performance (F1) of CSB, and CSB model pretrained with Advanced and Curricular NCP.

We observe that the results align with the results reported in Table 1 i.e. First, Pretrained models always outperform CSB. Second, Curricular NCP pretrained model generally outperforms Advanced

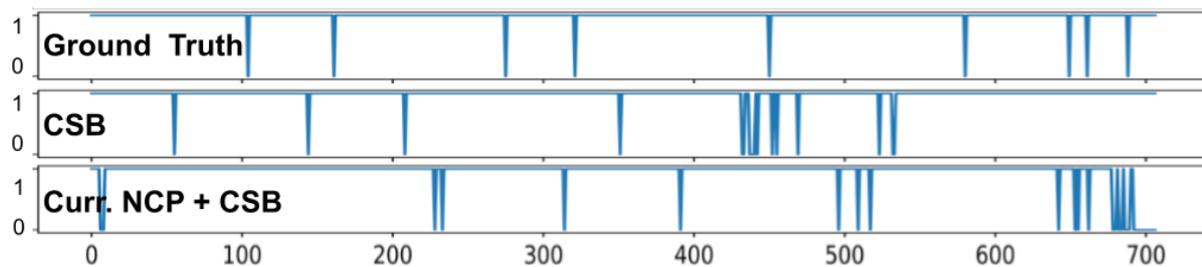

Figure 5: Segmentation break predictions across all sentences of a test transcript, illustrated in the ground truth annotation, annotation by CSB model and annotation by Curricular NCP pretrained CSB model. The pretrained model is able to catch the highly segmented area of the transcript.

NCP pretrained model. Furthermore, we observe a decreasing performance trend in all the models as WER increases. This is expected behaviour because as the data becomes more noisy, we lose valuable clues that reflect start and end of a segment. However, we observe that the pretrained models have a lower decrement in performance as compared to CSB as the WER increases. The overall performance decrement among CSB, Advanced NCP + CSB and Curricular NCP + CSB is -5.7% , -1.7% , -2.4% respectively. This shows that pretraining introduces robustness in the model.

6.5 Qualitative Analysis

To further analyze the advantages of pretraining, we visualize the segment break predictions across all sentences of a transcript from the test set. Figure 5 shows segment break annotations in the ground truth, and predictions by the CSB model and the Curricular NSP pretrained CSB model. x -axis represents the number of sentences and y -axis represents label predictions. As discussed in Section 4.2, we use the model after each sentence to predict segment breaks. Looking at the ground truth annotations, we can see that segment lengths can vary greatly within a transcript. Some segments are more dense than others. We can observe that Curricular NCP helps the model to correctly identify a region of dense segment breaks. Identifying such dense regions might require large training data to correctly understand the dynamics of segment sizes. In such cases, pretraining of NCP can make up for less labelled data.

6.6 Error Analysis

We further investigate the kind of errors the models (with and without pretraining) are making. In general, we note both CSB and pretrained CSB tend to over-predict segment breaks. Their precision and recall for label 0 are as follows - 14.6 and 22.1 for

CSB and 20.6 and 25.1 for Curricular NCP + CSB. This is consistent with Figure 5 where we observe that pretrained model is better at identifying highly segmented areas.

Next, we manually analyzed the kinds of errors the models are making. We find that both models over-rely on certain cues to over-predict segment breaks. For example, the models, with and without pretraining, were more likely to predict a segment break for samples in which the left context ended in a question but the ground truth data had no such bias. Similarly, among CSB’s segment break predictions, 8.29% had “yeah” in the beginning of the right context, whereas this number is only 6.63% in the ground truth segment breaks. Pretraining reduces this over-reliance (the corresponding number for Curricular NCP + CSB is 6.84%). Tables 5 and 6 provide more information. We leave further investigations into these errors for future work.

7 Conclusion

In this paper, we propose novel pretraining strategies for transcript segmentation. Our pretraining strategies address major challenges associated with transcript data. The pretraining strategies are based on the idea of next conversation prediction. This strategy by itself also forms a strong unsupervised baseline for segmentation. Additional improvements make NCP more relevant and useful to the segmentation task. We further introduced a curriculum in the pretraining strategies based on similarity of pretraining samples to the segmentation samples. Our results showed that our proposed pretraining strategies are robust to noise in training data and they are effective for improving performance of multiple model architectures for segmentation.

8 Limitations

NCP requires the dataset to be marked with sentence breaks. Segmentation datasets might not have this annotation. While an off-the-shelf sentence break identifier model can do this sub-task, this could introduce some noise to the training dataset.

While we have shown that NCP applies to multiple segmentation task architectures (Hierarchical and CSB in Tables 1 & 2), it might not be applicable across all segmentation architectures. Since NCP relies on its similarity to the segmentation task, pretraining on differently defined segmentation tasks might not yield benefits without alterations.

A different transcript segmentation dataset might be significantly different from NCP such that the pretraining's benefits taper off. However, it is hard to comment on this with the currently available datasets for this task.

We hope that future work explores these concerns and that our work can be a stepping stone in this exciting direction.

9 Ethical Considerations

We train our model on a publicly available podcast dataset that might contain (potentially harmful) social biases. Furthermore, since this an informal use of language, the text is rife with colloquialisms, some of which could be triggering or sexually explicit. Since, we have not employed any bias removal methods, model might predict segment breaks based on spurious correlations such as usage of specific pronouns or mention of specific genders. All the trained models are only tested on English language dataset and might not necessarily carry well to other languages.

A Appendix

A.1 Additional information on the Text Segmentation task

Transcript segments represent a mix of change in topics, sub-topics and/or nature of discourse. For example, new segments may start when the participants change their discussion from Health domain to Toastmasters or within health from mammograms to genetics. Other ways segments may change based on whether the discussion has changed from a short dialogue style conversation

Pretraining Example "Disimilar" to Segmentation Task	[...] get serious. so i think it's appropriate that this is the week that we're going to talk about don't just sit there. right. in this episode of the podcast. yes yes. so great." Table 4: Examples of "similar" and "dissimilar" samples to the downstream task. The ordering from top to bottom is also the order we follow for training Curricular NCP.

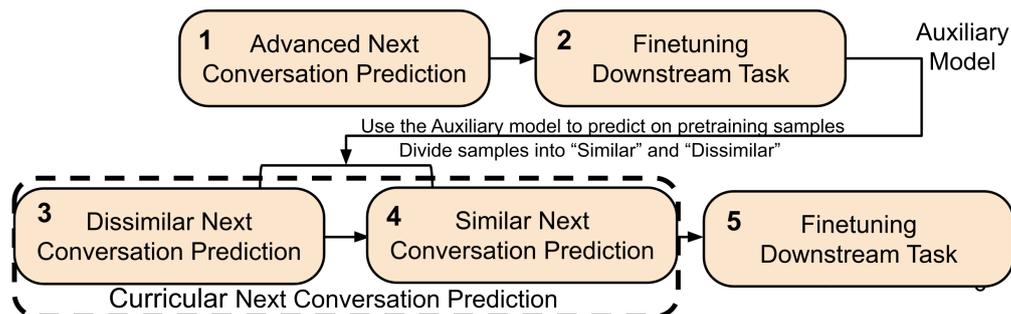

Figure 6: Proposed Curricular NCP Pretraining illustrated. First the auxiliary model is obtained to rank the pretraining samples into "similar" and "dissimilar". Following which the curriculum can be followed.

Models	SB	Not SB
CSB	5.07	1.38
Curr. NSP + CSB	4.56	1.01
Ground	3.87	3.31

Table 5: Percentage of samples which had a "?" within the last 10 characters of the left context. Here, "Segment Break" (SB) and "Not Segment Break" (Not SB) implies ground truth in "Ground" and predictions in case of the models. For example, 5.07% of samples predicted with a segment break for CSB had left context ending in "?". Both CSB and Curricular NSP + CSB tend to over predict segment breaks when the left context ends with a "?" compared to ground truth, which has no such bias.

Models	SB	Not SB
CSB	8.29	0.69
Curr. NSP + CSB	6.84	1.01
Ground	6.63	3.87

Table 6: Percentage of samples which had "yeah" within the first 5 words of the right context. Here, "Segment Break" (SB) and "Not Segment Break" (Not SB) implies ground truth in "Ground" and predictions in case of the models. For example, 6.84% of samples predicted with a segment break for the pretrained model had "yeah" within five tokens after the predicted segment break. While both CSB and Curricular NSP + CSB make incorrect predictions, the distribution is more closer to ground truth after pretraining.

to a long answer QA session. The individual segments are often too verbose and diverse (average length 206.5 words and standard deviation 500.13) to be presented unedited. Hence, we gave an idea

of what these segments look like in Figure 1, with individual sentences of a segment truncated.

A.2 Toolkits

We use NLTK toolkit Link: <https://www.nltk.org/> for computing WindowDiff https://www.nltk.org/_modules/nltk/metrics/windowdiff.html. NLTK version is 3.6.2.

A.3 Training and Inference Details

Number of parameters: BERT-base has 110 million parameters.

GPU Details: We use a NVIDIA GeForce RTX 2080 Ti machine to train and infer all our models. All experimental results except for Tables 6 and Tables 5 are reported over a mean of 3 runs.

A.4 Dataset License Details

The dataset we have used SliceCast-Podcasts, Link - <https://github.com/bmmidei/SliceCast#Small-scale-podcast-dataset> was licensed under the MIT License. Our research is consistent with the intended use.
