Based on the shared span prediction module, our model is able to extract values from the dialogue context directly, thereby being open-vocabulary and domain scalable. At the same time, it has successfully overcome the challenge of an unavailable ontology set. Moreover, it presents as the best-performed model in any framework with span prediction modules, where it has improved the margin of JGA by more than 3.5% from the STARC approach. None of the other approaches has ever studied their DST with multi-lingual pretrained models. By utilising the pretrained XLM-R model as the context encoder, our approach is the only method with cross-lingual transferability. Given its distinct advantages of being domain-adaptable and language transferable, a promising result in multi-domain DST at 53.2% is still competitive in the supervised setting.

To study the impact of essential designs in our model, we first analyse the performance of a mono-lingual model, BERT, and ablate it over different choices of domain classifiers. In Table 4, the vanilla model with undersampling of negative samples has the lowest JGA at 38.2%. This is because the shared span prediction layer lacks domain knowl-

Ablation	JGA (%)
BERT-base	
w. undersampling	38.23
w. joint domain classifier	41.10
w. independent domain classifier	49.04
+ dialogue history	51.11
XLM-RoBERTa-base	
w. independent domain classifier	51.67
+ dialogue history	53.21

Table 4: Ablation study of XQA-DST with different base models and training strategies on MultiWOZ 2.1.

edge and frequently generates false positive predictions for out-of-domain questions. Introducing a joint domain classifier at the output of the main model in parallel with θ_{gate} improves the JGA by about 3%, which convinces us about the effectiveness of domain classifiers. At the cost of the model size, the independent domain classifier significantly improves the JGA to 49.0% by removing the interference from asking out-of-domain questions. It encourages the model to learn to distinguish in-domain questions rather than additionally learning the relationship between the context and domains within a goal. We notice that implementing XLM-R instead of BERT further improves the performance to 51.7%. We suppose it is because of the well-trained RoBERTa model, and the multi-lingual pretraining does not greatly sacrifice the per-language performance. Lastly, due to the complexity of MultiWOZ dialogues, the history information is essential in accurately predicting current domains and extracting spans. Hence, appending the dialogue history has led our model to outperform most prior methods capable of zero-shot inference.

6 Conclusion

We introduce a new multi-domain and multi-lingual dialogue state tracker, XQA-DST, within an extractive question answering framework. It gives distinct advantages for avoiding relying on any predefined ontology and being open-vocabulary to new slots with unseen values. We have shown a strong domain and cross-lingual transferable ability of our model by outperforming famous baselines. We have demonstrated its competitive performance in multi-domain DST with a novel turn-domain filtering strategy and a multi-domain classifier in parallel. With the design of an XLM-R based multi-domain classifier, our approach is feasible for track-

ing states in multi-domain and multi-lingual scenarios. Therefore, it holds a strong potential to overcome the challenging data scarcity problem for either domains or languages in the real application of task-oriented dialogue systems.

Limitations

In the supervised DST experiments, our multi-domain classifier is effective when the range of domains is given. However, we have fixed weights for each domain projection layer, which inevitably makes the classifier not domain scalable. Though the shared span prediction layer is still scalable to all domains, the performance of our model will degrade if it encounters a dialogue in multiple unseen domains.

We recall that the independent multi-domain classifier provides a clearer training objective and significantly improves the JGA than the joint domain classifier. However, this is at the cost of model size and requires expensive computation resources. Therefore, we look forward to approaches that wisely incorporate the domain classifier.

In the cross-lingual experiments, we test the transfer performance for German and Italian, which have been used as the pretraining languages for XLM-R. Hence, we expect a degradation of cross-lingual performance for our model on low-resource languages that are not pretrained by XLM-R. In addition, our experiments rely on a back-translation from the target language to the source language. Though we have implemented a predefined label dictionary that collects vocabulary with similar semantics, it cannot perfectly handle the noise from an external translation system.

A Reproducibility Details

Training details We use both *XLM-RoBERTa-base* (125M) and *BERT-base-uncased* (110M) with pretrained weights from the Huggingface library of Transformers. We run all experiments on a single RTX 3080Ti with 12 GB memory. We fix the batch size at 16 for all models during training and use the batch size at 1 for evaluations. During training, it takes about 40 minutes to run an epoch on MultiWOZ 2.1, and its inference time for all evaluation examples is about 7 minutes. For the WOZ 2.0 dataset, it takes roughly 20 minutes to train the model. In the cross-lingual setting, the inference time is about 10 minutes due to the back-translation procedure.

Hyperparameters For two-stage fine-tuning experiments, we implement QA fine-tuned models

from the Huggingface library of Transformers without tuning their hyperparameters. For the XQuAD experiment, it implements the batch size at 40 and a learning rate of 3×10^{-5} for the first-stage fine-tuning. For the SQuAD 2.0 experiment, we use the fine-tuned weights and hyperparameters from *deepset/xlm-roberta-base-squad2*.

Dataset details For the supervised DST experiments, we split the datasets into train/dev/test sets as same as Heck et al. (2020). In domain adaptation experiments, the MultiWOZ 2.1 datasets are divided into 5 domains in accordance with Lin et al. (2021c), where the *hospital* and *police* domains are excluded. Lastly, the multi-lingual WOZ 2.0 datasets have the same split as Moghe et al. (2021).

Improving Prediction Backward-Compatibility in NLP Model Upgrade with Gated Fusion

Abstract

When upgrading neural models to a newer version, new errors that were not encountered in the legacy version can be introduced, known as *regression*¹ errors. This inconsistent behavior during model upgrade often outweighs the benefits of accuracy gain and hinders the adoption of new models. To mitigate regression errors from model upgrade, distillation and ensemble have proven to be viable solutions without significant compromise in performance. Despite the progress, these approaches attained an incremental reduction in regression which is still far from achieving backward-compatible model upgrade. In this work, we propose a novel method, *Gated Fusion*, that promotes backward compatibility via learning to mix predictions between old and new models. Empirical results on two distinct model upgrade scenarios show that our method reduces the number of regression errors by 62% on average, outperforming the strongest baseline by an average of 25%.

1 Introduction

In order to achieve a smooth continuous improvement of NLP applications, it is critical to guarantee consistent operation of the system after an upgrade. New errors introduced during the model upgrade interfere with the existing user experience and are considered to be a *regression* in the quality. Due to the difficulty of modularizing or explaining the behavior of deep neural networks, traditional software regression tests are inapplicable to neural based systems. The cost of arduous error analysis and model patching often exceeds the benefits of model upgrades. Developing methods that ensure backward compatibility during model upgrades without compromise in performance becomes a valuable research direction (Yan et al., 2021; Xie et al., 2021; Träuble et al., 2021; Cai et al., 2022).

*Work done during author’s internship at AWS AI Labs.

¹Within this work, *regression* denotes performance degradation in software systems, instead of the statistical technique for estimating relationships among variables.

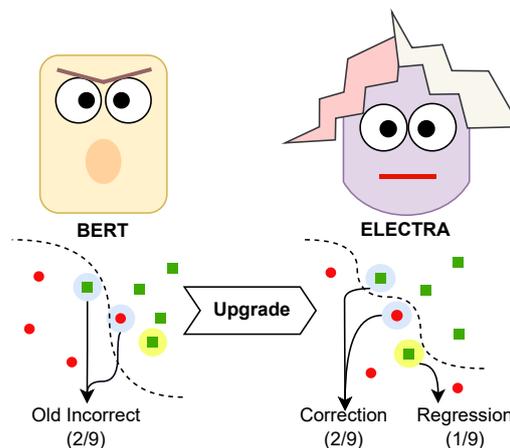

Figure 1: Illustration of regression errors when upgrading from BERT (Devlin et al., 2019) to ELECTRA (Clark et al., 2020) for classification. Red circles and green squares denote examples of different classes. Dashed lines represent decision boundaries.

The *prediction backward-compatible model upgrade* problem aims to improve consistency of correct classification predictions between legacy and upgraded models without accuracy loss. Yan et al. (2021) first studied backward compatibility during model upgrade on image classification tasks. They proposed to enforce the positive congruence of the new model with the old one by applying a knowledge distillation objective (Hinton et al., 2015) objective with re-weighting of training samples. Later, Xie et al. (2021) extended the work of Yan et al. (2021) by investigating the backward compatibility in NLP classification tasks. They found that their proposed distillation-based approach can help decrease the regression errors of specific linguistic phenomena in NLP classification tasks.

Despite progress with both distillation- and ensemble-based regression-mitigation approaches, there are limitations that prevent them from broad practical adoption in ML operations. Distillation-based methods attempt to transfer the prediction power of the old model to the new one on potential

regression instances (Hinton et al., 2015). However, given the huge complexity of current neural architectures and relatively scarce training data in downstream tasks, models could have insufficient data to reliably estimate the probable regression cases and carry out the transfer on them (Xie et al., 2021; Cai et al., 2022). On the other hand, model ensemble aggregates predictions from differently-trained new models but bears no connection with the legacy version (Yan et al., 2021). These limitations reveal the two major challenges when striving to ensure backward compatibility. First, the new model could have distinct inductive bias and prediction behavior than the old system, rooted from inherent differences such as architecture, model size, and pretraining procedure (Liu et al., 2021). Second, during new model training, a reliable mechanism is needed in place to bridge the gap between two models and mitigate potential inconsistencies.

Inspired by the strength and weakness of prior approaches, we propose *Gated Fusion* to integrate old and new models via gating mechanism (Hochreiter and Schmidhuber, 1997; Chung et al., 2014; Gu et al., 2016), essentially a light-weight ensemble of legacy and upgrade models connected via a learned fusion gate. Specifically, we add a *learned* gate on top of the new model. We combine the logits from old and new models according to the weight from the gate. We train our Gated Fusion model by minimizing the standard cross-entropy error. The intuition is that the gate could learn to put more weights on the old model when the new model cannot produce correct predictions, effectively doing fall-backs that optimizes backward compatibility.

Empirical results demonstrate that our proposed approach outperforms other competing methods significantly, where we can obtain on average 62% reduction of total negative flips, i.e. new errors caused by the model upgrade, without any degradation in accuracy performance. The effectiveness of Gated Fusion is validated across three diverse classification tasks and two distinct model upgrade scenarios (a) upgrade to larger model size (b) upgrade to advanced pretrained model, where consistent results are attained across the board.

Our main contributions are as follows:

- We propose Gated Fusion that integrates old and new models via gating mechanism for backward-compatible model upgrade;
- We evaluate competing methods on two distinct and challenging model upgrade scenarios

across three diverse classification tasks;

- Empirical results show that our proposed approach significantly outperforms competing methods and achieves regression reductions by a large margin across the board.

2 The Backward-Compatible Model Upgrade Problem

The goal of backward-compatible model upgrade is to minimize regression errors without compromising the accuracy performance during model upgrade (Yan et al., 2021; Xie et al., 2021). In this work, we aim to improve the backward compatibility of model predictions in the NLP classification tasks. Following Xie et al. (2021), we study the scenario where the underlying pretrained language model (LM) is being upgraded.

Let x be a natural language input with a class label $y \in \{1, 2, \dots, C\}$. $\mathcal{D} = \{x_i, y_i\}_{i=1}^N$ denotes a set of N examples with corresponding labels. A classifier f estimates the class probabilities given the input $\vec{f}(x) = (p(y = 1|x), \dots, p(y = C|x))^\top$. When upgrading from an *old* model f_{old} to a *new* model f_{new} , normally with distinct architectures and trained on the same data, an improved model f^* is produced based on f_{old} and f_{new} . Our goal is for f^* to minimize *regression errors* as an additional objective, while still achieving comparable performance to f_{new}^o , the new model trained in the vanilla setting. Note that f^* could be multiple times larger than f_{new}^o , with model ensemble of f_{new}^o as one example (Yan et al., 2021).

Measuring Backward Compatibility. The backward compatibility is measured via quantifying regression errors on a given regression measurement set $\mathcal{D}_{reg} = \{x_i, y_i\}_{i=1}^M$. \mathcal{D}_{reg} could be a hidden customer test set comprising critical use cases, a set of behavioral testing examples for targeted evaluation (Ribeiro et al., 2020), or the development split from the dataset of interest. In this work, we take the development set as our \mathcal{D}_{reg} for evaluation.

For classification, regression errors are characterized by *negative flips*, denoted as \mathcal{R}_{NF} – the portion of samples in \mathcal{D}_{reg} that flip from correct prediction $f_{old}(x_i) = y_i$ to incorrect output $f_{new}(x_i) \neq y_i$ during model upgrade:

$$\mathcal{R}_{NF}(\mathcal{D}_{reg}, \vec{f}_{old}, \vec{f}_{new}) = \frac{|\{x | f_{old} = y, f_{new} \neq y\}|}{|\mathcal{D}_{reg}|}. \quad (1)$$

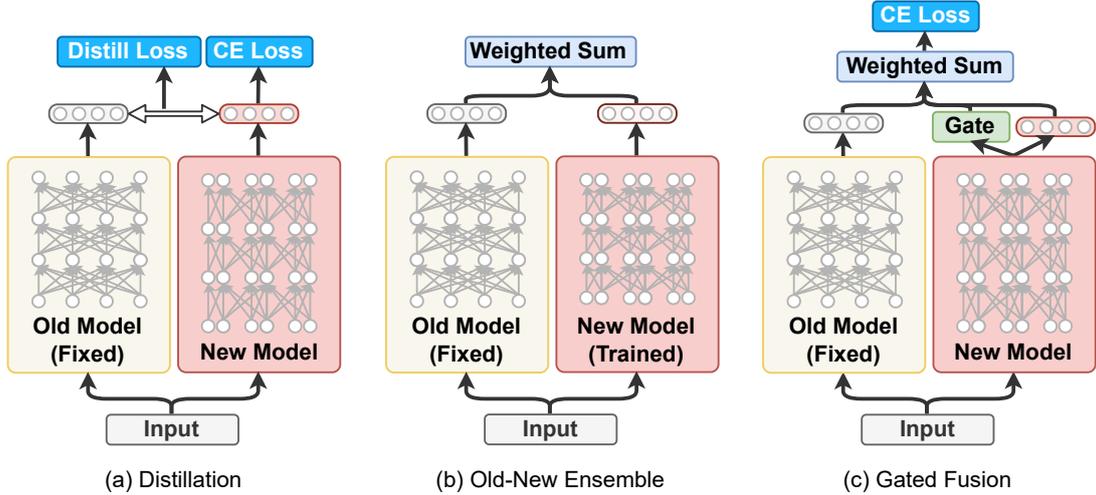

Figure 2: Methods to improve prediction backward compatibility during model upgrade. (a) Distillation-based approach to align predicted logits on potential regression instances (Xie et al., 2021). (b) Ensemble of old and new models via weighted sum of either predicted logits or probabilities. (c) Our proposed Gated Fusion that learns a gate as a soft switch to dynamically determine whether to fall back to previous predictions.

One thing to emphasize is that maximizing classifier performance does not necessarily help in minimizing \mathcal{R}_{NF} (Yan et al., 2021; Xie et al., 2021).

3 Gated Fusion: Methodology

3.1 Method Overview

To improve backward compatibility in model upgrade, it’s crucial to have a mechanism that detects potential regression errors and mitigates them when making predictions. We propose Gated Fusion (GF) to achieve this by learning a gate as a soft switch to choose between generating predictions by the new model or resorting to outputs of the old model. Gated Fusion is inspired by the gating mechanism widely used in other applications. For example, mixing word copying mode with word generation mode for language modeling (Merity et al., 2016) and summarization (See et al., 2017).

Our proposed Gated Fusion f_{GF}^* consists of the old model f_{old} , the new model f_{new} , and a gating network g_θ . The old model f_{old} is the legacy version before upgrade where the parameters are fixed. The new model f_{new} has the same architecture as f_{new}^o and is randomly initialized. The gating network g_θ is a multi-layer feed-forward network with sigmoid function. It produces a scalar weight α_{gate} in the range $[0, 1]$ from the output layer of f_{new} , denoted as \mathcal{E}_{new} :

$$\alpha_{gate}(x) = g_\theta(\mathcal{E}_{new}(x)). \quad (2)$$

We use α_{gate} to combine the logits of old and new

models as our final outputs:

$$l_{GF}^*(y|x) = (1 - \alpha_{gate}) \cdot \frac{l_{old}(y|x)}{T} + \alpha_{gate} \cdot l_{new}(y|x), \quad (3)$$

where $l(y|x)$ denotes predicted logits from models and T is the temperature scaling to regularize the magnitude of old model’s logits. f_{new} and g_θ are then jointly trained end-to-end with cross-entropy loss between our output logits $l_{GF}^*(y|x)$ and label distributions on downstream tasks.

The intuition behind Gated Fusion is that when f_{new} makes a mistake while f_{old} produces the correct output, the gate g_θ will learn to put more weight on f_{old} in order to minimize the final classification loss. This process effectively mitigates potential negative flips introduced by the model upgrade and thus improves the backward compatibility of final predictions.

3.2 Training and Inference

In practice, training Gated Fusion with randomly initialized f_{new} would make the shallow gating network quickly converge to favor the fully-trained f_{old} . To prevent this, we only train f_{new} for the first few epochs to ensure its competence before jointly training g_θ and f_{new} using $l_{GF}^*(x)$. In addition, we found that stopping gradient flow from g_θ to f_{new} can further prevent the performance decrease of the new model within Gated Fusion:

$$\alpha_{gate}(x) = g_\theta(\text{stop_grad}(\mathcal{E}_{new}(x))). \quad (4)$$

At inference time, Gated Fusion produces logits from f_{old} and f_{new} as well as the gate value α_{gate}

to make output predictions:

$$f_{GF}^*(x) = \text{Softmax}\left((1 - \alpha_{gate}) \cdot \frac{l_{old}}{T} + \alpha_{gate} \cdot l_{new}\right). \quad (5)$$

3.3 Inference with Cache

Our proposed Gated Fusion requires f_{old} to be hosted together with the new model. In reality, one could have a resource-constrained setting and request the old model to be discarded at inference. We note that in real applications, repetitive inputs are commonly seen in live traffic (Batrinca and Treleaven, 2015) and the backward compatibility of model upgrade entails that correct predictions can be preserved on the legacy instances already seen and predicted by the old model.

To simulate real scenarios, we randomly cache old model’s logits on a portion of test inputs. When getting out-of-cache instances, we use new model’s output embedding $\mathcal{E}_{new}(x)$ as key and euclidean distance as metric to search for the nearest cached instance. The cached old-model logits can then be used for Gated Fusion to make predictions without hosting f_{old} at inference.

4 Experiments Setup

4.1 Model Upgrade Scenarios

We conduct experiments on two representative model upgrade scenarios: (a) upgrade to a larger pretrained model of the same type, where we use BERT_{base} to BERT_{large}. (b) upgrade to a distinct pretrained model with the same size. We use BERT_{base} to ELECTRA_{base} (Clark et al., 2020) as this challenging model upgrade scenario for backward-compatibility, as they are pretrained under different self-supervised learning paradigms. The former uses masked language modeling (MLM) with reconstruction loss, while the latter is pretrained in generative-contrastive (adversarial) fashion with distributional divergence as the loss (Liu et al., 2021).

4.2 Datasets and Implementation

We evaluate our approach across three datasets. They represent different sentence-level classification tasks, from single-sentence to sentence-pair classification, with varying dataset sizes. We use: (a) Stanford Sentiment Treebank (SST-2), a single-sentence task to classify movie review sentiment, with 67k train and 0.9k dev set (Socher et al., 2013). (b) Microsoft Research Paraphrase Corpus (MRPC)

(Dolan and Brockett, 2005), a sentence-pair classification task for identifying paraphrases, with 3.7k train and 0.4k dev set. (c) Question Natural Language Inference (QNLI), a question-paragraph pair task to determine whether the paragraph contains the answer to the question, with 100k train and 5.5k dev set. Datasets are taken from GLUE Benchmark (Wang et al., 2018) and processed with scripts from Hugging Face².

For implementation, we use the sequence classification and pre-trained model parameters from Hugging Face Transformers³. Experiments are done in PyTorch (Paszke et al., 2019) with Tesla V100 GPUs and results are averaged over 5 random seeds. Learning rate, batch size, and train epoch are tuned during training new model alone on given tasks and then fixed for all backward-compatible solutions. In Gated Fusion, we first train f_{new} alone for first $(N - 1)$ epochs and then jointly train g_{θ} and f_{new} with Gated Fusion logits l_{GF}^* in the last epoch. Further implementation details can be found in the Appendix.

4.3 Baselines

We compare our approach with several strong baselines. (a) Train the new model directly on the target task without any adjustment, i.e. f_{new}^o . (b) The specialized distillation method proposed in Xie et al. (2021), where the KL-divergence of prediction probabilities between old and new models is applied when $p_{old}(y = y_i|x_i) > p_{new}(y = y_i|x_i)$. (c) Model ensemble via majority-voting that was shown to be very effective (Yan et al., 2021; Xie et al., 2021). Similarly, we use 5-seed new model ensemble as a strong baseline. (d) The ensemble of the old and new models probabilities, $p^*(y|x) = (1 - \alpha) \cdot p_{old}(y|x) + \alpha \cdot p_{new}(y|x)$, as well as ensemble of the old and new models logits, $l^*(y|x) = (1 - \alpha) \cdot l_{old}(y|x) + \alpha \cdot l_{new}(y|x)$, where α is searched among [0.5, 0.6, 0.7, 0.8, 0.9] to maximize backward-compatibility while achieving accuracy on par with the vanilla f_{new}^o .

5 Results and Analysis

5.1 Upgrade to a Larger Pretrained Model

Our first model upgrade scenario scales up the size of underlying pretrained language models. We experiment with BERT_{base} to BERT_{large}, where

Table 2: Negative flip rate \mathcal{R}_{NF} and model accuracy (%) of competing methods to optimize backward-compatibility without performance degradation during $\text{BERT}_{base} \rightarrow \text{ELECTRA}_{base}$ model upgrade.

the model size is tripled (110M vs 340M) and the model depth is doubled (12 vs 24 layers).

Table 1 shows the results. For f_{new}^o , we can observe that the negative flip rates \mathcal{R}_{NF} are usually much larger than the accuracy gains across tasks, which could be the reason to hinder new model adoptions in real-world applications. Besides, when dividing \mathcal{R}_{NF} over the error rate ($1 - accuracy$), we can observe that around 30% to 40% of all f_{new}^o prediction errors are in fact the *new* errors introduced during model upgrade. For improving prediction backward-compatibility, our proposed Gated Fusion outperforms other competing methods to considerably reduce \mathcal{R}_{NF} without degradation on accuracy. Note that best α values found for the two variants of old-new ensemble are both 0.5, hence producing identical results.

Compared to the vanilla new model, gated fusion obtains absolute \mathcal{R}_{NF} reductions of -1.40% on SST-2, -2.94% on MRPC, and -1.99% on QNLI. These translate to reducing the total negative flip cases by 64.2%, 71.4%, 73.2%, respectively. Compared to the strongest baseline (old-new ensemble), we obtain further absolute \mathcal{R}_{NF} reductions of -0.28% on SST-2, -0.49% on MRPC, and

-0.31% on QNLI, which translate to further reducing 12.8%, 11.9%, and 11.4% of negative flip cases. These results show the effectiveness of our method to mitigate a significant amount of regression errors during model upgrade.

5.2 Upgrade to a Different Pretrained Model

A more challenging upgrade scenario is when old and new models are pretrained under distinctive paradigms, producing two representation spaces of fairly different characteristics (Meng et al., 2021b). We experiment with BERT_{base} to ELECTRA_{base} in this scenario, where two models have the same size but are pretrained under utterly different schemes, i.e. generative versus adversarial.

Table 2 shows the results. For f_{new}^o , compared with upgrading to BERT_{large} , we observe larger accuracy gains and lower \mathcal{R}_{NF} on SST-2 and MRPC. However, on QNLI, upgrading to ELECTRA_{base} achieves a higher accuracy gain but an even a higher \mathcal{R}_{NF} . This implies that boosting accuracy and improving backward compatibility could be two related but different objectives.

For mitigation strategies, Gated Fusion achieves the lowest negative flip rates across datasets without any accuracy loss. We obtain absolute \mathcal{R}_{NF} re-

to ELECTRA _{base}	95.00 _{0.06}	88.58 _{0.57}	92.90 _{0.26}
Gated Fusion	95.02 _{0.16}	88.68 _{0.68}	92.98 _{0.17}
- drop old model	95.16 _{0.09}	88.63 _{0.94}	93.06 _{0.13}

Table 4: Accuracy (%) when dropping the old model within Gated Fusion at inference time.

ductions of -0.92% on SST-2, -1.33% on MRPC, and -2.01% on QNLI over the vanilla setup, reducing 56.4%, 35.7%, and 71.3% of overall negative flips, respectively. Compared with upgrading to BERT_{large}, we observe that upgrading to ELECTRA_{base} has much smaller relative negative flip reductions on SST-2 and MRPC, showing that it could be indeed harder to improve backward-compatibility when upgrading to a distinct pre-trained model. In contrast, similar relative negative flip reductions are observed on QNLI across two upgrade scenarios. This could be attributed to the abundant training data of the downstream task.

5.3 Drop Old Model at Inference Time

Our proposed method requires the old model to be hosted together with the new model. A natural question is whether we could train Gated Fusion with the old model and then discard it at inference time to host the new model only.

We first experiment with directly dropping the old model within Gated Fusion at inference time.

	SST-2	
	\mathcal{R}_{NF}	Accuracy
Old Model: BERT _{base}	-	92.00 _{0.27}
New Model: ELECTRA _{base}	1.63 _{0.20}	95.00 _{0.06}
Gated Fusion - 50% cache	1.26 _{0.10}	94.86 _{0.27}
Gated Fusion - 75% cache	0.99 _{0.25}	94.91 _{0.12}
Gated Fusion	0.71 _{0.18}	95.02 _{0.16}

Table 5: Negative flip rate \mathcal{R}_{NF} and model accuracy (%) of Gated Fusion with $X\%$ cache of old model logits at inference time.

Results in Table 4 show that dropping old model in Gated Fusion can still achieve comparable accuracy across the board, suggesting no performance degradation. Nonetheless, we observe that the negative flip rates also fall back to similar positions as training the new model in the vanilla setting.

However, in real application scenario, live inputs are often repetitively seen across time and ensuring backward-compatibility means that correct predictions on same instances can be preserved after model upgrade. We experiment with the caching method introduced in section 3.3 to store old model’s logits on random $X\%$ of test instances where Gated Fusion can later access them for inference. Results in Table 5 show that with higher percentage of cache, \mathcal{R}_{NF} is gradually reduced towards \mathcal{R}_{NF} of the original Gated Fusion, which is equivalent to 100% cache. Still, we observe a notable gap in \mathcal{R}_{NF} between the partial caching and full settings. We leave the examination of ways to achieve the upper bound in reduction in \mathcal{R}_{NF} with smaller cache to the future work.

	(Task, Label)	Examples
BERT _{base} → BERT _{large}	(SST-2, Positive)	[Sentence] A study in shades of gray, offering itself up in subtle plot maneuvers ...
	(SST-2, Negative)	[Sentence] Manages to be both repulsively sadistic and mundane.
	(MRPC, Not Equivalent)	[Sentence 1] Vivace was founded in 1999 and has raised over \$118 million in three rounds of venture financing. [Sentence 2] During difficult times for technology venture capital, Vivace raised over \$118 million in three rounds of venture financing.
	(QNLI, Entailment)	[Question] Why was there a depreciation of the industrialized nations dollars? [Sentence] Anticipating that currency values would fluctuate unpredictably for a time, the industrialized nations increased their reserves (by expanding their money supplies) in amounts far greater than before.
BERT _{base} → ELECTRA _{base}	(SST-2, Positive)	[Sentence] Aside from minor tinkering , this is the same movie you probably loved in 1994, except that it looks even better.
	(SST-2, Negative)	[Sentence] It showcases carvey’s talent for voices, but not nearly enough and not without taxing every drop of one’s patience to get to the good stuff .
	(MRPC, Equivalent)	[Sentence 1] Blair’s Foreign Secretary Jack Straw was to take his place on Monday to give a statement to parliament on the European Union. [Sentence 2] Blair’s office said his Foreign Secretary Jack Straw would take his place on Monday to give a statement to parliament on the EU meeting the prime minister attended last week.
	(QNLI, Not Entailment)	[Question] What is the main executive body of the EU? [Sentence] This means that the Commission has a monopoly on initiating the legislative procedure, although the Council is the "de facto catalyst of many legislative initiatives".

Table 6: Examples of regression errors present when upgrading to the vanilla new model f_{new}^o but fixed by our Gated Fusion approach, i.e. predictions of $(f_{old}, f_{new}^o, f_{GF}^*)$ are *(correct, incorrect, correct)*, respectively.

5.4 Limitations of New Model Ensemble

In previous works (Yan et al., 2021; Xie et al., 2021), new model ensemble via majority voting is shown to effectively reduce negative flips and posed as a difficult-to-beat baseline. Here, we increase the number of models in ensemble to examine its limitations. Results in Table 3 show that ensemble with more models generally help to obtain lower \mathcal{R}_{NF} . However, \mathcal{R}_{NF} converges quickly as number of models increased, where a notable gap remains between new model ensemble and Gated Fusion. Moreover, the results show once more that boosting accuracy does not necessarily improve the backward compatibility in model upgrade.

In principle, two sources could cause negative flips during model upgrade (a) the stochasticity during model training, including initializations, data loading order, and optimization process (Somepalli et al., 2022). (b) the distinctions between old and new model hypotheses, including architecture and pretraining data and procedure, leading to different representation space structures and prediction behaviors in terms of decision boundaries. Without an explicit connection to f_{old} , new model ensemble can only reduce negative flips primarily caused by the first factor, while our proposed Gated Fusion directly learns to mitigate regression errors regardless of their causes.

Besides, as large-scale generative models become more and more powerful and popular (Raffel

et al., 2020; Brown et al., 2020; Su et al., 2021), it would be difficult to fine-tune them multiple times on a target task for ensemble.

5.5 Analysis of Gated Fusion

Comparing f_{new}^o with f_{GF}^* , we can calculate the *fix rate* and *new fault rate* of our Gated Fusion method. During an upgrade, if there are 20 negative flips with f_{new}^o and 16 out of them can be mitigated by f_{GF}^* , we obtain the fix rate to be $16/20 = 80\%$. Similarly, if f_{GF}^* introduces another 4 new negative flips which are not present with f_{new}^o , the new fault rate is computed to be $4/20 = 20\%$. We calculate the 5-seed average of these two rates across different classification tasks and upgrade scenarios. In BERT_{base} to BERT_{large}, the averaged fix rates by Gated Fusion are 68.4% on SST-2, 83.8% on MRPC, and 82.9% on QNLI, with new fault rates being 4.1% on SST-2, 11.3% on MRPC, and 9.7% on QNLI. In BERT_{base} to ELECTRA_{base}, Gated Fusion achieves the averaged fix rates 58.0% on SST-2, 50.8% on MRPC, and 75.6% on QNLI, with new fault rates being 2.8% on SST-2, 15.2% on MRPC, and 4.0% on QNLI. These results show that, on average, Gated Fusion is able to eliminate 69.9% of total regression errors while adding only 7.9% new ones, comparing with doing model upgrade without any treatment, i.e. f_{new}^o .

Table 6 shows a few regression error cases fixed by our proposed approach. In general, Gated Fu-

sion can mitigate negative flips happened on different classes across diverse tasks as well as on inputs with variable lengths. With closer inspections of f_{GF}^* , we found that when f_{new} produces incorrect predictions and f_{old} gives correct outputs, g_θ is capable of putting larger weights on f_{old} to ensure the backward compatibility. We also observed that the gate g_θ is more prone to over-fitting when the downstream tasks have smaller training set, e.g. MRPC, or are more difficult in nature, e.g. single-sentence task SST-2 versus sentence-pair tasks, which causes Gated Fusion to introduce more new errors, i.e. higher new fault rates.

6 Discussion

Gated Fusion requires to host both old and new models at inference time, which could raise a concern regarding the increased computational burden. However, in practice, old model’s logits of previous inference instances can be cached in storage and later leveraged in our Gated Fusion. That is, we only need to host the new model with the gate at inference time and leverage old predictions from cache. And for the out-of-cache inputs, backward-compatibility would be less of an issue since users have not observed such examples to make conclusions on the underlying regression.

For real-world applications, there could be multiple model updates and thus multiple legacy versions. We note that in this scenario, user experience would be primarily grounded on predictions of the latest legacy version, which are also saved in cache. Our Gated Fusion can hence leverage them and make new model’s predictions compatible to those from the latest legacy version.

In addition, we emphasize that the main challenge in the regression reduction research problem is to find the best trade-off between model effectiveness and backward compatibility. In this work, we show that the weighted ensemble of old-new models with a learned gate, which we call Gated Fusion, achieves a better negative flip rate than previously explored methods for regression reduction, while straight-forward ensemble approaches cannot naturally weigh on this trade-off. We don’t claim to invent the gated ensemble of old and new models but rather that our main contribution is to show that by repurposing the classic gating mechanism, the gated ensemble can become the most competitive approach to the challenging model-upgrade regression reduction problem, with no overall per-

formance degradation on two realistic model update scenarios across three different datasets.

Recently, more and more NLP products have been deployed in the industry as this field matures. We would like to stress that as better NLP models are being developed, the backward-compatible model upgrade problem naturally emerges as the new research topic strongly motivated by the real-world challenges. While backward-compatibility is currently a niche research topic, we believe that there are many thrilling future directions worth to be investigated.

7 Related Work

[Yan et al. \(2021\)](#) first studied the backward compatibility of predictions during model upgrade on image classification tasks. Later, [Xie et al. \(2021\)](#) investigated the similar topic in natural language understanding and formulated it as a constrained optimization problem. They both show that customized variants of knowledge distillation ([Hinton et al., 2015](#)), which align the predictions of old and new models on potential regression errors, are effective approaches. A model ensemble has also shown to be surprisingly effective ([Yan et al., 2021](#); [Xie et al., 2021](#)), despite no explicit connection between old and new models. This was credited to variance reduction in model predictions, making it less prone to over-fitting and reducing regression errors indirectly. In this work, we leverage the gating mechanism to combine old and new models to further reduce model upgrade regression errors by a large margin across classification tasks.

[Cai et al. \(2022\)](#) analyzed and proposed backward congruent re-ranking to reduce regression in model upgrades for structured predictions tasks such as dependency parsing and conversational semantic parsing. [Träuble et al. \(2021\)](#) proposed an efficient probabilistic approach to locate data instances whose old predictions could be incorrect and update them with ones from the new model. [Zhou et al. \(2022\)](#) looked into forward compatibility, where new classes can be easily incorporated without negatively impacting existing prediction behavior. More recently, [Schumann et al. \(2023\)](#) inspected classification model regression during training data updates and mitigated the problem by interpolating between weights of the old and new models. On top of that, learning cross-model compatible embeddings has been extensively explored in visual search ([Chen et al., 2019](#); [Hu et al., 2019](#);

Wang et al., 2020). Several techniques have been proposed to optimize cross-model interoperability of embeddings, including metric space alignment (Shen et al., 2020), architecture search (Duggal et al., 2021), and aligning class centers between models Meng et al. (2021a). In this work, we focus on improving backward compatibility during model upgrade in terms of prediction behavior on classification tasks, i.e. old and new models should produce consistently correct predictions.

Reducing regression during model upgrade is also related to continual learning (Parisi et al., 2019; De Lange et al., 2019; Sun et al., 2019; Chuang et al., 2020; Sachidananda et al., 2021), incremental learning (Chaudhry et al., 2018; Shan et al., 2020) and concept drifting (Gama et al., 2014; Žliobaitė et al., 2016; Ganin et al., 2016; Zhuang et al., 2020; Lazaridou et al., 2021). In these problems, models are required to learn from and deal with continuously changing data (in terms of examples, classes or tasks), and also need to prevent the forgetting of previously learnt knowledge. This could be one potential cause of regression observed at inference. However, in backward-compatible model upgrade, a new model, usually with distinct network architecture, is trained from scratch to perform the same task and is expected to behave similarly wherever the previous model predicts correctly.

The gating mechanism is widely adopted by recurrent neural networks to effectively control information flows across networks (Hochreiter and Schmidhuber, 1997; Cho et al., 2014; Van Oord et al., 2016; Dauphin et al., 2017; Lai et al., 2019) and contextualize embeddings (Peters et al., 2018; Lai et al., 2020). It is then repurposed to act as a switch for the mixture of different prediction modes, notably to combine input word copying based on the pointer network (Vinyals et al., 2015) with the word generation from output vocabulary (Gu et al., 2016; Merity et al., 2016; See et al., 2017). Our proposed approach is inspired by these works and leverages the gating mechanism to effectively combine old and new models to improve backward compatibility during model upgrade.

8 Conclusion

Ensuring backward compatibility during model upgrade has become a critical topic in real-world NLP applications. In this work, we proposed a new approach, *Gated Fusion*, that achieves significantly better backward compatibility without

compromising accuracy performance on two challenging upgrade scenarios for NLP classification. Experiments demonstrated that our approach outperforms competing methods and achieves negative flip rate reductions by up to 73.2%. Our future research includes improving backward compatibility beyond classification to span detection, model upgrades with very large language models, and upgrades on training data or label schema. We hope that this work can inspire further research and make progress towards smoother transitions of prediction powers as NLP systems evolve.

Limitations

Our proposed method mostly works on the upgrades of underlying pretrained language models for NLP classification tasks. Potential limitations include applying our approach on distant tasks such as question answering or information retrieval, upgrade to models from different architecture families such as recurrent neural nets, and the inapplicability of our method to more recent learning formulation such as in-context learning via prompting.

Ethics Statement

Prediction backward compatibility during model upgrade is an emerging research topic to ensure positive congruency and smoother transitions from existing models towards more performant systems. With primary evaluation on accuracy and negative flips, we acknowledge that our method may also inherit social biases and other toxicity persisted in the legacy models. On the other hand, we have noted that fairness and safety have been one of principal criteria when developing system upgrades. Investigations of the inheritance of persistent toxicity and mitigation of it during backward-compatible upgrades merit interests of future research.

A Details on Experiment Settings

A.1 Model Training Hyper-parameters

We search among following hyper-parameter space for the training of the old model f_{old} and the new model in the vanilla setting f_{new}^o across all datasets:

- Learning Rate: $5e^{-6}$, $1e^{-5}$, $3e^{-5}$, $5e^{-5}$
- Batch Size: 16, 32
- Training Epochs: 3, 5, 8.

The selected hyper-parameters for each model with (*learning rate, batch size, training epoch*):

- BERT_{base}:
 - On SST-2: (lr $1e^{-5}$, batch 16, epoch 5)
 - On MRPC: (lr $3e^{-5}$, batch 16, epoch 5)
 - On QNLI: (lr $3e^{-5}$, batch 32, epoch 3)
- BERT_{large}:
 - On SST-2: (lr $1e^{-5}$, batch 16, epoch 5)
 - On MRPC: (lr $3e^{-5}$, batch 16, epoch 5)
 - On QNLI: (lr $3e^{-5}$, batch 32, epoch 3)
- ELECTRA_{base}:
 - On SST-2: (lr $1e^{-5}$, batch 16, epoch 5)
 - On MRPC: (lr $5e^{-5}$, batch 32, epoch 5)
 - On QNLI: (lr $3e^{-5}$, batch 32, epoch 3)

These model training hyper-parameters for a specific model on one specific dataset is then fixed and reused for all the competing methods to improve backward compatibility during model upgrade.

A.2 Distillation Hyper-parameters

The knowledge distillation method from Xie et al. (2021) imposed an additional loss $\lambda \cdot KL(l_{old}/T, l_{new}/T)$ on potential regression instances. We experimented the best possible hyper-parameters from the following:

- λ : 0.1, 1.0, 10.0
- Temperature T : 0.5, 1.0, 2.0

A.3 Details on Gated Fusion

We initialize the gate g_θ to be a two-layer feed-forward network with the architecture (*Dropout, Linear, LayerNorm, ReLU, Dropout, Linear, Sigmoid*) and fix the hidden size to be 64 across all our experiments.

During the training of Gated Fusion, we only train the f_{new} within f_{GF}^* for the first $(N - 1)$ epochs to ensure its competence, where N is the total training epochs. In the last training epoch, we jointly train g_θ and f_{new} using the Gated Fusion logits l_{GF}^* with the secondary learning rate $lr2$. To prevent the overfitting of the gate, we also apply

drop_gate where at each training step during the last epoch, there is $D\%$ to only train f_{new} within f_{GF}^* and $(1 - D)\%$ to train with l_{GF}^* .

The hyper-parameter space of Gated Fusion is listed as follows:

- Drop Gate (%): 40, 50, 60, 80
- Temperature T on old logits: 1.0, 1.2, 1.4, 1.6
- lr2: $5e^{-7}$, $1e^{-6}$, $3e^{-6}$, $1e^{-5}$, $3e^{-5}$

We found that to achieve good results, the gap in logit magnitude of f_{old} and f_{new} needs to be bridged by the temperature when upgrading from BERT_{base} to ELECTRA_{base}, with T being 1.6 on SST-2, 1.6 on MRPC, and 1.2 on QNLI. On the other hand, $T = 1$ gives good results across three datasets when upgrading from BERT_{base} to BERT_{large}. This could result from the distinct pretraining schemes between models where MLM seem to produce larger magnitude of output logits.

AMBICOREF: Evaluating Human and Model Sensitivity to Ambiguous Coreference

Yuewei Yuan and Chaitanya Malaviya and Mark Yatskar

University of Pennsylvania

{yuewei, cmalaviy, myatskar}@seas.upenn.edu

Abstract

Given a sentence “Abby told Brittney that she upset Courtney”, one would struggle to understand who “she” refers to, and ask for clarification. However, if the word “upset” were replaced with “hugged”, “she” unambiguously refers to Abby. We study if modern co-reference resolution models are sensitive to such pronominal ambiguity. To this end, we construct **AMBICOREF**, a diagnostic corpus of minimal sentence pairs with ambiguous and unambiguous referents. Our examples generalize psycholinguistic studies of human perception of ambiguity around particular arrangements of verbs and their arguments. Analysis shows that (1) humans are less sure of referents in ambiguous AmbiCoref examples than unambiguous ones, and (2) most coreference models show little difference in output between ambiguous and unambiguous pairs. We release **AMBICOREF** as a diagnostic corpus for testing whether models treat ambiguity similarly to humans.¹

1 Introduction

Ambiguity is a fundamental feature of language (Wasow et al., 2003) that some linguists believe arises because of a pressure for efficient communication (Haywood et al., 2005; Piantadosi et al., 2012). Recently, several works have highlighted the existence of ambiguity in tasks such as question answering (Min et al., 2020; Guo et al., 2021), frame disambiguation (Dumitrache et al., 2019), anaphora resolution (Poesio and Artstein, 2005) and language modeling (Aina and Linzen, 2021). Yet systematic evaluation of how models react to ambiguity across many types of language processing problems is missing. We contribute one such study about coreference resolution.

Coreference resolution is crucial to natural language understanding, especially in long contexts, such as dialog. Ambiguity may arise naturally

¹Our dataset and code is available at <https://github.com/LucyYYW/AmbiCoref>.

in dialog, but existing models do not have well-defined target behavior for such coreferences. In contrast, when people encounter coreferential ambiguity, they recognize it, and can ask for clarification. Existing resources, such as OntoNotes (Weischedel et al., 2013), do not provide fine-grained annotations of such instances to evaluate model behavior. This may result in models not being calibrated to handle the uncertainty in interpretations of ambiguous statements. In this work, we ask how sensitive to ambiguity are models trained on these resources?

To understand how existing coreference models react to ambiguity, we construct a diagnostic corpus, **AMBICOREF**. **AMBICOREF** is composed of minimal pairs with ambiguous and unambiguous referents, created from four types of templates. Ambiguity is achieved by reducing context sizes to one sentence, and creating sentences where participating verbs under-constrain the interpretation of their arguments. For example, in Table 1, line 2, our first template leverages ambiguity around verbs expressing subjective experiences.² The templates are designed by drawing on psycholinguistic studies (Springston, 1976; Caramazza et al., 1977; Rohde and Kehler, 2014) and a core contribution of our work is to generalize their observations to create thousands of instances. We achieve this by identifying VerbNet (Schuler, 2005) classes that are likely to contain appropriate verbs, and manually assigning them to templates. Combined with variability we introduce using noun lists, **AMBICOREF** contains over 96 thousand sentences.

We verify that humans perceive instances in **AMBICOREF** in intended ways by crowdsourcing judgements (§3). Annotators are asked to find the coreferent for a pronoun in a sentence, and rate their confidence, to account for the gradient in ambiguity judgements (Schutze, 1995). We find

²Such instances require specific syntactic arrangements: the ambiguous instance in line 2 is unambiguous if the pronoun is moved to the object position of bored.

	Type	Ambig.	Template	Count
1	Experiencer Obj (ECO-1)	✗	[<i>Emily</i>] _A told [<i>Jessica</i>] _B that [<i>she</i>] _A [saw] [Brian].	11336
2	Experiencer Obj (ECO-1)	✓	[<i>Emily</i>] _A told [<i>Jessica</i>] _B that [<i>she</i>] _? [bored] [Brian].	11336
3	Experiencer Obj (ECO-2)	✗	[<i>The mother</i>] _A told [<i>the sister</i>] _B that [<i>she</i>] _A [saw] the client.	11336
4	Experiencer Obj (ECO-2)	✓	[<i>The mother</i>] _A told [<i>the sister</i>] _B that [<i>she</i>] _? [bored] the client.	11336
5	Experiencer Sub (ECS-1)	✗	[<i>The aunt</i>] _A told [<i>Sarah</i>] _B that [the daughter] [met with] [<i>her</i>] _A .	4472
6	Experiencer Sub (ECS-1)	✓	[<i>The aunt</i>] _A told [<i>Sarah</i>] _B that [the daughter] [liked] [<i>her</i>] _? .	4472
7	Experiencer Sub (ECS-2)	✗	[<i>The father</i>] _A told [<i>the son</i>] _B that the client [met with] [<i>him</i>] _A .	4472
8	Experiencer Sub (ECS-2)	✓	[<i>The father</i>] _A told [<i>the son</i>] _B that the client [liked] [<i>him</i>] _? .	4472
9	Implicit Causality (IC)	✗	[<i>Abby</i>] _A [called] [<i>Jane</i>] _B because [<i>she</i>] _A [wanted to apologize].	8424
10	Implicit Causality (IC)	✓	[<i>Abby</i>] _A [called] [<i>Jane</i>] _B because [<i>she</i>] _? [is leaving soon].	8424
11	Transfer (TOP)	✗	[<i>Daniel</i>] _A [baked] [<i>the boy</i>] _B [a cake] [after] [<i>he</i>] _B [asked for one].	8424
12	Transfer (TOP)	✓	[<i>Daniel</i>] _A [baked] [<i>the boy</i>] _B [a cake] [before] [<i>he</i>] _? [had lunch].	8424

Table 1: Summary of the six template pairs that make up AMBICOREF. Template slot are indicated in square bracket, and clusters are marked with subscripts and color. All templates pair an unambiguous sentence with an ambiguous sentence, where they differ only in the choice of verb phrase.

that, for unambiguous instances, humans strongly associate the pronoun with the intended noun but for ambiguous ones, they show reduced confidence across all templates, where the majority of participants are either not confident or mark them as ambiguous. This suggests that humans process ambiguous and unambiguous sentences in AMBICOREF in qualitatively different ways.

AMBICOREF can be used to evaluate model behavior in the presence of ambiguity. We analyze five representative English models: three in CoreNLP (Manning et al., 2014), SpanBERT (Joshi et al., 2020), and NeuralCoref 4.0 (Wolf et al., 2020) (§4). Our main evaluation involves comparing coreference cluster assignments of the pronoun, between ambiguous and unambiguous samples. 4 out of the 5 models we analyze show almost no behavioral change. Unlike humans, coreference models largely do not alter their decisions in the presence of ambiguity. Our analysis implies models likely need to explicitly account for ambiguity to achieve human-like behavior in the face of ambiguous input.

2 Dataset Construction

To understand model sensitivity towards coreferential ambiguity, we build AMBICOREF using four types of templates, shown in Table 1. The templates are created in minimal pairs, and the only difference between the ambiguous and unambiguous counterparts lies in the choice of verb phrase. Note that while ambiguity is a graded phenomenon, we use the term “ambiguous” for instances that are *more likely* to elicit ambiguous human judgments and vice-versa. Verb phrases are extracted

from suitable verb classes in VerbNet (Schuler, 2005), identified by manual annotation of VerbNet clusters.³ Each template is instantiated with verbs, names, noun-phrases, and gender-appropriate pronouns, greatly expanding the variation in cases identified in previous studies.

2.1 Template Types

Experiencer Constraint for Objects (ECO) Springston (1976) propose the Experiencer Constraint for complement constructions which we operationalize in our templates. Verbs that mark their object as the experiencer of an emotion restrict the assignment of an object position pronoun to the subject of a declarative communication verb. Conversely, the assignment is unconstrained when the pronoun is the subject of an experiencer verb. For example, in row 2 of Table 1, a pronoun in the subject position of “bored” is ambiguous (but would not be so in the object position). If the main verb does not impose an experiencer constraint, row 1, then a pronoun in the subject position is unambiguous. We instantiate two variants with names (rows 1,2) and general entities (rows 3,4).

Experiencer Constraint for Subjects (ECS)

The Experiencer Constraint also suggests that verbs that mark their subjects as the experiencer of the emotion restrict the assignment of a subject position pronoun. The assignment of the pronoun is unconstrained when it is in the object position. For

³We consider verbs from verb classes 31: Psych-Verbs (Verbs of Psychological State), 13: Verbs of Change of Possession, 37: Verbs of Communication as they conceptually align well with conditions required for ambiguity. Verbs within clusters were individually evaluated for appropriateness for templates by the authors.

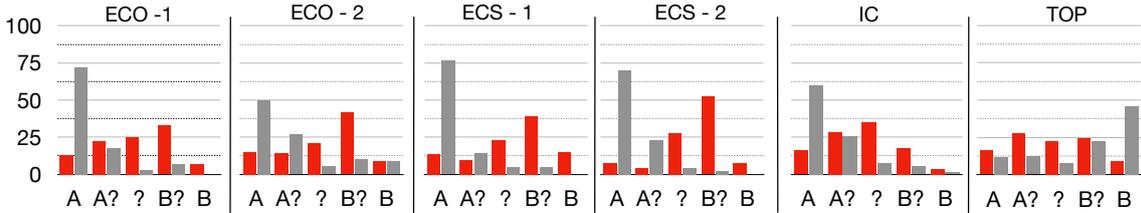

Figure 1: Human annotation of ambiguous (■) and unambiguous (■) sentences. We abbreviate human annotations by whether they identified noun A or B and whether they annotate definitely or likely (marked with ?). For example A? indicates, noun A, likely. The ground truth for unambiguous instances, from left to right, corresponds to A, A, A, A, A, B. Annotators read unambiguous examples as intended, and reduce their confidence on ambiguous examples.

example, in Table 1, row 6, “liked” is ambiguous when a pronoun is placed in the object position (but not in the subject position). We instantiate variants with names (rows 5,6) and entities (rows 7,8).

Implicit Causality (IC) Caramazza et al. (1977) hypothesize that implicit causality of a verb can determine the direction of pronoun assignment. For example, in Table 1 row 9, the phrase “wanted to apologize” establishes a cause for why “Emily called,” so the pronoun is constrained to the subject of “call”. Conversely, in row 10, the phrase “is leaving soon” fails to create such a relationship, leaving the pronoun ambiguous. For these templates (rows 9,10), we vary the names of the entities involved, and pair verbs (i.e. called) with constructed phrases that imply causality (i.e. apologizing), manually.

Transfer of Possession (TOP) Rohde and Kehler (2014) suggests that in transfer-of-possession contexts such as, “John passed the comic to Bill. *He...*”, the pronoun is equally likely to refer back to subject and non-subject. We draw upon this observation, and create a template around verbs that involve source-goal possession transfers. We distill the example to one sentence and pair the transfer event with a reason. For example, in Table 1 row 11, the phrase “asked for one” constrains the pronoun to be the receiver of “bake”. Conversely, before having lunch provides no such constraint, because either the receiver or giver could have “had lunch” before the event. Templates vary the names, verbs, objects, reasons, and preposition (rows 11,12).

2.2 Filling Template Slots

For each template, we construct a list of appropriate verb phrases, reasons (for IC and TOP templates), and shared list of gendered names and noun-phrases. Verb phrases were constructed by manually inspecting VerbNet classes. To control for name bias, we randomly sample names

from popular name lists⁴ from the last 50 years, and reuse gendered noun-phrase lists from Winobias (Zhao et al., 2018). Excluding name and noun-phrase variations, templates have 114, 45, 81, 82 instances for ECO, ECS, IC, and TOP, respectively.

3 Human Judgements

The templates used to create AMBICOREF generalize several psycholinguistic studies using lexical resources. Next, we verify that humans perceive ambiguity in these examples in the intended ways. We extract a subset of data for each template and ask Amazon Mechanical Turk workers which person a pronoun refers to (marked as A or B in Table 1) and assign confidence (*definitely*, or *likely*). Annotators were also allowed to mark the referent as entirely *ambiguous*. One sentence was sampled for each template and verb slot, uniformly at random. We collected 3 annotations per instance.⁵ See Appendix A for details on the collection of human judgements.

Figure 1 summarizes our results. Human judgements for unambiguous templates favor the intended coreference decision. For unambiguous ECO, ECS, IC, TOP instances, the intended reading is selected as likely or definitely, 83.2%, 91.9%, and 85.8%, 68.3% of the time, respectively. For ambiguous instances, annotations display a substantial shift toward ambiguity. As shown in previous work, humans display substantial disagreement on ambiguous instances (Poesio et al., 2019). This is reflected in many templates, such as TOP, where humans produce almost uniform responses.

⁴<https://www.ssa.gov/oact/babynames/decades/>

⁵In ambiguous cases, annotators do not reliably annotate a particular category, but often guess with low confidence. As such, we do not only report a majority opinion per instance, but instead simply report multiple annotations per sentence to see overall trends.

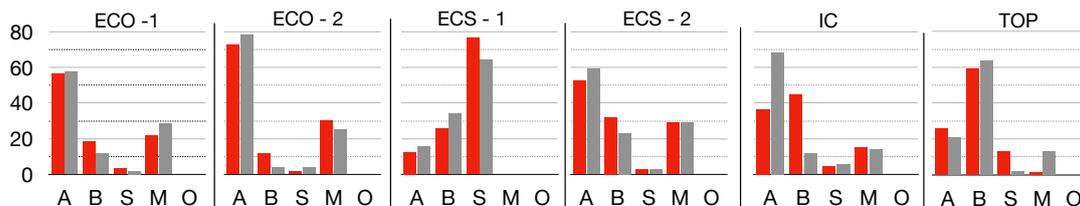

Figure 2: Percentage of ambiguous (■) and unambiguous (■) instances that fall into each of our five cases for the SpanBERT-based model across all templates. All other models show negligible shifts (red and grey distributions are almost identical). The ground truth for unambiguous instances, from left to right, corresponds to A, A, A, A, A, B.

4 Model Evaluation

We now examine if we can detect sensitivity to ambiguity in existing coreference resolution models by evaluating on AMBICOREF. We experiment⁶ with five representative models: NeuralCoref 4.0 model from Hugging Face⁷, SpanBERT (Joshi et al., 2020) representation within the independent framework for end-to-end coreference (Joshi et al., 2019), and the three models in Stanford CoreNLP (Manning et al., 2014): deterministic (Lee et al., 2013), statistical (Clark and Manning, 2015) and neural mention ranking (Clark and Manning, 2016). All models were trained on the CoNLL 2012 dataset (Pradhan et al., 2012).

Here, we evaluate the model’s final predictions, not their distribution over possible choices. The reason is two-fold: (1) not all models produce a distribution and (2) initial analysis revealed that the models are miscalibrated, as in other settings (De-sai and Durrett, 2020; Jiang et al., 2021), making it unreliable to interpret their output scores directly.

4.1 Setup

In this section, we ask, are there differences between how models process similar unambiguous and ambiguous examples? As our examples are synthetically generated, we use the unambiguous examples as a form of control. If a model is unable to link the pronoun with the correct noun on unambiguous examples for at least 40% of examples, we omit that template during evaluation.

We analyze model behavior by breaking it into cases that cover all possible cluster assignments for the pronoun in a single sentence. We compute the percentage of time a model outputs a cluster with:

- case **A**: the pronoun and noun A
- case **B**: the pronoun and noun B
- case **S**: the pronoun as a singleton

⁶Roughly one week of continuous Colab GPU compute.

⁷<https://github.com/huggingface/neuralcoref>

Model	Mean EMD %	Templates
SpanBERT	11.7	5
CoreNLP Neural	3.5	5
NeuralCoref 4.0	4.0	5
CoreNLP Statistical	1.2	3
CoreNLP Deterministic	0.6	5

Table 2: Mean Earth Mover’s Distance between matched ambiguous and unambiguous case distributions and the number of templates where models get at least 40% of unambiguous cases correct.

- case **M**: the pronoun, noun A, and noun B
- case **O**: the pronoun and any other span

For example, Figure 2 contains SpanBERT’s output distribution over these cases for each template. For each such distribution where the model’s performance is above threshold, we compare ambiguous (red bar) and unambiguous (grey bar) distributions using Earth Mover’s Distance (EMD) (Pele and Werman, 2009)⁸. Table 2 reports the number of templates above threshold, and their mean EMD.

4.2 Results

Overall, most models we evaluated show essentially no change in output distribution over cases between ambiguous and unambiguous templates, as evidenced by near zero EMD. Most models are evaluated on five of six templates, but TOP is often excluded, representing a hard unambiguous case for most systems in its own right.

Of the models we evaluated, only SpanBERT shows significant deviation in behavior with ambiguous inputs. Figure 2 breaks down SpanBERT’s performance on each template. While average EMD is higher than for other models, it still largely doesn’t change predictions. When deci-

⁸Earth Mover’s distances represent the amount of probability mass required to match two probability distributions. Hence, they help us compare distributions for ambiguous and unambiguous instances in a more interpretable way, than other possible measures like KL divergence.

sions change, often the pronoun is linked with the other noun. For example, in ambiguous cases of ECO-1, SpanBERT reduces merged outputs, and instead links the pronoun with noun B more frequently. In ambiguous cases, other models largely link the first noun-phrase (A) to the pronoun.

5 Discussion and Conclusion

Overall, our results suggest that model behavior significantly deviates from how humans treat ambiguous coreference. We lend more evidence that models miss aspects of how people understand language, especially in discourse (Upadhye et al., 2020). The reason is likely in part that models are trained on resources which do not account for distributions in judgments. As a result, models do not have well-defined behavior when ambiguity arises and are poorly calibrated.

Training models with finer-grained coreference judgments could allow models to better align with human behavior. Techniques to improve model calibration could also be effective, allowing models to abstain or seek clarification when ambiguity arises. We hope that AMBICOREF can serve as a diagnostic set for future modeling approaches in evaluating their sensitivity to instances of ambiguity in language.

6 Limitations

Our study focuses entirely on coreference in the English language with models trained in high-resource settings. Furthermore, the cases of ambiguity we identify are English-specific and the names we insert into templates are popular American names. It is an open question as to how our results generalize to low-resource non-American-English settings.

The language we use to evaluate models is templatic. While we make an effort to account for unnatural data, by only evaluating templates models do well at, models struggle to completely solve all our unambiguous examples. This presents a challenge for future model builders. On the other hand, our templates may not reflect a particular real world distribution that models will be tested on.

A Human Judgement Tests

In all our human judgement tests, we required annotators to be based primarily in English-speaking countries: the US, UK, Canada or Australia. Further, annotators needed to have at least 1000 approved HITs and a HIT acceptance rate of at least 98%. Each HIT contained 10 examples, and we estimated the completion time for each HIT to be ~5 minutes, so we paid \$1.25 per HIT, for a pay rate of \$15 per hour.

For our human judgement tests, we first ran a qualification round to ensure high-quality annotations. In this round, we asked annotators to complete a single HIT with 10 examples (5 unambiguous, 5 ambiguous randomly ordered). For each annotator who completed this round, we compute their accuracy by measuring how often they responded with the correct referent (or the ambiguous label), while ignoring their confidence. The top 100 annotators were qualified to work on the main task.

For our main task, we had 625 sentences labeled in total, with 3 assignments per sentence. Each annotator was asked to work on not more than 5 HITs, so that we get a diverse set of judgements. Similar to the qualification round, we asked each annotator to label the referent (or the ambiguous label) and their confidence. We group the annotations into 5 options: (Noun A, definitely), (Noun A, likely), Ambiguous, (Noun B, likely), and (Noun B, definitely). The human judgement labels for each template type were aggregated by computing the fraction of annotations in each of the five options. Our annotation interface for the main task is shown in Figure 3.

Instructions - [click to hide](#)

You have been qualified for the final task on coreference resolution.

Please work on **at most 5 HITs** for this task (ideally 3 to 4 HITs). We will not be able to compensate you for your work on more than 5 HITs.

You will be presented 10 sentences.

- Each sentence contains at least two nouns, and a nominative third-person singular pronoun (he/she).
- If three nouns appear in the sentence, please only consider the first two nouns as possible candidates.
- Following each sentence, there will be a question asking you which noun the specified pronoun refers to, or if you find the pronoun ambiguous.

For example, **Chloe told Emma that she was sad. Who was sad?**

- *Definitely Chloe* - I feel confident that "she" refers to "Chloe";
- *Probably Chloe* - I think "she" refers to "Chloe" as opposed to "Emma" but I feel unsure;
- *Mostly ambiguous* - I find it completely ambiguous whether "she" refers to "Chloe" or "Emma";
- *Probably Emma* - I think "she" refers to "Emma" as opposed to "Chloe" but I feel unsure;
- *Definitely Emma* - I feel confident that "she" refers to "Emma";

Different people may have different judgments and tolerance for ambiguity, so please feel free to use your intuitive judgments.

Are you a native speaker of English?

Abstract

Unsupervised out-of-domain (OOD) detection is a task aimed at discriminating whether given samples are from the in-domain or not, without the categorical labels of in-domain instances. Unlike supervised OOD, as there are no labels for training a classifier, previous works on unsupervised OOD detection adopted the one-class classification (OCC) approach, assuming that the training samples come from a single domain. However, in-domain instances in many real world applications can have a heterogeneous distribution (i.e., across multiple domains or multiple classes). In this case, OCC methods have difficulty in reflecting the categorical information of the domain properly. To tackle this issue, we propose a two-stage framework that leverages the latent categorical information to improve representation learning for textual OOD detection. In the first stage, we train a transformer-based sentence encoder for *pseudo labeling* by contrastive loss and cluster loss. The second stage is *pseudo label learning* in which the model is re-trained with pseudo-labels obtained in the first stage. The empirical results on the three datasets show that our two-stage framework significantly outperforms baseline models in more challenging scenarios.

1 Introduction

Deep neural networks show outstanding performance on benchmark datasets that have the same training and test domains. However, once the model is deployed to the real world, it can face out-of-domain (OOD) instances that make the model predict unreliable outcomes related to AI safety issues (Amodei et al., 2016; Hendrycks and Gimpel, 2017). For this reason, the OOD detection task aims to discriminate whether given instances are from in-domain (IND) or not. One of the main OOD detection approaches is to use a classifier that predicts the labels of IND samples, based on the

fact that the classifier has lower confidence in predicting the OOD samples than the IND (Hendrycks and Gimpel, 2017; Lee et al., 2018).

As this approach targets only supervised tasks that require IND labels to train the classifier, it has a limitation on unsupervised tasks. To overcome this problem, recent studies have proposed unsupervised OOD detection (or the without label scenario) that can be utilized in a more general use case (Xu et al., 2021; Jin et al., 2022). This setting can be regarded as one-class classification (OCC) because it uses only IND instances without labels and aims to distinguish novel samples from IND instances. Within this background, unsupervised OOD detection methods introduce OCC approaches such as OC-SVM and SVDD (Xu et al., 2021; Sohn et al., 2020). Meanwhile, self-supervision based models exploit a novel property named inlier priority (Wang et al., 2019) by using pseudo labels that are generated for surrogate supervision (e.g., rotation transformation (Hendrycks et al., 2019)).

In the field of natural language processing (NLP), this approach is adopted in combination with self-supervised methods of pretrained-language models (Manolache et al., 2021a). However, there are tasks where the categorical labels of training data are not available, while the IND has categorical distributions (e.g., summarization, topic modeling). OCC methods can suffer in this scenario (Jin et al., 2022; Park et al., 2021) due to the absence of IND labels, because it is difficult for the model to explicitly reflect the latent categorical distribution.

To tackle this problem, we propose a two-stage framework for textual out-of-domain detection that embeds similar INDs close together by considering latent categorical information of heterogeneous IND instances without labels, and then detects OOD instances based on the learned embedding space. To achieve this, in the first stage, we conduct *pseudo labeling* of training samples by using an unsupervised clustering method combined with contrastive

* indicates corresponding author.

loss. Next, the model from the first stage is refined by the given pseudo labels, which we call *pseudo label learning* (PLL). We find that this second stage of PLL greatly improves the representation learning for IND instances. After training is done, the inference step uses a confidence score function that measures the likelihood of whether an input is IND or OOD.

Our experimental results on three real-world datasets with the pre-trained RoBERTa (Liu et al., 2019) as a base architecture show that the proposed framework substantially outperforms the baseline models in various settings. In addition, we conduct embedding space analysis to confirm the effectiveness of PLL and show that it learns a more suitable representation for OOD detection by increasing inter-cluster distance significantly, which makes OOD samples more distinct from the clusters.

In summary, our main contributions are as follows:

- We propose a new framework for text OOD detection that effectively utilizes latent categorical information of IND through two successive steps of clustering for obtaining pseudo labels and then re-learning the pseudo labels for better representation learning.
- We provide a systematic analysis of the result by dividing OOD instances into near-OOD and far OOD depending on how close they are to IND samples. Our method works especially well on near-OOD, a more challenging scenario, in comparison with other methods. We also analyze the embedding space to confirm the effectiveness of our PLL approach.
- We empirically demonstrate that our proposed method is highly effective in multi-domain settings where the IND distribution has high variability, by increasing the inter-cluster distances and placing OOD out of detection boundaries of each cluster.

2 Related Work

Out of Domain Detection. OOD detection aims to distinguish OOD instances from IND to prevent a model trained for IND from making wrong predictions in the real applications. One of the main approaches is to rely on a classifier for IND labels, supposing that the softmax probability value of the IND will be larger than OOD (Hendrycks and

Gimpel, 2017). Furthermore, (Liang et al., 2018; Lee et al., 2018; Hsu et al., 2020) improve this method by adding perturbation to the inputs, which further increases the softmax probability of IND. In the NLP field, Hendrycks et al., 2020 find out that transformer-based models are more effective than convolutional neural networks (LeCun et al., 1998) or long short-term memory (Hochreiter and Schmidhuber, 1997) based models in detecting textual OODs. To improve OOD detection performance for the models, (Zhou et al., 2021) utilize supervised contrastive loss that creates a more compact representation. However, these approaches cannot be used without IND labels.

Unsupervised Out of Domain Detection. Self-supervised methods can handle this issue by using augmentation techniques (Sehwag et al., 2020; Wang et al., 2019). Manolache et al., 2021a adopt this approach by utilizing the training scheme introduced in ELECTRA (Clark et al., 2019). They use a generator to replace random masked tokens in the input and train a discriminator to predict whether each token is replaced by the generator or not. Xu et al., 2021 focus on the findings that different layers of BERT Devlin et al., 2019 can capture different linguistic information. They compute the Mahalanobis distance using the embeddings in each layer and construct a new vector consisting of the distance values across all the layers. This new feature vector is used as input to OCC-based OOD detection methods. However, these models are difficult to perform well when INDs are in heterogeneous domains (or multiple classes), because they do not explicitly reflect the multimodal IND distribution. Cluster-based approaches can help alleviate this problem since they assume that the IND has a latent class distribution in its feature space. Jin et al., 2022 introduce a clustering method for representation learning to reflect categorical distributions on the embedding space. Our approach is motivated by (Jin et al., 2022), but our method generates pseudo labels and uses them explicitly to reinforce this categorical information, which greatly improves the performance.

3 Proposed Framework

In this section, we describe our two-stage framework for unsupervised OOD detection. First, the purpose of stage 1 is to generate pseudo labels that include categorical information of IND samples. We train a sentence encoder based on a pre-trained

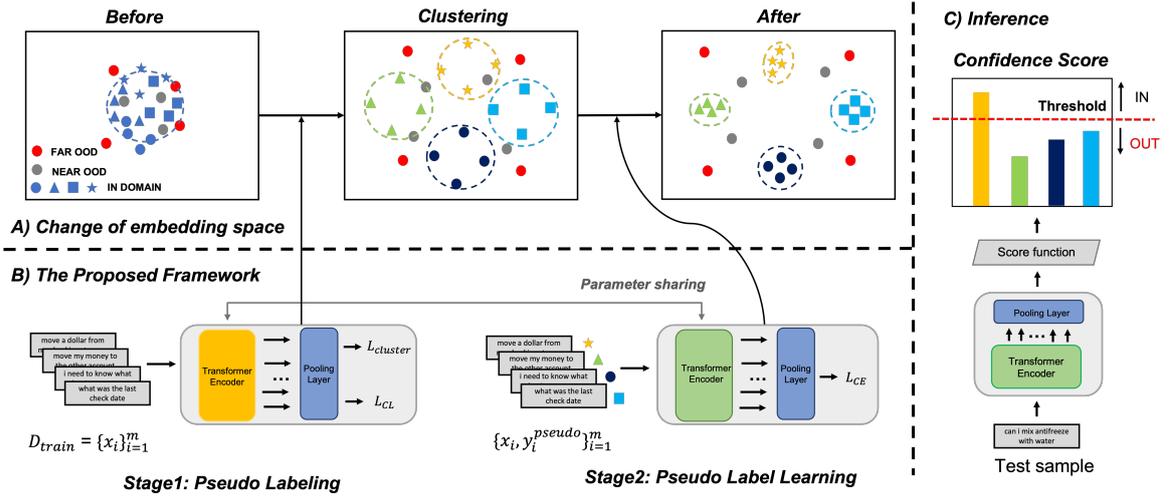

Figure 1: The overall framework of the proposed method. A) illustrates the change of representations in the embedding space during two stages of the training phase. B) shows the proposed framework. It consists of two stages of *pseudo labeling* (stage1) and *pseudo label learning* (stage2). C) shows the inference phase to detect OOD samples using a confidence score function. D_{train} is a training dataset that contains only IND samples x_i , without labels. y_i^{pseudo} is the pseudo label for x_i generated in stage 1.

transformer for *pseudo labeling* of IND training samples using contrastive loss and cluster loss. After then, in stage 2, we perform *pseudo label learning*, designed to explicitly utilize the pseudo labels for reinforcing the categorical information through a classification task. Finally, we use a scoring function that indicates the confidence of being IND to detect OOD samples at test time. Our proposed framework is illustrated in Figure 1.

3.1 Pseudo Labeling

The *pseudo labeling* stage is designed to generate pseudo labels y_i^{pseudo} for each x_i in $D_{train} = \{x_i\}_{i=1}^M$. To do that, we assume that IND data have K categories that are represented in the latent semantic space. Let μ_k denote the centroid of each cluster k and ψ be a transformer-based sentence encoder:

$$e_i = \psi(x_i).$$

For each sample x_i , we use the Student's t -distribution to compute a soft assignment probability q_{ik} , meaning the probability that the sample i belongs to the cluster k , by the following equation (Van der Maaten and Hinton, 2008):

$$q_{ik} = \frac{(1 + \|e_i - \mu_k\|_2^2)^{-\frac{\alpha+1}{2}}}{\sum_{k=1}^K (1 + \|e_i - \mu_k\|_2^2)^{-\frac{\alpha+1}{2}}},$$

Here, α represents the degrees of freedom of the Student's t -distribution. In this work, we set $\alpha =$

1. The cluster centroids and the soft assignment probability can be refined iteratively by using an auxiliary target distribution proposed by (Xie et al., 2016) as:

$$p_{ik} = \frac{q_{ik}^2 / f_k}{\sum_{k=1}^K q_{ik}^2 / f_k},$$

where $f_k = \sum_{j=1}^M q_{jk}$ is the soft cluster frequency to normalize q_{ik} raised to the second power. This target distribution first sharpens the soft assignment probability q_{jk} by raising it to the second power and then normalizes it by the associated cluster frequency. The soft assignment is optimized based on KL-divergence between $p_i = (p_{i1}, \dots, p_{iK})$ and $q_i = (q_{i1}, \dots, q_{iK})$:

$$l_i^C = KL(p_i || q_i) = \sum_{k=1}^K p_{ik} \log \frac{p_{ik}}{q_{ik}}$$

The clustering objective is then defined as follows:

$$L_{cluster} = \frac{1}{M} \sum_{i=1}^M l_i^C$$

This loss function encourages learning from cluster assignment with high confidence and debiasing imbalanced cluster assignment.

Following (Zhang et al., 2021), we also adopt contrastive learning to improve clustering performance. Contrastive loss scatters the samples while closely embedding samples sharing the same properties. For contrastive learning, we use dropout

mask augmentation which simply feeds the same input to the transformer-based encoder¹ twice (Gao et al., 2021). Using this augmentation method, we construct a positive pair (x_i^0, x_i^1) from the same x_i with different dropout masks. We try to minimize the following contrastive learning loss:

$$l_i^{CL} = -\log \frac{\exp(\text{sim}(z_{i^0}, z_{i^1})/\tau)}{\sum_{j=1}^{2M} \mathbb{I}_j \cdot (\exp(\text{sim}(z_{i^0}, z_j)/\tau))},$$

where $z_i = g(\psi(x_i))$ and g is a network of fully-connected layers. We choose $\text{sim}(\cdot)$ as the dot product between a pair of normalized outputs, i.e., $\text{sim}(z_i, z_j) = z_i^T z_j / (\|z_i\|_2 \|z_j\|_2)$. Then the overall contrastive learning objective is defined as:

$$L_{CL} = \frac{1}{2M} \sum_{i=1}^{2M} l_i^{CL}$$

In summary, the final objective for stage 1 is the following:

$$L_{stage1} = L_{cluster} + \lambda L_{CL} \quad (1)$$

After training the model for pseudo labeling by using the stage1 loss, we assign the pseudo label y_i^{pseudo} for each $x_i \in D_{train}$ using the soft assignment probability.

3.2 Pseudo Label Learning

Contrastive learning is useful for clustering and pseudo labeling because contrastive loss separates samples apart from each other to prevent overlap in the representation space. However, it is not sufficient for OOD detection because OOD samples can be located close to the cluster boundaries as illustrated in Figure 1. Therefore, we introduce *pseudo label learning* (PLL), which allows the text encoder to learn representations that are more suitable for OOD detection. PLL explicitly uses pseudo labels to further separate clusters in the embedding space. Therefore, we fine-tune the model by targeting pseudo labels y_i^{pseudo} using the cross-entropy loss. The loss function in stage 2 is as follows:

$$L_{stage2} = L_{CE} = - \sum_{i=1}^M y_i^{pseudo} \cdot \log(p_i)$$

where p_i is the predicted probability distribution for the pseudo label.

¹Transformer already has dropout mask in fully-connected layer and attention probabilities

3.3 Confidence score function

Next, we introduce the confidence score function s for OOD detection that uses a classifier in stage 2. The scoring function s aims to map the representations of instances to confidence scores, where higher scores indicate higher confidence for being IND. In the following, we present several options for this scoring function.

Maximum Softmax Probability (MSP). Hendrycks and Gimpel, 2017 suggest the maximum class probability among K training classes in the softmax layer as an OOD indicator. This method has been extensively used as a baseline for OOD detection (Hendrycks et al., 2020; Zhou et al., 2021), which defines the score as:

$$s = 1 - \max\{p_k \mid k = 1, \dots, K\}.$$

Energy Score (Energy). Liu et al., 2020 propose energy based score that theoretically outperforms the softmax based score, which is defined as:

$$s = -\log \sum_j^K (w_j^T h)$$

where w_j is the weight of the j^{th} class in the softmax layer, and h is the input to the softmax layer. A higher s means higher probability density in OOD classes and thus implies lower IND likelihood.

Mahalanobis Distance (Maha). Podolskiy et al., 2021 showed that the distance-based scoring function can outperform other methods in a supervised setting, which is defined as:

$$s = -\min_k (h - \mu_k)^T \Sigma_k^{-1} (h - \mu_k)$$

where μ_k is the mean vector and Σ_k is the covariance matrix of each latent class k . Then, given an instance x during inference, it calculates the confidence score as the minimum Mahalanobis distance among the K classes.

4 Experiments

In this section, we present the experimental setting for the evaluation of the proposed framework. We describe the used datasets and how to construct IND and OOD samples under unsupervised OOD scenarios.

4.1 Dataset

To evaluate the proposed model, we select the following three real world datasets.

Dataset	Ratio	Model	AUROC	AUIN	AUOUT	AUROC	AUIN	AUOUT
			Near OOD			Far OOD

Table 1: OOD detection performance with different IND class ratios (25%, 50%, and 75%) on three datasets, CLINC150, HWU64, and BANKING77. Scores in bold type are the best results. For all of our methods, we report the averaged results using Mahalanobis distance-based score and the number of clusters equal to the number of IND classes due to space limitations. We collected the results for other methods (Xu et al., 2021, Manolache et al., 2021b) by running their released codes.

CLINC150 (Larson et al., 2019) is a dataset designed for OOD detection. The training set contains 15,000 utterances with 10 domains and 150 classes (e.g., travel.timezone, home.reminder, and credit_cards.rewards_balance). This dataset also provides 1,000 OOD samples that are not within any of 150 classes. For evaluation, we use 4,500 IND and 1,000 OOD samples from the test set.

HWU64 (Xingkun Liu and Rieser, 2019) includes 8,954 utterances for 64 intents with 21 domains (e.g., alarm_set, cooking_recipe, and calendar_query). For evaluation, we use 1,076 IND samples from the test set.

BANKING77 (Casanueva et al., 2020) contains 8,622 utterances related to banking with 77 different fine-grained intents in the training set. Despite consisting of a single domain, this dataset is challenging, as it requires fine-grained differentiation between very similar intents. For evaluation, we use 3,080 IND samples from the test set.

4.2 Experimental setting

We carefully design experimental scenarios assuming that training data consist of instances distributed across multiple domains with any category given. Inspired by Zhang et al., 2022, we divide OOD samples into two types: near-OOD and far-OOD. We suppose that the near-OOD samples are distributed in the same domain with the training samples but labeled as different categories, whereas the far-OOD samples are distributed in distinct domains. The proposed scenarios are more challenging because OOD can share characteristics with IND.

For our scenarios, we randomly select a subset of classes in the training data as IND, with IND class ratios of 25%, 50%, and 75% and use the remaining classes as near-OOD. Following (Zhang et al., 2022), we use the OOD samples in the CLINC150 dataset as far-OOD. We split each dataset five times with different random seeds, which are shared

across all the models for a fair comparison.

4.3 Baselines

We compare our method with the following unsupervised OOD detection methods: MDF (Xu et al., 2021) and DATE (Manolache et al., 2021a). **MDF** utilizes full features from all the layers of a pretrain-transformer model and calculates the Mahalanobis distance vector from the layer representations, which is in turn used as input to OC-SVM. In addition, there are additional training stages such as IMLM (In-domain Masked Language Model) and BCAD (Binary Classification with Auxiliary Dataset) before feature extraction. **DATE** is a pseudo label based approach. It uses a self-supervised learning method of ELECTRA that distinguishes whether each token is replaced or not to generate anomaly scores from the loss obtained by pseudo-labeled tokens.

4.4 Evaluation Metric

To evaluate our proposed method, we report three different metrics following (Liang et al., 2018; Xu et al., 2021). The area under the receiver operating characteristic curve (AUROC) depicts the relationship between the true positive rate and the false positive rate. A higher score indicates improved distinction between IND and OOD by the model. The area under the precision-recall curve (AUPR) shows the precision and recall against each other, for IND and OOD testing sentences, denoted by AUIN and AUOUT, respectively.

4.5 Implement details

For a fair comparison, we also select *roberta-base* from Huggingface’s Transformers (Wolf et al., 2020) as a base architecture for the sentence encoder, the same as MDF. In stage 1, we choose $\tau = 0.5$, $\lambda = 10$, and $\alpha = 1$. We use a constant learning rate of $3e-6$ to optimize the sentence encoder and $3e-4$ to optimize $g(\cdot)$ and the liner layer for soft cluster assignment. In stage 2, we set the learning rate to $3e-5$. We use the Adam optimizer (Kingma and Ba, 2015) with a batch size of 128 for both stages. We used the same hyperparameters for all datasets and splits following Manolache et al., 2021a.

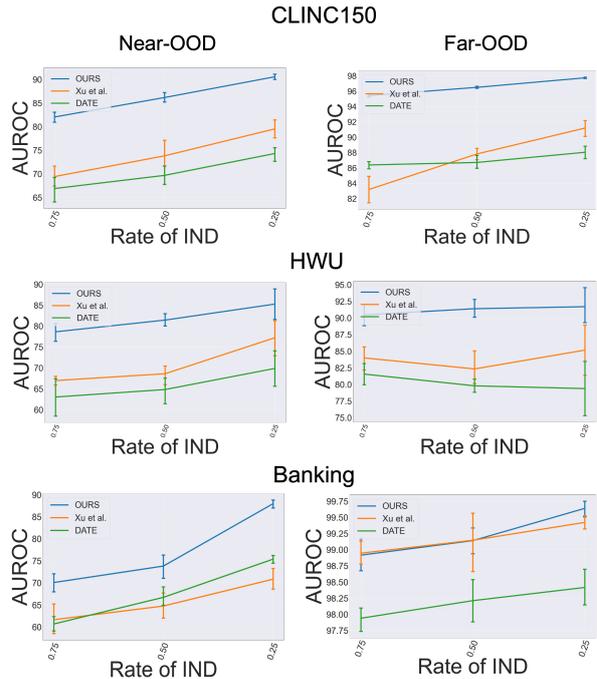

Figure 2: The OOD detection performance with respect to different ratios of IND classes (0.25%, 0.50%, and 0.75%).

5 Result

5.1 Comparisons with baseline methods

Table 1 presents the performance of each method on the three datasets with different IND class ratios (25%, 50%, and 75%). The proposed framework outperforms two baselines, DATE and MDF, by a large margin for the AUROC, AUIN, and AUOUT scores across all three datasets regardless of IND class ratios in the near-OOD and far-OOD setting, except just one case (BANKING77 with the ratio 0.75). In particular, our method greatly improves the performance over other methods on the near-OOD dataset, which represents a more challenging scenario. This shows that the proposed method is robust in multi-domain IND settings regardless of OOD types. In HWU64 dataset that contains more heterogeneous domains than the other two datasets, the OCC-based models, MDF and DATE, appear to have weaknesses in more heterogeneous domain settings, but our method shows good performance. In addition, in the BANKING77 that is the least heterogeneous setting, our method shows similar or higher performance than the other methods as well.

Figure 2 shows the performance with respect to the IND class ratio on three datasets. The performance of all models tend to increase when the ratio

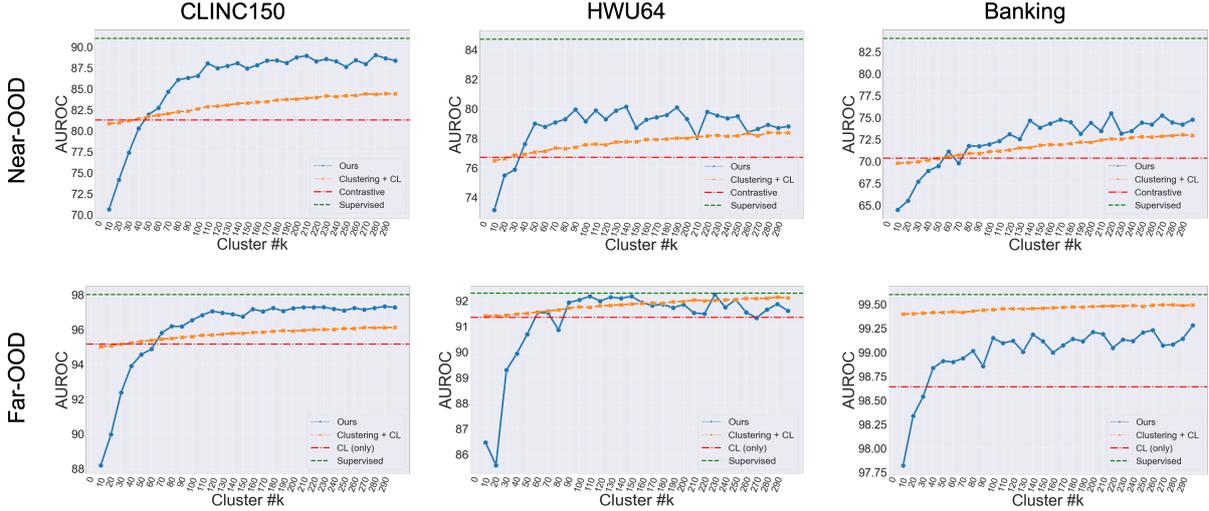

Figure 3: Effect of the number of clusters K with an ablation study. The first row is for the near-OOD setting, the second row is for the far-OOD setting. The columns sequentially correspond to the results on CLINC150, HWU64, and Banking77 datasets for the IND class ratio of 0.75. We compare our proposed method (shown in blue) with the result using only L_{stage1} (orange) and the result using only L_{CL} (red). The green line denoted as *supervised* shows the result when the ground truth labels of IND classes are used during training.

decreases, which is as expected, because fewer IND classes imply less heterogeneous IND distributions and hence easier scenarios. In addition, our method shows more accurate and robust performance with smaller variances (shown as vertical line segments). However, OCC-based methods are more susceptible to randomness during training because they need to bind one characteristic.

5.2 Number of clusters K

The selection of the number of clusters K is an open problem for unsupervised OOD detection since there is no validation OOD set to choose the hyperparameter value. For the results shown in Table 1 and Figure 2, we set K as the number of IND labels given. To measure the influence of K , we plot the change of performance as K is increased in Figure 3. The blue curve indicates our method and the orange line indicates clustering based method with clustering loss and contrastive loss. We find that a larger number of clusters K generally leads to better results for OOD detection. As K increases, the blue curve moves upward to the right, showing that the larger number of clusters allows more detailed consideration of IND samples. It allows more OOD samples to be pushed away from the clusters. In other words, OOD samples that are placed inside a cluster can be located in between as the clusters become more segregated. Therefore, choosing an appropriately large K is ad-

Dataset	Model	Near OOD	Far OOD
CLINC150	MSP	76.51	89
	Energy	78.55	91.53
	Mahalanobis	87.21	96.52
HWE	MSP	69.32	78.34
	Energy	71.32	83.31
	Mahalanobis	78.63	90.46
BANKING77	MSP	58.62	88.07
	Energy	58.87	92.23
	Mahalanobis	70.34	98.57

Table 2: Performance comparison using different confidence score functions. In this result, we set the number of clusters K equal to the number of IND classes in each dataset

vantageous for OOD detection. This is empirically demonstrated in Figure 3.

5.3 Ablation study

As shown in Figure 3, our two-stage approach combining clustering and PLL outperforms clustering-based approaches (shown in orange and red) especially on near-OOD setups. This result reveals that PLL at the second stage utilizes more categorical information than the clustering-based models in stage 1. In far-OOD, our method shows lower performance in only one case (BANKING77) with a very small margin (less than 0.5%). The green line indicates the performance of the oracle model that is supervised by ground truth labels of IND samples during training. In CLINC150, the perfor-

Dataset	Model	max	min	mean	median
CLINC150	Clustering(Only)	4.268	2.464	3.508	3.566
	PLL	18.776	4.46	9.92	8.968
HWU	Clustering(Only)	7.523	3.577	5.439	5.35
	PLL	16.997	5.588	10.082	9.153
BANKING	Clustering(Only)	5.054	3.706	4.428	4.386
	PLL	16.44	5.654	12.1	12.114

Table 3: Intra-cluster variance statistics

mance of our proposing model with high enough k can be almost close to the green line in the near-OOD setting. In addition, our methods show similar performance with the supervised model on the HWU64 dataset in far-OOD settings.

Regarding to the choice for a scoring function, Mahalanobis distance shows the best result regardless of datasets and OOD settings (Table 2). This is because MSP and energy-based methods are based on the predicted class probabilities while pseudo labels can contain errors. In contrast, Mahalanobis distance is based on representations, so it can be more robust to clustering results even when there are miss-labeled instances.

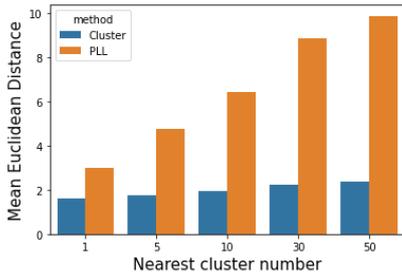

Figure 4: Inter-cluster distance statistics with different numbers of nearest cluster centers.

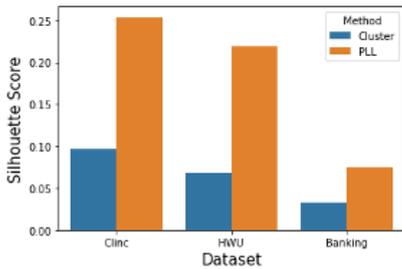

Figure 5: Average silhouette score before and after PLL.

5.4 Analysis of representation space

To investigate why our PLL approach improves OOD detection performance over clustering-based methods, we additionally examine three metrics: intra-cluster variance, inter-cluster distance, and

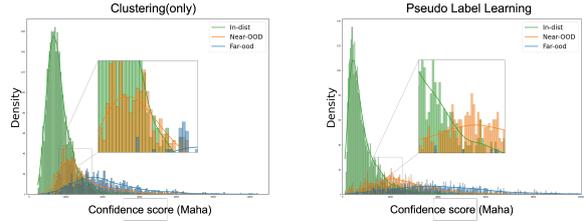

Figure 6: Distributions of the confidence scores before PLL (left) and after PLL (right) on CLINC150 dataset with IND class ratio of 0.75. The confidence score distribution is shown in green for IND, yellow for near-OOD, and blue for far-OOD.

the silhouette score. Table 3 shows the statistics of intra-cluster variance, which can indicate the degree of clustering of the data representations within a cluster. Specifically, we average the distances of the representations of samples with the same pseudo label to the cluster center in the test set as intra-cluster variance, then report min/max/mean/median values on all clusters. And Figure 4 shows the inter-class distances. We average dot product distances between each class center to its C nearest class centers, then average results from all classes as inter-class distance. The x -axis denotes the number of nearest centers C . We find that the intra-cluster variance becomes higher when the clustering is followed by PLL, which means PLL can ruin intra-cluster distribution. However, the inter-cluster distances are also significantly increased through PLL. To find out the balance of the two distances, we compare the silhouette scores before and after PLL in Figure 5, which shows that PLL improves the silhouette scores by a large margin. This implies that PLL can make the clusters far apart from each other and therefore OOD sample to be placed in between the clusters.

5.5 Visualizations

We visualize the confidence score distributions to confirm the effectiveness of our PLL scheme. Figure 6 shows the confidence score distribution on CLINC150 test set with the IND ratio of 0.75. Although the score distributions of near-OOD and IND still overlap when we apply clustering only, after performing PLL, the score distribution for IND shifted to the left, while the distributions of both OOD samples shifted to the other side. Therefore, the score distributions become more discriminable between IND and OOD samples through PLL.

6 Conclusion

In this work, we proposed a two-stage framework for unsupervised OOD detection that effectively utilizes the categorical information of IND instances by pseudo labeling and pseudo label learning. In addition, for a more systematic analysis of OOD performance, we introduced the near-OOD setting, which is a more challenging yet realistic scenario. In most of our experimental settings, our framework outperforms the baseline models with significant margins. We further justify the improvement of the proposed model’s OOD detection performance by analyzing the embedding space with inter or intra-cluster distances and silhouette scores. In future work, we will further investigate how to reduce intra-cluster variations while maintaining inter-cluster distances.

Limitations

The proposed methods show relatively stable performance with respect to the number of clusters (K), but it still has a limitation of choosing the optimal one. In particular, we conduct the experiment by setting the maximum value of K to 300. However, a too large K can degrade the model performance by reducing the number of samples per cluster for classification in stage 2. In addition, since the proposed framework depends on a clustering method, its performance can be limited by the clustering performance. Experiments are only conducted on three intent task datasets due to the near-OOD and the far-OOD settings in heterogeneous domains. We remain those limitations for future works.

Abstract

Recently introduced *instruction-paradigm* empowers non-expert users to leverage NLP resources by defining a new task in natural language. Instruction-tuned models have significantly outperformed multitask learning models (without instruction); however they are far from state-of-the-art task-specific models. Conventional approaches to improve model performance via creating datasets with large number of task instances or architectural changes in the model may not be feasible for non-expert users. However, they can write alternate instructions to represent an instruction task. *Is Instruction-augmentation helpful?* We augment a subset of tasks in the expanded version of NATURAL INSTRUCTIONS with additional instructions and find that it significantly improves model performance (up to 35%), especially in the low-data regime. Our results indicate that an additional instruction can be equivalent to ~ 200 data samples on average across tasks.¹

1 Introduction

Large-scale benchmarks such as Imagenet (Russakovsky et al., 2015), SQuAD (Rajpurkar et al., 2018) and architectural development in models such as CNNs (Amari et al., 2003) and transformers (Vaswani et al., 2017) have propelled our progress in deep learning. However, creating high-quality benchmarks by controlling its artifacts (Gururangan et al., 2018; Mishra et al., 2020), developing new models, and training them is hard for non-expert users. Recently introduced *instruction-paradigm* empowers non-expert users, practitioners, and domain experts in other fields to leverage NLP resources (Weller et al., 2020) as they now can describe their tasks in natural language without requiring to create task-specific datasets or developing models². Even though the instruction paradigm

has led to the development of models that significantly outperform multitasking baselines, model performance has remained far behind the supervised learning model trained with task-specific data (Efrat and Levy, 2020; Mishra et al., 2021b).

Non-expert users can write multiple instructions per task each of which covers multiple perspectives spanning over a variety of linguistic features; many of these can be created automatically by replacing certain words with their synonyms without changing the overall semantics of instruction. Can the relatively inexpensive process of instruction augmentation improve the model’s performance in the *instruction-paradigm*, similar to the role data-augmentation has played conventionally in machine learning (Feng et al., 2021)? *Instruction-paradigm* is pivotal where it is expensive or infeasible to gather training data. How effective is instruction augmentation in low-data regimes?

Multi-variant instructions (original + augmented instructions) also can help evaluate the robustness of instruction-following models to respond to variant instructions. This is similar to the model robustness evaluation (Jia et al., 2019) that is done by creating variant data instances. Multi-variant instruction-based setup will also help gauge the true potential of instruction-following systems since in a real-world setting, users can write task instructions in many different ways.

The expanded version of NATURAL INSTRUCTIONS (Mishra et al., 2021b; Wang et al., 2022b)³ provides a rich collection of the diverse category of tasks that covers a variety of reasoning skills, domains, and languages. This constantly evolving benchmark is growing in size with respect to time. We take 426 tasks⁴ and creates variant instructions

³<https://github.com/allenai/natural-instructions>

⁴These were the accepted tasks in the expanded version of NATURAL INSTRUCTIONS in September 2021. The expanded dataset is also known as NATURAL INSTRUCTIONS v2 or SUPER-NATURALINSTRUCTIONS.

*Equal Contribution

¹Code and dataset is available at <https://github.com/Ravsehajsinghpuri/Multi-Variant-Instructions>

²Related work is presented in App. A

for each task. In NATURAL INSTRUCTIONS, the number of instances was limited to 6500 to reduce massive data imbalance, we leverage the remaining instances of source datasets in constructing instances of our variant instruction tasks. We experiment with 3 types of learning scenarios (i) task-specific (TS), (ii) multi-task (MT), and (iii) cross-task (CT) and observe that instruction augmented models outperform their single-instruction counterparts by 17%, 11%, and 11%, respectively when averaged over all experiments across the evaluation tasks. Interestingly, instruction augmentation is more effective on the low-data regime (average across 1%, 5%, and 10% data) as we see a performance gain of 26%, 16%, and 11% in TS, MT, and CT settings, respectively. We also quantify the contribution of each of the additional instructions and find that an additional instruction can be equivalent to ~ 200 data samples on average across tasks.

2 Multi-Variant Instruction Dataset

We construct a Multi-Variant Instruction dataset on top of various tasks in NATURAL INSTRUCTIONS. In total, our dataset has 426 different NLP tasks; each of which contains multi-variant instructions.

2.1 Variant Instruction Task

An instruction task in NATURAL INSTRUCTIONS contains the definition of the task, positive examples, negative examples, and instances. Figure 1 shows the schematic representation of variant instruction tasks where the blue boxes show the parts that differentiate variant instruction tasks from their original counterparts in NATURAL INSTRUCTIONS. While constructing a variant instruction task, we alter the definition and instances of the instruction task.

Parameter	Value
Avg. # of variants per task	4.59
Avg. # of instances per task	9510.64
Avg. # of positive examples per task	3.15
Avg. # of negative examples per task	2.30

Table 1: Multi-Variant Instructions dataset statistics

2.2 Dataset Creation Process

Computer Science graduate students who participated in the data creation process are asked to create as many variant instruction tasks as possible. They are instructed to change the definition

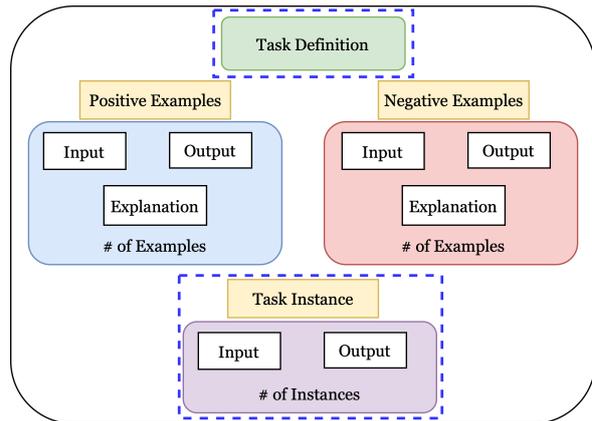

Figure 1: Schematic representation of instructional prompts (Wang et al., 2022b) - Dotted blue box represents entities that are changed in constructing variant instruction task.

(without changing the semantic meaning of the definition in the original task) and instances (by random sampling from the set of instances in the source dataset which is not part of instruction tasks in NATURAL INSTRUCTIONS). They are allowed to use automated tools such as Semantic Control (Ross et al., 2021), Text Style Transfer (Reif et al., 2021), NL-Augmenter (Dhole et al., 2021). Sometimes, the participants create variant instruction tasks manually. Table 5 and Table 6 in App. B illustrates examples of alternate definitions across variant instructions created for our dataset.

2.3 Dataset Properties and Statistics

Table 1 shows the statistics of our meta-dataset. Note that, variant instruction tasks contain all instances from NATURAL INSTRUCTIONS, so the average number of instances per task is higher than 6500 (which is a constraint in NATURAL INSTRUCTIONS). We describe various attributes of our dataset in the following.

2.3.1 Semantic Textual Similarity

Semantic Textual Similarity (STS) should be high between original instruction and augmented instructions as they represent the same task. We compute the pair-wise STS score between definitions of original instruction and variant instructions. Figure 2 shows the mean and SD of STS score between original instruction and its variants across 426 tasks. More detail is presented in App. C.

Analysis of dataset properties From all dataset properties, we can observe that STS score is higher for almost all the tasks. This indicates that all aug-

Task ID	Task Name	Task Category	# of Variants

Table 2: Number of variant instructions for 8 different tasks

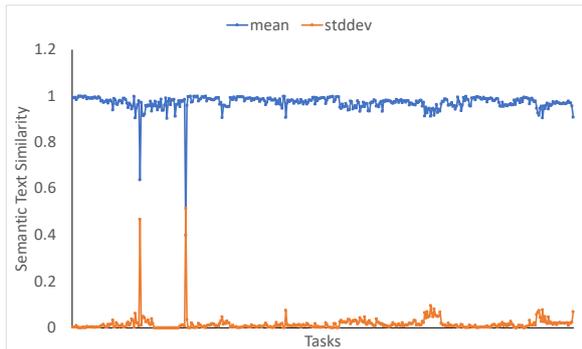

Figure 2: Semantic text similarity between original instruction and its variants.

mented variants are semantically similar to the original instruction. Moreover, we can see a significant variation in terms of word dissimilarity and length of definitions (see App. C). From this, we can conclude that the variants created in our meta-dataset for each task have sufficient variations in terms of words and length yet sustain semantic similarity with original instruction.

3 Experimental Setup

3.1 Models

BART-base (Lewis et al., 2019) and T5-base (Rafel et al., 2020) models are used with default hyperparameters from Huggingface (Wolf et al., 2019) to perform experiments. We use Single Instruction (SI) learning as baseline where only original instruction is used to fine-tune the model. We propose Multi-Variant Instruction (MVI) learning where variants are used to fine-tune models. We use the same number of instances for both original and variant instruction learning to accurately gauge the importance of additional instructions.

3.2 Experiments

We perform three experiments: (1) Task-Specific, (2) Multi-Task, and (3) Cross-Task. All experiments are performed using 1%, 5%, 10%, 50% and 100% instances from the task for fine-tuning. Here, we divide instances into train, test and dev splits by randomly sampling in the ratio 70%, 20% and 10%, respectively. Evaluation is performed on the test set of original instructions. As SI is dependent on NATURAL INSTRUCTIONS which has exactly one instruction per task, this limits our experiments to use only one instruction in the SI setting while comparing it with MVI which has multiple variant instructions.

Task-Specific Here, we fine-tune the baseline and our model on one task and evaluate on the same task. We have performed task-specific learning on 3 different tasks - winogrande_answer_generation, winogrande_question_modification_person, and qasc_answer_generation. In addition, we also analyze two different tasks in other task categories like tweetqa_question_generation and odd-man-out_classification_no_category for generation and classification tasks respectively.

Multi-Task To perform multi-task learning, we use 8 different tasks spanning across 4 different categories. Table 2 shows the different number of variant instructions for 8 tasks and their categories. In this setting, we fine-tune the baseline and our model on all 8 tasks combined and evaluate on each task. However, we use only two positive and two negative examples to satisfy the maximum token limit of the BART-base.

Cross-Task Here, we fine-tune the model on a set of tasks and evaluate on a different set of tasks. Here, we use 274 different tasks for training by sampling 10% instances from each task and evaluate on a set of 8 tasks which are the same as in the

multi-task setup. In addition to sampling instances, we also sampled number of tasks by taking 1%, 5%, 10%, 50%, and 100% tasks. We also investigate the extent of cross-task generalization in low-data regimes; we do this by randomly sampling 1%, 5%, and 10% instances for fine-tuning.

Metric We use the Rouge-L metric (Lin, 2004) for evaluation in all our experiments, following the evaluation in NATURAL INSTRUCTIONS.

4 Results and Analysis

4.1 Experimental Results

Task-Specific Figure 3 shows the comparison between SI and MVI across a different number of instances sampled for fine-tuning. From this, we can observe that MVI outperforms SI by 17% on average. The performance difference between MVI and SI increases to 26% in a low data regime (average performance with 1%, 5%, and 10% instances for fine-tuning). We observe similar results for the additional 2 tasks we have analyzed (present in App. D).

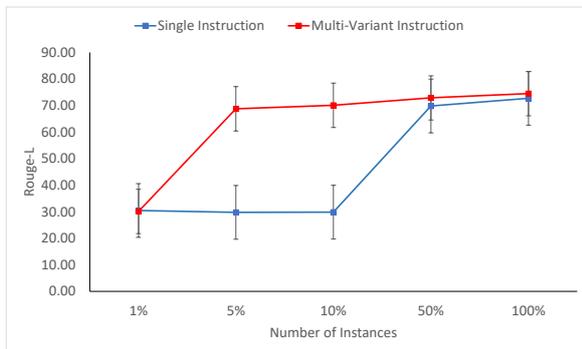

Figure 3: Comparison across SI and MVI learning in task-specific setting; Results are averaged over 3 tasks.

Multi-Task Figure 4 presents the comparison between SI and MVI for multi-task setting. We can observe that MVI outperforms SI by 11% on an average. Moreover, we can see higher improvement in low data regime (~16%). Our model achieves high performance boost (~35%) at 1% instances setting. App. E contains more details.

Cross-Task Figure 5 shows a comparison between SI and MVI for 100% tasks in cross-task setting (see Figure 9 in App. F for other settings). We can observe that MVI outperforms SI by 9% on an average. App. F contains more details.

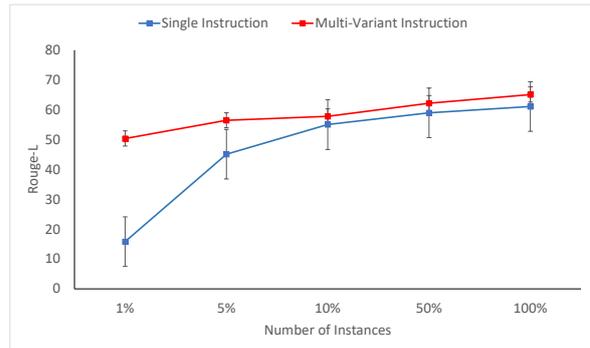

Figure 4: Comparison across SI and MVI learning in multi-task setting by varying number of instances.

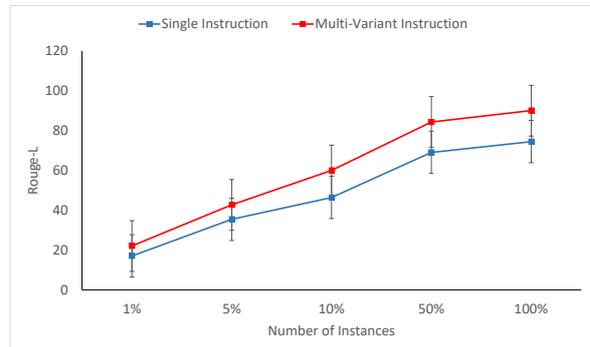

Figure 5: Comparison between SI and MVI learning in cross-task setting by varying number of instances and fixing number of tasks to 100%.

4.2 Analysis

How Many Data Samples is a Variant Instruction Worth? We calculate the contribution of an additional instruction with respect to data samples in the following way: we calculate model performance for BART-base in MVI with 5% instances. We interpolate the model performance plot in SI to find out the percentage of instances needed to match performance in MVI (with 5% instances). We divide the average number of instance difference by average number of instruction variants to get the number that indicates worth of an additional instruction in terms of data samples. Using the above described procedure, we calculate the contribution for additional instruction in all three settings and summarize the results in Table 3. We use MVI performance with 5% instances as the base because a typical instruction-paradigm is designed in a "low-data regime" where non-expert users can teach a task to a model without requiring to create a dataset. However, we also calculated the instruction-equivalence using MVI with 10% instances as the base and report the results in Table

3. On an average across TS, MT and CT, we conclude that an additional variant instruction alone is worth ~ 200 instances.

Base	Task-Specific	Multi-Task	Cross-Task	Average
5%	456.2	94.1	152.3	234.2
10%	460.4	58.2	279.6	266.1

Table 3: Weight of each additional instruction in terms of number of data samples across task-specific, multi-task and cross-task settings.

Equal Data Analysis We believe that each instruction variant is equivalent to ~ 200 data instances. To show this by experiment, we perform equal data analysis and observe that model trained using our approach shows competitive performance compared to single-instruction learning by using only N/V instances where N is the total number of instances in the original task and V is the number of instruction variants for this task. See App. G for more details.

Is Model Robust to Instruction Perturbations?

Here, we introduce 3 perturbations while testing SI and MVI: (1) we perturb the instruction by removing the task definition, (2) we perturb the instruction by changing the order of positive and negative examples by placing positive examples followed by negative different from training setup, and (3) we perturb the instruction by removing all positive and negative examples from the test set. We evaluate the model’s robustness across these perturbations (performance change while the change in instruction) which are excluded from the training data. Here, Table 4 for task-specific setting on T5-base (see Table 11 in App. H for multi-task results). We can clearly observe that our approach is robust to all three instruction perturbations whereas model trained with single-instruction learning is not able to perform equally well on perturbed test sets compared to its original test counterpart. A similar trend is observed in the multi-task setting as well (see App. H).

5 Conclusion

We introduced instruction augmentation to improve existing LMs in terms of improving performance and usability to non-expert users. To this extent, we created multi-variant instructions for 426 NLP tasks. Our experiment results show that instruction augmentation improves model performance in task-specific, multi-task and cross-task learning

# of Instances	SI		Perturbation 1		Perturbation 2		Perturbation 3	
	Original	Ours	Original	Ours	Original	Ours	Original	Ours
1%	0.90	25.21	1.60	18.03	1.02	23.16	5.12	9.71
5%	0.98	75.72	2.18	75.32	1.36	75.50	5.52	74.26
10%	50.88	78.20	20.76	78.07	50.49	78.37	40.31	77.22
50%	76.55	82.16	68.88	82.15	76.50	82.16	75.34	81.92
100%	79.38	83.16	73.51	82.97	79.34	83.12	78.71	82.40

Table 4: Comparison of performance in task-specific setting across SI and MVI learning.

paradigms. We find that instruction augmentation is more effective in low-data regime. Our results further indicate that an additional instruction can be equivalent to ~ 200 instances on an average. We hope our work will bring more attention to developing unconventional techniques (beyond dataset creation and model training) to empower non-expert users to leverage NLP resources and teach a task without having domain knowledge.

Limitations

We use BART-base and T5-base for all our experiments, however, we wish to experiment with different language models in future to show the benefit of our approach. Our analysis includes only tasks in English language, hence, it is important to see if our approach can be extended to non-English tasks as well. We feel that developing diverse instruction augmentation techniques will be pivotal to achieving more improvements as future research.

A Related Work

Prompt Learning Due to the success of large LMs, research paradigm in ML/DL has been shifted to prompt-based learning to achieve generalization and eliminate the need of creating task-specific models and large scale datasets (Liu et al., 2021). Past attempts have been made using prompt-based learning to solve various tasks including text classification (Yin et al., 2019), Natural Language Inference (NLI) (Schick and Schütze, 2020), Question Answering (QA) (Jiang et al., 2020), Information Extraction (IE) (Chen et al., 2021; Cui et al., 2021) and many more (Liu et al., 2021). Recently, T0 model (Sanh et al., 2021) is proposed which uses prompts to achieve zero-shot generalization across various NLP tasks. We were motivated by the work of Le Scao and Rush (2021) which shows that prompting is often worth 100s of data points on average. Our work instead focuses on instructions that are often different in terms of length, language, and capacity to represent a task (Wang et al., 2022b). Additionally, in contrast to prior works, we focus on the use of automatic methods for instruction augmentation and evaluate its efficacy across low-data to high-data regime in task-specific, multi-task, cross-task setups.

Instruction Learning Efrat and Levy (2020) studies whether existing LMs understands instructions. After that, many works have been proposed to show that models follow language instructions (Hase and Bansal, 2021; Ye and Ren, 2021; Gupta et al., 2021; Zhong et al., 2021). Furthermore, (Weller et al., 2020) has developed a framework that focuses on developing NLP systems that solve new tasks after reading their descriptions. Mishra et al. (2021b) has proposed natural language instructions for cross-task generalization of LMs. Along with that, PromptSource and FLAN (Wei et al., 2021; Sanh et al., 2021) were built for leveraging instructions and achieving zero-shot generalization on unseen tasks. Moreover, Parmar et al. (2022) shows the effectiveness of instructions in multi-task settings for the biomedical domain. Mishra et al. (2021a) discuss the impact of task instruction reframing on model response. Min et al. (2021) introduce a framework to better understand in-context learning. Ouyang et al. (2022) propose the InstructGPT model that is fine-tuned with human feedback to follow instructions. Wang et al. (2022a) has developed instruction-based multi-task

framework for few-shot Named Entity Recognition (NER) tasks. In addition, many approaches have been proposed to improve model performance using instructions (Wu et al., 2022; Lin et al., 2021; Wang et al., 2022b; Luo et al., 2022; Kuznia et al., 2022; Patel et al., 2022; Mishra and Nouri, 2022).

B Example of Variants

Table 5 and Table 6 show the examples of different variants created from the task117_afs_argument_similarity_gun_control and task018_qasc_answer_generation respectively.

C Multi-Variant Dataset Additional Details

C.1 Semantic Textual Similarity

We use en_core_web_md semantic similarity model of SpaCy to compute STS in our experiments. We also calculate STS score between definitions of variants of the same task. At the end, we calculate their mean and Standard Deviation (SD) for each task.

In the plot, the two exception points are task058 (Answer generation task based on babi dataset (Weston et al., 2015)) and task097 (Structured text generation task based on SCAN dataset (Lake and Baroni, 2018)) where the original instructions are very long and the variant task contains a short definition which causes the strong variation in STS. We also discuss the Word-Level Dissimilarity and Length Diversity properties of our dataset below.

C.2 Word-Level Dissimilarity

To show the quality and diversity of variant instructions, we calculate the pair-wise edit distance between the definition of the original instruction and its variant instructions. We also calculate distance between definitions of variant instructions of the same task, further normalize by the highest distance to obtain a dissimilarity score. We compute the mean and SD of these scores for each task and show it in Figure 6.

C.3 Length Diversity

It is necessary to see how task definition lengths vary between original instructions and their variants. To understand this, we compute the percentage difference between the length of the maximum instruction definition and the minimum instruction definition for each task and show it in Figure 7.

Original instruction along with its augmented variant instructions	
ORIGINAL INSTRUCTION	<p>Definition: We would like you to classify each of the following sets of argument pairs (discussing Gun Control) into either SIMILAR or NOT SIMILAR. A pair of arguments is considered SIMILAR if the arguments are about the same FACET (making the same argument), and is considered NOT SIMILAR if they do not have the same FACET. VARIANT INSTRUCTION 4	<p>Definition: Writing a accurate responded to the yielded matter founded on its associated fact. Deliver sure that your reply is contained in the associated doing. Aspects to avoidance: Don't be creative and introduce any newer word that is not talked in the associated facto! Recall that, the associated fact has been rearranged to form the issue. Thereby, the corrects responding phrase gotta lie within the related doing. <i>Focus & Circumspect:</i> The correct responding can be a word, expression, or even a sentences.</p> <p>Negative Examples: Input: <input> Output: <output> Explanation: <explanation></p> <p>Positive Examples: Input: <input> Output: <output> Explanation: <explanation></p>
VARIANT INSTRUCTION 5	<p>Definition: Writing a correct answers to the granted question bases on its associated doing. Make sure that your respond is contained in the associated doing. Matters to shirk: Don't be creative and introduces any novo word that is not referenced in the associated facto! Remind that, the associated fact has been reconfigured to forms the question. So, the corrects respond words ought lies within the related doing. <i>Concentrate & Careful:</i> The accurate reply can be a word, phrase, or yet a sentences.</p> <p>Negative Examples: Input: <input> Output: <output> Explanation: <explanation></p> <p>Positive Examples: Input: <input> Output: <output> Explanation: <explanation></p>

Table 6: Example of an instruction for an answer generation task with its variant instructions - task018_qasc_answer_generation

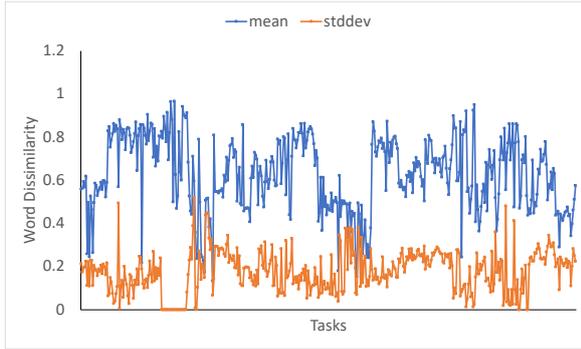

Figure 6: Word-level dissimilarity between original instruction and its variants.

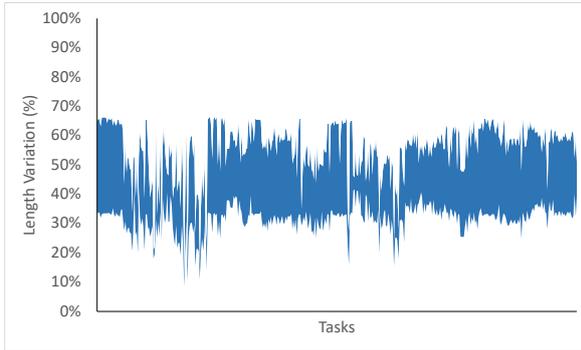

Figure 7: Definition length variation between original instruction and its variants.

D Task-Specific Results

Table 7 shows the results for task-specific experiments for task010_winogrande_answer_generation, task012_winogrande_question_modification_person and task018_qasc_answer_generation. We also performed experiments for other task categories like task210_tweetqa_question_generation and task113_odd-man-out_classification_no_category for generation and classification tasks respectively and summarize our results in Table 8. From the average results, we can observe that multi-variant instruction learning helps model to improve performance in task-specific learning.

E Multi-Task Results

The results for multi-task learning experiments are shown in Table 9.

F Cross-Task Results

The results for cross-task learning experiments are shown in Table 12. Figure 9 compares single-instruction learning and our approach in cross-task setting.

G Equal Data Analysis

We keep the original number of instances in SI learning, however, reduce the number of instances used in MVI learning by sampling N/V number of instances randomly for each task where N is the total number of instances in the original task and V is the number of instruction variants for this task. We perform these experiments in both task-specific and multi-task settings using BART-base. Table 10 summarizes the results of these experiments, and we can observe that the model trained using our approach shows competitive performance compared to single-instruction learning by using only N/V instances.

The results for cross-task learning experiments are shown in Table 12. Figure 9 compares single-instruction learning and our approach in cross-task setting.

H Robustness Analysis

Is single-instruction learning robust? As Figure 8 illustrates, LM fine-tuned with single-instruction learning or original setting is not robust to instructions written in a different way; this includes transformation techniques like paraphrasing, adding spelling mistakes, grammatical mistakes etc. Our experiment results show that model trained using the proposed multi-variant instruction learning technique is able to perform reasonably well and is robust to variant instructions in both multi-task setting, as evident by lower performance difference between single instruction evaluation and multi-variant instruction evaluation setup.

I Contribution of Individual Variants

Do each of the variant instructions contribute equally towards performance gain? To analyse the contribution of each of the variant instructions, we study the performance gain by adding a single variant instruction at one time. We perform this analysis in TS setting (task_010) and MT setting and summarize the results in Table 13 and Table 14 respectively. We observe that all variants do not contribute equally, e.g. MVI_All above are often smaller than individual MVIs. Identifying optimal variants, however, will be a scope for future work.

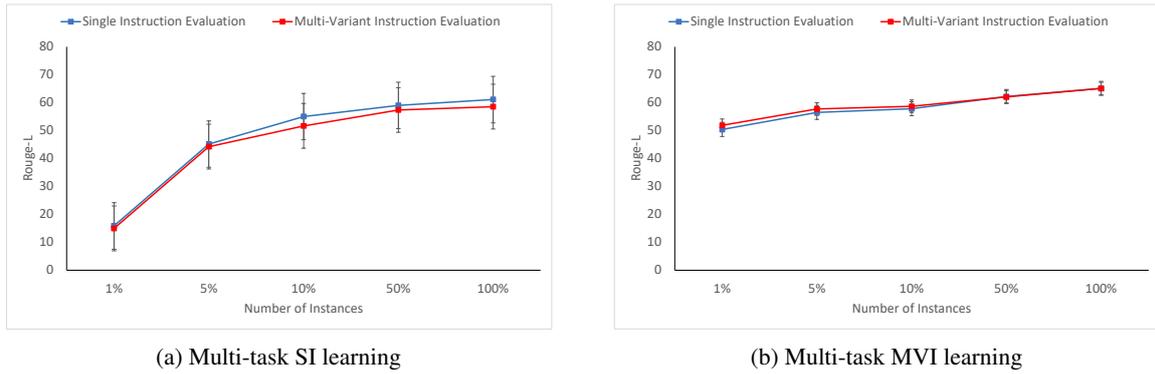

Figure 8: Robustness comparison of SI vs. MVI in multi-task setting - LM fine-tuned using MVI learning is more robust to variants as compared to SI learning.

Abstract

Adversarial attack aims to perturb input sequences and mislead a trained model for false predictions. To enhance the model robustness, defending methods are accordingly employed by either data augmentation (involving adversarial samples) or model enhancement (modifying the training loss and/or model architecture). In contrast to previous work, this paper revisits the masked language modeling (MLM) and presents a simple yet efficient algorithm against adversarial attacks, termed [MASK] insertion for defending (MI4D). Specifically, MI4D simply inserts [MASK] tokens to input sequences during training and inference, maximizing the intersection of the new convex hull (MI4D creates) with the original one (the clean input forms). As neither additional adversarial samples nor the model modification is required, MI4D is as computationally efficient as traditional fine-tuning. Comprehensive experiments have been conducted using three benchmark datasets and four attacking methods. MI4D yields a significant improvement (on average) of the accuracy between 3.2 and 11.1 absolute points when compared with six state-of-the-art defending baselines.

1 Introduction

Pretrained Language Models (PLMs) have rapidly advanced the performance of the Natural Language Processing (NLP) tasks, such as text/document classification. Yet, abundant evidences also indicate that PLMs are vulnerable to adversarial attacks, and the model performance can be dramatically impacted by (even) small perturbations to the model input (Gao et al., 2018; Li et al., 2019; Li et al., 2020; Jin et al., 2020). As a result, adversarial defenses have received significant attention, with the ultimate goal of achieving the robust model accuracy on both the clean (original) and polluted (adversarial) inputs.

*Corresponding author.

A large amount of research effort has been dedicated to adversarial defenses, ranging from the data augmentation, the model enhancement, to the randomized smoothing. Among data augmentation studies, recent works introduce small but controllable perturbations to pollute clean data and produce adversarial samples (Yoo and Qi, 2021; Dong et al., 2021; Zhou et al., 2021; Li et al., 2021; Meng et al., 2022), while the model is later trained on both the clean and polluted inputs. However, due to the additional adversarial samples, data-augmentation methods suffer from the requirement of enormous computational resources for training. Additionally, model-enhancement approaches focus on polishing the vanilla model via manipulating the training loss or network architecture, without acquiring additional adversarial data (Wang et al., 2021; Le et al., 2022; Liu et al., 2022). Yet, those methods often require extensive search among numerous candidates to determine optimal hyperparameters. Another line of work is to apply ensemble-based randomized smoothing techniques (Ye et al., 2020; Zeng et al., 2021). Unfortunately, they induce substantial overhead due to the ensemble classification; more importantly, their performance are unstable to different types of attacks (Zhang et al., 2022; Xu et al., 2022).

Our aim is then to explore a robust adversarial defending algorithm, which neither relies on additional adversarial data (as data augmentation), nor adjusts the training loss and network architecture (as model enhancement), nor requests ensemble-based training (as randomized smoothing). By contrast, this paper revisits the masked language modeling (MLM) and further proposes a compact and performance-preserving algorithm, termed [MASK] insertion for defending (MI4D). Specifically, MI4D only requires to insert [MASK] tokens at the beginning of input sequences to produce *masked inputs*. During training, (only) masked inputs are employed for the model fine-tuning, while

later polluted samples are masked in the same manner for inference. In contrast to the traditional MLM, the prediction task of [MASK] tokens is less emphasized in the proposed MI4D. Yet, the injected [MASK] plays a role of maximizing the intersection between the convex hull after attacking and that of the original (clean) input, thereby enhancing the defending performance.

The main contributions of the proposed work are summarized as follows:

- A novel [MASK] insertion for defending (MI4D) algorithm is proposed, neither relying on additional adversarial data nor modifying the training model nor requesting ensemble-based classification;
- MI4D is characterized by simply injecting [MASK] tokens at the beginning of input sequences during training and inference. Accordingly, the span of the convex hull (after injecting) is critical to retain more solution space as the clean one to enhance successful defense;
- Empirically, our proposed method outperforms six recent baselines on a combination of three standard benchmarks and four attacking methods, advancing the best state-of-the-arts by on average 3.2-11.1 absolute points in accuracy.

2 Related work

Constructing misleading samples to fool the trained neural-network models, adversarial attacks in the text domain can be mainly classified into two categories of the character- and word-level perturbation. The work of (Gao et al., 2018; Li et al., 2019) belongs to the character-level attack, from which the input is polluted by removing, substituting or inserting letters. On the other hand, word-based attacks usually involve the step of determining word importance, and replacing with their synonyms to maximize the prediction error of the model (Li et al., 2020; Jin et al., 2020).

Adversarial defense, by contrast, aims to form a robust model with high accuracy on both clean (original) and polluted (adversarial) samples. One of the most effective approaches is through the data augmentation (as shown in Fig. 1(a)), where adversarial samples are produced and fed into the model training. Specifically, **A2T** (Yoo and Qi, 2021) generates adversarial samples via

employing a gradient-based method to identify important words, and iteratively substitutes with their synonyms using a DistilBERT similarity. **FreeLB** (and its variants) (Zhu et al., 2020; Li et al., 2021) imposes norm-bounded noises on embeddings of input sentences to produce adversarial samples. **ADFAR** (Bao et al., 2021) applies a frequency-aware randomization on both original and adversarial samples (by other attacking methods) to form a randomized adversarial set. This augmentation set is then combined with original and adversarial samples to train the model. More recently, in (Meng et al., 2022), **ADCL** generates adversarial examples using a geometry attack, which are later utilized as hard positive samples to train the model following a self-supervised contrastive learning. Xu et al. propose **WETAR-D** (Xu et al., 2022) as a sample reweighting method, in which the sample weight is adjusted by minimizing the loss from the validation set mixed of both original and adversarial examples.

Besides the data augmentation, another line of studies is proposed for the model enhancement to refine the model architecture and/or training loss, without acquiring additional adversarial samples (as shown in Fig. 1(b)). Among them, **SHIELD** (Le et al., 2022) modifies the last layer of an trained model and transforms it into an ensemble of multiple-expert predictors with stochastic weights. **Flooding-X** (Liu et al., 2022) introduces a regularization technique to prevent the overfitting of training samples. Wang et al. (Wang et al., 2021) propose **InfoBERT** to employ two mutual-information-based regularizers for suppressing noisy information between the input and the latent representation, and for increasing the correlation between local and global features. A similar work is found in (Zhang et al., 2022), where an information bottleneck layer (**IB**) is inserted between the encoder and the final classifier. This **IB** layer is utilized to extract robust and task-related features.

Additionally, a set of ensemble-based randomized smoothing methods have been proposed, shown in Fig. 1(c). **SAFER** (Ye et al., 2020), for instance, constructs stochastic input ensembles and leverages statistical properties of ensembles to classify testing samples. In **RanMASK** (Zeng et al., 2021), few input tokens are randomly substituted using [MASK] for fine-tuning, while testing samples are also masked (at different locations) to form

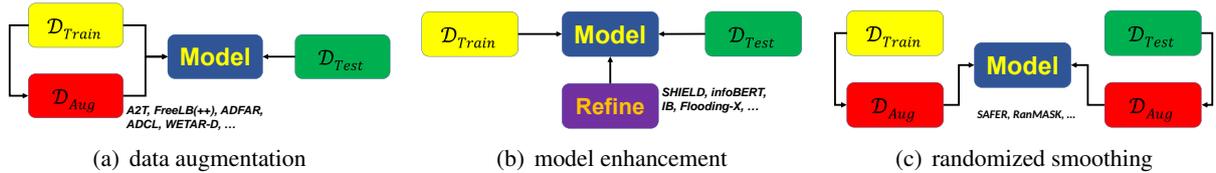

Figure 1: Comparison of existing adversarial defending methods.

several masked versions. The final prediction is then made by a majority vote from the ensemble of these masked versions.

The proposed method is different from existing approaches: (1) compared to adversarial based augmentation, no additional samples are required, and significant computational overhead is avoided accordingly; (2) compared to the model-enhancement ones, the proposed method is hyperparameter insensitive, which maintains the vanilla model training (loss and architecture) but only changes input formats; (3) compared to randomized smoothing, the ensemble based inference is no longer required.

3 Proposed method

Adversarial attack in text domain perturbs input sequences to maximally mislead the classification model, while this section presents a simple yet effective algorithm to reduce the model vulnerability, termed [MASK] insertion for defending (MI4D).

3.1 [MASK] insertion for defending

The proposed method MI4D is characterized by the normal fine-tuning process (the same network architecture and training loss as the vanilla model), while the only difference lies in the inserted [MASK] tokens at the beginning of input sequences during training and inference. Specifically, given the tokenized input sequence \mathbf{x} (i.e., $\mathbf{x} = [\text{CLS}] \mathbf{x}_1 \cdots \mathbf{x}_{|\mathbf{x}|} [\text{SEP}]$), where \mathbf{x}_i represents the i -th token from \mathbf{x} . For the text classification task, we aim to optimize an encoder $Enc(\cdot)$ and a Multilayer Perceptron (MLP) layer $f(\cdot)$ to map \mathbf{x} to a desirable label y , i.e., $f(Enc(\mathbf{x})) \mapsto y$.

Let b_M be the pre-defined masking budget (or the fraction of masked tokens). Then, MI4D injects M consecutive masks after [CLS] within \mathbf{x} to form a masked sequence, that is, $\mathbf{x}' = [\text{CLS}] [\text{MASK}]_1 \cdots [\text{MASK}]_M \mathbf{x}_1 \cdots \mathbf{x}_{|\mathbf{x}|} [\text{SEP}]$, and $M = \lceil |\mathbf{x}| * b_M \rceil$.

Next, only \mathbf{x}' (instead of \mathbf{x}) is utilized for training, while $Enc(\cdot)$ is leveraged to extract the latent representation for \mathbf{x}' and the normal loss (such

as the cross-entropy based) function $\mathcal{L}(\mathbf{x}', y)$ is adopted. During inference, with an unseen sequence $\bar{\mathbf{x}}$, the insertion procedure is repeated to inject M consecutive masks to $\bar{\mathbf{x}}$, i.e., $\bar{\mathbf{x}}' = [\text{CLS}] [\text{MASK}]_1 \cdots [\text{MASK}]_M \bar{\mathbf{x}}_1 \cdots \bar{\mathbf{x}}_{|\bar{\mathbf{x}}|} [\text{SEP}]$. The label of $\bar{\mathbf{x}}$ is finally produced by $f(Enc(\bar{\mathbf{x}}'))$.

3.2 Analysis

Notably, RanMASK (Zeng et al., 2021) substitutes input tokens with [MASK], while MI4D injects [MASK]. Despite its simplicity, conceptually and computationally, MI4D has strong theoretical results as the following claim: *RanMASK is the lower bound of MI4D in terms of adversarial defending performance.*

To prove the claim, given the tokenized input \mathbf{x} , the output of a self-attention module \mathbf{Y} is derived by

$$\mathbf{Y} = \text{softmax}(\mathbf{X}\mathbf{W}_1\mathbf{W}_2^\top\mathbf{X}^\top)\mathbf{X}\mathbf{W}_3,$$

where $\mathbf{X} \in \mathbb{R}^{|\mathbf{x}| \times d}$ is the latent representation of \mathbf{x} , d is the hidden dimension, and \mathbf{W}_k ($\forall k \in [1, 3]$) are projection matrices with compatible dimensions. The property of softmax dictates that each row of \mathbf{Y} (written as \mathbf{y}_i) is a convex construction of $\mathbf{X}\mathbf{W}_3$ (written as $\tilde{\mathbf{X}}$), i.e., $\mathbf{y}_i \in \mathcal{C}(\tilde{\mathbf{X}})$, where $\mathcal{C}(\tilde{\mathbf{X}})$ stands for the convex hull of $\tilde{\mathbf{X}}$ (see Fig. 2 for the area enclosed by thick dashed lines). The same process happens in multi-head attention modules. They operate in different projected spaces but the observation of the convex construction still holds.

We hypothesize that the successful defense rate (against attacks) is determined by the intersection of the new convex hull (a defending method creates) with the original convex hull (the clean data forms), and the larger intersection results in the better defending performance. This leads to the following assumption.

Assumption 1. *Given the latent representation of the clean input and its adversarial version in \mathbf{X} and \mathbf{X}' , for a very small $\epsilon \approx 0$,*

$$\mathbb{P}(\text{successful defense}) = \frac{\text{Vol}(\mathcal{C}(\mathbf{X}'_\epsilon) \cap \mathcal{C}(\mathbf{X}_\epsilon))}{\text{Vol}(\mathcal{C}(\mathbf{X}_\epsilon))},$$

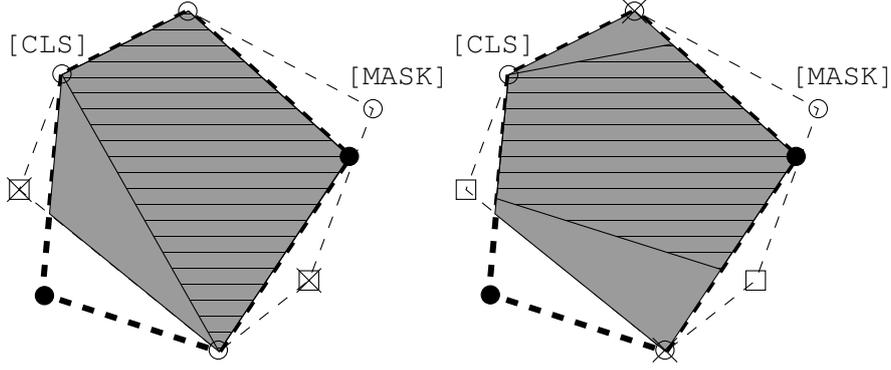

Figure 2: Illustration of the proof to Corollary 1. Circles represent tokens from the input sequence as vectors in projected space. Black circles are attacked and further replaced by the square ones. Gray (Stripped) areas are the intersection of MI4D (RanMASK) convex hull with the original data convex hull. Left: removing attacked tokens; Right: removing two good tokens. Removed tokens are marked by cross.

where $\text{Vol}(\cdot)$ is a function to estimate the volume of a geometric object, and \mathbf{X}_ϵ is the ϵ ball centred at \mathbf{X} .

The ϵ ball spans the convex hulls to the dimension of the ambient space so that volume always exists. More importantly, it also reflects the model tolerance to the variation of vector representations, indicating small disturbance will not affect the model output. To ease notation, we omit the ϵ in later development.

MI4D differs from RanMASK at no random elimination of input tokens, but a simple insertion of [MASK] while keeping clean and polluted tokens. This choice leads to the fact that the convex hull formed by MI4D always contains those by RanMASK as guaranteed by the following lemma.

Lemma 1. *Given a set \mathbf{X} , we have $\mathcal{C}(\mathbf{S}) \subseteq \mathcal{C}(\mathbf{X})$ for any subset $\mathbf{S} \subseteq \mathbf{X}$. The equality holds when $\mathbf{S} = \mathbf{X}$ trivially or otherwise \mathbf{S} contains all the anchor points of $\mathcal{C}(\mathbf{X})$, i.e., the convex hull vertices.*

Proof. Let \mathcal{X} be the index set for \mathbf{X} and a subset $\mathcal{S} \subseteq \mathcal{X}$ gives the indices for \mathbf{S} . For any point $p \in \mathcal{C}(\mathbf{S})$, $p = \sum_{i \in \mathcal{S}} \lambda_i \mathbf{x}_i$ such that $\lambda_i \geq 0$ and $\sum \lambda_i = 1$, i.e., the convex condition. Apparently $p \in \mathcal{C}(\mathbf{X})$ as well by setting $\lambda_j = 0$ for $j \in \mathcal{X} \setminus \mathcal{S}$.

For any point $x_i \in \mathbf{X}$, it is either an anchor point or an internal point referring to $\mathcal{C}(\mathbf{X})$. If \mathbf{S} contains only anchor points, $\mathcal{C}(\mathbf{S}) = \mathcal{C}(\mathbf{X})$ as the internal points can be ‘‘absorbed’’. To see this, assume \mathbf{x}_1 is an internal point, then $\mathbf{x}_1 = \sum_{i>1} \beta_i \mathbf{x}_i$ and all β_i s for $i > 1$ satisfying convex condition. Then

$$p = \sum_{i=1} \lambda_i \mathbf{x}_i = \sum_{i>1} (\lambda_i + \lambda_1 \beta_i) \mathbf{x}_i.$$

Therefore, $\mathcal{C}(\mathbf{X}) = \mathcal{C}(\mathbf{X}_{-1})$ where \mathbf{X}_{-1} is the set of vectors after removing \mathbf{x}_1 . After eliminating internal points, the convex hull will still be the same. \square

The immediate result from above lemma is the following corollary stating the relations between convex hulls generated by MI4D and RanMASK.

Corollary 1. *Convex hull generated by MI4D always contains those by RanMASK.*

Proof. Let \mathbf{X} be the latent representation of input tokens for MI4D (including [MASK] tokens), and \mathcal{X} the corresponding indices set. RanMASK runs several, say n , times of random eliminations but keeping [MASK] tokens, i.e., leading to index subsets \mathcal{S}_i ($\mathcal{S}_i \subset \mathcal{X}$ ($i = 1 \sim n$)). Clearly, from **Lemma 1**, we have $\forall i, \mathcal{C}(\mathbf{S}_i) \subseteq \mathcal{C}(\mathbf{X})$, where \mathbf{S}_i is the corresponding representations in \mathbf{X} indexed by \mathcal{S}_i . Equality holds only when \mathbf{S}_i contains all anchor points set in $\mathcal{C}(\mathbf{X})$. \square

Next, we are ready to formalize and prove the claim as the following proposition.

Proposition 1. *Given Assumption 1, MI4D has at least the same successful defending rate as that of RanMASK. In other words, MI4D has at least equally good adversarial defense performance as RanMASK.*

Proof. Let \mathbf{X}' (\mathbf{X}) be the adversarial (original) representations in latent space, and \mathbf{S}_i be the i -th subset of \mathbf{X}' . The successful defending probability of MI4D and RanMASK at the i -th run is defined as p_m and p_{r_i} , respectively. We have

$$p_m = \frac{\text{Vol}(\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{X}'))}{\text{Vol}(\mathcal{C}(\mathbf{X}))},$$

and

$$p_{r_i} = \frac{\text{Vol}(\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{S}_i))}{\text{Vol}(\mathcal{C}(\mathbf{X}))}.$$

For RanMASK to succeed, the successful \mathbf{S}_i s have to be chosen and become majority and hence the final success probability of RanMASK $p_r = \mathbb{P}(\exists i, \mathbf{S}_i \text{ success} \wedge \text{successful sets are majority})$. Clearly,

$$\begin{aligned} p_r &\leq \min(\mathbb{P}(\exists i, \mathbf{S}_i \text{ success})), \\ &\quad \sum_{k \geq \lceil n/2 \rceil} B(k; n, \max_i \{p_{r_i}\}) \\ &\leq \min(\max_i \{p_{r_i}\}, \sum_{k \geq \lceil n/2 \rceil} B(k; n, \max_i \{p_{r_i}\})) \\ &\leq p_m, \end{aligned}$$

where $B(k; n, p)$ is the probability of k out of n trials successes with probability p , i.e., $\binom{n}{k} p^k (1-p)^{n-k}$. The last inequality comes from Corollary 1 as $p_m \geq p_{r_i} (\forall i)$ and hence $p_m \geq \max_i (p_{r_i})$. \square

Overall, an illustration is shown in Fig. 2 with the convex hull of MI4D (\mathcal{C}_m) and those of RanMASK (\mathcal{C}_r) with two different random eliminations. The gray area shows the intersection of MI4D convex hull with the original convex hull \mathcal{C} , i.e., $\mathcal{C} \cap \mathcal{C}_m$, while stripe areas are the intersections of those of RanMASK, i.e., $\mathcal{C} \cap \mathcal{C}_r$. We know that $\mathcal{C} \cap \mathcal{C}_m$ always contains $\mathcal{C} \cap \mathcal{C}_r$. As such, the span of the convex hull after [MASK] insertion is critical to retain more solution space to enhance successful defense. Additionally, we also infer that the position of inserted [MASK] tokens and the number of insertions are less important (multiple of them differ only at the positional encoding), as they may well be in the ϵ ball of the same [MASK] token itself. These inferences are verified in the ablation study.

4 Experiments

4.1 Setup

Datasets. Experiments are carried on three text classification benchmarking datasets, including **SST2** (Socher et al., 2013) (sentiment classification on the Stanford Sentiment Treebank corpus), **AGNEWS** (Zhang et al., 2015) (category classification for news articles from more than 2000 news sources), **IMDB** (Maas et al., 2011) (document polarity classification using the online IMDB database).

Attacking algorithms. Four adversarial attacking methods are implemented using *TextAttack* (Morris et al., 2020) to pollute input sequences, that is,

- **DeepWordBug** (Gao et al., 2018) deletes, replaces, and inserts characters to inputs;
- **TextBugger** (Li et al., 2019) performs perturbations of space insertion, char deletion/swapping, and synonym substitution;
- **BERT-Attack** (Li et al., 2020) substitutes key words using a pre-trained masked model;
- **TextFooler** (Jin et al., 2020) replaces important words with their synonyms.

Evaluation Metrics. Three measurements are considered to evaluate the model robustness against adversarial attacks. Specifically, **Cln%** refers to the model classification accuracy on the original clean data. **Aua%** is the classification accuracy under certain adversarial attacks, and higher Aua% means better defending performance. **Suc%** is defined as the number of examples successfully being fooled against the number of all attempted attacks; accordingly, lower Suc% indicates the higher model robustness.

All experiments are performed five trials with random seeds for each dataset. For each run, the training is performed with batches of 32 sequences of length 512. The maximal number of training epoch is 10. Meanwhile, 10% samples are randomly selected from the training set to form the validation set, and the training stops if the validation accuracy fails to improve for one epoch. On the other hand, 1,000 testing examples are randomly selected for the evaluation purpose. This is the typical experimental setting as (Wang et al., 2021; Zhang et al., 2022; Zeng et al., 2021). More details are provided in Appendix A.1.

4.2 Main results

The following state-of-the-art defending methods are employed to compare with the proposed MI4D, including **WETAR-D** (Xu et al., 2022), **FreeLB++** (Li et al., 2021), **IB** (Zhang et al., 2022), **InfoBERT** (Wang et al., 2021), **Flooding-X** (Liu et al., 2022), and **RanMASK** (Zeng et al., 2021). Among them, the first two methods are based on adversarial data augmentation, while IB, InfoBERT and Flooding-X are for the model enhancement. The last one represents the randomized smoothing method.

Table 1: Averaged defending performance (over five trails) obtained by MI4D and current SOTAs using four attacking methods, including TextFooler, BERT-Attack, Deepwordbug, and TextBugger. The number with bold, † and * represents the best, second, and third result, respectively.

The RoBERTa-base model (Liu et al., 2019) is employed as the **Baseline**. All contender methods are re-implemented using their released codes, and their key configurations are summarized in Appendix A.1. Their results are competing with those reported. Additionally, for MI4D most of the hyperparameters, such as learning rate, are consistent with the vanilla RoBERTa-base, while the masking budget b_M is set as 30%. The comparison results over five trails are shown in Table 1.

To begin with, the proposed MI4D achieves comparative results of averaged Cln% (94.35%) across all three clean testing datasets. The performance is only second to that of Flooding-X (averaged 94.40%), while a consistent improvement is observed in comparison with other existing methods. Importantly, MI4D achieves the state-of-the-art defending accuracy in terms of Aua (60.18%) and Suc (36.40%) outperforming all contenders. Notably, all methods seemingly perform better against character-level attacks (Deepwordbug and TextBugger), which demonstrates the difficulty of defending word-based attacks. Yet, MI4D still achieves the largest improvement (in comparison

with the Baseline) and secures averaged 43.85 and 46.85 absolute percent points on Aua% and Suc% for the TextFooler and BERT-Attack, respectively.

By contrast, another [MASK] based approach (i.e., RanMASK) scores the worst performance across three datasets. The main difference between RanMASK and ours lies in the usage of [MASK] tokens (substitution or insertion). By replacing residual tokens after attacking, RanMASK could further destroy the original semantic of input sequences. However, MI4D spans the semantic convex hull to increase the chance of including original anchor points, as Lemma 1 and Corollary 1 indicated, so as to enhance the defending performance.

4.3 Ablation study

To better understand the effectiveness of the proposed method, a series of careful analysis is carried out. Again, all results are reported as an averaged accuracy over five trials.

On the masking location. To start with, the ablation experiment is performed to understand the impact from the location of inserted [MASK] tokens. In comparison with adding [MASK] right

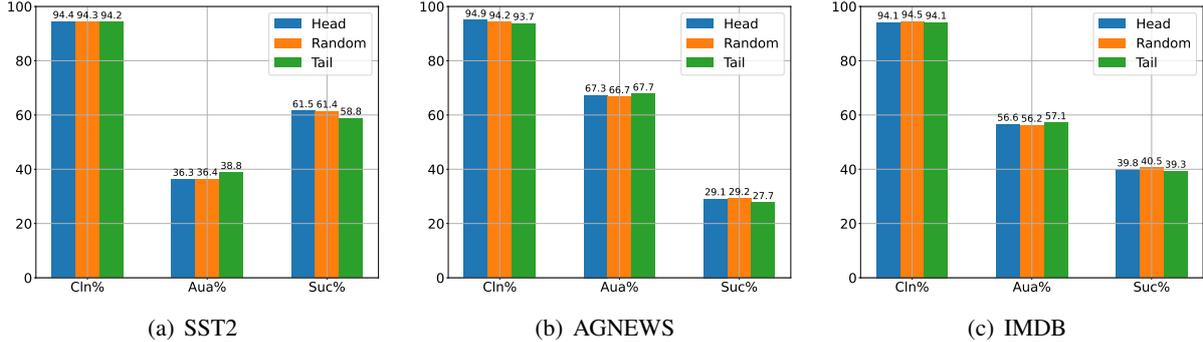

Figure 3: Impact analysis of the masking location from either adding [MASK] after [CLS] (labeled as *Head*), randomly (labeled as *Random*) or at the end of the input sequence (labeled as *Tail*).

after the [CLS] (labeled as *Head* hereafter), the *Random* one is implemented to randomly insert [MASK] following a uniform sampling until b_M is met (where b_M is the masking budget). Similarly, we also consider to insert at the end of the input sequence (labeled as *Tail*).

With $b_M=0.3$, the comparison result using three datasets and the TextFooler attack is shown in Fig. 3 (results from other attack methods can be found in Appendix A.2). Clearly, the proposed method is insensitive to the masking location, due to the similar performance achieved by either *Head*, *Random* or *Tail* insertion. This shows positional encoding has negligible effect as we asserted in analysis, as the position embedding is less important compared to the token embedding. In MI4D context, exactly same [MASK] tokens are inserted and they do not change the relative order of existing tokens. Therefore position embeddings can be seen as a disturbance to “tag” on token embeddings to create the small variation, and have less impact on MI4D.

On the masking budget. The following experiments are to evaluate the impact of the masking budget (b_M) on the proposed method. Obviously, with a higher value of b_M , more [MASK] tokens will be inserted that could lead to more perturbed samples. Specifically, experiments are conducted by varying b_M from 0.1 to 0.9. We need to point out that for the dataset of SST2, with $b_M=0.1$ it is equivalent to injecting only 1 [MASK] token due to the average length of input sequences. As such, we are particularly interested in the model performance with/out [MASK].

The comparison is shown in Fig. 4 for the MI4D performance against the TextFooler attack on three datasets (results from other attack methods can

be found in Appendix A.3). Notably, the results demonstrate the robustness of the proposed method to different masking budgets. That is, MI4D observes a stable defending performance across all three evaluation metrics for different masking budgets. As the span of the convex hull is utterly important rather than its multiplicity, this observational experiment once again confirms our inference in the Analysis.

4.4 Discussion

In this section, we investigate different strategies of utilizing [MASK] tokens, and further seek for a reasonable explanation for the result. Again, experiments are conducted with [MASK] being inserted after [CLS] and $b_M=0.3$.

When to insert. First, we discuss the [MASK] insertion whether for training and/or inference. That is, three scenarios are considered to insert [MASK]: (1) only during the training, (2) only during the inference, and (3) both training and testing (equivalent to MI4D).

The comparison is shown in Table 2. The “Train only” variant is observed with the worst performance for the mostly collapsed convex hull, while others have more “developped” convex hull to embrace the original solution space. We highlight that including [MASK] in training is to fine-tuning token embedding as a semantic place holder, and hence a “wild card”. Accordingly, the capacity to span the convex hull to more likely intersect with original one is further enhanced, although [MASK] is employed for extensive pre-training of PLMs before.

What to substitute. Hereafter the impact from substituting/masking different types of tokens is discussed, where tokens are cast as *polluted* (be-

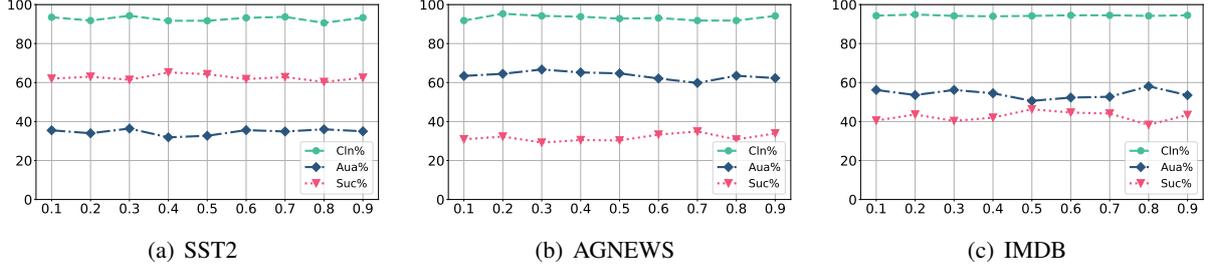

Figure 4: Comparison of the defending performance as a function of the masking budget (b_M), against the TextFooler attack across three datasets (where x-axis represents b_M).

Table 2: Averaged defending performance via masking training and/or testing samples for MI4D, while the Baseline method (vanilla RoBERTa-base) is adopted for reference.

ing attacked) and *normal* (remaining unchanged). The following experiment then involves MI4D and three other variants for comparison, that is to (1) only substitute *polluted* (labeled as Mask_Pol), (2) only substitute *normal* (labeled as Mask_Normal), and (3) substitute randomly (explicitly as RanMASK). Fig. 5 illustrates the defending accuracy of masking different types of tokens from the SST2 dataset (results from other datasets can be found in Appendix A.4).

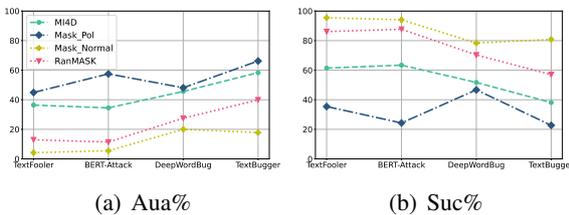

Figure 5: Comparison of the model performance against categorizes of masked tokens with SST2.

The comparison results clearly imply that the best performance is achieved via substituting/masking polluted tokens (*i.e.*, Mask_Pol), while Mask_Normal is the worst. In our hypothe-

sis, when polluted tokens are replaced by [MASK], it generates the convex hull that has the maximum overlap with the original one and hence leads to the best chance to defense. By contrast, Mask_Normal introduces more noise by maintaining perturbed but removing normal tokens. Notably, as there is no clue about adversarial attacking on which specific tokens in reality, Mask_Pol and Mask_Normal then reveals the theoretically best and worst defending outcome (or the **upper** and **lower** bound), respectively.

RanMASK is then a special combination of Mask_Pol and Mask_Normal, as tokens of either *polluted* or *normal* are randomly masked out with a predefined probability. On the other hand, the proposed MI4D becomes an effective solution for masking inputs (due to the uncertainty of which tokens being polluted during testing), that is consistently better than RanMASK (randomly mask tokens). Again, the reason is that MI4D includes all by exploiting the fact that polluted tokens are still informative, to some extent, when they are combined with residuals ones, to create a larger convex hull overlapping (compared to RanMASK)

with the original one. That is shown clearly in Proposition 1.

[MASK] or others. The last experiment aims to investigate the possibility of injecting different tokens, instead of [MASK]. Specifically, the [PAD] token is selected and further inserted into the original input sequence. Note that, in this regard, all other configurations (such as the masking budget and the random insertion) remain explicitly the same, but only to replace [MASK] with [PAD] for the injection. Table 3 reports the averaged performance using the SST2 dataset with four attacks. As observed, the performance using [PAD] is similar to that of [MASK], indicating we can insert [MASK] (or similar) as a “wild card” to increase the span of the convex hull.

Table 3: Averaged defending performance via injecting [PAD] (instead of [MASK]) tokens.

	TextFooler			BERT-Attack		
	Cln%	Aua%	Suc%	Cln%	Aua%	Suc%
[MASK]	94.3	36.4	61.4	94.3	34.5	63.4
[PAD]	94.1	36.4	61.4	93.5	32.8	64.9
	Deepwordbug			TextBugger		
	Cln%	Aua%	Suc%	Cln%	Aua%	Suc%
[MASK]	94.4	45.6	51.7	94.2	58.3	38.1
[PAD]	93.2	44.7	52.0	93.1	63.1	32.3

5 Conclusion

We propose a novel adversarial defending algorithm (MI4D), that is hyperparameter insensitive and structure free. The proposed method simply inserts [MASK] tokens at the beginning of input sequences, and follows the normal fine-tuning to train the model. Theoretically speaking, we have argued that adding additional [MASK], while remaining other residual tokens, creates a large convex hull overlapping with that of the clean one to increase the defending probability. Empirically, in comparison to existing state-of-the-arts, the proposed algorithm exhibits superior performance on three benchmark datasets with four attack methods. In future work, we could combine with external knowledge for more strategical masking. More importantly, MI4D is agnostic to downstream tasks, *i.e.*, we could incorporate it into other applications.

Limitations

Our theoretic analysis is constructed on a crucial assumption asserting that the successful defense probability is determined by the volume of the convex hull formed by the input. Although our empirical study results confirmed the inferences based on this

assumption repeatedly (shown in Section 4.4), we are still seeking direct dynamics of the convex hull to the prediction/classification probability where a more rigorous result may be derived. We envisage that the understanding of the current model behavior can lead to more robust models against adversarial attacks and hence further improvement to text classification.

A Appendix

A.1 Training Details

The RoBERTa-base model (Liu et al., 2019) is employed as the contextual encoder. The dropout rate across all layers is set as 0.1. The Adam optimizer with a dynamic learning rate is adopted, for which the learning rate is warmed up for 10 thousand steps to a maximum value of $2e^{-5}$ before decaying linearly to a minimum value of $1e^{-6}$ (by the cosine annealing) and a gradient clip of $(-1, 1)$. Additionally, for WETAR-D, 50% of samples are polluted in the validation set (the size of 256); for FreeLB++, the number of search steps (for adversarial samples) is 30; for IB, the hidden dimension for the IB layer is set as 150 and the penalty of the IB loss is 0.1; for InfoBERT, the penalty of the mutual-information loss is 5×10^{-2} ; for RanMASK, the masking budget is set as 30%, while the majority vote is adopted for the final classification stage. At last, all models are performed using a machine with NVIDIA Tesla V100 PCIe of 32G GPU memory.

A.2 Impact from the location of inserting [MASK]

The model accuracy is evaluated by adding the [MASK] token in different locations, *i.e.*, either after [CLS] (termed *Head*), randomly (termed *Random*) across the input sequence, or at the end (termed *Tail*). The comparison is shown in Fig 6, and the result illustrates that the proposed method achieves a similar performance regardless of the inserted [MASK] location.

A.3 Impact from the [MASK] budget

The model accuracy is also evaluated as a function of the masking budget. The comparison is shown in Fig 7, and the result illustrates that the proposed method achieves a stable performance regardless of different budgets.

A.4 Result from masking different types of tokens

Fig. 8 shows the comparison of the defending results with different types of tokens being masked. Clearly, masking all polluted but retaining normal tokens leads to the best performance, while masking normal tokens is the worst. The proposed MI4D achieves the competitive outcome by injecting additional [MASK] tokens while keeping others. The result indicates that the larger the insertion between

new convex hull (after masking) with the original one, the better defending performance.

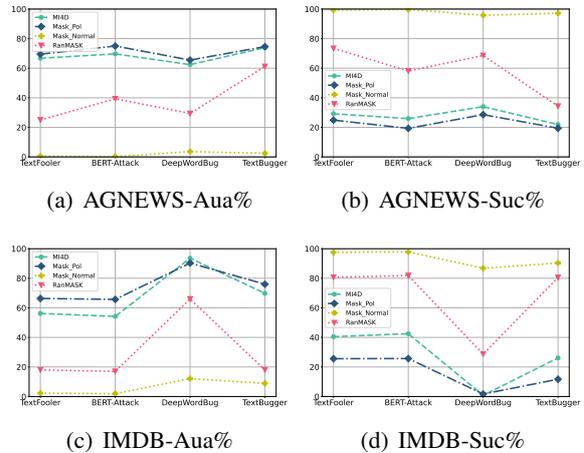

Figure 8: Comparison of the model performance against categories of masked tokens.

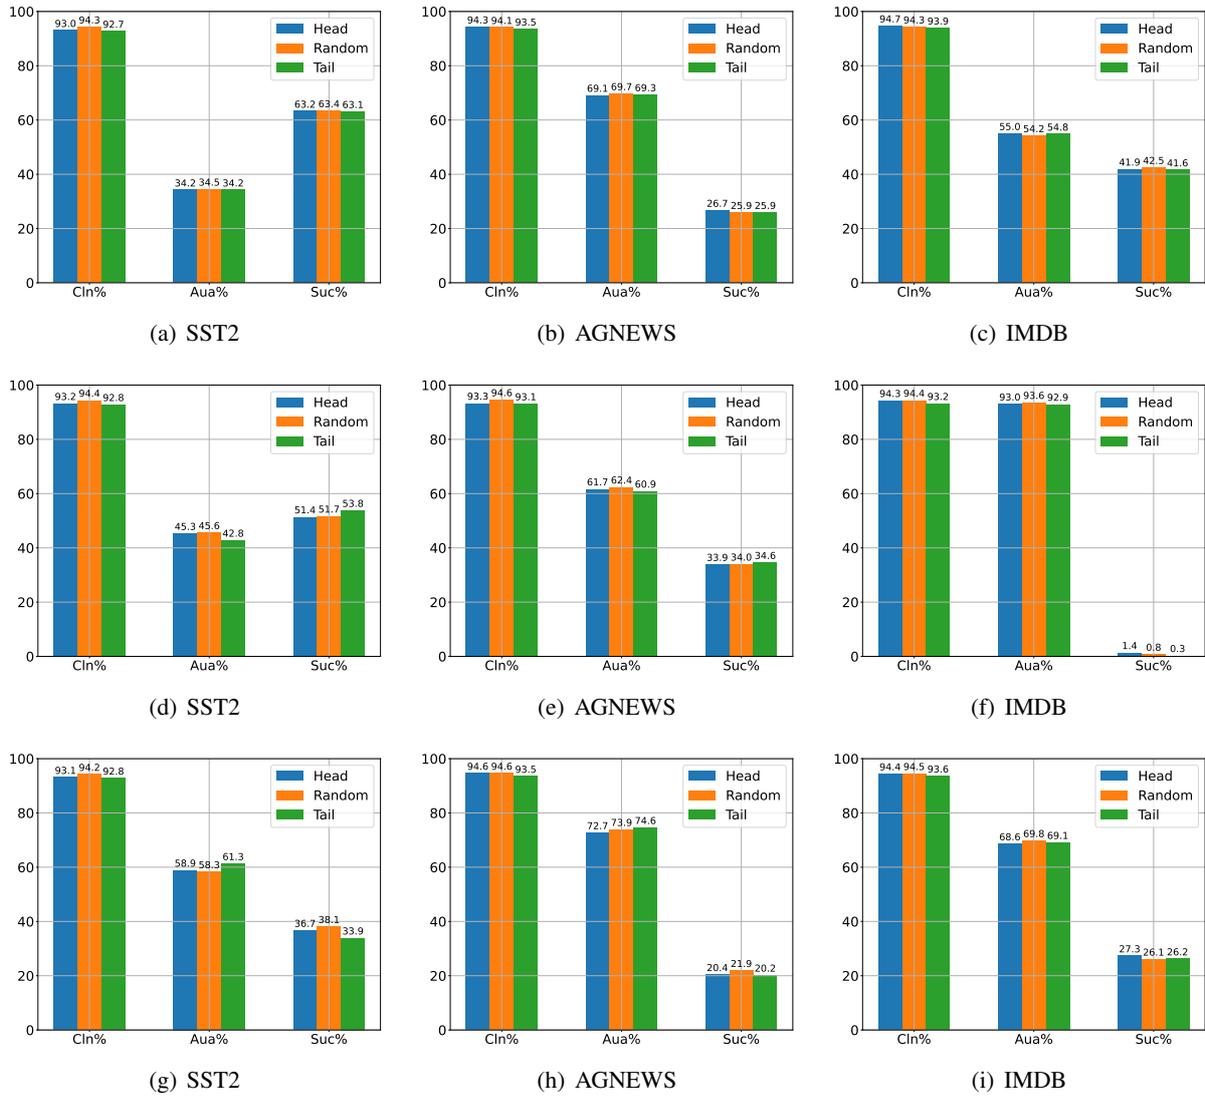

Figure 6: Comparison of the defending performance as a function of inserting [MASK] after [CLS] (labeled as *Head*), randomly (labeled as *Random*), or at the end of the input sequence (labeled as *Tail*). Among them, (a)-(c) is for the BERT-Attack, (d)-(f) is for DeepWordBug, and (g)-(i) is for TextBugger, respectively.

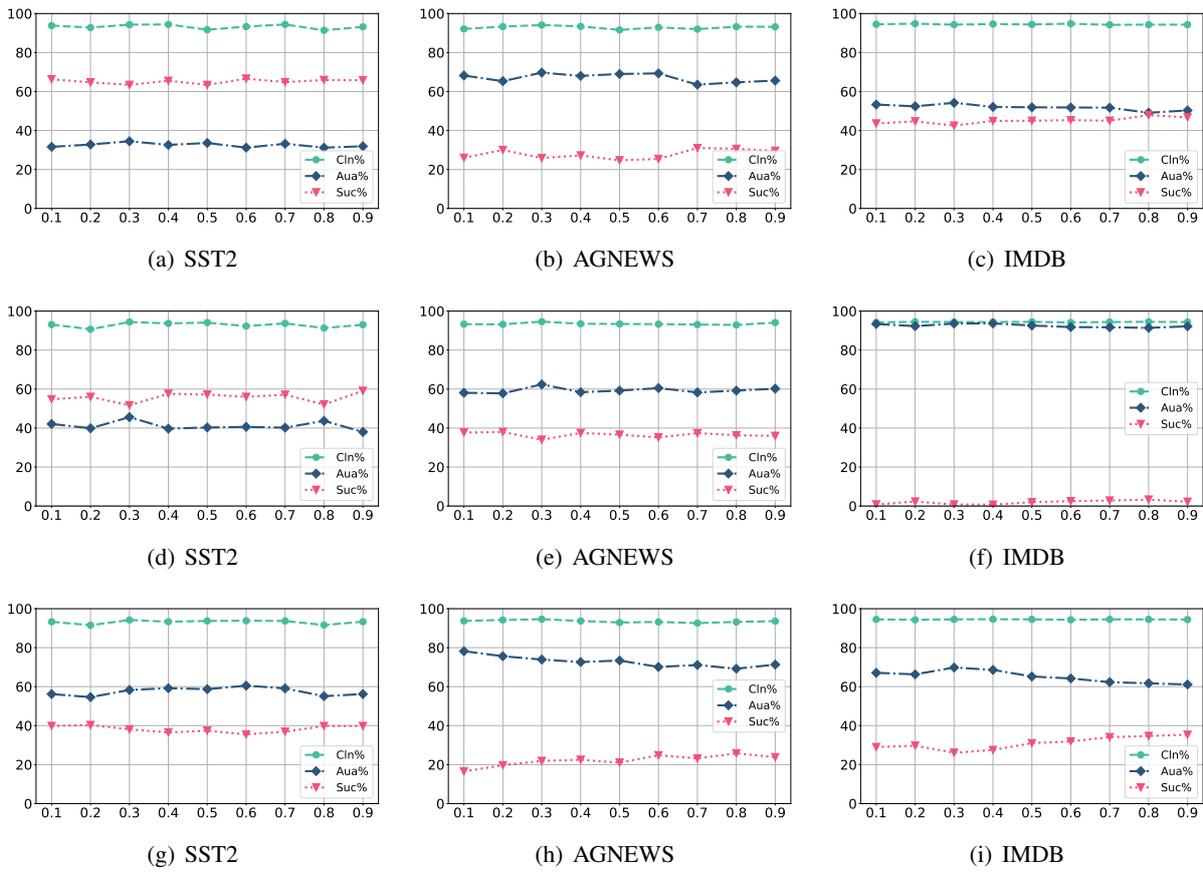

Figure 7: Comparison of the defending performance as a function of masking budget. Among them, (a)-(c) is for the BERT-Attack, (d)-(f) is for DeepWordBug, and (g)-(i) is for TextBugger, respectively.

ViDeBERTa: A powerful pre-trained language model for Vietnamese

Abstract

This paper presents ViDeBERTa, a new pre-trained monolingual language model for Vietnamese, with three versions - ViDeBERTa_{small}, ViDeBERTa_{base}, and ViDeBERTa_{large}, which are pre-trained on a large-scale corpus of high-quality and diverse Vietnamese texts using DeBERTa architecture. Although many successful pre-trained language models based on Transformer have been widely proposed for the English language, there are still few pre-trained models for Vietnamese, a low-resource language, that perform good results on downstream tasks, especially Question answering. We fine-tune and evaluate our model on three important natural language downstream tasks, Part-of-speech tagging, Named-entity recognition, and Question answering. The empirical results demonstrate that ViDeBERTa with far fewer parameters surpasses the previous state-of-the-art models on multiple Vietnamese-specific natural language understanding tasks. Notably, ViDeBERTa_{base} with 86M parameters, which is only about 23% of PhoBERT_{large} with 370M parameters, still performs the same or better results than the previous state-of-the-art model. Our ViDeBERTa models are available at: <https://github.com/HySonLab/ViDeBERTa>.

1 Introduction

In recent years, pre-trained language models (PLMs) and Transformer-based architecture models have been essential in the advancement of Natural Language Processing (NLP). Large-scale Transformer-based pre-trained models with the capacity to derive a contextual representation of the languages in the training data include GPT (Radford et al., 2019; Brown et al., 2020), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019b), ELECTRA (Clark et al., 2020), T5 (Raffel et al., 2020), and DeBERTa (He

et al., 2020, 2021). Following pre-training, these models performed at the cutting edge on various downstream NLP tasks (Devlin et al., 2019). The development of pre-trained models in other languages, including Vietnamese (PhoBERT (Nguyen and Nguyen, 2020); ViBERT (Tran et al., 2020); ViT5 (Phan et al., 2022)), and Arabic (Antoun et al., 2021), has been spurred on by the success of pre-trained models in English. In order to enhance performance across several languages by learning both general and language-specific representations, multilingual pre-trained models (XLM-R (Conneau et al., 2020), mT5 (Xue et al., 2021), and mBART (Liu et al., 2020) are also being developed.

Most recently, PhoBERT (Nguyen and Nguyen, 2020), the first large pre-trained model for Vietnamese that inherits the RoBERTa (Liu et al., 2019) architecture, has demonstrated the effectiveness of the trained language model compared with current methods modernized in four Vietnamese-specific tasks, including Part of Speech Tagging (POS), Dependency Parsing, Named Entity Recognition (NER), and Natural Language Inference (NLI). Nevertheless, there are still rooms to build an improved pre-trained language model for Vietnamese. Firstly, PhoBERT was pre-trained on a relatively small Vietnamese dataset of 20GB of uncompressed texts, while pre-trained language models can be significantly improved by using more pre-training data (Liu et al., 2019). Secondly, Question answering (QA) is one of the most impactful tasks that has mainly focused on the computational linguistics and artificial intelligence research community within information retrieval and information extraction in recent years. However, there are a few pre-trained models for Vietnamese that produce efficient results in the QA tasks, especially PhoBERT (Nguyen and Nguyen, 2020) and ViT5 (Phan et al., 2022). Last but not least, some previous works point to DeBERTa architecture (He et al., 2020, 2021) using several novel techniques

*: Co-first authors. †: Correspondent author.

that can significantly outperform RoBERTa and improve the efficiency of model pre-training and the performance of downstream tasks in some respects.

Inspired by that, we introduce an improved large-scale pre-trained language model, ViDeBERTa, trained on CC100 Vietnamese monolingual, following the architecture and pre-training methods of DeBERTaV3 (He et al., 2021). We comprehensively evaluate and compare our model with competitive baselines, i.e., the previous SOTA models PhoBERT, ViT5, and the multilingual model XLM-R on three Vietnamese downstream tasks, including POS tagging, NER, and QA. In this work, we focus on two main categories of QA: Machine Reading Comprehension (MRC) and Open-domain Question Answering (ODQA). The experiment results show the performance of our model surpasses all baselines on all tasks. Our main contributions are summarized as follows:

- We present and implement ViDeBERTa with three versions: ViDeBERTa_{small}, ViDeBERTa_{base}, and ViDeBERTa_{large} which are the improved large-scale monolingual language models pre-trained for Vietnamese based on the DeBERTa architecture and pre-training procedure.
- We also conduct extensive experiments to verify the performance of our pre-trained models compared to previous strong models in terms of Vietnamese language modeling. Our empirical results demonstrated the state-of-the-art (SOTA) results on Vietnamese downstream tasks: POS tagging, NER, and QA, thus confirming the effectiveness of our improved pre-trained language model for Vietnamese.
- Our model, ViDeBERTa, which works with *huggingface* and *transformers*, is available to the public. We expect that ViDeBERTa will be an effective pre-trained model for many NLP applications and research in Vietnamese and other low-resource languages.

2 Related work

Pre-trained language models for Vietnamese. PhoBERT (Nguyen and Nguyen, 2020) is the first large-scale PLM for Vietnamese, which has the same architecture as BERT (Devlin et al., 2019) and the same pre-training approach as RoBERTa (Liu et al., 2019) for more robust performance. This

model was trained on a Vietnamese Wikipedia corpus of 20GB word-level texts and produced SOTA results on Vietnamese understanding tasks such as POS, NER, Dependency parsing, and NLI. Following PhoBERT, ViBERT (Tran et al., 2020) and ViELECTRA are public monolingual language models for Vietnamese based on BERT and ELECTRA pre-training techniques (Clark et al., 2020) that are pre-trained on syllable-level Vietnamese textual data. Recent works such as BARTpho (Tran et al., 2021) and ViT5 (Tran et al., 2020) are pre-trained for Vietnamese text summarization.

Fine-tuning tasks. This work utilizes three Vietnamese natural language understanding (NLU) tasks, including POS tagging, NER, and QA, for fine-tuning and evaluating our model’s performance. For POS tagging and NER, PhoBERT still produces better results than ViELECTRA, PhoNLP, and ViT5 (Nguyen and Nguyen, 2020, 2021; Phan et al., 2022). While early QA (Voorhees et al., 1999; Brill et al., 2002; Ferrucci et al., 2010) systems were commonly complex and had many parts, MRC models have evolved and now suggest a simpler two-stage retriever-reader framework (Chen et al., 2017). A context retriever first selects a small subset of passages where some of them contain the answer to the question then a machine reader can carefully review the retrieved contexts and determine the correct answer. The tasks based on QA have gained much attention in recent years in the Vietnamese natural language processing and computational linguistics community. However, to the best of our knowledge, there is only the work (Van Nguyen et al., 2022) that proposes the first Vietnamese retriever-reader QA system employing a transformer-based model (XLM-R) evaluated on the ViQuAD corpus (Nguyen et al., 2020).

3 ViDeBERTa

3.1 Pre-training data

In this work, we use a large corpus CC100 Dataset of 138GB uncompressed texts (Monolingual Datasets from Web Crawl Data) (Conneau et al., 2020) as a pre-training dataset. This corpus includes data for romanized languages and monolingual data for more than 100 languages.

According to Nguyen and Nguyen (2020); Tran et al. (2021), pre-trained language models trained on word-level data can perform better than those trained on syllable-level data for word-level Vietnamese NLP tasks. As a result, we perform word

and sentence segmentation using a Vietnamese toolkit PyVi¹ on the pre-training dataset. After that, we use a pre-trained SentencePiece tokenizer from DeBERTaV3 (He et al., 2021) to segment these sentences with sub-word units, which have a vocabulary of 128K sub-word types.

3.2 Model Architecture

Our model, ViDeBERTa, follows the DeBERTaV3 architecture by He et al. (2021), which is trained using the self-supervise learning objectives of MLM and RTD task and a new weight-sharing Gradient-Disentangled Embedding Sharing (GDES) to enhance the performance of the model. We present three versions of our model, ViDeBERTa_{xsmall}, ViDeBERTa_{base}, and ViDeBERTa_{large} with 22M, 86M, and 304M backbone parameters, respectively.

The details of our model architecture hyper-parameters are listed in Table 1.

Table 1: Statistic of our model hyper-parameters. #layer and #heads denote the numbers of layers and attention heads of ViDeBERTa model versions, respectively.

Model	#layers	#heads	hidden size
ViDeBERTa _{xsmall}	6	12	768
ViDeBERTa _{base}	12	12	768
ViDeBERTa _{large}	24	12	1024

3.3 Optimization

We employ our model based on the DeBERTaV3 implementation from (He et al., 2021). We use Adam (Kingma and Ba, 2015) as the optimizer with weight decay (Loshchilov and Hutter, 2018) and use a global batch size of 8,192 across 32 A100 GPUs (80GB each) and a peak learning rate of 6e-4 for both ViDeBERTa_{xsmall} and ViDeBERTa_{base}, while peak learning rate of 3e-4 was used for ViDeBERTa_{large}. We pre-train ViDeBERTa_{xsmall} and ViDeBERTa_{base} for 500k training iterations and ViDeBERTa_{large} for 250k training iterations.

4 Experiments and Results

4.1 POS tagging and NER

4.1.1 Experimental setup

For POS tagging and NER tasks, we use standard benchmarks of the VLSP POS tagging dataset² and the PhoNER dataset (Truong et al., 2021).

¹<https://pypi.org/project/pyvi/>

²<https://vlsp.org.vn/vlsp2013/eval/ws-pos>

We follow the procedure in Devlin et al. 2019; Nguyen and Nguyen 2020 to fine-tune our pre-trained model for POS tagging and NER tasks. In particular, a linear layer for prediction is appended on top of our model architecture (the last Transformer layer). We then use Adam (Kingma and Ba, 2015) to optimize our model for fine-tuning with a fixed learning rate of 1e-5 and batch size of 16 (He et al., 2021). The final results for each task and each dataset are averaged and reported over five independent runs with different random seeds.

We compare the performance of ViDeBERTa models with the solid baselines, including PhoBERT, XLM-R, and ViT5, for these tasks. Here, XLM-R is a multilingual masked language model pre-trained on 2.5 TB of CommonCrawl dataset of 100 languages, which includes 137GB of Vietnamese texts.

4.1.2 Main results

Model	POS	NER	MRC
	Acc.	F ₁	F ₁
XLM-R _{base}	96.2 [†]	—	82.0 [‡]
XLM-R _{large}	96.3 [†]	93.8*	87.0 [‡]
PhoBERT _{base}	96.7 [†]	94.2*	80.1
PhoBERT _{large}	96.8 [†]	94.5*	83.5
ViT5 _{base1024-length}	—	94.5*	—
ViT5 _{large1024-length}	—	93.8*	—
ViDeBERTa _{xsmall}	96.4	93.6	81.3
ViDeBERTa _{base}	96.8	94.5	85.7
ViDeBERTa _{large}	97.2	95.3	89.9

Table 2: Test results (%) for three tasks POS tagging (POS for short), NER, and MRC on test sets. Note that “Acc.” abbreviates the accuracy. †, *, and ‡ denote scores taken from the PhoBERT paper (Nguyen and Nguyen, 2020), the ViT5 paper (Phan et al., 2022), and the ViQuAD paper (Nguyen et al., 2020), respectively.

Table 2 shows the obtained scores of ViDeBERTa compared to the baselines with the highest reported results. It can be seen clearly that our model produces significantly better results than the baselines and achieves new SOTA performance on both POS tagging and NER tasks.

For POS tagging, ViDeBERTa obtains 0.9% and 0.4% absolute higher accuracy than the large-scale multilingual model XLM-R (Nguyen et al., 2020) and the previous SOTA model PhoBERT (Nguyen and Nguyen, 2020), respectively. Table 2 also shows our ViDeBERTa_{xsmall} obtains 96.4% accuracy that are better than the baseline XLM-R_{large}

and ViDeBERTa_{base} obtains 96.8% that are competitively the same as the PhoBERT_{large}.

For NER, our ViDeBERTa_{large} achieves F₁ score at 95.3% and improves 0.8% absolute higher score than the previous SOTA models ViT5_{base1024-length} and PhoBERT_{large}. Furthermore, ViDeBERTa_{large} and ViDeBERTa_{base} perform 1.5% and 0.7% absolute higher scores than the baseline XLM-R_{large} on the PhoNER corpus.

4.2 Question Answering

4.2.1 Experimental setup

For QA, we evaluate our model on two main tasks: MRC and ODQA. For ODQA, we propose a new framework ViDeBERTa-QA, that uses a BM25 (Robertson et al., 2009) as a retriever and ViDeBERTa as a text reader.

Figure 1 depicts an overview of our ViDeBERTa framework for the Vietnamese Open-domain Question answering task. The statistics of the ViQuAD dataset used for the task, which is introduced by Nguyen et al. (2020), are summarized in Table 3.

Corpus	#article	#passage	#question
Train	138	4,101	18,579
Dev	18	515	2,285
Test	18	493	2,21
Full	174	5,109	23,074

Table 3: Statistics of the ViQuAD dataset for QA. “#article”, “#valid”, and “#test” denote the number of articles, passages, and questions in the ViQuAD, respectively.

We compare ViDeBERTa to the best model XLM-R (Nguyen et al., 2020) and PhoBERT³ for Vietnamese MRC. We also compare our framework, ViDeBERTa-QA, to strong baselines DrQA (Chen et al., 2017), BERTserini (Yang et al., 2019a), and the first Vietnamese ODQA system XLMRQA (Van Nguyen et al., 2022) that uses XLM-R_{large} as a reader. We use the ViQuAD corpus introduced by Nguyen et al. (2020) for assessing these tasks. ViQuAD is a Vietnamese corpus that comprises over 23k triples and each triple includes a question, its answer, and a passage containing the answer.

Similar to POS tagging and NER, we use Adam (Kingma and Ba, 2015) as an optimizer with a learning rate of 2e-5 and a batch size of 16. We report

³We carefully fine-tune PhoBERT for the MRC task following the fine-tuning approach that we use for ViDeBERTa.

the final results as an average over five independent runs with different random seeds.

4.2.2 Main results

Table 2 presents the results obtained by ViDeBERTa and two baselines XLM-R (reported by Nguyen et al. (2020)) and PhoBERT for MRC on ViQuAD corpus. We find that our ViDeBERTa performance outperforms both XLM-R and PhoBERT in terms of F₁ score.

In particular, the previous SOTA model XLM-R_{large} for Vietnamese MRC obtains 87%. Clearly, ViDeBERTa helps boost the XLM-R with about 2.9% absolute improvement, obtaining a new SOTA result at 89.9%. In addition, both versions ViDeBERTa_{base} and ViDeBERTa_{large} also outperform PhoBERT_{base} and PhoBERT_{large} by large margins, respectively. Especially, ViDeBERTa_{xsmall} (22M parameters) produces 1.2% absolute higher score than PhoBERT_{base} (135M parameters) and ViDeBERTa_{base} (86M parameters) produces 2.2% absolute higher score than PhoBERT_{large} (370M parameters) but uses far fewer parameters than PhoBERT.

For ODQA, Table 4 shows the obtained F₁ scores for ViDeBERTa-QA and its baselines on the test set. Obviously, ViDeBERTa-QA achieves better scores than the previous SOTA XLMRQA, BERTserini, and DrQA at the top k passages, selected by retrievers, is 10 and 20. In particular, ViDeBERTa-QA performs 0.85% (at $k = 20$) and 0.4% (at $k = 10$) absolute higher scores than the previous SOTA system. At smaller k ($= 1, 5$), ViDeBERTa performs better BERTserini and DrQA by a large margin; however, XLMRQA does better than ViDeBERTa-QA.

Model	Top k selected passages			
	1	5	10	20
DrQA [*]	37.86	37.86	37.86	37.86
BERTserini [*]	55.55	58.30	57.98	58.09
XLMRQA [*]	61.83	64.99	64.49	64.49
ViDeBERTa _{xsmall}	52.76	56.24	56.93	57.40
ViDeBERTa _{base}	58.55	61.37	61.89	62.43
ViDeBERTa _{large}	61.23	63.57	64.89	65.34

Table 4: Test scores (F₁ in %) for ODQA on ViQuAD corpus with different k values. Note that [*] indicates the results reported following Van Nguyen et al. (2022).

4.3 Discussion

According to the results on both downstream tasks of POS tagging and NER in Table 2, we find that

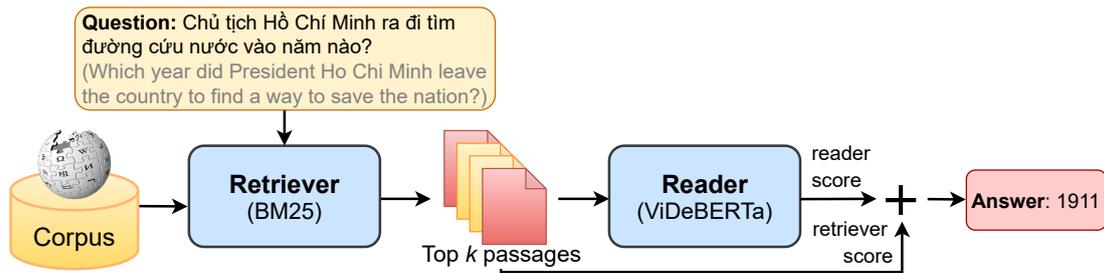

Figure 1: An overview of ViDeBERTa-QA framework for Vietnamese Open-domain Question Answering task.

ViDeBERTa_{small} (86M) with fewer parameters (i.e. only about 15% of XLM-R_{large} 560M and 25% of PhoBERT_{large} 370M) but still performs slightly better than XLM-R_{large} and competitively the same as the previous SOTA PhoBERT_{large}. One possible reason is that our model inherits the robustness of DeBERTaV3 architecture and pre-training techniques, which are demonstrated superior performance by He et al. (2020, 2021). Moreover, using more high-quality pre-training data (138GB) can help ViDeBERTa significantly improve its performance compared to PhoBERT (using 20GB).

For Vietnamese QA, the results on the MRC task show that ViDeBERTa outperforms PhoBERT by a large margin. It is worth noting that PhoBERT set a maximum length of 256 subword tokens for both versions while ViDeBERTa set a larger one of 512. As a result, our models are more scalable than PhoBERT for long contexts. The results obtained by ViDeBERTa-QA on ODQA also suggest that our framework achieves the best performance with large top k passages selected by the retriever (i.e. $k = 10, 20$).

5 Conclusion

In this paper, we have introduced ViDeBERTa, a new pre-trained large-scale monolingual language model for Vietnamese. We demonstrate the effectiveness of our ViDeBERTa by showing that ViDeBERTa with fewer parameters performs better than the recent strong pre-trained language models as XLM-R, PhoBERT, and ViT5, and achieves SOTA performances for three downstream Vietnamese language understanding tasks, including POS tagging, NER, and especially QA. We hope that our public ViDeBERTa model will boost ongoing NLP research and applications for Vietnamese and other low-resource languages.

Limitations

While we have shown that ViDeBERTa can achieve state-of-the-art performance on a variety of NLP tasks for Vietnamese, we believe that more analyses and ablations are required to better understand what facets of ViDeBERTa contributed to its success and what knowledge of Vietnamese that ViDeBERTa captures. We leave these further explorations to future work.

A Background of DeBERTa

DeBERTa enhances BERT with disentangled attention and a more powerful mask decoder. The disentangled attention mechanism is distinct from prior methods in that it uses two distinct vectors to represent each input word: one for the content and one for the location. The words’ attention weights are calculated using disentangled matrices based on both their relative placements and contents. Similar to BERT, DeBERTa has been pre-trained using masked language modeling. The disentangled attention process already accounts for the relative locations and contents of the context words but not for their absolute positions, which are usually crucial for prediction. DeBERTa improves MLM by utilizing a better mask decoder at the MLM decoding layer and absolute position information of the context words.

A.1 Masked Language model

Large-scale Transformer-based PLMs are often pre-trained using a self-supervision aim called Masked Language Model (MLM) (Devlin et al., 2019) to learn contextual word representations in enormous volumes of text. In further detail, we corrupt a given sequence $X = \{x_i\}$ into \tilde{X} by randomly masking 15% of its tokens and train a language model parameterized by θ to reconstruct X by anticipating the masked tokens \tilde{x} conditioned on \tilde{X} :

$$\max_{\theta} \log p_{\theta}(X|\tilde{X}) = \max_{\theta} \sum_{i \in C} \log p_{\theta}(\tilde{x}_i = x_i|\tilde{X}), \quad (1)$$

where C is the sequence’s index set for the masked tokens. The authors of BERT suggest keeping 10% of the masked tokens unchanged, replacing another 10% with tokens chosen at random, and replacing the remaining tokens with the [MASK] token.

A.2 Replaced token detection

Like ELECTRA, which was trained with two transformer encoders in GAN style, DeBERTaV3 (He et al., 2021) improves DeBERTa by using the training loss in the generator is MLM and discriminator is Replaced Token Detection (RTD). The loss function of the generator can be written as follows:

$$L_{MLM} = \mathbb{E} \left(- \sum_{i \in C} \log p_{\theta_G}(\tilde{x}_{i,G} = x_i|\tilde{X}_G) \right), \quad (2)$$

where θ_G and \tilde{X}_G are the parameter and the input of the generator by masking 15% tokens in X , respectively.

The discriminator’s input sequence is constructed by replacing masked tokens with new tokens sampled according to the generator’s output probability:

$$\tilde{x}_{i,D} = \begin{cases} \tilde{x}_i \sim p_{\theta_G}(\tilde{x}_{i,G} = x_i|\tilde{X}_G), & i \in C \\ x_i, & i \notin C \end{cases} \quad (3)$$

The loss function of the discriminator is written as follows:

$$L_{RTD} = \mathbb{E} \left(- \sum_i \log p_{\theta_D}(\mathbb{1}(\tilde{x}_{i,D} = x_i)|\tilde{X}_D) \right), \quad (4)$$

where θ_D is the parameter of the discriminator, $\mathbb{1}(\cdot)$ is the indicator function, and \tilde{X}_D is the input to the discriminator constructed by Equation 4. Then L_{MLM} and L_{RTD} are optimized jointly by the final loss $L = L_{MLM} + \lambda L_{RTD}$, where λ is the weight of the discriminator loss.

Besides using the RTD training loss like ELECTRA (Clark et al., 2020), DeBERTaV3 improves DeBERTa by using a new weight-sharing method called Gradient-Disentangled Embedding Sharing (GDES) (He et al., 2021). The experimental results conducted by He et al. indicate that GDES is an effective weight-sharing method for language model pre-trained with MLM and RTD tasks.

NapSS: Paragraph-level Medical Text Simplification via Narrative Prompting and Sentence-matching Summarization

Abstract

Accessing medical literature is difficult for laypeople as the content is written for specialists and contains medical jargon. Automated text simplification methods offer a potential means to address this issue. In this work, we propose a *summarize-then-simplify* two-stage strategy, which we call NapSS, identifying the relevant content to simplify while ensuring that the original narrative flow is preserved. In this approach, we first generate reference summaries via sentence matching between the original and the simplified abstracts. These summaries are then used to train an extractive summarizer, learning the most relevant content to be simplified. Then, to ensure the narrative consistency of the simplified text, we synthesize auxiliary *narrative prompts* combining key phrases derived from the syntactical analyses of the original text. Our model achieves results significantly better than the seq2seq baseline on an English medical corpus, yielding 3%~4% absolute improvements in terms of lexical similarity, and providing a further 1.1% improvement of SARI score when combined with the baseline. We also highlight shortcomings of existing evaluation methods, and introduce new metrics that take into account both lexical and high-level semantic similarity. A human evaluation conducted on a random sample of the test set further establishes the effectiveness of the proposed approach. Codes and models are released here: <https://github.com/LuJunru/NapSS>.

1 Introduction

The medical literature is vast, and continues to expand quickly. Most patients (laypeople), however, are unable to access this information because it is written for specialists and so dense and laden with jargon. As the recent ‘infodemic’ has shown, access to reliable and comprehensible information about citizens’ health is a fundamental need: for example, a European Health Literacy Survey (HLS-EU) reports that “at least 1 in 10 (12%) respondents

Complex Medical Abstract – ABS	Plain-Language Summary - PLS
S1. We included two trials involving 754 participants.	S1. Two good quality randomized controlled trials involving 754 women were identified.
S2. One new trial of 660 participants showed the same success rate of vacuum procedure of 98.2% by both methods (risk ratio (RR) 1.00, 95% confidence interval (CI) 0.98 to 1.02).	S2. Rapid negative pressure application reduced the duration of the procedure without any evidence of differences in outcomes for the mother or infant.
S3. The two included trials showed significant reductions in the time between applying the vacuum cup and delivery, (one trial (74 women): mean difference (MD) -6.10 minutes, 95% CI -8.83 to -3.37 and the other trial (660 women): with median difference -4.4 minutes, 95% CI -4.8 to -4.0).	S3. Rapid method of negative pressure application should be recommended for vacuum extraction assisted vaginal delivery.
S4. The two included trials showed no significant difference in detachment rate (RR 0.85, 95% CI 0.38 to 1.86, 2 studies, 754 women), no significant difference in Apgar score below seven at one minute (RR 1.04, 95% CI 0.51 to 2.09) and five minutes (RR 1.0, 95% CI 0.29 to 3.42), no significant differences in scalp abrasions or lacerations, cephalhematoma, subgaleal hemorrhage and hyperbilirubinemia.	
S5. There were no significant differences between the two methods in all secondary outcomes.	
S6. The rapid negative pressure application for vacuum assisted vaginal birth reduces duration of the procedure whilst there is no evidence of differences in maternal and neonatal outcomes.	
S7. Rapid method of negative application should be recommended for vacuum extraction assisted vaginal delivery.	

Figure 1: A typical sample of Medical Text Simplification task. The abstract and plain-language summary are split into sentences for easy inspection. Key phrases in each sentence, and marks of chosen sentences in reference summary are in bold.

show insufficient health literacy and almost 1 in 2 (47%) has insufficient or problematic health literacy” (Sørensen et al., 2015). Automated text simplification methods offer a potential means to address this issue, and make evidence available to a wide audience as it is published. However, performing paragraph-level simplification of medical texts is a challenging NLP task.

Online medical libraries such as Cochrane library,¹ provide synopses of the medical literature across diverse topics, and manually-written plain language summaries. We are interested in developing accurate automated medical text simplification systems upon those libraries to help timely popularization of medical information to lay audience.

¹<https://www.cochranelibrary.com/>

We show a typical example of a technical abstract and associated simplified summary from a recently introduced paragraph-level medical simplification corpus (Devaraj et al., 2021a) in Figure 1. The sample consists of a technical abstract (ABS) written for experts, and a manually authored Plain-Language Summary (PLS) of the same publication collected from the Cochrane website. The dataset only provides raw abstract-PLS pairs. For easy inspection, we further add sentence splitting and highlight key phrases.

As this example illustrates, a text simplification system needs to first have an overview of the key details reported in the abstract (e.g., that the review synthesizes ‘two trials’) and must also infer that there ‘were no significant differences’ when ‘rapid negative pressure application’ was applied to all participants, and thus that the ‘rapid method should be recommended’. This entails an overall understanding of the key concepts to simplify, while preserving a consistent narrative flow. Built upon this general framing, the system should identify that the most representing sentences in the abstract are sentences 1, 6, 5 and 7. The key challenges here for a model include: (i) identifying the most important content to simplify within the synopsis; (ii) preserving the original narrative flow from a linguistic and medical point of view; (iii) synthesising the findings in a simple and consistent language.

To address these challenges, we propose a *summarize-then-simplify* two-stage framework NapSS—**N**arrative **P**rompting and **S**entence-matching **S**ummarization—for paragraph-level medical text simplification. The *narrative prompt* is designed to promote the factual and logical consistency between abstracts (ABSs) and PLSs, while the *simplification-oriented summarizer* identifies and preserves the relevant content to convey and simplify.

In the first stage, we construct intermediate summaries via sentence matching between the abstract and the PLS sentences based on their Jaccard Distance. This preliminary set of summaries is used to fine-tune a simplification-oriented summarizer which at inference time identifies and extracts the most relevant content to be simplified from the technical abstracts. This extractive summarizer is simplification-aware in that the reference summary is built with PLS ground truth.

In the second stage of simplification, the intermediate summary is concatenated to a narrative

prompt generated by synthesising the main concepts, entities, or events mentioned in text resulting from the syntactic analysis of the PLSs. The prepared input is passed to a seq2seq model (e.g., BART (Lewis et al., 2020)) to produce a plain-language output.

Our contributions can be summarized as follows:

- We introduce NapSS, a two-stage *summarize-then-simplify* approach for paragraph-level medical text simplification, leveraging extractive summarization and narrative prompting.
- We design a *simplification-aware summarizer* and a narrative prompt mechanism. The former is based on a Pre-trained Language Model (PLM) fine-tuned for extractive summarization on an intermediate set of summaries built via sentence matching between the technical and simplified text. The latter synthesises key concepts from the medical text by syntactic dependency parsing analyses, promoting the overall consistency with the narrative flow.
- We conduct a thorough experimental assessment on the Cochrane dataset for paragraph-level medical simplification, evaluating the different features of the generated text (i.e., simplicity and semantic consistency) using several automatic metrics, and the model generalization on sentence-level simplification. Additionally, to mitigate the limitations of the automatic metrics, we designed and conducted a human evaluation assessment, involving “layperson” readers and medical specialists. The results demonstrated the state-of-the-art performance on quality and consistency of the simplified text.

2 Related work

We review three lines of work relevant to this effort: text simplification, extractive summarization, and prompting.

2.1 Text Simplification

Work on text simplification has mainly focused on sentence-level simplification, using the Wikipedia-Simple Wikipedia aligned corpus (Zhu et al., 2010; Woodsend and Lapata, 2011) and the Newsela simplification corpus (Xu et al., 2015). There has been less work on document-level simplification, perhaps owing to a lack of resources (Sun et al., 2021; Alva-Manchego et al., 2019).

The medical domain stands to benefit considerably from automated simplification: The medical literature is vast and technical, and there is a need to make this accessible to non-specialists (Kickbusch et al., 2013). Some research uses those medical documents and deploys various simplification methods based on lexical and syntactic simplification (Damay et al., 2006; Kandula et al., 2010; Llanos et al., 2016). The recent release of the Cochrane dataset provided a new parallel corpus of technical and lay overview of published medical evidence (Devaraj et al., 2021a).

2.2 Extractive Summarization

Extractive summarization aims to select the most important words, sentences, or phrases from input texts and combine them into a summary. Many approaches have been proposed: ranking and selecting sentences based on their graph overlap (Mihalcea and Tarau, 2004), deriving the relevance of the sentences within the text using WordNet (Pal and Saha, 2014), extracting information by named entity recognition (Maddela et al., 2022), and using continuous vector representations to perform semantic matching and sentence selection (Liu and Lapata, 2019; Narayan et al., 2018b; Gui et al., 2019; Lu et al., 2020; Pergola et al., 2021a).

There are some works that focus on extractive summarization of biomedical texts (Mishra et al., 2014; Sun et al., 2022). These have either aimed to provide a summary via graph-based methods or via sequence extraction to present key information in structured (tabular) form (Gulden et al., 2019; Aramaki et al., 2009). In this work we follow a standard *sentence matching* extractive summarization method (Goldstein et al., 1999; Zhong et al., 2020) and fine-tune a pre-trained language model to perform sentence classification. We use extractive summaries as an intermediate step.

2.3 Prompting

Recent work has shown that language models can be *prompted* to perform tasks without supervision (i.e., “zero-shot”) (Radford et al., 2018; Brown et al., 2020). Prompts have been shown to work across a wide range of NLP tasks, e.g., sentiment classification, “reading comprehension”, and “commonsense reasoning” (Seoh et al., 2021; Petroni et al., 2019; Pergola et al., 2021b; Jiang et al., 2019; Lu et al., 2022; Zhu et al., 2022; Wei et al., 2022). Recent work has shown that prompt-based methods can be used even with smaller language models

(Schick and Schütze, 2020; Gao et al., 2020). In this work we focus on a novel use of prompts: Assisting generation of simplified text.

3 Methods

We first define the Paragraph-level Text Simplification task, introducing the relevant notations, and then present the NapSS model.

3.1 Task Formulation

In many cases, text simplification can be viewed as a generative task with additional constraints regarding the simplicity of the generated text. Analogously to text summarization, paragraph-level text simplification can be formulated as follows: for a given *complex* paragraph with M sentences, $\mathbf{x} = \{\{x_1^1, x_2^1, \dots, x_{N_{x_1}}^1\} \dots \{x_1^M, x_2^M, \dots, x_{N_{x_M}}^M\}\}$, the aim is to generate a *plain-language summary* (PLS) $\hat{\mathbf{y}} = \{\hat{y}_1, \hat{y}_2, \dots, \hat{y}_{N_s}\}$, summarizing and simplifying the original paragraph, with N_{x^m} denoting the length of the m -th sentence \mathbf{x}^m .

3.2 NapSS

We now describe NapSS, a text simplification approach based on a *summarize-then-simplify* two-stage pipeline with the aims of (i) identifying the relevant content to simplify while (ii) ensuring that the original narrative flow is preserved. First, we generate a preliminary summary by using a *simplification-oriented BERT summarizer*, an extractive model fine-tuned beforehand to identify the most relevant content to attend and simplify (§3.2.1). These preliminary summaries are then combined with a *narrative prompt*, a synthetic set of key phrases describing the main concepts, entities, or events discussed in the original text and derived from its syntactic analysis (§3.2.2). The overall working flow of our proposed NapSS model is illustrated in Figure 2. We next provide the details of each of these modules.

3.2.1 Sentence-matching Summarization

The idea behind the summarization stage is to identify the most important content within a given technical abstract (with respect to target simplifications). We automatically construct an intermediate “reference” summary dataset using the simplification training set with which to fit a simplification-oriented summarizer. Specifically, we train the latter as a binary sentence classifier, which provides a simple extractive summarization approach.

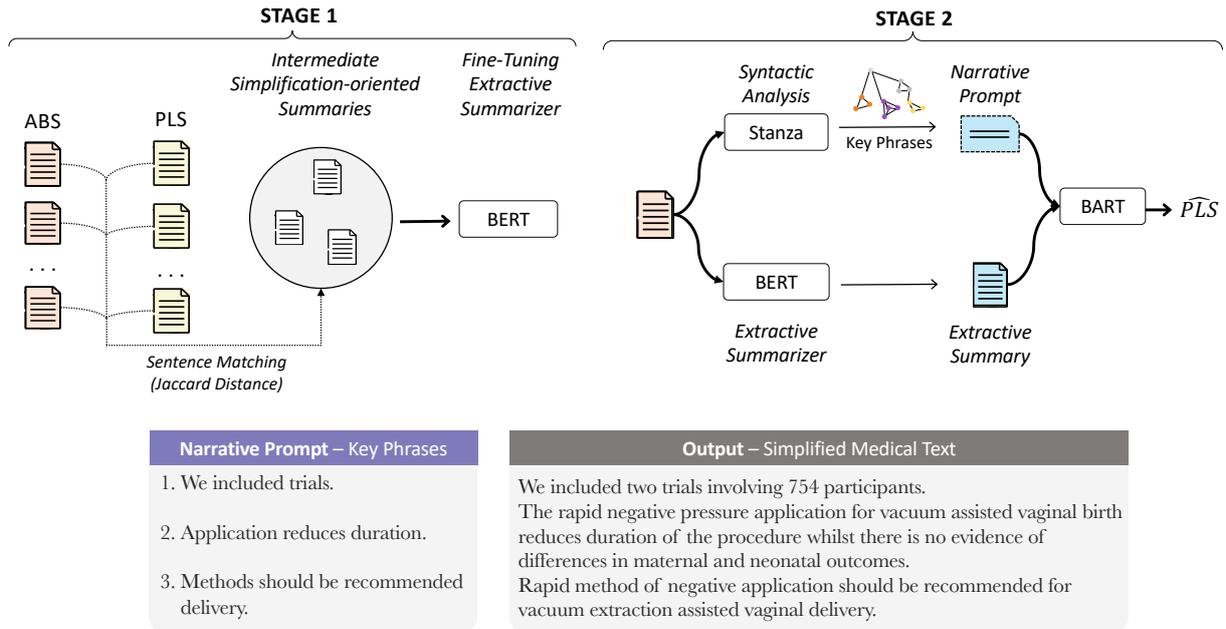

Figure 2: Overview of the two-stage pipeline in the NapSS model. In the first stage, we perform sentence “labelling” using Jaccard Distances (Jaccard, 1912) over abstract (ABS) sentences in reference to PLS sentences, generating a set of intermediate summaries. A binary BERT-based (Devlin et al., 2018) classifier is fine-tuned over these summaries and used, at test time, to generate an extractive summary x' . During the second stage (right side), we perform syntactic dependency parsing over the PLS sentences to extract key phrases k . These are concatenated to form a narrative prompt and combined with the extractive ABS summary to serve as input of the simplification module for the generation of plain-language outputs \widehat{PLS} . In the bottom part, we reported an example of narrative prompt and simplified text generated by NapSS on the ABS introduced in Figure 1.

Algorithm 1 details the process of building this pseudo reference summary dataset. The input to the algorithm are the sets of sentences from the technical abstract (ABS) and the corresponding simplified text (PLS). For each PLS sentence, we calculate the Jaccard Distance to every ABS sentence, and select the one with the lowest score. The set of selected ABS sentences constitute an intermediate extractive summary of the technical abstract. The complexity of Algorithm 1 is $O(N_x \cdot N_y \cdot D)$, where D denotes the size of entire corpus.

Based on the intermediate summary dataset, we fine-tune a BERT model to perform binary classification over sentences. At inference time, the resultant trained *simplification-oriented summarizer* is used to select sentences from the technical abstract which will be simplified. These are concatenated and then passed to a BART model (Lewis et al., 2020) along with the narrative prompt.

As an example, the bottom left of Figure 2 shows 3 PLS sentences guiding the automatic labelling (0/1) of 7 ABS sentences. The intermediate extracted summary x' derived via Jaccard matching is used at training time, while at inference time we extract this using the trained model.

3.2.2 Narrative Prompting

Intuitively, the simplification-oriented summarizer should identify the most important content in ABS which should be simplified. However, the similarity matching with which we train the sentence classifier may be noisy and miss relevant information constituting the narrative flow, resulting in errors that lead to omissions in outputs. Therefore, in our NapSS model, we incorporate another simple mechanism, *narrative prompting*, to encourage factual consistency between the input and output.

Inspired by recent work on *chain-of-thought* “reasoning” (Wei et al., 2022), we assume a logical narrative chain can be explicitly constructed with key phrases extracted via syntactic dependency parsing, and then used as a prompt. Specifically, we use a light natural language processing tool Stanza² for dependency parsing on every abstract sentence to extract key phrases. Algorithm 2 details the algorithmic process of our narrative prompting. The algorithm takes abstract sentences as input, runs a dependency parse on each, collects the root token and its closest child tokens to form key phrases in

²<https://stanfordnlp.github.io/stanza/>

Algorithm 1 Build reference summary dataset

- 1: Input require: abstract sentence sets $\{\mathbf{x}_{1\sim M}^m\}$,
- 2: PLS sentence sets $\{\mathbf{y}_{1\sim Q}^q\}$
- 3: Initialization: Empty positive sentence set x_{pos}
- 4: **for** PLS sentence $\mathbf{y}^q \in \{\mathbf{y}_{1\sim Q}^q\}$ **do**
- 5: Initialization: Minimum Jaccard Distance
 $\text{Dist}_q \leftarrow 10.0$,
- 6: corresponding sentence index $\text{Ind}_q \leftarrow 0$
- 7: **for** abstract sentence $\mathbf{x}^m \in \{\mathbf{x}_{1\sim M}^m\}$ **do**
- 8: $\text{Dist}_{qm} = \text{JaccardDistance}(\mathbf{y}^q, \mathbf{x}^m)$
- 9: **if** $\text{Dist}_{qm} < \text{Dist}_q$ **then**
- 10: $\text{Dist}_q \leftarrow \text{Dist}_{qm}$
- 11: $\text{Ind}_q \leftarrow m$
- 12: **end if**
- 13: **end for**
- 14: **if** $\mathbf{x}^{\text{Ind}_q} \notin x_{pos}$ **then**
- 15: add $\mathbf{x}^{\text{Ind}_q}$ in x_{pos}
- 16: **end if**
- 17: **end for**
- 18: Negative sentence set $x_{neg} = \{\mathbf{x}_{1\sim M}^m\} - x_{pos}$

Algorithm 2 Build narrative prompt

- 1: Input require: abstract sentence sets $\{\mathbf{x}_{1\sim M}^m\}$
- 2: Initialization: Empty key phrases queue x_{que}
- 3: **for** abstract sentence $\mathbf{x}^m \in \{\mathbf{x}_{1\sim M}^m\}$ **do**
- 4: $\text{DTree} = \text{DependencyParsing}(\mathbf{x}^m)$
- 5: $\mathbf{x}_{root}^m = \text{DTree.Root}()$
- 6: $\mathbf{x}_{root_l}^m, \mathbf{x}_{root_r}^m = \text{DTree.Children}(\mathbf{x}_{root}^m)$
- 7: $k^m = \mathbf{x}_{root_l}^m \mathbf{x}_{root}^m \mathbf{x}_{root_r}^m$
- 8: add k^m in x_{que}
- 9: **end for**
- 10: Prompt $k^M = k^1 \langle /s \rangle k^2 \langle /s \rangle \dots \langle /s \rangle k^m$

natural linguistic orders, and assembles these as the narrative prompt. Let k^m denotes the key phrase of sentence \mathbf{x}^m , the narrative prompt k^M equals to $[k^1 \langle /s \rangle k^2 \langle /s \rangle \dots \langle /s \rangle k^m]$, in which “ $\langle /s \rangle$ ” is a special separation token. The complexity of this building algorithm is $O(N_x \cdot D)$. As shown in Figure 2, key tokens are shown with bold fonts in every abstract sentences.

3.2.3 Text Simplification

The resulting input of the second text simplification stage is composed by $[k^M \langle /s \rangle \mathbf{x}']$, as depicted in the bottom right part of Figure 2. NapSS adopts encoder-decoder PLM models as the backbone for generative text simplification. Let $L_{gen_{TS}}$ be the

loss of the generative text simplification task:

$$L_{gen_{TS}} = -\frac{1}{N_k + N_{x'}} \sum_{t=1}^{N_k + N_{x'}} y_t \log \hat{y}_t \quad (1)$$

where N_k , $N_{x'}$ are the lengths of the narrative prompt k^M and of the extractive summary \mathbf{x}' , respectively.

4 Experimental Assessment

4.1 Experimental Setup

Dataset We build and evaluate NapSS on the first published paragraph-level medical text simplification dataset (Devaraj et al., 2021a). The dataset is derived from the Cochrane library of systematic reviews and contains 4,459 parallel pairs of technical (ABS) and simplified (PLS) medical abstracts curated by domain experts. The average length of abstract is around 300 to 700 tokens, while the average length of PLS is around 130 to 390 tokens (Devaraj et al., 2021a). All abstract and PLS text are preprocessed to have a total token length lower than 1,024, which is a typical input upper bound of large PLM models. The dataset was split into 3,568 training, 411 development and 480 testing instances. To our knowledge, this is the only accessible paragraph-level text simplification dataset.

For the summarization model, the derived summary dataset contains 51,635 training, 5,856 development, and 7,009 testing sentences (constructed from the respective dataset splits). This dataset contains around 53% positive sentences and 47% negative sentences, which is relatively balanced, and consistent with the proportion of average amount of PLS sentences and average amount of paired abstract sentences. We describe hyperparameter selection in the Appendix Section A.1.

Evaluation Metrics For evaluation we largely adopt the metrics used in prior work on this task and dataset (Devaraj et al., 2021a). These can be placed into three groups: readability metrics, lexical similarity metrics, and simplification metrics. The readability metrics include the Flesch–Kincaid grade level score (FK) (Kincaid et al., 1975) and the automated readability index (ARI) (Senter and Smith, 1967). Lexical similarity metrics are widely adopted to evaluate text generation, including ROUGE-1, ROUGE-2, ROUGE-L (Lin, 2004) and BLEU (Papineni et al., 2002). The simplification metrics include SARI (Xu et al., 2016), which is an editing-base metric especially designed for

Models	Readability		Lexical Similarity				Simplification	Semantic Similarity	Comprehensive
	FK	ARI	Rouge-1	Rouge-2	Rouge-L	BLEU	SARI	BertScore	BLEURT
Vanilla BART	10.89	14.32	46.79	19.23	43.55	11.5	38.72	23.94	-0.194
UL-BART (Devaraj et al., 2021a)	11.97	13.73	38.00	14.00	36.00	39.0	40.00	/	/
UL-BART (by us)	9.30	12.40	43.25	16.36	40.22	7.9	40.08	24.64	-0.309
NapSS (our)	10.97	14.27	48.05	19.94	44.76	12.3	40.37	25.73	-0.155
NapSS BioBART	10.98	14.24	47.66	19.77	44.39	11.9	40.21	25.61	-0.166
NapSS (+UL)	8.67	11.80	45.39	16.77	42.53	9.1	41.12	23.13	-0.219
NapSS (-Prompt)	9.86	13.06	45.62	20.01	44.83	12.1	39.68	25.57	-0.158
NapSS (-Summary)	10.62	13.99	46.91	19.51	44.18	11.8	39.62	25.29	-0.167

Table 1: Overall results on the testing set. UL BART is the previous SOTA, and we report results from our re-implementation of this. The inconsistency between (Devaraj et al., 2021a) and our re-implementation is due to the inavailability of evaluation code. For NapSS, we provide 2 groups of results by changing backbone model of text simplification module. The robustness verification of proposed NapSS is provided in appendix B. We further provide fusion and ablation results based on BART version of NapSS. NapSS (-Prompt) refers to remove the narrative prompt, while NapSS (-Summary) is to replace the abstract summary with full abstract.

text simplification task. In our setting, SARI would reward the *generation* of words occurring only in the paired PLSs, and avoidance of ABS words not occurring in the corresponding PLS.

Simple automated metrics fail to capture semantic agreement between outputs and references. We therefore consider two additional metrics: BertScore (Zhang et al., 2019) and BLEURT (Selam et al., 2020). BertScore was originally designed to evaluate semantic similarity via BERT (Devlin et al., 2018) embeddings. Alva-Manchego et al. (2021) and Devaraj et al. (2022) recently assessed and verified its effectiveness on the text simplification task. BLEURT is a metric finetuned on both lexical BLEU metric and semantic BertScore metric. Along with the automatic assessment, we also conduct a manual (human) evaluation of the simplicity, fluency and factuality whose evaluation criteria are detailed Section §4.2.3.

Prior work did not publicly provide code to perform evaluations beyond computing ROUGE.³ Therefore, we mainly compare results according to our re-implementation of evaluation metrics.

Baseline “Vanilla” BART is a pretrained encoder-decoder architecture, based on transformers, whose auto-regressive decoder made it a suitable a strong baseline for text generation. In ours setting, we adopted a specific checkpoint version⁴ additionally fine-tuned on the XSUM dataset (Narayan et al., 2018a; Devaraj et al., 2021b), providing higher performance on text summarization. The only other model developed for paragraph-level

medical text simplification is *UL-BART* (Devaraj et al., 2022), is also based on BART but integrates an auxiliary “unlikelihood” (UL) penalty to demote generation of technical jargon, which improved the readability and simplicity of outputs compared to the base BART model.

4.2 Results

4.2.1 Automatic Metrics

We report quantitative results in Table 1 comparing the main models and the ablation studies. We notice that UL-BART can generate text which is more readable (lower FK and ARI) and simpler (higher SARI) than the “Vanilla” BART. However, the model struggles to maintain lexical and semantic similarity (lower ROUGE, BLUE, and higher BLEURT) to the human references, perhaps because omitting jargon terms as the modified objective degrades coherence.

By contrast, NapSS improves lexical similarity by 3% to 4% in terms of ROUGE and BLEU scores while maintaining a comparable SARI score. NapSS additionally improves the semantic similarity between the model outputs and the human references at the cost of a slightly higher FK and ARI scores, demonstrating an higher semantic consistency while simplifying the medical text. For the sake of completeness, we also tested whether replacing the “Vailla” BART backbone with a specialised medical PLM, such as BioBART (Yuan et al., 2022), would lead to better performance. Surprisingly, the replacement did not lead to any significant change in any of the adopted metrics.

We further explored the integration of the auxiliary “unlikelihood” (UL) loss in NapSS (+UL), aiming at increasing the degree of simplification

³<https://github.com/Ash0logn/Paragraph-level-Simplification-of-Medical-Texts>

⁴<https://huggingface.co/facebook/bart-large-xsum>

Models	FK	ARI	BLEU	SARI	BLEURT
Vanilla BART	4.91	6.83	9.71	43.47	-0.663
UL-BART (by us)	4.76	7.61	8.75	40.83	-0.654
NapSS (our)	6.32	7.99	10.1	45.78	-0.648
NapSS (+UL)	5.49	8.25	12.8	44.46	-0.553

Table 2: Zero-shot inference results. All above models are only fine-tuned on the Cochrane dataset (2021a), then run zero-shot inference on the TICO-19 testing set.

while preserving semantic consistency. The resulting model yielded further state-of-the-art performance on the overall text simplicity with an increase of $\sim 0.8\%$ in readability and 1.1% in SARI score. NapSS (-Prompt) and (-Summary) refer to two ablation models. The first one removes the narrative prompt, leading to improved readability but decreased simplification (lower SARI). The second one show that the full abstract is necessary for improving the lexical similarity.

We report and discuss in Appendix C the binary classification performance of the extractive summarization module used in stage one.

4.2.2 Out-of-Domain Evaluation

To evaluate the generalization ability of NapSS, we evaluate the model on a *different* medical text simplification dataset: TICO-19 (Shardlow and Alva-Manchego, 2022). Unlike the Cochrane dataset, this is designed for sentence-level simplification and contains over 6k parallel technical and simplified sentences related to COVID-19.

Table 2 reports results. The ‘‘Vanilla’’ BART and UL-BART have the best performance on readability while NapSS yields over $\sim 2\%$ improvement in terms of simplicity. Integrating NapSS with the ‘‘unlikelihood’’ (UL) penalty (NapSS (+UL)) achieves around $\sim 1\text{-}3\%$ boost on lexical and semantic evaluation. The overall results highlight that our approach can preserve a high level of semantic consistency for simplification at the sentence level, yet with slightly reduced readability.

4.2.3 Human Evaluation

We designed and conducted a manual evaluation of the outputs generated by the simplification models to provide additional insights into *fluency* and *factuality*; the latter is especially difficult to assess with existing automatic metrics.

Evaluation Procedure We randomly sampled 100 unsimplified instances (ABSs) from the test set and paired each with simplified outputs gener-

Models	Simplicity	Fluency	Factuality	(Experts)	Overall
UL BART (by us)	1.43	1.53	1.17	0.99	4.13
NapSS	1.12	1.54	1.66	1.28	4.32

Table 3: Human evaluation result by each category.

ated by two models, one from UL-BART (Devaraj et al., 2021a) and one from the proposed NapSS. Each simplified text was assessed by three different annotators. We hired 6 annotators to participate in this evaluation, who are postdoctoral researchers and PhD students in computer science. Each was assigned 100 instances; this took nearly 8 hours to complete. Additionally, we hired two expert annotators who have professional background in the medical domain to obtain a reliable evaluation on the factual consistency between the complex and the simplified text. Annotators were paid \$19 per hour. To ensure that annotators shared a common understanding of our evaluation criteria, we held a tutorial session with detailed instructions and provided 20 instances as a trial run. We then resolved any annotation inconsistencies afterwards.

Evaluation Criteria We followed a previous approach to ask annotators to give numerical scores for each instance (Alva-Manchego et al., 2021). Considering the requirement for the simplification tasks and text styles characterizing medical documents (Devaraj et al., 2022), we separated numerical scores into three aspects: simplicity, fluency and factuality. Annotators can select a numerical rating (from 0, 1, and 2) for each aspect. Appendix A.2 provides details for each category.

Results In Table 3, we present average annotator scores assigned to all aspects. Our model achieves higher overall and average scores on Fluency and Factuality, respectively. UL-BART model got higher score on Simplicity because this model sometimes generates too simple outputs. Simplicity from our evaluation schema only focuses on evaluating the length of the text and the vocabulary. It does not involve the evaluation of the content. Therefore, if the generated text only contains a conclusion from the paragraph, our evaluator would give a higher score on Simplicity. On the contrary, the fluency and factuality aspects focus on evaluation at the context and semantic level, where our model got a higher score in the assessment. As Factuality is an aspect that the evaluation is subject to evaluators’ background knowledge, therefore we selected those instance been given three different

Figure 3: Case study and error analysis on a typical example from the testing set. Smearred sentences illustrate factual improvement by NapSS, while underlined parts reveal information omission of our model outputs.

scores from basic evaluators to create an experts set. We can see experts’ evaluation also shows the same trend. We believe the narrative prompt benefits this improving. Our model tends to produce a reasonable reduction in the context while keeping the majority of critical points. It is also useful for the model to calibrate grammar and plausibility with prompts. Combined with narrative prompt, NapSS generates simplification more consistent with the original text than the UL-BART. We can observe the better performance on human evaluation results also correlated with the improvement in semantic and comprehensive metrics, which proves the necessity of semantic level simplification evaluation.

4.2.4 Case Study and Error Analysis

We present a case study and error analysis based on the examples reported in Figure 3.⁵ The Abstract (ABS) mentions the the analysis of 5 studies on the effects of the continuous (CAS) or intermittent (IAS) androgen suppression therapy on advanced prostate cancer. The UL-BART model generated a slightly longer simplified text than NapSS. Specifically, sentence 4 from the UL-BART output mixed and linked the biochemical progression assessment with the IAS and CAS side-effect for potency. In contrast, sentence 3 generated by NapSS is more

relevant to the findings of all studies considered.

On the other hand, the last sentence 5 from the UL output reported a meaningful finding in consistency with reference sentence 7 from the PLS and reference sentence 7 from the ABS. NapSS instead omitted this information, probably because the related PLS sentences were not considered sufficiently relevant by the model.

5 Conclusions

We proposed a *summarize-then-simplify* two-stage model—NapSS—for paragraph-level medical text simplification. The first component is a “simplification-oriented” summarizer, which we trained over a heuristically derived set of “psuedo” references derived via sentence matching. At inference time, the summarizer extracts the most relevant content to be simplified. This is combined with an additional “narrative prompt” intended to promote consistency, and then passed to an encoder-decoder model to produce the simplified text. Experiments on a paragraph-level medical text simplification showed that, under several automatic metrics and human evaluation (involving “laypeople” and medical specialists), this method realized significant improvements with respect to both simplification quality and consistency.

⁵Better with colors

Limitations

Our study is primarily based on the Cochrane paragraph-level medical text simplification dataset (Devaraj et al., 2021a). While this dataset provides richer and more elaborated text than previous sentence-level medical datasets, such as TICO-19 (Shardlow and Alva-Manchego, 2022), it is worth noting that experimental documents tend to share a common pattern whose structure consists of: (i) discussing statistics about the clinical trials considered, (ii) list the experimental assessments, (iii) summarize the conclusions of the related findings.

Despite the already significant difficulty of the task, a limited variety of documents would inevitably introduce linguistic bias, hindering the model generalization and our current ability to conduct thorough assessment of the methodologies.

Moreover, although we made effort to examine the factuality aspect with expert annotators, we acknowledge that factuality is a subjective aspect and existing methods may not be sufficient to verify.

Ethics Statement

This work is based on publicly available medical datasets (Devaraj et al., 2021a; Shardlow and Alva-Manchego, 2022). As stated by the authors of datasets, no personal identification information were released. Current language technologies generally—and automated simplification models such as the one proposed in this work—still introduce “hallucinations” and factual inaccuracies into outputs; at present we would therefore recommend against deploying fully automated generative models for medical texts.

A Experimental Setup

A.1 Hyperparameters

For the summarization stage, we adopt NLTK⁶ for the building of reference summary dataset, and fine-tune a distilbert-base-uncased-finetuned-sst-2-english⁷ PLM as the classifier. The chosen PLM is a distilbert-base-uncased(Sanh et al., 2019) checkpoint additionally fine-tuned on SST-2 dataset(Socher et al., 2013), which is a sentiment binary classification corpus. The hidden size of the checkpoint is 768 and the corresponding vocabulary size is 30,522. The random seed is 42. The batch size is set to 16 and the accumulation steps is set to 1 on 2 quadro_rtx_6000 GPUs. The optimizer is BertAdam⁸ with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-6$. The weight of decay is 0.01. The learning rate is $2e-5$ without warmup. It takes 0.5 hour in total to fine-tune the checkpoint on the training set, and predict over development and testing sets.

And for the simplification stage, except for possible replacement of backbone encoder-decoder PLM, we adopt exact same settings with the SOTA baseline (Devaraj et al., 2021a), including training strategy and sampling method during the predictive generation. It takes less than 20 mins to fine-tune the PLM, while requires 2 hours to generate simplified text over entire testing set on same GPUs.

⁸<https://github.com/google-research/bert/blob/master/optimization.py>

A.2 Annotation Schema

To overcome the aforementioned limitations on evaluation metrics, we followed a previous approach to ask our annotators give numerical scores for each instances (Alva-Manchego et al., 2021). Considering the requirement on simplification task and feature of text in medical domains (Devaraj et al., 2022), we designed our numerical scores into three aspects: Simplicity, Fluency and Factuality. Annotator can select one numerical score under each aspect, which include three options 0,1 and 2. Higher score stands for annotator consider the paragraph level performance under that aspect is excellent, vice versa. In here, we provide detail explanation of each aspect.

Simplicity aspect considers how simple that text is to read. This category assess the generated text by annotator’s impression of simplicity, in terms of length of the texts and use of vocabulary. A good simplified text is expected to omit unnecessary numerical descriptions and explain jargons that are hard to be understood by layman readers.

Fluency aspect considers the how fluent the text is. That is, to assess the simplified text by annotator’s impression on connectivity and fluency. A good simplified paragraph should consider the fluency among sentences, such as use of conjunction words or adversative words for sentences. This category also includes the evaluation on overall grammar correctness of each sentences, and penalty on duplicate sentences generated by the model.

Factuality considers how consistent is the simplified text with the original text. This category requires annotators to assess the generated text by compare the facts that mentioned from the original text and those included in the generated text. A good simplified text should includes all the important information appears in the original text. Any paraphrase on the simplified text that lead to different meaning and against the original texts, or any omits on important information should consider to give penalize under this category.

B Robustness of NapSS

We finetune our NapSS model with another two random seeds 123 and 2023. The results of three experiments in 4 share high similarity, confirming the robustness of our proposed pipeline.

Models	Readability		Lexical Similarity				Simplification	Semantic Similarity	Comprehensive
	FK	ARI	Rouge-1	Rouge-2	Rouge-L	BLEU	SARI	BertScore	BLEURT
NapSS (seed=42)	10.97	14.27	48.05	19.94	44.76	12.3	40.37	25.73	-0.155
NapSS (seed=123)	10.89	14.17	48.38	20.24	45.11	12.5	40.36	25.67	-0.149
NapSS (seed=2023)	10.85	14.09	48.29	20.09	45.02	12.4	40.31	25.60	-0.148

Table 4: Robustness checking of our NapSS.

C Summarizer Results

We fine-tuned two different bert-based classifiers, the aforementioned distillbert one, and another BioLinkBERT-base⁹, which is a bert-based model pretrained on PubMed abstracts concerning citation links (Yasunaga et al., 2022). Although the BioLink backbone was pretrained on medical corpus, the general Distillbert fine-tuned on similar binary classification dataset performed better.

Models	Accuracy	F1
BioLinkBERT-base	61.91	67.04
Distilbert-base-uncased-finetuned-sst-2-english	62.50	68.91

Table 5: Performance on the constructed testing set.

Abstract

Extreme Multi-label Text Classification (XMTC) has been a tough challenge in machine learning research and applications due to the sheer sizes of the label spaces and the severe data scarcity problem associated with the long tail of rare labels in highly skewed distributions. This paper addresses the challenge of tail label prediction by leveraging the power of dense neural retrieval model in mapping input documents (as queries) to relevant label descriptions. To further enhance the quality of label descriptions, we propose to generate pseudo label descriptions from a trained bag-of-words (BoW) classifier, which demonstrates better classification performance under severe scarce data conditions. The proposed approach achieves the state-of-the-art (SOTA) performance of overall label prediction on XMTC benchmark datasets and especially outperforms the SOTA models in the tail label prediction. We also provide a theoretical analysis for relating the BoW and neural models w.r.t. performance lower bound.

1 Introduction

Extreme multi-label text classification (XMTC) is the task of tagging documents with relevant labels in a very large and often skewed candidate space. It has a wide range of applications, such as assigning subject topics to news or Wikipedia articles, tagging keywords for online shopping items, classifying industrial products for tax purposes, etc.

The most difficult part in solving the XMTC problem is to train classification models effectively for the rare labels in the long tail of highly skewed distributions, which suffers severely from the lack of sufficient training instances. Efforts addressing this challenge by the text classification community include Bayesian modeling of graphical dependencies among labels (Gopal and Yang, 2010; Gopal et al., 2012), novel loss or regularization of label embeddings (Babbar and Schölkopf, 2019a; Wei

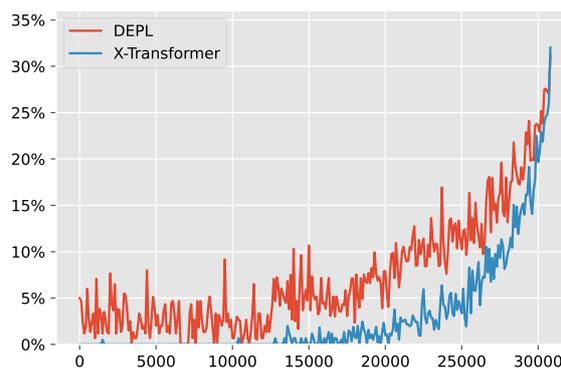

Figure 1: The classification performance of X-Transformer and DEPL (ours) measured in macro-averaged $F1@19$ on the Wiki10-31K dataset.

et al., 2021), clustering-based algorithms (Chang et al., 2020; Khandagale et al., 2019; Prabhu et al., 2018), and so on. Despite the remarkable progresses made so far, the problem is still very far from being well solved. Figure 1 shows the performance of X-Transformer (Chang et al., 2020), one of the state-of-the-art (SOTA) XMTC models, on the Wiki10-31K benchmark dataset (with over 31k labels). The horizontal axis is the ranks of the labels sorted from rare to common and the vertical axis is the text classification performance measured in macro-averaged $F1@19$ (higher the better) for binned labels (100 labels per bin). The blue curve is the result of X-Transformer, which has the scores close to 0 (worst possible score) for nearly half of the total labels. In other words, SOTA methods in XMTC still perform poorly in tail label prediction.

In this paper, we seek solutions for tail label prediction from a new angle: we introduce a novel framework, namely the Dual Encoder with Pseudo Label (DEPL). It treats each input document as a query and uses a neural network model to retrieve relevant labels from the candidate space based on the textual descriptions of the labels. The underlying assumption is, if the label descriptions are

highly informative for text-based matching, then the retrieval system should be able to find relevant labels. The system would be particularly helpful for tail label prediction as the retrieval effectiveness does not necessarily rely on the availability of a large number of training instances, which is what the tail labels are lacking.

The next research question that we tackle is how to obtain highly informative descriptions for each label without human annotation. In reality, class names are often available but they are typically one or two words, which cannot be sufficient for retrieval-based label prediction. Therefore, we propose to augment the label description with statistical learning algorithms. Specifically, we train linear support vector machine (SVM) model with the bag-of-words (BoW) features, such as tf-idf, to automatically generate informative keywords for each label, which we call the *pseudo description* of the label. Since the learned label embeddings of the BoW classifier encode token importance information, it is natural and efficient to leverage them for keywords extraction. In sections 4 and 6, we further provide theoretical motivations and empirical evidence to show the advantage of unsupervised statistical features for classification under extreme scarce data conditions.

The result of our approach (DEPL) is shown as the red curve in Figure 1, which significantly outperforms the blue curve of X-Transformer not only in the tail-label region but also in all other regions. We also observed similar improvements by DEPL over strong baselines on other benchmark datasets (see section 6). Our main contributions are summarized as the following:

1. We propose DEPL, a retrieval-based model to alleviate the difficulty in tail label prediction by matching the semantics between documents and augmented label descriptions which are generated automatically by a statistical model with BoW features.
2. We provide theoretical analyses to motivate the usage of BoW feature for classification under scarce data setting, and prove a performance lower bound of the neural model.
3. We did extensive experiments with different tail label evaluation metrics to show that our method significantly and consistently outperforms strong baselines on multiple challenging benchmark datasets.

2 Related Work

XMTC Classifier Traditional BoW classifiers rely on the bag-of-words features such as one-hot vector with tf-idf weights, which capture the word importance in a document. Examples include one-vs-all SVM models such as DiSMEC (Babbar and Schölkopf, 2017), ProXML (Babbar and Schölkopf, 2019b), PPDSparse (Yen et al., 2017), tree-based models such as Parabel (Prabhu et al., 2018) and Bonsai (Khandagale et al., 2019).

To compensate for the lack of semantics in BoW features, deep learning models were proposed for XMTC. Examples include CNN-based models such as XML-CNN (Liu et al., 2017) and SLICE (Jain et al., 2019), RNN-based models such as AttentionXML (You et al., 2018) and Transformer-based models such as X-Transformer (Chang et al., 2020), LightXML (Jiang et al., 2021) and APLC-XLNet (Ye et al., 2020).

Label Description The SiameseXML (Dahiya et al., 2021) for XMTC encodes both input documents and label descriptions with pretrained word embeddings with shallow networks and leverages the embedding matching. The SOTA pretrained Transformer-based models (Chang et al., 2020; Jiang et al., 2021) leverage the label descriptions to build label clusters. To generate label descriptions, Chai et al. (2020) adopt reinforcement learning to produce extended label descriptions from predefined label descriptions. However, the algorithm can not scale to the extreme label space and relies on the availability of sufficient training data.

3 Proposed Method

3.1 Preliminaries

Let $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{y}_i)_{i=1}^{N_{\text{train}}}\}$ be the training data where \mathbf{x}_i is the input text and $\mathbf{y}_i \in \{0, 1\}^L$ are the binary ground truth labels of size L . Given an instance \mathbf{x} and a label l , a classification system produces a matching score of the text and label:

$$f(\mathbf{x}, l) = \langle \phi(\mathbf{x}), \mathbf{w}_l \rangle$$

where $\phi(\mathbf{x})$ represent the document feature vector and \mathbf{w}_l represents the label embedding of l . The dot product $\langle \cdot, \cdot \rangle$ is used as the similarity function.

Typically, the label embedding \mathbf{w}_l is randomly initialized and trained from the supervised signal. While learning the embedding as free parameters is expressive when data is abundant, it could be difficult to be optimized under the scarce data situation.

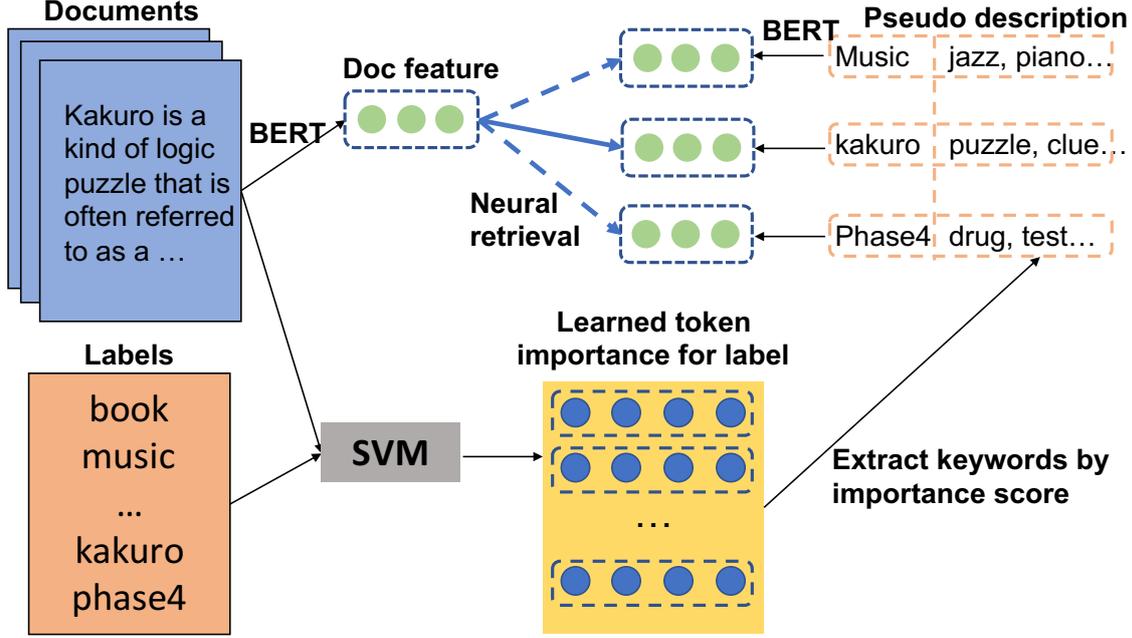

Figure 2: The proposed DEPL framework. First, we train a BoW classifier (SVM) and extract the top keywords from the label embeddings according to the learned token importance. Then, we concatenate the keywords with the original label names to form pseudo descriptions. Finally, we leverage the neural retrieval model to rank the labels according to semantic matching between document text and label descriptions.

Sketch of Method DEPL tackles the long-tailed XMTTC by neural retrieval with generated pseudo label descriptions, as shown in figure 2. Instead of learning the label embedding from scratch, the retrieval module directly leverages the **semantic matching** between the document and label text, providing a strong inductive bias on tail label prediction. Next, we introduce the components of our system in details.

3.2 Generated Pseudo Label Description

As the provided label names are usually short and noisy, we augment it with generated pseudo label description from a SVM model. As the tf-idf features $\phi_t(\mathbf{x})$ used by SVM are sparse, we also call the statistical model a *sparse* model:

$$f_{\text{sparse}}(\mathbf{x}, l) = \langle \phi_t(\mathbf{x}), \mathbf{w}_l^{\text{svm}} \rangle$$

The label embedding weight $\mathbf{w}_l^{\text{svm}}$ is optimized with the hinge loss:

$$\mathcal{L}_{\text{hinge}} = \frac{1}{LB} \sum_{i=1}^B \sum_{l=1}^L \max(0, 1 - \tilde{y}_l \cdot f_{\text{sparse}}(\mathbf{x}_i, l))$$

where $\tilde{y}_l = 2y_l - 1 \in \{-1, 1\}$, B is the batch size.

For a trained SVM model, $\mathbf{w}_l^{\text{svm}}$ has the dimension equal to the vocabulary size and each value

w_l^{svm} of the label embedding denotes the learned importance of the token i w.r.t label l . We select the top k most important tokens (ranked according to the importance score) as keywords, which are appended to the original label name to form the pseudo label description:

$$\text{pseudo_label}(l) = \text{label_name}(l) \oplus \text{keywords}(l)$$

where \oplus is the append operation.

3.3 Retrieval Model with Label Text

DEPL leverages the semantic matching of document and label texts via a dual encoder model (Gao and Callan, 2021; Xiong et al., 2020; Luan et al., 2020; Karpukhin et al., 2020). We use the BERT (Devlin et al., 2018) model as the backbone of our neural encoder, which is shared for both the document and label text encoding. Since a neural model encodes textual inputs into condensed vector representations, we call them *dense* models.

The similarity between text and label representation is measured by:

$$f_{\text{dual}}(\mathbf{x}, l) = \langle \phi_{\text{doc}}(\mathbf{x}), \phi_{\text{label}}(\text{text}(l)) \rangle$$

where $\text{text}(l)$ is the textual information of the label l . When the textual information only includes the label name given in the dataset, we call the model

DE-ret. Otherwise, when the textual information includes the generated pseudo label description, we call the model **DEPL**.

The document embedding $\phi_{\text{doc}}(\mathbf{x})$ is obtained from the CLS embedding of the BERT model followed by a linear pooling layer:

$$\phi_{\text{doc}}(\mathbf{x}) = \mathbf{W}_{\text{doc}} \cdot \text{BERT}(\mathbf{x}, \text{CLS}) + \mathbf{b}_{\text{doc}}$$

where $\text{BERT}(\mathbf{x}, \text{CLS})$ represents the contextualized embedding of the special CLS token. \mathbf{W}_{doc} and \mathbf{b}_{doc} are the weights and biases for the document pooler layer.

For the label embedding $\phi_{\text{label}}(\text{text}(l))$, we take an average of the last hidden layer of BERT followed by a linear pooler layer:

$$\phi_{\text{label}}(\text{text}(l)) = \mathbf{W}_{\text{label}} \cdot \psi_{\text{bert}}(\text{text}(l)) + \mathbf{b}_{\text{label}} \quad (1)$$

$$\psi_{\text{bert}}(\text{text}(l)) = \frac{1}{|\text{text}(l)|} \sum_{j=1}^{|\text{text}(l)|} \text{BERT}(\text{text}(l), j) \quad (2)$$

where $\text{BERT}(\text{text}(l), j)$ represents the contextualized embedding of the j -th token in $\text{text}(l)$ obtained from the last hidden layer of the BERT model. $\mathbf{W}_{\text{label}}$ and $\mathbf{b}_{\text{label}}$ are the weights and biases for the label pooler layer. In the equation 2, the average embedding of label tokens yields better performance empirically than the CLS embedding possibly because the keywords are not natural language, and BERT may not effectively aggregate such type of information into CLS.

Learning with Negative Sampling Since calculating all the label embeddings for each batch is both expensive and prohibitive by the memory limit, we resort to negative sampling strategies for in-batch optimization. Specifically, we sample a fixed-sized subset of labels for each batch containing: 1) all the positive labels of the instances in the batch, 2) the top negative predictions by the sparse classifier as the hard negatives, and 3) the rest of the batch is filled with uniformly random sampled negatives labels.

Let \mathcal{S}_b be the subset of labels sampled for a batch. The objective for the dual encoder is:

$$\mathcal{L}_{\text{dual}} = -\frac{1}{B|\mathcal{S}_b|} \sum_{i=1}^B \left(\sum_{p \in \mathbf{y}_i^+} \log \sigma(f_{\text{dual}}(\mathbf{x}_i, p)) + \sum_{n \in \mathcal{S}_b \setminus \mathbf{y}_i^+} \log \sigma((1 - f_{\text{dual}}(\mathbf{x}_i, n))) \right)$$

where B is the batch size, \mathbf{y}_i^+ is the positive labels for instance i , and σ is the sigmoid function.

3.4 Connection of Sparse and Dense Model

Complementary features: the sparse model uses the tf-idf feature based on corpus-level token statistics, while the dense model relies on the knowledge of the language learned during pretraining. The two types of features focus on different aspects of the text corpus and the combination of the two brings gains in performance.

Difference from ensemble: utilizing the augmented text for retrieval is better than a pure ensemble of sparse and dense methods such as in X-Transformer. In the ensemble method, the semantic meaning of important tokens in a label embedding learned from sparse classifier is not leveraged. By extracting the keywords from the sparse label embedding and presenting them as pseudo label descriptions, our model can additionally exploit the value of those key token semantics.

3.5 Enhance Classification with Retrieval

Our introduced retrieval model can be combined with a neural classifier for a performance boost on overall label classification (since our retrieval model is primarily targeted on improving tail label performance). In a neural classification system, the label embedding is treated as free parameters to be learned from supervised data, which is more expressive for labels with abundant training instances. The neural classifier learns the function:

$$f_{\text{cls}}(\mathbf{x}, l) = \langle \phi_{\text{doc}}(\mathbf{x}), \mathbf{w}_l^{\text{cls}} \rangle \quad (3)$$

We propose to enhance the classification model with the retrieval mechanism by jointly fine-tuning:

$$f_{\text{dual-cls}}(\mathbf{x}, l) = \frac{\sigma(f_{\text{dual}}(\mathbf{x}, l)) + \sigma(f_{\text{cls}}(\mathbf{x}, l))}{2} \quad (4)$$

The classification and retrieval modules share the same BERT encoder. We refer to the system as **DEPL+cls**. The object function $\mathcal{L}_{\text{dual-cls}}$ is similar to $\mathcal{L}_{\text{dual}}$ except for replacing f_{dual} with $f_{\text{dual-cls}}$.

The **DEPL+cls** model looks like an ensemble of the two systems at first sight, but there are two major differences: 1) As the BERT encoder is shared between the classification and retrieval modules, it doesn't significantly increase the number of parameters as in (Chang et al., 2020; Jiang et al., 2021); and 2) when the two modules are optimized together, the system can take advantages of both units according to the situation of head or tail label predictions.

4 Theoretical Analyses of DEPL

4.1 Rethinking Dense and Sparse Model for Imbalanced Text Classification

We analyze dense and sparse models from a gradient perspective for classification problems with skewed label distribution.

Preliminary: The predicted probability optimized by the binary cross entropy (BCE) loss is:

$$\mathcal{L}_{\text{BCE}} = - \sum_{l=1}^L y_l \log p_l + (1 - y_l) \log(1 - p_l)$$

The derivative of \mathcal{L}_{BCE} w.r.t the logits s_l is:

$$\frac{\partial \mathcal{L}_{\text{BCE}}}{\partial s_l} = \begin{cases} p_l - 1 & \text{if } y_l = 1 \\ p_l & \text{otherwise} \end{cases} \quad (5)$$

Q1: *Why would sparse model with BOW feature benefit tail label prediction?*

Applying the chain rule to equation 5, the gradient of \mathcal{L}_{BCE} w.r.t the document feature $\phi_n(\mathbf{x})$ is:

$$\frac{\partial \mathcal{L}_{\text{BCE}}(y_l, p_l)}{\partial \phi_n(\mathbf{x})} = \begin{cases} (p_l - 1)\mathbf{w}_l & \text{if } y_l = 1 \\ p_l \mathbf{w}_l & \text{otherwise} \end{cases}$$

By optimizing parameters θ of feature extractor, the document representation is encourage to move away from the negative label representation, that is:

$$\phi_n(\mathbf{x}; \theta') \leftarrow \phi_n(\mathbf{x}; \theta) - \eta p_l \mathbf{w}_l$$

where η is the learning rate.

For a dense model, the parameter θ of the feature extractor (such as BERT) is shared for all the data, so the optimization of the feature extractor is affected by the distribution of labels in the training data. Since a tail label appears more often as a negative target, the feature extractor is likely to under-represent the tail label information, making a tail label more difficult to be predicted. In comparison, the sparse feature like tf-idf is derived in an unsupervised manner from corpus statistics, which is independent of training label distribution. Therefore, the sparse feature may maintain better representation power to separate the tail labels.

Q2: *What is the advantage of a retrieval system on tail label prediction?*

In a typical classification system, labels are treated as indices whose embeddings are randomly

initialized and learned from supervised signals. The gradients of \mathcal{L}_{BCE} w.r.t the label feature is:

$$\frac{\partial \mathcal{L}_{\text{BCE}}(y_l, p_l)}{\partial \mathbf{w}_l} = \begin{cases} (p_l - 1)\phi_n(\mathbf{x}) & \text{if } y_l = 1 \\ p_l \phi_n(\mathbf{x}) & \text{otherwise} \end{cases}$$

The label embedding is updated by:

$$\begin{aligned} \mathbf{w}'_l &= \mathbf{w}_l + \frac{\eta}{N_{\text{train}}} \sum_{i: y_{il}=1} (1 - p_{il}) \phi_n(\mathbf{x}_i) \\ &\quad - \frac{\eta}{N_{\text{train}}} \sum_{i: y_{il}=0} p_{il} \phi_n(\mathbf{x}_i) \end{aligned}$$

As most of the instances are negative for a tail label, the update of tail label embedding is inundated with the aggregation of negative features, making it hard to encode distinctive feature reflecting its identity. Therefore, learning the tail label embedding from supervised signals alone can be distracting. Although previous works leverage negative sampling to alleviate the problem (Jiang et al., 2021; Chang et al., 2020), we argue that a fundamental solution is to inject the label information into the embedding. Our proposed retrieval system presents a natural way to incorporate label text for enhanced performance of tail label prediction.

4.2 Analysis on Performance Lower Bound

We will show the connection between DEPL and a sparse SVM classifier (for pseudo label extraction) by a performance lower bound. Specifically, DEPL outperforms a sparse model with high probability given that the selected keywords are important and the sparse classifier can separate the positive from the negative instances with non-trivial margin.

Notation: Let $\phi_t(\mathbf{x})$ be the normalized tf-idf feature vector of text with $\|\phi_t(\mathbf{x})\|_2 = 1$. The sparse label embeddings $\{\mathbf{w}_1, \dots, \mathbf{w}_L\}$ satisfies $\|\mathbf{w}_l\|_2 \leq 1, w_{li} > 0$. In fact, label embeddings can be transformed to satisfy the condition without affecting the prediction rank. Let z_l be the top selected keywords from the sparse classifier, which is treated as the pseudo label. Define the sparse keyword embedding \mathbf{v}_l with $v_{li} = w_{li}$ if i is an index of selected keywords and 0 otherwise.

In the following, we define the keyword importance and the classification error margin.

Definition 1. *For label l and $\delta \geq 0$, the sparse keyword embedding \mathbf{v}_l is δ -bounded if $\langle \phi_t(\mathbf{x}), \mathbf{v}_l \rangle \geq \langle \phi_t(\mathbf{x}), \mathbf{w}_l \rangle - \delta$.*

Definition 2. *For two labels p and n , the error margin μ is the difference between the predicted scores $\mu(\phi(\mathbf{x}), \mathbf{w}_p, \mathbf{w}_n) = \langle \phi(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle$.*

The main theorem is stated as below:

Theorem 3. Let $\phi_t(\mathbf{x})$ and $\phi_n(\mathbf{x})$ be the sparse and dense (dimension d) document feature, \mathbf{w}_l be the label embedding and \mathbf{z}_l be the δ -bounded keywords. For a positive label p , let $\mathbb{N}_p = \{n_1, \dots, n_{M_p}\}$ be a set of negative labels ranked lower than p . The error margin $\epsilon_i = \mu(\phi_t(\mathbf{x}), \mathbf{w}_p, \mathbf{w}_{n_i})$ and $\epsilon = \min(\{\epsilon_1, \dots, \epsilon_{M_p}\})$. An error \mathcal{E}_i of the neural classifier occurs when

$$\mu(\phi_n(\mathbf{x}), \phi_n(\mathbf{z}_p), \phi_n(\mathbf{z}_{n_i})) \leq 0 \quad (6)$$

The probability of any such error happening satisfies

$$P(\mathcal{E}_1 \cup \dots \cup \mathcal{E}_{M_p}) \leq 4M_p \exp\left(-\frac{(\epsilon - \delta)^2 d}{50}\right)$$

When $(\epsilon - \delta) \geq 10\sqrt{\frac{\log M_p}{d}}$, the probability is bounded by $\frac{1}{M_p}$.

Discussion: An error event occurs when the sparse model makes a correct prediction but the neural model doesn't. If the neural model avoids all such errors, the performance should be at least as good as the sparse model, and Theorem 3 gives a bound of that probability.

The term δ measures the importance of selected keywords (smaller the more important), the error margin ϵ measures the difficulty the correctly predicted positive and negative pairs by the sparse model. The theorem states that the model achieves a lower bound performance as sparse classifier if the keywords are informative and error margin is non-trivial. Proofs are in section A.2 for interested readers and limitations are discussed in section 8.

5 Evaluation Design

Dataset	N_{train}	N_{test}	\bar{L}_d	L	$ \mathbb{L}_{tail} $
EURLex-4K	15,539	3,809	5.30	3,956	2,413
AmazonCat-13K	1,186,239	306,782	5.04	13,330	3,936
Wiki10-31K	14,146	6,616	18.64	30,938	26,545
Wiki-500K	1,779,881	769,421	4.75	501,070	338,719

Table 1: Corpus Statistics: N_{train} and N_{test} are the number of training and testing instances respectively; \bar{L}_d is the average number of labels per document, and L is the number of unique labels. $|\mathbb{L}_{tail}|$ is the number of tail labels with $1 \sim 9$ positive training instances.

5.1 Datasets

We conduct our experiments on 4 benchmark datasets: EURLex-4K, AmazonCat-13K, Wiki10-31K and Wiki-500K. The statistics of the datasets

are shown in Table 1. An unstemmed version of EURLex-4K is obtained from the APLC-XLNet github¹ and the rest are from the Extreme classification Repository².

For comparative evaluation of methods in tail label prediction, we consider the subset of labels with $1 \sim 9$ positive training instances. Those tail-label subsets correspond to 63.48%, 29.53%, 88.65% and 67.60% of the total labels in the 4 datasets respectively. With mostly more than half of the labels as tail labels, the distributions are indeed highly skewed.

5.2 Tail Label Evaluation Metrics

Micro-averaged PSP@k: The PSP (Jain et al., 2016a) metric re-weights the score of each instance according to the label frequency:

$$PSP@k = \frac{1}{k} \sum_{l=1}^k \frac{\mathbb{1}_y(\mathbf{p}_l)}{\text{prop}(\mathbf{p}_l)}$$

where the propensity score $\text{prop}(\mathbf{p}_l)$ in the denominator gives higher weights to tail labels.

Since the micro-averaged metric gives an equal weight to the per-instance scores, it can still be dominated by the system's performance on the head labels but not the tail labels. As an alternative, we adopt a macro-averaged metric to evaluate tail label performance.

Macro-averaged F1@k: The macro-averaged metric (Yang and Liu, 1999) gives an equal weight to all the labels (we apply it to tail labels specifically). It is defined as the average of the label-specific $F1@k$ values, calculated based on a contingency table for each label, as shown in table 2. The precision, recall and $F1$ for a predicted ranked list of length k are computed as $P = \frac{TP}{TP+FP}$, $R = \frac{TP}{TP+FN}$, and $F1 = 2 \frac{P \cdot R}{P+R}$.

Table 2: Contingency table for label l .

	l is true label	l is not true label
l predicted	True Positive (TP _{l})	False Positive (FP _{l})
l not predicted	False Negative (FN _{l})	True Negative (TN _{l})

For micro-averaged PSP@k, we choose $k = 1, 3, 5$ as in previous works. For macro-averaged F1@k, we choose $k = 19$ for Wiki10-31K because it has an average of 18.64 labels and $k = 5$ for the rest datasets.

5.3 Baselines

For the tail label evaluation, our method is compared with the SOTA deep learning models including X-Transformer (Chang et al., 2020), XLNet-APLC (Ye et al., 2020), LightXML (Jiang et al., 2021), and AttentionXML (You et al., 2018). X-Transformer, LightXML, and XLNet-APLC employ pre-trained Transformers for document representation. We reproduced the results of single model (given in their implementation) predictions with BERT as the base model for LightXML, BERT-large for X-Transformer, XLNet for XLNet-APLC, and LSTM for AttentionXML. The AttentionXML utilizes label-word attention to generate label-aware document embeddings, while the other models generate fixed document embedding.

We use the SVM model with tf-idf feature as our choice of sparse classifier and BERT-base as our dense model for neural retrieval and classification. Implementation details, more baselines and settings are discussed in appendix A.1.

6 Evaluation Results

Our experiments reveal the effectiveness of our model on the tail label prediction and we also include and discuss the performance on the overall prediction in appendix A.1.4.

6.1 Results in Tail Label Prediction

SVM on Tail Label Prediction The results evaluated with the F1 metric averaged on the tail labels are shown in figure 3. Surprisingly, a simple statistical SVM baseline achieves competitive results on the tail label predictions. We observe that SVM model can outperform most of the pretrained Transformer-based models on the tail label prediction, and outperform the AttentionXML on the Wiki10-31K dataset. This provides an empirical evidence for the robust performance of a sparse model on tail label prediction. As we analyzed in section 4, the SVM model utilizes the unsupervised statistical feature as document representation, which potentially suffers less from the data scarcity issue. The empirical result serves as an evidence for our theoretical analysis that the joint optimization of feature extractor and label embedding is difficult when data is limited.

Neural Classifier on Tail Label Prediction

The neural classifiers include LightXML, X-Transformer, XLNet-APLC and AttentionXML.

Specifically, the AttentionXML model leverages a label-word attention to calculate a label specific document representation. As we observe in figure 3, among the baseline models, the AttentionXML performs the best on the tail label predictions, beating the other baselines on 3 out of the 4 benchmark datasets. The superior performance could come from the local word and label matching which benefits the tail label prediction.

As mentioned in section 3, X-Transformer model ensembles a neural classifier and a SVM model by directly summing the prediction scores. Although X-Transformer outperforms SVM on the overall label prediction, it underperforms SVM on 3 out of 4 benchmark datasets. This shows that model performance on tail label is dragged down by the neural model prediction, and a simple ensemble does not fully exploit the advantage of the sparse model. Compared with the X-Transformer, our model achieves better performance on both macro-F1 and micro-PSP metrics, showing the advantage of leveraging the retrieval of augmented label descriptions rather than a pure ensemble.

DEPL Performance On the 3 smaller scale benchmark datasets, EURLex-4K, AmazonCat-13K and Wiki10-31K, our model directly ranks all the labels. On the large Wiki-500K dataset, our model leverages the prediction of cluster-based algorithm in X-Transformer and replaces the reranker with our retrieval model.

Our proposed models perform the best on the Macro-F1 metric with the DEPL model consistently and significantly showing the best performance on all the benchmark datasets. A macro t-test (Yang and Liu, 1999) is conducted to justify the significance of improvement over the SVM and previous best neural model. The significant performance gains over the SVM model shows that our retrieval framework can outperform the sparse model which serves as label keywords extractor. We attribute the success of model on tail label prediction to the retrieval module that focuses on the semantic matching between the document and label text. The DEPL performs better than the DEPL+cls as it is less affected by the large amount of training instances for head labels and thus more biased on the tail label prediction.

According to the evaluation with the PSP metric shown in table 3, it also confirms that our proposed models DEPL and DEPL+cls improves over the previous SOTA neural models on all the benchmark

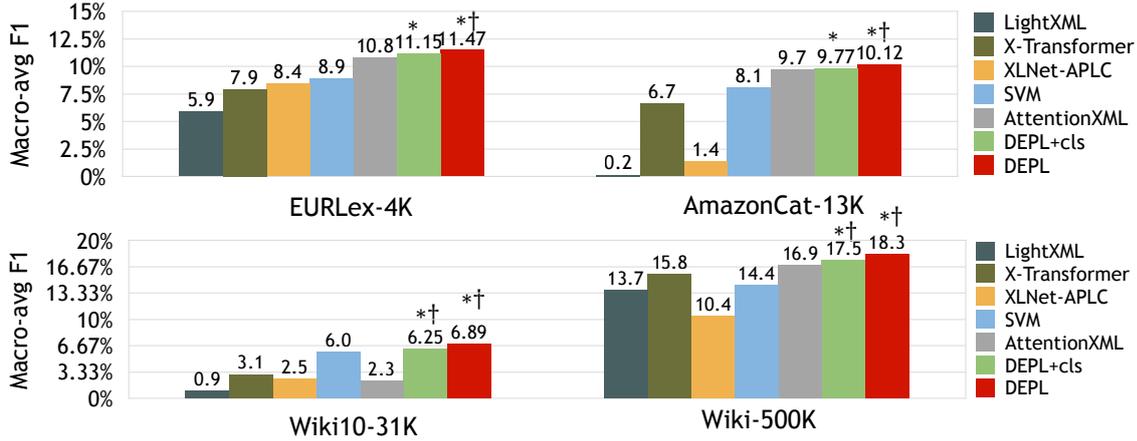

Figure 3: Tail-label prediction results in $F1@k$ on the labels with 1 ~ 9 positive training instances, with $k = 19$ for the Wiki10-31K dataset and $k = 5$ for the rest. * and † indicates the macro t-test is significant ($p < 0.05$) over SVM and previous best neural model respectively.

Table 3: Tail label prediction results of methods in $PSP@k$, with * indicating significant improvement ($p < 0.05$) over the previous best model on the micro sign test.

Table 4: Examples of SVM generated keywords from Wiki10-31K. The classifier is trained with only 1 positive training instance per label. The top 20 keywords are shown. with meaningful words highlighted in red manually.

Label Text	#training instance	Top Keywords
phase4	1	trials clinical protection personal directive processed data trial drug phase eu processing patients sponsor controller legislation regulation art investigator study
ensemble	1	boosting kurtz ferrell weak algorithms learners misclassified learner kearns ensemble charges bioterrorism indictment doj indict cae correlated 2004 reweighted boost
kakuro	1	nikoli kakuro puzzles crossword clues entries entry values sums cells cross digits dell solvers racehorse guineas aa3aa digit clue kaji

datasets, with * indicates significant improvement ($p < 0.05$) over the previous best model on the micro sign test (Yang and Liu, 1999). The Wiki10-31K dataset has the most skewed distribution as the most frequent label covers more than 85% of the training instances, resulting in a low PSP score. Since DEPL relies on the semantic matching between the document and label text, it is less affected by the dominating training pairs, and thus the PSP@1, PSP@3 beats the SOTA models by a larger margin. The DEPL+cls achieves worse performance on this dataset, because the classification counterpart of the model would benefit more on

the head label predictions and tend to rank the head labels at the top.

Metric Comparison Although the PSP metric gives higher weight to the tail labels, it is a micro-averaged metric over the scores of each instance, which can still be affected by the performance on the more common categories that cover most of the instances. For example, SVM model doesn't stand out under the PSP metric, which has lower overall label performance. Since the F1 metric is calculated specifically on the set of tail labels, we argue that it provides a more accurate and fine-

grained evaluation on tail label prediction, which better reveals the success of XMTC models on predicting rare categories.

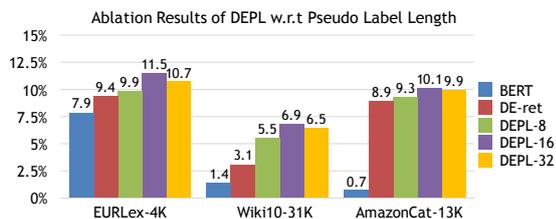

Figure 4: The ablation-test results of DEPL in Macro-averaged F1@k metric with varying length of pseudo label descriptions.

6.2 Ablation on Generated Pseudo Label

Table 4 shows examples of the SVM generated keywords trained on the Wiki10-31K dataset for labels with only 1 training example. We manually highlight the meaningful terms related to the label meaning. For example, the label name *phase4* is ambiguous, whose meaning needs to be inferred from the corresponding document. From the keywords *trial*, *clinical*, *drug*, *etc*, we deduce that the topic is about medical testing phase. In another example, *kakuro* is a Japanese logic puzzle known as a mathematical crossword and the game play involves in adding number in the cells. Generating a description for *kakuro* requires the background knowledge, but the keywords automatically learned from the sparse classifier provide the key concepts. Although not all the keywords can provide rich semantics to complement the original label name, they may serve as a context for the label to make it more distinguishable from others.

In figure 4, we conduct an ablation test on the length of the pseudo label and the performance is measured by Macro-avg F1@k. The BERT classifier is included as a baseline with no label text information. As we observe that the longer description of length 16 performs the better, but when length is 32, the performance doesn't increase as the text may become noisy with more unrelated keywords.

The DE-ret model is a pure retrieval baseline (avg length 3) with only the label name. While it achieves good performance on the EURLex-4K and AmazonCat-13K datasets, it still performs poorly on the Wiki10-31K dataset. This shows that generating the keywords from the sparse classifier can enhance the text quality. Furthermore, the gener-

ated text allows DEPL to use the semantic information of the label keywords, which is ignored in the SVM model. This could be another reason why our model performs better than the SVM baseline on the Wiki10-31K dataset.

7 Conclusion

In this paper, we propose a novel neural retrieval framework (DEPL) for the open challenge of tail-label prediction in XMTC. By formulating the problem as to capture the semantic mapping between input documents and system-enhanced label descriptions, DEPL combines the strengths of neural embedding based retrieval and the effectiveness of a large-margin BoW classifier in generating informative label descriptions under severe data sparse conditions. Our extensive experiments on very large benchmark datasets show significant performance improvements by DEPL over strong baseline methods, especially in tail label description.

8 Limitations

Our paper mainly focuses on the evaluation and improvement over the pretrained Transformer-based models such as X-Transformer, LightXML and APLC-XLNet by leveraging the recent advances in dense retrieval with BERT model. However, there are other works such as proposing reranking losses (Wei et al., 2021), regularization (Babbar and Schölkopf, 2019a) with other architectures are not included for comparison.

As pointed out by the reviewers, the performance bound analysis in section 4 adopts a strong assumption that the neural embeddings are random matrices. This could be very different in real application because the random matrices do not encode any semantic information. We acknowledge this limitation and provide more references on that. We rely on the mathematical tool based on random matrix theory, namely the *Johnson-Lindenstrauss* (JL) lemma. This tool was also adopted by Luan et al. (2020) under information retrieval setting, which provides the connection between dense and sparse retrievers. The bound is on its loose end because embeddings from BERT are more meaningful than random matrices (also verified from their empirical study). In our work, we study use the JL lemma to connect sparse and dense classifiers. The bound is reasonable considering that it is on its loose end, but, still, there is no guarantee when applied with real BERT embeddings.

A Appendix

A.1 Experiments

A.1.1 All-label Evaluation Metric

We introduce the micro-averaged $P@k$ as the metric for all-label prediction. Given a ranked list of the predicted labels for each test document, the **micro-averaged $P@k$** is:

$$P@k = \frac{1}{k} \sum_{i=1}^k \mathbb{1}_{y_i^+}(p_i) \quad (7)$$

where p_i is the i -th label in the list \mathbf{p} and $\mathbb{1}_{y_i^+}$ is the indicator function.

A.1.2 More Baseline

For the overall prediction of all labels, we also include the baselines of sparse classifiers: DisMEC (Babbar and Schölkopf, 2017), PfastreXML (Jain et al., 2016b), Parabel (Prabhu et al., 2018), Bonsai (Khandagale et al., 2019), and we

use the published results for comparison. We provide an implementation of linear SVM model with our extracted tf-idf features as another sparse baseline, and a BERT-base classifier as another dense classifier (used to initialize DEPL).

A.1.3 Implementation Details

For the sparse model, since the public available BoW feature doesn’t have a vocabulary dictionary, we generate the tf-idf feature by ourselves. We tokenize and lemmatize the raw text with the spaCy (Honnibal and Montani, 2017) library and extract the tf-idf feature with the Sklearn (Pedregosa et al., 2011) library, with unigram whose df count is ≥ 2 and df frequency $\leq 70\%$ of the total documents.

We use the BERT model as the contextualize function for our retrieval model, which is initialized with a pretrained dense classifier. Specifically, we fine-tune a 12 layer BERT-base model with different learning rates for the BERT encoder, BERT pooler and the classifier. The learning rates are $(1e - 5, 1e - 4, 1e - 3)$ for Wiki10-31K and $(5e - 5, 1e - 4, 2e - 3)$ for the rest datasets. For the negative sampling, we sample batch of 500 instances for Wiki10-31K, and 300 for EURLex-4K and AmazonCat-13K. For Wiki-500K dataset, we leverage the cluster-based algorithm in X-Transformer, and perform label re-ranking using our DEPL model to replace the linear model in X-Transformer. We use a negative batch size of 500 for to train the re-ranker.

We include 10 hard negatives predicted by the SVM model for each instances. We used learning rate $1e - 5$ for fine-tuning the BERT of our retrieval model and $1e - 4$ for the pooler and label embeddings. For the pseudo label descriptions, we concatenate the provided label description with the generated the top 20 keywords. The final length is truncated up to 32 tokens after BERT tokenization. We use length 16 of pseudo label description as the default setting for DEPL.

A.1.4 Results in All-label Prediction

The performance of our models evaluated on the all-label prediction by the micro-averaged $P@k$ metric is reported in table 5. Our model is compared against the SOTA sparse and dense classifiers. DEPL+c achieves the best or second best performance on all the 4 benchmark datasets, achieving comparable results to the previous best SOTA models.

Table 5: The all-label prediction results of representative classification systems evaluated in the micro-avg P@k metric. The bold phase and underscore highlight the best and second best model performance.

We argue that though our models perform significantly better on the tail label prediction, the improvement is not announced in the overall label prediction. One of the problem is on the choice of evaluation metric: the micro-averaged precision metric is averaged over instances and can be dominated by the common categories with more test instances. Therefore, the metric is incapable of reflecting the tail label performance. We want to emphasize that over 26, 545 (88.65%) labels in the Wiki10-31K dataset belong to the tail labels with less than 10 training instances, constituting a majority of the label space. The overall classification precision (P@k) only reflects a part of the success of a classification system, and the tail label evaluation is yet another part. The results also shows while our model improves on the tail label prediction, the overall label prediction comparable to the other dense and sparse SOTA models.

When our model is compared on the Wiki-500K dataset, our backbone is the same as X-Transformer. DEPL achieve on par performance with Wiki-500k showing that the quality of overall ranking is similar. However, the DEPL+c achieves better performance, demonstrating the enhanced performance by combining retrieval with classification.

By comparing the DEPL+c and its retrieval-based counterpart DEPL, we uncover a trade-off between the head label and tail label prediction. We observe that the DEPL outperforms the DEPL+c on the tail label prediction, but not on the all-label prediction. This shows that incorporating a classifier with label embeddings trained from supervised

signal can boost performance on a high data regime. The dense classifier could learn more expressive label representation from the frequent co-occurrence of document and label pairs when the training instances are abundant, while the retrieval system is better at matching the semantic of document and label texts when data is scarce. Each of the modules captures a certain aspect of the data heuristic for text classification and a combination of them by sharing the BERT encoder yields better performance.

Lastly, the sparse classifiers generally underperform the neural models and are comparable to our implement of SVM. We observe that DEPL can outperform the sparse models, which agrees with our theoretical analysis. Although the pseudo labels are extracted from the SVM classifier, the neural retrieval model can additionally leverage the keyword semantic information and correlation of them, which is ignored in the SVM classifier. The pseudo label descriptions encode both the term importance and key semantics of labels.

A.1.5 More Ablation Tests

Model Pre-training We fine-tune our retrieval model on a pre-trained neural classifier (BERT) and table 6 shows that without using the pre-trained model, there is a significant drop in the precision and PSP metrics.

Negative Sampling We used the top negative predictions by the SVM model as the choice of hard negative labels. By default, we use 10 hard negatives for each instance in the batch. In table 6, we

Table 6: Ablation-test results of DEPL under different training conditions.

DEPL with mean-pooling	17.20	16.90	16.95

observe a performance drop when no hard negatives or only 5 hard negatives are used for training.

CLS vs. Mean-pooling Table 7 shows an ablation test for the design of label description encoder. We observe that using a mean-pooling over the last layer of label keyword embeddings outperforms that using the CLS embedding by a large margin. This could be because the label keywords are not natural language the optimization using CLS embedding is more difficult.

A.2 Proof

We include the assumptions and proofs of Theorem 3.

Assumptions Similar to Luan et al. (2020), we treat neural embedding as fixed dense vector $\mathbf{E} \in \mathbb{R}^{d \times v}$ with each entry sampled from a random Gaussian $N(0, d^{-1/2})$. $\phi_n(\mathbf{x}) = \mathbf{E}\phi_t(\mathbf{x})$ is weighted average of word embeddings by the sparse vector representation of text. According to the *Johnson-Lindenstrauss (JL) Lemma* (Johnson and Lindenstrauss, 1984; Ben-David et al., 2002), even if the entries of \mathbf{E} are sampled from a random normal distribution, with large probability, $\langle \phi_t(\mathbf{x}), \mathbf{v} \rangle$ and $\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}\mathbf{v} \rangle$ are close.

Lemma 4. Let \mathbf{v} be the δ -bounded keyword-selected label embedding of \mathbf{w} . For two labels p, n , the error margins satisfy:

$$|\mu(\phi_t(\mathbf{x}), \mathbf{w}_p, \mathbf{w}_n) - \mu(\phi_t(\mathbf{x}), \mathbf{v}_p, \mathbf{v}_n)| \leq \delta$$

Proof. By the definition of δ -bounded keywords,

$$\langle \phi_t(\mathbf{x}), \mathbf{w}_p \rangle - \delta \leq \langle \phi_t(\mathbf{x}), \mathbf{v}_p \rangle \leq \langle \phi_t(\mathbf{x}), \mathbf{w}_p \rangle \quad (8)$$

$$-\langle \phi_t(\mathbf{x}), \mathbf{w}_n \rangle \leq -\langle \phi_t(\mathbf{x}), \mathbf{v}_n \rangle \leq -\langle \phi_t(\mathbf{x}), \mathbf{w}_n \rangle + \delta \quad (9)$$

Adding equation 8 and equation 9 finishes the proof:

$$\langle \phi_t(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle - \delta \leq \langle \phi_t(\mathbf{x}), \mathbf{v}_p - \mathbf{v}_n \rangle \leq \langle \phi_t(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle + \delta \quad (10)$$

□

Lemma 5. Let $\phi_t(\mathbf{x})$ and $\phi_n(\mathbf{x})$ be the sparse and dense (dimension d) document feature, \mathbf{w}_l be the label embedding and \mathbf{z}_l be the δ -bounded keywords. Let p be a positive label and n be a negative label ranked below p be the sparse classifier. The error margin is $\epsilon = \mu(\phi_t(\mathbf{x}), \mathbf{w}_p, \mathbf{w}_n)$. An error \mathcal{E} of neural classification occurs when $\mu(\phi_n(\mathbf{x}), \phi_n(\mathbf{z}_p), \phi_n(\mathbf{z}_n)) \leq 0$. The probability $P(\mathcal{E}) \leq 4 \exp(-\frac{(\epsilon-\delta)^2 d}{50})$.

Proof. By the JL Lemma (Ben-David et al., 2002): For any two vectors $\mathbf{a}, \mathbf{b} \in \mathbb{R}^v$, let $\mathbf{E} \in \mathbb{R}^{d \times v}$ be a random matrix such that the entries are sampled from a random Gaussian. Then for every constant $\gamma > 0$:

$$P\left(|\langle \mathbf{E}\mathbf{a}, \mathbf{E}\mathbf{b} \rangle - \langle \mathbf{a}, \mathbf{b} \rangle| \geq \frac{\gamma}{2} (\|\mathbf{a}\|^2 + \|\mathbf{b}\|^2)\right) \leq 4 \exp\left(-\frac{\gamma^2 d}{8}\right) \quad (11)$$

Let $\gamma = \frac{2}{5}(\epsilon - \delta)$, $\mathbf{a} = \phi_t(\mathbf{x})$ and $\mathbf{b} = \mathbf{v}_p - \mathbf{v}_n$. Since $\|\mathbf{a}\|_2 = 1$ and $\|\mathbf{b}\|_2 \leq (\|\mathbf{v}_p\|_2 + \|\mathbf{v}_n\|_2)^2 \leq 4$, the JL Lemma gives

$$P(|\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}(\mathbf{v}_p - \mathbf{v}_n) \rangle - \langle \phi_t(\mathbf{x}), \mathbf{v}_p - \mathbf{v}_n \rangle| \geq \epsilon - \delta) \quad (12)$$

$$\leq 4 \exp\left(-\frac{(\epsilon - \delta)^2 d}{50}\right) \quad (13)$$

To complete the proof, we need to show $P(\mathcal{E}) \leq Eq.12$:

$$\mathcal{E} \implies |\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}(\mathbf{v}_p - \mathbf{v}_n) \rangle - \langle \phi_t(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle| \geq \epsilon \quad (14)$$

$$\implies |\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}(\mathbf{v}_p - \mathbf{v}_n) \rangle - \langle \phi_t(\mathbf{x}), \mathbf{v}_p - \mathbf{v}_n \rangle| \geq \epsilon - \delta \quad (15)$$

where the equation 15 is derived by Lemma 4:

$$|\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}(\mathbf{v}_p - \mathbf{v}_n) \rangle - \langle \phi_t(\mathbf{x}), \mathbf{v}_p - \mathbf{v}_n \rangle| \quad (16)$$

$$\geq |\langle \mathbf{E}\phi_t(\mathbf{x}), \mathbf{E}(\mathbf{v}_p - \mathbf{v}_n) \rangle - \langle \phi_t(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle| - \quad (17)$$

$$|\langle \phi_t(\mathbf{x}), \mathbf{w}_p - \mathbf{w}_n \rangle - \langle \phi_t(\mathbf{x}), \mathbf{v}_p - \mathbf{v}_n \rangle| \quad (18)$$

$$\geq \epsilon - \delta \quad (19)$$

Therefore $P(\mathcal{E}) \leq Eq.12$, which completes the proof. □

Proof of Theorem 3

Proof. The Lemma 2 shows that

$$P(\mathcal{E}_i) \leq 4 \exp\left(-\frac{(\epsilon_i - \delta)^2 d}{50}\right) \leq 4 \exp\left(-\frac{(\epsilon - \delta)^2 d}{50}\right) \quad (20)$$

By an union bound on the error events $\{\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_{M_p}\}$,

$$P(\mathcal{E}_1 \cup \dots \cup \mathcal{E}_{M_p}) \leq \sum_{i=1}^{M_p} 4 \exp\left(-\frac{(\epsilon_i - \delta)^2 d}{50}\right) \quad (21)$$

$$= 4M_p \exp\left(-\frac{(\epsilon - \delta)^2 d}{50}\right) \quad (22)$$

□

When $(\epsilon - \delta)^2 \geq 10\sqrt{\frac{\log M_p}{d}}$, we have $\exp\left(-\frac{(\epsilon - \delta)^2 d}{50}\right) \leq \frac{1}{4M_p^2}$ and therefore $P(\mathcal{E}_1 \cup \dots \cup \mathcal{E}_{M_p}) \leq \frac{1}{M_p}$.

Unsupervised Keyphrase Extraction via Interpretable Neural Networks

Abstract

Keyphrase extraction aims at automatically extracting a list of “important” phrases representing the key concepts in a document. Prior approaches for unsupervised keyphrase extraction resorted to heuristic notions of phrase importance via embedding clustering or graph centrality, requiring extensive domain expertise. Our work presents a simple alternative approach which defines keyphrases as document phrases that are salient for predicting the topic of the document. To this end, we propose INSPECT—an approach that uses self-explaining models for identifying influential keyphrases in a document by measuring the predictive impact of input phrases on the downstream task of the document topic classification. We show that this novel method not only alleviates the need for ad-hoc heuristics but also achieves state-of-the-art results in unsupervised keyphrase extraction in four datasets across two domains: scientific publications and news articles.¹

1 Introduction

Keyphrase extraction is crucial for processing and analysis of long documents in specialized (e.g., scientific, medical) domains (Mekala and Shang, 2020; Betti et al., 2020; Wang et al., 2019). The task is challenging, as the notion of phrase importance is context- and domain-dependent. Therefore, developing domain-agnostic keyphrase annotation guidelines and curating representative hand-labeled datasets is not feasible. This motivates the need for generalizable unsupervised approaches to keyphrase extraction.

Unsupervised keyphrase extraction methods have used heuristic notions of phrase importance (Mihalcea and Tarau, 2004; Shang et al., 2018; Campos et al., 2018). Popular proxies for phrase importance include phrase clustering based on statistical features like word density (Florescu and

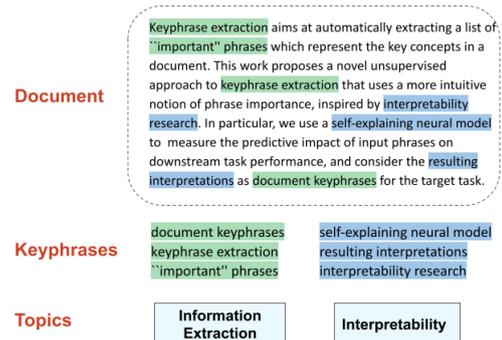

Figure 1: A comprehensive set of keyphrases should highlight important phrases for all major topics in a document. INSPECT identifies such keyphrases using interpretable neural models by measuring how use phrases are for predicting the topic of a text.

Caragea, 2017a; Campos et al., 2018) and structural features like graph centrality (Bougouin et al., 2013; Ding and Luo, 2022) or more recently neural embedding clustering techniques (Bennani-Smires et al., 2018; Zhang et al., 2022; Ding and Luo, 2021; Sun et al., 2020). However, such methods do not generalize to new domains as they require experts to carefully construct domain-specific heuristics (Mani et al., 2020).

Historically, topic models (Blei et al., 2001; Blei and McAuliffe, 2007; Wallach, 2006) have relied on salient words and phrases in a document, which are similar to the notion of keyphrases, although to the best of our knowledge there is no prior work that identified keyphrases using topic models. In this work, we hypothesize that end-to-end neural models for topic classification latently rely on salient phrases for document representation and topic classification. Consequently, if we can interpret model decisions via highlighting salient and influential features (phrases) used for neural topic prediction, we can identify such keyphrases.

Inspired by this intuition, we propose INSPECT—a novel and simple framework to identify keyphrases by leveraging interpretable text classi-

^{*}Equal Contribution

¹Code: <https://github.com/rishabhjoshi/inspect>.

fiers to highlight phrases important for predicting the topics in a text. Specifically, we adapt an interpretable classifier SelfExplain (Rajagopal et al., 2021) to jointly predict the topic of an input document and to identify the salient phrases influencing the prediction. The model is distantly supervised using topic labels from off-the-shelf topic-models, eliminating the need for any human/expert annotations. We consider SelfExplain’s output interpretations as keyphrases for the input document (§2).

INSPECT can be trained on documents of any domain without keyphrase annotations and using distant topic supervision, making them easily adaptable to new domains. We contribute two versions of our method: i) INSPECT— individual models trained for topic-classification for each target dataset. ii) INSPECT-GEN—a more general model pre-trained on a large in-domain corpus, without finetuning on pre-specified target datasets.

We evaluate INSPECT and INSPECT-GEN on four benchmark datasets across two domains: scientific documents and news articles (§3). Our results in §4 show that INSPECT improves keyphrase extraction performance over strong baselines by 0.8% F1 on average, without any domain-specific processing. INSPECT-GEN further improves the performance, outperforming the state of the art in unsupervised keyphrase extraction on 3 out of 4 datasets by 2.7% F1 on average. Our experiments suggest that INSPECT-GEN has strong generalization capabilities, and can be used out-of-the-box without finetuning on individual datasets. Importantly, INSPECT alleviates the need for heuristics and expert-labelled annotations, and thus can be applied to a wide range of domains and problems where keyphrase extraction is important. Our results confirm that the latent keyphrases obtained from an interpretable model correlate with human annotated keyphrases, opening new avenues for research on interpretable models for information extraction.

2 The INSPECT Framework

The goal of the INSPECT framework is to extract important keyphrases in long documents. Following the hypothesis that neural text classifiers latently leverage important keyphrases for predicting topics in text, INSPECT extracts keyphrases through interpreting topic classification decisions. It builds upon an interpretable model, SelfExplain (Rajagopal et al., 2021), which learns to attribute

text classification decisions to relevant phrases in the input. However, SelfExplain was designed and tested in supervised settings and for single-sentence classification; in this work we explore its extension to unsupervised keyphrase extraction from long documents. In what follows, we describe the base SelfExplain model (§2.1) and the distant supervision setup for *topic classification* (§2.4). We outline the training mechanism to jointly predict topics and highlight salient phrases in the document as model interpretations (§2.2) and finally extract the resulting phrase interpretations as important keyphrases in the document (§2.3).

2.1 Base Interpretable Model

Feature attribution methods for model interpretability include two predominant approaches, (i) post-hoc interpretations of a trained model (Jin et al., 2020; Kennedy et al., 2020; Lundberg and Lee, 2017; Ribeiro et al., 2016), and (ii) intrinsically (by-design) interpretable models (Alvarez-Melis and Jaakkola, 2018; Rajagopal et al., 2021). We adopt the latter approach, specifically SelfExplain (Rajagopal et al., 2021) as our phrase attribution model, as the model directly produces interpretations, though in principle any phrase based interpretability techniques could be employed.

SelfExplain augments a pre-trained transformer-based model (RoBERTa (Liu et al., 2019) in our case) with a local interpretability layer (LIL) and a global interpretability layer (GIL) which are trained to produce local (relevant features from input sample) and global (relevant samples from training data) interpretations respectively. The model can be trained for any text classification tasks using gold task supervision, and produces local and global interpretations along with model predictions. Since our goal is to identify important phrases from the input sample, we use only the LIL layer. The LIL layer takes an input sentence and a set of candidate phrases and quantifies the contribution of a particular phrase for prediction through the activation difference (Shrikumar et al., 2017; Montavon et al., 2017) between the phrase and sentence representations.

2.2 Keyphrase Relevance Model

SelfExplain is designed to process single sentences and uses all the phrases spanning non-terminals in a constituency parser as units (candidate phrases) for interpretation. This is computationally expensive for our use-case. To facilitate long document topic

classification, we instead define the set of noun phrases (NPs) as the interpretable units, which aligns with prior work in keyphrase extraction of using noun phrases as initial candidate phrases (Shang et al., 2018; Mihalcea and Tarau, 2004; Bougouin et al., 2013). INSPECT splits a long document into constituent passages, extracts NPs as candidates, and attributes the contribution of each NP for predicting the topics covered in the passage.

For each text block \mathbf{X} in the input document, we preprocess and identify a set of candidate phrases $\mathbf{CP}_X = \mathbf{cp}_1, \mathbf{cp}_2, \dots, \mathbf{cp}_N$ where N is the number candidate phrases in \mathbf{X} . From the base RoBERTa model, we obtain contextual [CLS] representations of the entire text block $\mathbf{h}_{[CLS]}$ and individual tokens. We compute phrase representations $\mathbf{h}_1 \dots \mathbf{h}_N$ for each candidate by taking the sum of the RoBERTa representations of each token in the phrase.

To compute the relevance of each phrase, we construct a representation of the input without the contribution of the phrase, \mathbf{z}_i , using the activation differences between the two representations. We then pass it to a classifier layer in the local interpretability module to obtain the label distribution for prediction.

$$\mathbf{z}_i = g(\mathbf{h}_i) - g(\mathbf{h}_{[CLS]}); \quad \ell_i = f(\mathbf{W}^T \mathbf{z}_i + \mathbf{b}) \quad (1)$$

where g is the ReLU activation function and W and b are the weights and bias of the classifier. Here ℓ_i denotes the label distribution obtained on passing the phrase-level representations \mathbf{z}_i through a classification layer f which is either the sigmoid or the softmax function depending on the prediction task (multi-label versus multi-class). We denote the label distribution from the base RoBERTa model for predicting the output using the whole input block as $\ell_{[CLS]}$. We train the model using the cross entropy loss \mathcal{L}_y with respect to the multi-label gold topics \mathbf{Y}_i for instance i and an explanation specific loss \mathcal{L}_e using the mean of all phrase-level label distributions such that $\ell_e = \sum_{i=1}^P \ell_i$.

$$\mathcal{L}_y = - \sum_{j=1}^N \mathbf{y}_j \log(\ell_{[CLS]}), \quad \mathcal{L}_e = - \sum_{j=1}^N \mathbf{y}_j \log(\ell_e) \quad (2)$$

The classifier is regularized jointly with α regularization parameter² using explanation and classification loss: $\mathcal{L} = (1 - \alpha)\mathcal{L}_y + \alpha\mathcal{L}_e$.

² $\alpha = 0.5$

2.3 Inference

During inference, for each predicted label $y \in \mathbf{Y}$, where \mathbf{Y} denotes set of all predicted labels for input text \mathbf{X} , INSPECT calculates an importance score r_i^y with respect to the predicted label y using the difference between the label distribution ℓ_i^y for a candidate phrase \mathbf{cp}_i and the one obtained using the entire input $\ell_{[CLS]}^y$ as $r_i^y = \ell_{[CLS]}^y - \ell_i^y$.

This score denotes the influence of a candidate keyphrase on the predicted topic. This score denotes the influence of a phrase on the predicted topic—the closer ℓ_i^y is to $\ell_{[CLS]}^y$ the less important phrase i is for predicting the topic. Since the relevance scores are computed with respect to a particular predicted topic and its label distribution, the scores for the same input are not comparable across different predicted topics in multi-label classification (since label distributions can vary in magnitude). To aggregate important keyphrases across all predicted topics, we pick the ones that positively impact prediction for each topic (having a positive influence score) as a set of keyphrases.

$$\mathbf{KP}(x) = [\mathbf{cp}_i \mid \forall r_i^y > 0; y \in \mathbf{Y}; i \in \{1 : N\}]$$

2.4 Distant Supervision via Topic Prediction

Obtaining annotations for keyphrases in specialized domains is challenging for supervised keyphrase extraction (Mani et al., 2020). Instead, we train the interpretable model in a distant supervision setup for multi-class topic classification and use model interpretations to identify keyphrases, without any keyphrase annotations. Topical information about a document are known to be essential for identifying diverse keyphrases (Bougouin et al., 2013; Sterckx et al., 2015). Further, a comprehensive set of keyphrases should represent the various major topics in the document to be useful for different long document applications (Liu et al., 2010). We hypothesize that by using topic classification as our end-task, our model will learn to highlight—via interpretations it is designed to provide—important and diverse keyphrases in the input document.

While certain domains like news articles have extensive datasets with human annotated topic labels, others like scientific articles or legal documents require significant effort for human annotation. INSPECT can be trained using annotated topic labels when they exist. In other domains where such annotations are scarce, INSPECT can be trained using labels extracted unsupervisedly using topic models

(Gallagher et al., 2017). Experiments in §4 show results using both settings.

3 Experimental Setup

3.1 Evaluation Datasets

We evaluate INSPECT in two domains using four popular keyphrase extraction datasets—scientific publications (SemEval-2017 (Augenstein et al., 2017a), SciERC (Luan et al., 2018), SciREX (Jain et al., 2020)) and news articles (500N-KPCrowd (Marujo et al., 2013)). Dataset details and statistics are shown in Table 1.

3.2 Topic Labels

We create distant supervision for INSPECT by labeling the above datasets using document topics as labels. We leverage existing topic annotations when such annotations exist. In the 500N-KPCrowd news based dataset, we use existing topic labels (tags or categories such as Sports, Politics, Entertainment) in a one-class classification setting. For the scientific publications domain, we use topic models (Gallagher et al., 2017) to extract $T = 75$ topics where each document can be labeled with multiple topics. The scientific domain datasets are trained in a multi-label classification setup.

3.3 Training Data and Settings

We train INSPECT in two settings:

1. **INSPECT** - Here we assume availability of training documents for each of our datasets. We train the model for topic prediction using only the documents and topic labels from the training set of each dataset obtained using the

approach outlined in §3.2). The training data in this setting, is most closely aligned to the test data, as the documents are of the same topic distribution.

2. **INSPECT-Gen** - We assume no access to training documents and train the model on a large external set of documents of a similar domain (ICLR papers for scientific, BBC News for news) but not necessarily of similar topic distribution as the test data (eg. SemEval-2017 has Physics papers). We use ICLR OpenReview dataset with topics obtained using off-the-shelf topic modeling³ for the scientific domain and BBC News corpus (Greene and Cunningham, 2006) with pre-labelled topics for the news domain.

The model from each setting is then evaluated on the held-out test data of each evaluation dataset.

For the external data, we collect over 8,317 full papers from ICLR and obtained 75 topic labels using topic modeling⁴. We removed 22 topic labels that were uninformative (list in Appendix Table 6) and used the rest to train our model in a multi-label classification setup. The BBC News corpus (Greene and Cunningham, 2006) consists of 2,225 news article documents, each annotated with one of five topics (business, entertainment, politics, sport, or tech).

We pre-process each document (for training and inference) by splitting it into text blocks of size 512 tokens, where consecutive blocks overlap with a stride size of 128. Following Shang et al. (2018),

³https://github.com/gregversteeg/corex_topic

⁴https://github.com/gregversteeg/corex_topic

for each block we consider all Noun Phrases (NPs) as candidate phrases and extract them using a Noun Phrase extractor from the Berkeley Neural Parser⁵. All hyperparameters were chosen based on development set performance on SciERC. Our final models were trained with a batch size of 8 a learning rate of $2e-5$ for 10 epochs. The classification layer dimension was 64 and α was 0.5. We provide more implementation details, including hyperparameter search in Appendix §A.2.

3.4 Baselines

We compare our method against seven unsupervised keyphrase extraction techniques — TF-IDF (Florescu and Caragea, 2017a), TopicRank (Bougouin et al., 2013), Yake (Campos et al., 2018), AutoPhrase (Shang et al., 2018; Liu et al., 2015), UKE-CCRank (Liang et al., 2021), MDERank (BERT)⁶ (Zhang et al., 2022) and SifRank (Sun et al., 2020). Out of the chosen baselines, Yake, TF-IDF and AutoPhrase are statistical, TopicRank is graph-based and SifRank, UKE-CCRank and MDERank are neural embedding based methods. For INSPECT setting, we compare with baselines that only use training data documents—TF-IDF, TopicRank, Yake, AutoPhrase, UKE-CCRank and MDERank. For the INSPECT-GEN setting, we compare with TF-IDF and AutoPhrase trained on our external corpora and SifRank which uses the external corpora to obtain prior likelihood scores for the phrases.

Following prior work and task guidelines (Augenstein et al., 2017a; Jain et al., 2020), INSPECT produces **span level** keyphrases and distinguishes each occurrence of a keyphrase. In contrast, methods like SifRank, AttentionRank, UKE-CCRank and MDERank are phrase level keyphrase extractors which don’t provide span level outputs. To maintain common evaluation, we adapt these methods to span level keyphrase extraction by matching each output keyphrase to all occurrences of the phrase in the document. As our method applies a cutoff on relevance scores and picks any phrase with a positive relevance score as a keyphrase, we cannot be directly compared with baselines which rank candidate phrases and pick top-K phrases as important. To establish a fair setting for evaluation, we choose the average of the number of keyphrase predictions from our model as the ‘K’ across all

⁵<https://pypi.org/project/benepar/>

⁶As of Oct 2022, the authors have not released their model.

Dataset	Method	F1 Score		
		Micro	Macro	Weighted
SciERC	RoBERTa	0.842	0.651	0.767
	INSPECT	0.836	0.658	0.771
SciREX	RoBERTa	0.609	0.404	0.641

baselines.

3.5 Evaluation Metrics

Topic Prediction Evaluation: To ensure high-quality interpretations from our model, it is imperative that it performs well on topic prediction. We first evaluate INSPECT’s performance on topic prediction using micro, macro, and weighted F1 score of the classifier’s predictions compared to true labels across all labels.

Keyphrase Extraction Evaluation: For our primary evaluation of keyphrase extraction, we evaluate using span match of our predictions and the true labels (human annotated keyphrases). In addition to measuring quality of keyphrases, this evaluation also measures the quality of explanations from our interpretable topic model by measuring how well the keyphrases extracted by INSPECT align with human annotated keyphrases. Prior works (Shang et al., 2018; El-Beltagy and Rafea, 2009; Bougouin et al., 2013) have mainly focused on *exact match* performance. However, a recent survey highlights that the measure is highly restrictive (Papagiannopoulou and Tsoumakas, 2019) as simple variations in preprocessing can misalign phrases giving an inaccurate representation of the model’s capabilities (Boudin et al., 2016).

Alternatively, *partial span match* using the word level overlap between the predicted and gold span ranges, has also been explored (Rousseau and Vazirgiannis, 2015). But, it is sometimes lenient in scoring. Papagiannopoulou and Tsoumakas (2019) suggest *average of the exact and partial matching* as an appropriate metric based on empirical studies. Therefore, we evaluate performance using the average of the exact and partial match F1 scores

Dataset	Method	Exact Match F1	Partial Match F1	Avg Exact Partial F1
SciERC	TF-IDF	0.0627	0.2860	0.1743
	TopicRank	0.2533	0.5680	0.4110

between predicted and true phrases keyphrases.

4 Results

4.1 Topic Prediction with INSPECT

First, we compare INSPECT’s effectiveness in classifying the topics with the corresponding non-interpretable encoder baseline, using micro, macro, and weighted F1 score of the classifier’s predictions compared to gold standard annotations. The results in Table 2 show that our approach outperforms a strong RoBERTa (Liu et al., 2019) baseline for topic prediction across all of our evaluation datasets. The difference is more pronounced in larger datasets (SciREX, ICLR, and BBC News), and strong performance on the topic classification task provides confidence that highlighted interpretations are for relevant and major topics in the text.

4.2 Keyphrase Span Match Performance

Next, we study the utility of INSPECT in highlighting keyphrases via model interpretations. The results for INSPECT are detailed in Table 3 and, for INSPECT-GEN in Table 4.

Results in Table 3 show that even with access to only training set of documents from each dataset, on 3 out of 4 datasets INSPECT outperforms all

baselines with ~ 0.8 average F1 improvements. In the news domain (500-KPCrowd dataset) INSPECT performs comparably to prior best method. INSPECT has low exact match scores but higher partial match scores indicating misalignments between predicted and gold spans. Additionally, 500N-KPCrowd annotates all instances of a keyphrase as a reference span which favours phrase level methods like AttentionRank in the current evaluation setup. In SciREX, we observe very poor performance of UKE CCRank as it ranks common phrases like “image”, “label”, “method”, etc, very high.

In the INSPECT-GEN setting, with access to a larger dataset of external documents, our model outperforms prior methods in 3 out of 4 datasets with ~ 2.7 points average F1 improvements. In the 500N-KPCrowd dataset, INSPECT performs comparably to SifRank with improved Partial Match F1. As Table 4 illustrates, we notice that the model consistently performs better in the INSPECT-GEN setting when compared with the INSPECT setting, showing that the method benefits from more training data. We particularly see large improvements over the INSPECT setting in the scientific datasets, showing that training on a larger set of documents

Dataset	Method	Exact Match F1	Partial Match F1	Avg Exact Partial F1
SciERC	TF-IDF	0.2162	0.4434	0.3298
	AutoPhrase	0.2416	0.6130	0.4273
	SifRank	0.2248	0.7357	0.4803
	INSPECT-GEN	0.4371	0.7114	0.5743
SciREX	TF-IDF	0.1780	0.4008	0.2894
	AutoPhrase	0.2583	0.4993	0.3788
	SifRank	0.1234	0.3957	0.2595
	INSPECT-GEN	0.2601	0.4893	0.3747
SemEval17	TF-IDF	0.1810	0.3398	0.2604
	AutoPhrase	0.1104	0.4874	0.2989
	SifRank	0.2804	0.6336	0.4570
	INSPECT-GEN	0.3246	0.6218	0.4732
500N-KPCrowd	TF-IDF	0.1398	0.3578	0.2488
	AutoPhrase	0.1701	0.3918	0.2805
	SifRank	0.1847	0.4125	0.2986
	INSPECT-GEN	0.1776	0.4194	0.2985

Table 4: Span-match results for unsupervised keyphrase extraction in INSPECT-GEN (trained on ICLR and BBC News corpus). Best performance is indicated in Bold. **INSPECT outperforms most baselines.**

helps generalize the model in this setting. Our results further show that variations in topic distribution between training and test data don’t significantly impact results. INSPECT can thus benefit from large unlabeled documents from similar domains to improve results.

INSPECT improves performance in settings with human annotated topics (news) as well as when topics are extracted using unsupervised topic modeling (scientific). Additionally, most baselines rely on carefully constructed pre- and post-processing to eliminate common phrases and produce high-quality candidates (Liang et al., 2021; Ding and Luo, 2021; Sun et al., 2020). In contrast, INSPECT achieves competitive results without domain expertise and processing for extracting quality keyphrases. Therefore, INSPECT can be easily adapted to new domains without human annotations for topics and with minimal domain knowledge, as we show across two domains.

Our results demonstrate that phrase attribution techniques from interpretability literature can be leveraged to identify high-quality document keyphrases by measuring predictive impact of input phrases on topic prediction. These results also show that our interpretable model in INSPECT produces high quality keyphrases as phrase explanations which correlate with human annotated keyphrases, evaluating the interpretability aspect of our framework. Crucially, as these keyphrases correlate with human annotated keyphrases, our results validate our initial hypothesis that neural models latently use document keyphrases for tasks like topic classification.

Type	Recall	
	Exact	Partial
Metric	60.65	78.34
Task	58.27	90.45
Material	72.17	86.69
Scientific Term	78.87	95.13
Method	65.31	95.41
Generic	63.16	86.06

Table 5: Exact and partial span match recall scores for different types of keyphrases on the SciERC dataset.

5 Discussion

Here, we present an analysis on the common error types in INSPECT and discuss the strengths and weaknesses of INSPECT using qualitative examples.

Entity Type Analysis: We leverage the entity type information in SciERC to observe the performance of INSPECT on specific types of keyphrases. From Table 5, we see that INSPECT performs best on keyphrases labelled as *Scientific Terms* and *Materials*. *Generic* phrases and *Metrics* are usually not representative of topical content, and thus, our method performs poorly on them. On manual analysis, we noticed that many phrases marked as *Task* are very unique and infrequent, making them harder to identify. A high partial match recall but a low exact match recall for *Method* type suggest that many predicted keyphrases are misaligned with the gold labels. We believe that alternative downstream tasks can be explored in future to help tailor our approach to capture specific types of entities, based on application requirements.

Qualitative Analysis In Figure 2 we show two randomly selected abstracts from the SciERC

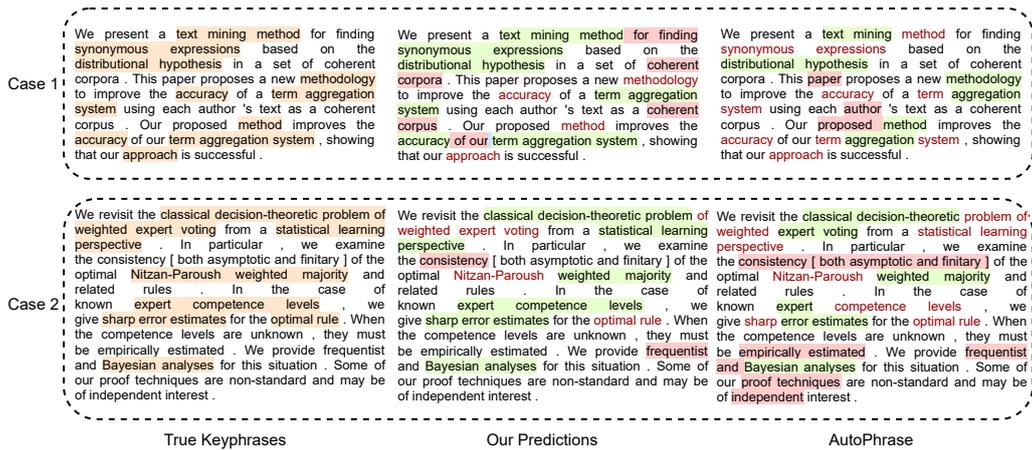

Figure 2: Two data points randomly chosen from the SciERC dataset. Orange spans represent gold standard annotations. Green spans in the predictions represent correctly predicted spans, whereas red spans are spans wrongly predicted as being keyphrases and red text are keyphrases that the model did not identify.

dataset. We see that INSPECT tends to extract longer phrases compared to AutoPhrase, which tends to extract mostly unigrams or bigrams. Overall, our approach is able to extract more relevant phrases than the baseline. Both INSPECT and AutoPhrase tend to miss generic phrases like ‘approach’ (e.g., as seen in case 1). Case 2 also demonstrates the INSPECT’s ability TO predict complete phrases, like ‘classical decision-theoretic problem’, instead of AutoPhrase’s prediction – ‘classical decision-theoretic’ which is incomplete. From both these examples, we see that INSPECT is usually able to correctly extract Scientific Terms, and struggles to extract Generic phrases and Metrics. This can be attributed to the usage of topic models to extract the content’s topical information.

6 Related Work

Unsupervised keyphrase extraction is typically treated as a ranking problem, given a set of candidate phrases (Shang et al., 2018; Campos et al., 2018; Florescu and Caragea, 2017a). Broadly, prior approaches can be categorized as statistical, graph-based, embedding-based, or language model based methods; Papagiannopoulou and Tsoumakas (2019) provide a detailed survey.

Statistical methods exploit notions of information theory directly. Common approaches include TF-IDF based scoring (Florescu and Caragea, 2017a) of phrases with other co-occurrence statistics to enhance performance (Liu et al., 2009; El-Beltagy and Rafea, 2009). Campos et al. (2018) shows the importance of incorporating statistical information of the context of each phrase to improve

performance. Statistical approaches typically treat different instances of a phrase equally, which is a limitation.

Graph-based techniques, on the other hand, broadly aim to form a graph of candidate phrases connected based on similarity to each other. Then core components of the graph are chosen as key phrases. Amongst these, PageRank (Brin and Page, 1998) and TextRank (Mihalcea and Tarau, 2004) assign scores to nodes based on their influence. A common extension is to use weights on the edges denoting the strength of connection (Wan and Xiao, 2008; Rose et al., 2010; Bougouin et al., 2013). Position Rank (Florescu and Caragea, 2017b) and SGRank (Danesh et al., 2015) combine the ideas from statistical, word co-occurrence and positional information. Some approaches, especially applied in the scientific document setting, make use of citation graphs (Gollapalli and Caragea, 2014; Wan and Xiao, 2008), and external knowledge bases (Yu and Ng, 2018) to improve keyphrase extraction. In this work, we focus our approach on a general unsupervised keyphrase extraction setting applicable to any domain where such external resources may not be present.

Finally, embedding based techniques (Bennani-Smires et al., 2018; Papagiannopoulou and Tsoumakas, 2018; Zhang et al., 2022) make use of word-document similarity using word embeddings (Sun et al., 2020; Liang et al., 2021), while language-model based techniques use word prediction uncertainty to decide informativeness (Tomokiyo and Hurst, 2003). Ding and Luo (2021) uses attention scores to calculate phrase importance

with the document in an unsupervised manner.

7 Conclusion and Future Work

In this work, we introduced INSPECT, a novel approach to unsupervised keyphrase extraction. Our framework uses a neural model that explains text classification decisions to extract keyphrases via phrase-level feature attribution. Using four standard datasets in two domains, we show that INSPECT outperforms prior methods and establishes state-of-art results in 3 out of 4 datasets. Through qualitative and quantitative analysis, we show that INSPECT can produce high-quality and relevant keyphrases. INSPECT presents applications of interpretable models beyond explanations for humans.

8 Limitations

Our method uses model explanations for each predicted topic to highlight keyphrases in text. A direct limitation of this method is that our importance scoring is topic-specific and cannot be used to provide an overall rank across topics. Our method therefore cannot provide a ranked list of top-5 or top-10 keyphrases as often done in prior work. While this is a limitation, our current technique of producing a set of all predicted keyphrases is useful in domains like scientific articles where keyphrases are used for downstream applications. Further, as our method produces topic-specific keyphrases, it could potentially miss some keyphrases which are not associated to any predicted topic. Therefore, our approach is beneficial in settings where topic prediction is accurate and feasible to ensure high quality and good coverage of keyphrases. Finally, this work was also limited by the specific choice of the downstream task - namely, topic prediction. Other downstream tasks, like summarization, can potentially help us gain additional insights from attribution.

A Appendix

A.1 Evaluation Datasets

SemEval-2017 (Augenstein et al., 2017a) consists of 500 abstracts taken from 12 AI conferences covering Computer Science, Material Science, and Physics. The entities are annotated with Process, Task, and Material labels, which form the fundamental concepts in scientific literature. Identification of the keyphrases was subtask A of the ScienceIE SemEval task (Augenstein et al., 2017b).

SciERC (Luan et al., 2018) extends SemEval-2017 by annotating more entity types, relations, and co-reference clusters to include broader coverage of general AI. The dataset was annotated by a single domain expert who had high (76.9%) agreement with three other expert annotators on 12% subset of the dataset.

SciREX (Jain et al., 2020) is a document-level information extraction dataset, covering entity identification and n-ary relation formation using salient entities. Human and automatic annotations were used to annotate 438 full papers with salient entities, with a distant supervision from the Papers With Code⁷ corpus. This dataset can help verify the performance of models on full papers.

500N-KPCrowd (Marujo et al., 2013) is a keyphrase extraction dataset in the news domain. This data consists of 500 articles from 10 topics annotated by multiple Amazon Mechanical Turk workers for important keywords. Following the baselines on this datasets, we pick keywords that were among the top two most frequently chosen by the human annotators. Since no span-level information for these keywords is given, we annotate all occurrences of the chosen keywords in the document to obtain a list of span labels, which we use to evaluate all the models.

A.2 Implementation Details

Here, we present the hyper-parameters for all experiments along with their corresponding search space. We chose all hyperparameters based on the development set performance on the SciERC dataset.

We considered RoBERTa (Liu et al., 2019) and XL-NET (Yang et al., 2019) based encoders and finally chose RoBERTa for faster compute times. We experimented with learning-rates from the set of $1e-5, 2e-5, 5e-5, 1e-4$ and $2e-4$. We chose $2e-5$ as the final learning rate. Our batch size of 8 was chosen after experimenting with 4, 8, 12 and 16. The size of the weights matrix in the classification layer was chosen to be 64 from a set of 16, 32, 64 and 128. The α parameter used for regularization was fixed at 0.5. We tried values between 0.1 and 0.9 and did not find significant difference. We saved the model based on best weighted F1 on the topic prediction task. All training runs took less than 3 hours on 2 Nvidia 2080Ti GPUs, except on the ICLR dataset, which took 8 hours. All results are from a single run.

Large Language Models are few(1)-shot Table Reasoners

Wenhu Chen

University of Waterloo, Vector Institute

wenhuchen@uwaterloo.ca

Abstract

Recent literature has shown that large language models (LLMs) are generally excellent few-shot reasoners to solve text reasoning tasks. However, the capability of LLMs on table reasoning tasks is yet to be explored. In this paper, we aim at understanding how well LLMs can perform table-related tasks with few-shot in-context learning. Specifically, we evaluated LLMs on popular table QA and fact verification datasets like WikiTableQuestion, FetaQA, TabFact, and FEVEROUS and found that LLMs are competent at complex reasoning over table structures, though these models are not pre-trained on any table corpus. When combined with ‘chain of thoughts’ prompting, LLMs can achieve very strong performance with only a 1-shot demonstration, even on par with some SoTA models. We show that LLMs are even more competent at generating comprehensive long-form answers on FetaQA than tuned T5-large. We further manually studied the reasoning chains elicited from LLMs and found that these reasoning chains are highly consistent with the underlying semantic form. We believe that LLMs can serve as a simple yet generic baseline for future research. The code and data are released in <https://github.com/wenhuchen/TableCoT>.

1 Introduction

The problem of structured knowledge grounding has been extensively studied for many years. Tables, as one of the most popular (semi)-structured forms to store world knowledge receive significant attention from the natural language processing (NLP) community. Traditional approaches mostly rely on synthesizing executable languages like SQL or SPARQL to access the information inside the table. However, these symbolic languages normally make a rigid assumption about the table and cannot capture the semantics of text chunks inside the table. Such issues are even more pronounced with web tables due to their irregular forms. To fully

understand web tables, both structured reasoning and textual reasoning are required. Such challenges have attracted many researchers to work in the field. Recently, a wide range of table-based tasks have been proposed like table question answering (Pasupat and Liang, 2015; Chen et al., 2020c; Zhu et al., 2021; Chen et al., 2021b; Talmor et al., 2020; Chen et al., 2020a; Nan et al., 2022), table fact verification (Chen et al., 2019; Aly et al., 2021), table-based generation (Chen et al., 2020b; Parikh et al., 2020; Nan et al., 2021), and table-grounded conversation (Budzianowski et al., 2018; Nakamura et al., 2022). This wide range of table-based tasks all come with different input-output formats and domains. Due to the heterogeneity of these tasks, models achieving the best results on these tasks normally need to be fully fine-tuned on the specific downstream dataset with 10K-100K examples to achieve reasonable performance.

Recently, there have been efforts like Unified-SKG (Xie et al., 2022) aiming to unify these heterogeneous table-based tasks as a generic text-to-text format. UnifiedSKG has shown that using T5-3B (Raffel et al., 2020) with the text-to-text format can already achieve state-of-the-art performance on almost all the table-based tasks without task-specific designs. However, the proposed text-to-text models still need to be fully fine-tuned on the downstream tasks. UnifiedSKG also identified that T0-style (Sanh et al., 2022) cross-task transfer can only achieve almost random performance.

Wei et al. (2022); Wang et al. (2022); Zhou et al. (2022); Drozdov et al. (2022) have recently discovered that large language models (Brown et al., 2020; Chowdhery et al., 2022; Ouyang et al., 2022) can be used to solve complex mathematical and commonsense reasoning tasks with few-shot in-context learning. Inspired by this discovery, we aim at understanding whether these LLMs can also solve complex table-based reasoning tasks. Though the LLMs are not specifically designed to encode ta-

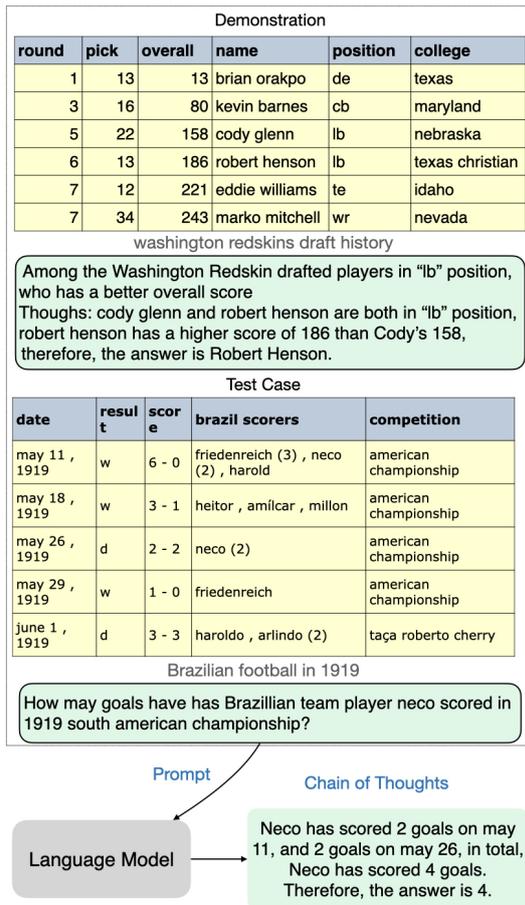

Figure 1: In-context learning for table-related tasks with chain-of-thoughts reasoning.

bles, given the enormous number of tables present in the pre-training corpus, we believe they are also competent at reasoning over table information.

In this paper, we experimented with few-shot in-context learning for LLMs as depicted in Figure 1. Instead of fine-tuning the model, we only provide a few examples to showcase the desired input-output format as the condition for the model to follow to solve unseen test examples. We experiment with several prompting variants including (1) direct prediction, (2) Chain of Thoughts (Wei et al., 2022) (CoT), (3) Chains of thoughts with self-consistency (Wang et al., 2022) (CoT+SC). We evaluate these methods on WikiTableQA (Pasupat and Liang, 2015), FetaQA (Nan et al., 2022), TabFact (Chen et al., 2019) and FEVEROUS (Aly et al., 2021). Our results reveal that LLMs (Ouyang et al., 2022; Chen et al., 2021a; Chowdhery et al., 2022) can achieve striking performance with only 1 or 2 demonstrations, e.g. 48.8% on WikiTableQuestions and 78.8% on TabFact, which are on par some near-SoTA models (Yu et al., 2021; Eisen-

schlos et al., 2020). On other datasets like FetaQA with long-form answers, our human evaluation reveals that GPT-3 can significantly outperform the fine-tuned T5-large by more than 30% in terms of correctness and adequacy.

Furthermore, we manually studied the chain of thoughts elicited from LLMs and found that the rationale is highly consistent with the ‘ground truth’ semantic forms when the model predictions are correct. We found that these models are surprisingly competent at performing symbolic operations over the table, like maximum, minimum, counting, comparison, addition, and difference. However, we also identify several issues of the LLMs on these table reasoning tasks: (1) due to the token limitation, the model is unable to generalize to ‘huge’ tables with 30+ rows, which is the major error source, (2) LLMs can sometimes make simple mistakes when performing symbolic operations.

Due to the simplicity and generality, we believe LLMs with CoT should be used as an important baseline for any future table-related research.

2 Related Work

2.1 Reasoning over Tables

Table-based reasoning is traditionally accomplished by semantic parsing to execute commands on tables like WikiTableQuestions (Pasupat and Liang, 2015), WikiSQL (Zhong et al., 2017), and Spider (Yu et al., 2018). These models aim to synthesize SQL/SPARQL to interact with tables. However, these machine languages have a rigorous requirement regarding the tables, e.g. the value in the same column should follow the same data type. Such rigorous assumptions are frequently violated by web tables containing unnormalized free-form text in cells. Therefore, language understanding inside the table is essential to achieve a better score. Recently, Yin et al. (2020); Herzig et al. (2020); Liu et al. (2021); Deng et al. (2022) have proposed to pre-train table and text to learn joint representation. These pre-trained models can use joint representation to perform reasoning implicitly without relying on symbolic execution. By pre-training the model on large-scale crawled or synthesized data, these models can normally achieve the best-known performance on table tasks. However, these models still require a significant amount of fine-tuning on the downstream datasets. Unlike these methods, we are interested in in-context learning, where the model can only learn with a

few examples (demonstration) without any fine-tuning. One contemporary work similar to ours is BINDER (Cheng et al., 2022), which utilizes Codex to synthesize SQL to execute logical forms against tables for question answering. One big difference is that BINDER (Cheng et al., 2022) involves logical form execution, if the execution fails, BINDER will fall back to using language models to answer the question, which is more similar to ours.

2.2 In-context Learning with LLMs

GPT-3 (Brown et al., 2020) and other large language models demonstrated strong abilities to perform few-shot predictions without fine-tuning, where the model is given a description of the task in natural language with few examples. Scaling model size, data, and computing are crucial to enable this learning ability. Recently, (Rae et al., 2021; Smith et al., 2022; Chowdhery et al., 2022; Du et al., 2022) have proposed to train different types of large language models with different training recipes. The LLMs have demonstrated a striking capability utilizing the few-shot prompts to accomplish unseen tasks without any fine-tuning, which is found to be an emergent capability not presented in smaller language models.

2.3 Chain of Thoughts Reasoning

Although LLMs (Brown et al., 2020; Chowdhery et al., 2022) have demonstrated remarkable success across a range of NLP tasks, their ability to demonstrate reasoning is often seen as a limitation. Such capability cannot be acquired simply by scaling up the model size. Recently, the ‘chain of thoughts’ prompting (Wei et al., 2022) has been discovered to empower LLMs to perform complex reasoning over text. By providing the model with several exemplars of reasoning chains, LLMs can learn to follow the template to solve difficult unseen tasks. Later, Wang et al. (2022) propose to use self-consistency with CoT to further improve performance. Later on, Kojima et al. (2022) discovered that LLMs can even perform reasoning without any demonstration by using appropriate prompts. These recent findings reveal the strong capability of LLMs to perform complex reasoning. However, the current studies are still heavily focused on text-based tasks like question answering, common sense reasoning, etc. The models’ capability to reason over tables is yet unknown. In this paper, we are specifically interested in understanding LLMs’ capability to

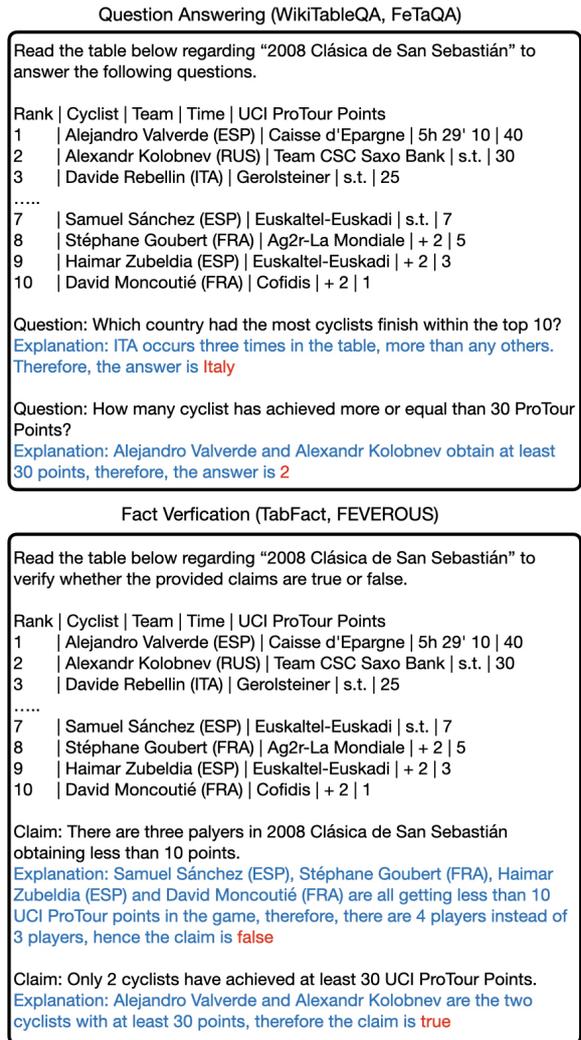

Figure 2: Prompts used for question answering and fact verification tasks.

reason over web tables with CoT prompting.

3 Method

We experiment with different in-context learning methods to solve the table-based reasoning tasks. To formulate the prompt, we linearize the table and concatenate it with a few examples as demonstrations of the language model to predict the output from an unseen test example. The format is described in Figure 2. We mainly investigate three different variants for language model prompting, including (1) Direct Prediction, (2) Chain of Thoughts (CoT), and (3) Chain of Thoughts + Self-Consistency decoding (CoT+SC). For self-consistency methods, we use LLMs to generate five diverse reasoning paths and then use majority voting to select the most voted answer.

To limit the budget and constrain the input token length, we truncate the input tables to contain only

the first 22 rows and the first 8 columns. For each cell, we truncate the word length to contain only the first 10 words. Through such truncation, we can restrict the input token length to within 2000 tokens. We will talk about the impact of input token length on the final performance.

4 Experimental Results

For the GPT-3 experiments, we used the four provided models, Ada, Babbage, Curie, and Davinci with 350M, 1.3B, 6.7B, and 175B parameters respectively. We mainly use Davinci-text-002 (Ouyang et al., 2022) in our experiments. We also report results for Codex (Chen et al., 2021a) (Davinci-code-002) on some datasets. We use a temperature of 0.7 without any frequency penalty and without top-k truncation. We found that the model performance is robust to the sampling strategies and the hyper-parameters. These models are mainly trained on web-crawled data and code data, without any specialized training on table corpus.

4.1 Datasets

Here we list all of our datasets as follows:

WikiTableQuestions Pasupat and Liang (2015) consists of complex questions annotated based on Wikipedia tables. Crowd Workers are asked to compose a series of complex questions that include comparisons, superlatives, aggregation, or arithmetic operations. The annotated dataset is cross-validated by other crowd workers. In our experiments, we use the unseen test set for evaluation. We evaluate the standard test set with roughly 4000 questions. In this dataset, we adopt the answer exact match as our evaluation metric.

FetaQA Nan et al. (2022) consists of free-form table questions. These questions are mostly complex questions that require integrating information from discontinuous chunks in the table. Instead of having short answers, the dataset annotates long free-form answers. Unlike other datasets using copies of short text spans from the source, the questions in FetaQA require a high-level understanding. We adopt sacre-BLEU and human evaluation as our evaluation metrics. The evaluation set contains a total of 2003 examples.

TabFact Chen et al. (2019) consists of both simple and complex claims annotated by crowd workers based on Wikipedia tables. In the simple

subset, the claims normally do not involve higher-order operations like max/min/count, etc. While the complex subset mainly contains claims involving higher-order operations. We evaluate the original test set containing 12,779 examples. We report binary classification accuracy on the set.

FEVEROUS Aly et al. (2021) consists of compositional claims annotated by crowd workers regarding Wikipedia tables. Since the dataset contains both table-supported and text-supported claims. We filter out text-supported claims and only keep the 2,295 table-supported claims as our test set. Different from TabFact, FEVEROUS consists of more complex tables with irregular structures like multi-row, multi-column, multi-table, etc. We report dev-set accuracy.

4.2 Baselines

In these experiments, we mainly consider the following baseline models.

Pre-trained Encoder-Decoder Model Pre-trained encoder-decoder model is one of our competitors, which aims to encode the table as a plain sequence into the encoder, and then apply the decoder to generate either an answer or a verdict. In this paper, we mainly compare against T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) as our baselines.

Pre-trained Table Understanding Model This family of models is specifically pre-trained on the table-related corpus, which utilizes specific architecture to encode table structure and handle symbolic computation. In this paper, we mainly consider TAPAS (Herzig et al., 2020), TABERT (Yin et al., 2020), and TAPEX (Liu et al., 2021).

Neural Symbolic Model This family of models includes a non-pre-trained neural symbolic model, which can synthesize machine language to interact with the table. This line of work includes LogicFactChecker (Zhong et al., 2020), Neural-Symbolic Machine (Liang et al., 2018), etc.

4.3 Main Results

Here we show our main results for different datasets as follows.

WikiTableQuestions As can be seen from Table 1, directly asking GPT-3 to generate answers can only lead to 26% EM score. However, if we prompt the model with the CoT demonstrations,

Type	Model	Test EM
Train	Pasupat and Liang (2015)	37.1
Train	Zhang et al. (2017)	43.7
Train	Liang et al. (2018)	43.7
Train	Agarwal et al. (2019)	44.1
Train	Wang et al. (2019)	44.5
PT + FT	Herzig et al. (2020)	48.8
PT + FT	Yu et al. (2021)	52.7
1-shot	GPT-3 Direct	24.0
2-shot	GPT-3 Direct	27.3
1-shot	GPT-3 CoT	44.2
2-shot	GPT-3 CoT	45.7
2-shot	Codex CoT	48.8

Table 1: Experimental Results on WikiTableQuestions. PT means pre-training and FT means fine-tuning.

GPT-3 is more likely to follow the logical operation to derive the answers. With two demonstrations, GPT-3 can achieve roughly 46% EM score. By switching from GPT-3 to Codex, we are able to further improve the EM score to over 48.8%. These results are particularly surprising given that TAPAS has a built-in module to complete symbolic operations, while GPT-3 was not trained on any table-specific dataset. These results demonstrate GPT-3’s built-in capabilities to perform diverse types of reasoning over tables.

FetaQA As demonstrated in Table 2, we compare GPT-3 with different fine-tuned models from Nan et al. (2022). Unlike the other datasets with short phrase answers, the goal of this dataset is to generate a complete long-form answer. Unlike WikiTableQuestion, the questions normally do not involve complex operations like max, min, compare, average, etc. The long-form answer is similar to the role of CoT. Therefore, we only applied ‘direct generation’ in this experiment. In terms of BLEU score (Papineni et al., 2002), GPT-3 is still a bit behind the fine-tuned T5-large. However, the BLEU score cannot reflect the faithfulness and correctness of the model generation. Thus, we follow Nan et al. (2021) to do human evaluation over the four aspects: (1) fluency (whether the generated sentence contains the linguistic error), (2) correctness (whether the generated sentence answers the question correctly), (3) faithfulness (whether the generated sentence is grounded on the input table), and (4) adequacy (whether the generated sentence is comprehensive enough to cover all the answers). We list our results in Table 3. Similarly, we also sample 100 model predictions and manually evaluate their quality and adopt binary scores for each

Type	Model	sacreBLEU
zero-shot	Pipeline (Nan et al., 2022)	9.16
FT	Pipeline (Nan et al., 2022)	11.00
FT	T5-small (Nan et al., 2022)	21.60
FT	T5-base (Nan et al., 2022)	28.14
FT	T5-large (Nan et al., 2022)	30.54
1-shot	GPT-3 Direct	26.88
2-shot	GPT-3 Direct	27.02

Table 2: Experimental Results on FetaQA. PT means pre-training and FT means fine-tuning.

Source	Fluency	Correct	Adequate	Faithful
Pipeline	85.2	25.4	23.6	23.6
T5-large	94.6	54.8	50.4	50.4
Human	95.0	92.4	95.6	95.6
GPT-3	98.0	84.0	78.0	90.0

Table 3: Human Evaluation Results on FetaQA.

example. As can be seen, GPT-3 can significantly outperform T5-large over all the aspects, i.e. more than 30% improvement over correctness, adequacy, and faithfulness. The evaluation indicates that the model output is almost on par with the average human performance on this dataset.

TabFact As demonstrated in Table 4, we compare GPT-3 against the other pre-trained and fine-tuned models including TAPAS (Eisenschlos et al., 2020), TAPEX (Liu et al., 2021), etc. We show that GPT-3 direct prediction is already getting a decent accuracy of 72%, which is slightly higher than Logic FactChecker (Zhong et al., 2020). When combined with CoT reasoning, the model accuracy increases to over 77%. Similar to before, we found that Codex can generate more accurate reasoning chains, thus achieving better accuracy of 78.8%, which is only 2% lower than pre-trained table understanding model TAPAS (Eisenschlos et al., 2020). The more intriguing property about LLM + CoT is that the intermediate rationale can be produced without any training. All the existing trained models do not have the capability to produce the intermediate reasoning steps due to the lack of annotation in the dataset.

FEVEROUS We demonstrate our results on FEVEROUS dev-set in Table 5 and compare different-sized UnifiedSKG models (built with T5). We found that GPT-3’s performance with direct prediction is similar to UnifiedSKG-base. Similar to TabFact, we found that the model performance can be boosted with ‘chain of thoughts’ prompt-

FT	UnifiedSKG-3B (Xie et al., 2022)	82.40
1-shot	GPT-3 Direct	74.20
2-shot	GPT-3 Direct	75.22
1-shot	GPT-3 CoT	75.70
2-shot	GPT-3 CoT	76.44
1-shot	GPT-3 CoT+SC	77.22

Table 5: Experimental Results on FEVEROUS. PT means pre-training and FT means fine-tuning.

ing. The best-performing model is roughly between UnifiedSKG-base and UnifiedSKG-large. Compared to TabFact, the model’s overall performance is weaker mainly because the table structure in FEVEROUS is more irregular, containing lots of segments and subtables. Such structural difficulties pose great challenges to GPT-3.

Model Scaling We investigate the model scaling’s impact on the final performance and plot our findings in Figure 3. On the WebTableQuestions dataset, we found that model size is essential for achieving the best performance. As can be seen, the 6.7B GPT-3 model is only achieving half of the performance of the 175B GPT-3 model. Similarly, on TabFact, we found that the smaller models with 6.7B or fewer parameters are almost getting random accuracy, which is even worse than QA tasks. This again suggests that LLMs’ reasoning ability over web tables is emergent as the model scales up.

4.4 Case Study

We demonstrate a few examples in Figure 4 where GPT-3 makes correct predictions. In the first example, GPT-3 is able to first identify all the Belgian

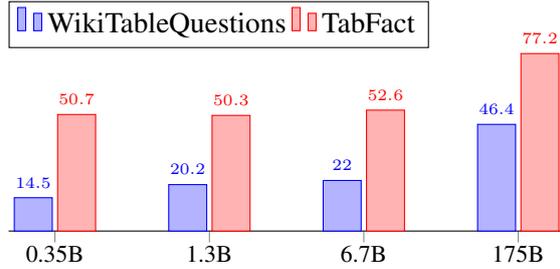

Figure 3: The model performance with respect to model size on WikiTableQuestions and TabFact.

riders from the table and then perform the addition of $3+3+1=7$ precisely. In the second example, GPT-3 can identify the players with the position of ‘d’ and count the number correctly to refute a false claim. In the third example, we can see that GPT-3 is able to associate multiple blocks of information to generate a comprehensive long-form answer. The elicited ‘chain of thoughts’ in these examples are highly aligned with the underlying semantic forms. These findings suggest that LLMs like GPT-3 can provide high-quality explanations to justify their decision-making.

We also provide a few mistakes made by GPT-3 in Figure 5. In the first example, GPT-3 miscounts the ‘number of countries above 1 billion box office’ because it misidentifies ‘world’ also as a country. In the second example, GPT-3 misunderstood ‘2nd highest’ as ‘highest’, which leads to prediction error. In the last example, GPT-3 misunderstands the semantics of the question and answers ‘left office time’ instead of ‘took office time’. These examples show the typical errors of grounding the inputs to the wrong rows or columns of the table.

4.5 Analysis

Impact of Number of Shots First of all, we conduct an ablation study to understand the impact of a number of shots in the final performance. In order to control the budget, we only sample 200 samples from WikiTableQuestions, TabFact and FEVEROUS for this ablation study. As can be seen from Figure 7, GPT-3 is not quite sensitive to the number of provided demonstrations. Increasing from 1-shot to 2-shot can often benefit the model, however, increasing the shot number further does not yield more performance gain. We conjecture that instruct fine-tuning used in GPT-3 (Ouyang et al., 2022) can easily extrapolate the task meaning, thus, having a single demonstration is already enough for the model to understand the task.

Place	Rider	Country	Team	Points	Wins
1	Sylvain Geboers	Belgium	Suzuki	3066	3
2	Adolf Weil	Germany	Maico	2331	2
3	Torlief Hansen	Sweden	Husqvarna	2052	0
4	Roger De Coster	Belgium	Suzuki	1865	3
5	Joel Robert	Belgium	Suzuki	1730	1
6	Heikki Mikkola	Finland	Husqvarna	1680	2
7	Willy Bauer	Germany	Maico	1276	0
8	Gaston Rahier	Belgium	ČZ	1112	0
9	Pierre Karsmakers	Netherlands	Husqvarna	1110	0
10	Dave Bickers	United Kingdom	ČZ	1076	0

Question: total wins by belgian riders?

According to the table, Sylvain Geboers, Roger De and Joel Robert are Belgian riders and they have totally 3+3+1=7 wins. Therefore, the answer is 7.

name	pos	height	2012 club
Merrill Moses	gk	m	New York athletic club
Peter Varellas	d	m	the Olympic club
Peter Hudnut	cb	m	Los Angeles wp club
Jeff Powers	cf	m	Newport wp foundation
Adam Wright	d	m	New York athletic club
Shea Buckner	d	m	New York athletic club
Layne Beaubien	d	m	New York athletic club
Tony Azevedo	d	m	New York athletic club
Ryan Bailey	cf	m	Newport wp foundation
Chay Lapin	gk	m	long beach shore aquatics

Claim: more players have the position of gk than any other position.

There are 2 players with the position of gk and 5 players with the position of d. 2 is less than 5, therefore, the claim is false.

Year	Title	Role	Notes
1970	House of Dark Shadows.	Willie Loomis	-
1971	Daughters of Darkness	Stefan	-
1971	Night of Dark Shadows	Alex Jenkins	-
1976	A Small Town in Texas	Deputy Lenny Lutz	-
1978	Killer's Delight	Danny	-
1981	Pennies from Heaven	The Detective	-
1984	Racing with the Moon	Mr. Nash	-
1984	Impulse	Bob Russell	-
1984	Gimme an 'F'	Bucky Berkshire	-

1991	The Dark Wind	Jake West	-
1993	Surf Ninjas	Mac	-
2016	The Job Interview	The Applicant	Short film

Question: What were John Karlen's roles in 1970 and 1978?

John Karlen's roles in 1970 were Willie Loomis in House of Dark Shadows and Stefan in Daughters of Darkness. His role in 1978 was Danny in Killer's Delight.

Figure 4: 'Correct' predictions from WikiTableQuestions, TabFact, and FetaQA datasets, where the 'blue' text are the outputs from the GPT-3, 'red' means the correct rows to reference.

Quality Evaluation of Reasoning Chains We conduct a human evaluation to assess whether GPT-3 is making the correct prediction with the correct reasons. Specifically, we sample 100 reasoning paths from the correctly predicted examples and manually study whether these reasoning chains are grounded on the table or simply 'hallucination'. As can be seen from Figure 7, we found that around 90% of reasoning chains are faithful to the infor-

Rank	Country	Box Office	Year	office from national
1	Canada/United States	\$10.8 billion	2012	-
2	China	\$3.6 billion	2013	59% (2013)
3	Japan	\$1.88 billion	2013	61% (2013)
4	United Kingdom	\$1.7 billion	2012	36.1% (2011)
5	France	\$1.7 billion	2012	33.3% (2013)
6	South Korea	\$1.47 billion	2013	59.7% (2013)
7	India	\$1.4 billion	2012	-
8	Germany	\$1.3 billion	2012	-
9	Russia	\$1.2 billion	2012	-
10	Australia	\$1.2 billion	2012	4.1% (2011)
11	Italy	\$0.84 billion	2013	30% (2013)
12	Brazil	\$0.72 billion	2013	17% (2013)
-	World	\$34.7 billion	2012	-

Question: how many countries had at least \$1 billion in box office?

Canada/United States, China, Japan, United Kingdom, France, South Korea, India, Germany and Russia, Australia and world all had at least \$1 billion in box office. Therefore, the answer is 11.

no in series	title	directed by	original air date
47	knight of the drones (part 1)	sidney hayers	september 30 , 1984

Question: On which dates did Harold Martin take office as President of the Congress of New Caledonia?

Harold Martin took office as President of the Congress of New Caledonia on 3 June 1998, 3 July 2007 and 3 March 2011.

Figure 5: 'Wrong' predictions from WikiTableQuestions, TabFact, and FetaQA datasets, where 'blue' text are the outputs from the GPT-3, 'red' means the region of the correct cell to reference, and 'green' means the reference trusted by GPT-3.

mation in the table, and only less than 10% of the reasoning chains are hallucinated. Based on this

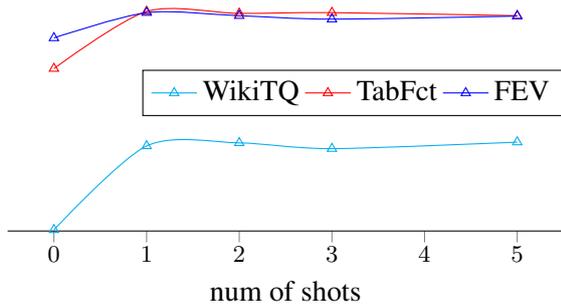

Figure 6: k-shot ablation study over WikiTableQuestions and TabFact and FEVEROUS.

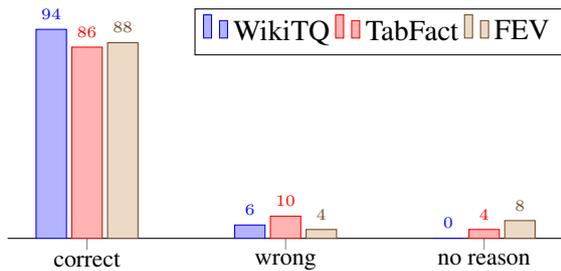

Figure 7: human evaluation of ‘reasoning chains’ in WikiTableQuestions, TabFact, and FEVEROUS.

evaluation, we believe that LLMs are not guessing the answers correctly by chance.

We believe these ‘reasoning chains’ are useful in many aspects: (1) the chains can provide a rationale to humans to justify the decision-making process. (2) one of the notorious annotation tasks is to annotate the ‘underlying’ semantic form for many NLP tasks, which require expertise for human annotators, on the other hand, the annotation cost is huge. Using GPT-3 to demonstrate useful natural language ‘semantic forms’ could potentially greatly lower the annotation burden of these tasks.

Impact of Table Size An important factor for model performance is the size of the table. Here we want to understand how relevant the model performance is w.r.t the input table length. We group the table token length into different groups like ‘0-100’, ‘100-200’, etc, and plot the group-wise accuracy for WikiTables and TabFact in Figure 8. As can be seen from the table, we found that GPT-3’s performance is highly sensitive to the table size. As the table size grows, the accuracy almost decreases monotonically. After the table size exceeds 1000 tokens (e.g. 1500 word pieces), GPT-3’s performance almost degrades to random guesses. This ablation study reveals one of the drawbacks of using LLMs for table reasoning. To further enhance

LLMs’ performance, we need to develop better methods to maintain more consistent performance across different-sized tables.

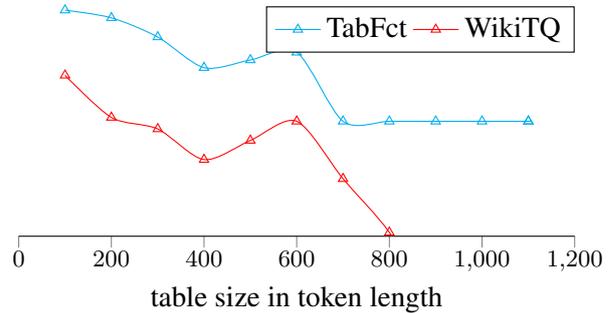

Figure 8: Model performance on WikiTableQuestions and TabFact w.r.t the input table size.

Discussions In this study, we investigate the possibilities of prompting LLMs to perform complex reasoning tasks over tables. However, we do not believe LLM prompting can replace the existing symbolic methods. LLMs have several favorable properties: (1) no annotation is needed, and (2) the functional coverage is broader than symbolic methods. However, LLM prompting exhibits unpredictable randomness and cannot generalize to large tables. In contrast, symbolic models are (1) agnostic to the table size, and (2) can reliably perform designed functions without much randomness. But they in general require a significant amount of annotated data to learn.

In conclusion, these two types of models are complementary to each other. To push the limit forward, we need to investigate how to combine the merits of these two types of methods. For example, the symbolic methods can perform certain operations to narrow down to a targeted region in the table, and then LLMs can be used to reason over the limited information.

5 Conclusion

In this paper, we investigate whether the current LLMs (GPT-3) can be directly utilized to perform table reasoning tasks. Surprisingly, though LLMs are not optimized for table-based tasks, we found these models highly competent in performing complex table reasoning tasks, especially when combined with ‘chain of thoughts’ prompting. We believe this study can open new possibilities for LLM application in table-related tasks to either directly predict the output or to serve as an auxiliary tool for annotating complex intermediate forms.

Limitations

Our approach has several limitations: (1) the proposed approach is still far from state-of-the-art performance, and there is still room for improve before it can be used as an alternative. (2) the method is still costly, we show that the model can only achieve superior performance when scaling up. Smaller-sized models are still weak at table reasoning. Therefore, we need to consider how to empower smaller models with such reasoning capabilities.

Realistic Citation Count Prediction Task for Newly Published Papers

Jun Hirako Ryohei Sasano Koichi Takeda

Abstract

Citation count prediction is the task of predicting the future citation counts of academic papers, which is particularly useful for estimating the future impacts of an ever-growing number of academic papers. Although there have been many studies on citation count prediction, they are not applicable to predicting the citation counts of newly published papers, because they assume the availability of future citation counts for papers that have not had enough time pass since publication. In this paper, we first identify problems in the settings of existing studies and introduce a realistic citation count prediction task that strictly uses information available at the time of a target paper’s publication. For realistic citation count prediction, we then propose two methods to leverage the citation counts of papers shortly after publication. Through experiments using papers collected from arXiv and bioRxiv, we demonstrate that our methods considerably improve the performance of citation count prediction for newly published papers in a realistic setting.

1 Introduction

In recent years, the number of academic papers in various fields has increased drastically. Accordingly, the demand for techniques for predicting papers that will become influential in the future is growing to help readers identify those papers and support efficient knowledge acquisition. In this study, we adopt the citation count as a measure of future impact, following several previous studies (e.g., Chubin and Garfield, 1979; Aksnes, 2006), and we address the citation count prediction task, which entails predicting how many times a target paper will be cited in the future.

There have been many studies on citation count prediction (e.g., Fu and Aliferis, 2008; van Dongen et al., 2020). However, none of those settings is strictly applicable to predicting the citation count of newly published papers, because they assume

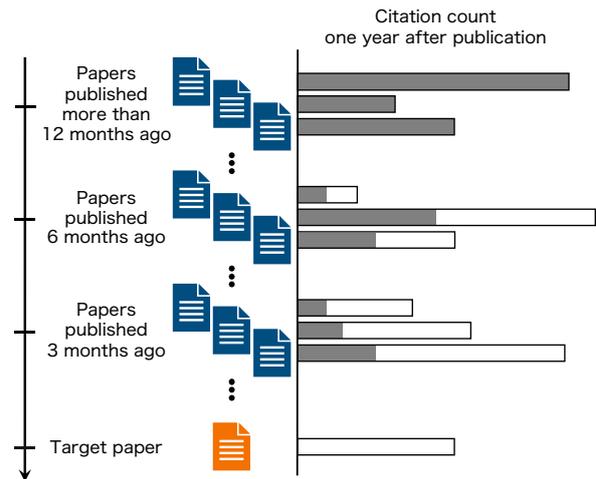

Figure 1: Comparison of a realistic citation count prediction setting with existing research settings. Each bar (■+□) represents the citation count one year after publication, which existing studies assume to be available, while the gray part (■) represents the citation count that is actually available at the time of a target paper’s publication.

the availability of future citation counts for papers shortly after publication. For example, consider the case of predicting the citation counts one year after publication. For training and testing, the correct citation count of the target paper one year after publication must be known; hence, only papers published more than one year ago are used in the experiments. Consequently, even for papers published less than one year before the target paper, the number of citations one year after publication is available, and these citation counts are commonly used to train the prediction model. The bars (■+□) in Figure 1 represent the citation count information used in such settings. However, in actually predicting the future citation count of newly published papers, the correct citation counts one year after the publication of papers published less than one year ago are not available; what is actually available is the gray part of each bar (■) in the figure.

The unrealistic assumption in previous studies might appear to have a limited impact on the performance of a prediction model. However, information on the future citation counts of recently published papers could cause leakage of research trends in the near future, which turns out to have a non-negligible impact on performance. Hence, in this study, we first show that the settings of existing studies leak future information that contributes significantly to the prediction performance. We then introduce a realistic citation count prediction task that strictly uses information available at the time of a target paper’s publication.

Furthermore, we propose two methods to capture research trends in the near future that are applicable even in our realistic setting. The first method is **citation count complementation**, which uses papers published less than one year ago as training data by estimating the citation count one year after publication from the current citation count. The second method leverages the **degree of early adoption** by using the property that papers that cite more recent papers and papers that cite more frequently cited papers tend to receive more attention in the future.

2 Datasets

For the experiments here, we used two datasets: a CL dataset, consisting of papers in the field of computational linguistics, and a Bio dataset, consisting of papers in the field of biology.

To construct the **CL dataset**, we collected 16,940 papers submitted to arXiv in the Computation and Language (cs.CL) category¹ from June 2014 to June 2020. We considered preprints suitable for this study because they include papers that have not been peer-reviewed and are expected to have a large variance in their future impact. We then obtained the publication dates of papers that cited the collected papers from Semantic Scholar² to calculate the citation count for each elapsed month after the publication of each paper in the dataset.

We created 13 subsets, each of which consists of papers published in one of the months from June 2019 to June 2020 and papers published in the five years prior to that month. Within each subset, the papers published in the latest month were used for evaluation, and the remainder was used for training. For example, one subset consists

of papers published from May 2015 to May 2020, of which papers published in May 2020 were used for evaluation and the remainder for training. The subsets created in this way have the same properties as cross-validation, where there is overlap in the papers for training, but the papers for evaluation are completely different. The average numbers of papers per subset for training and evaluation are 13,227 and 500.2, respectively. In the experiments, we used the subset that used papers published in June 2019 for evaluation as the development set and the remaining 12 subsets to train and evaluate the model.

To construct the **Bio dataset**, we collected 7,535 papers submitted to the Biochemistry and Plant Biology, Pharmacology and Toxicology areas of bioRxiv³ from May 2015 to April 2021. As with the CL dataset, we created 12 subsets with papers published in each month from May 2020 to April 2021 as the papers for evaluation. The average numbers of papers per subset for training and evaluation were 5,913 and 257, respectively.⁴

3 Task Formulation

3.1 Leakage in Existing Settings

Most previous studies on citation count prediction adopted the citation count n years after publication as the target citation count for prediction (e.g., Fu and Aliferis, 2008; van Dongen et al., 2020). Those studies used datasets consisting of papers published in a specific time period. Specifically, they used a set of newly published papers by year or a set of randomly selected papers as the evaluation set, and the rest as the training set. The citation count prediction model was then trained using the citation counts n years after the publication of each paper in the training set, and the prediction performance was evaluated by predicting the citation counts of the papers in the evaluation set.

In reality, the citation counts n years after publication are available only for papers published more than n years after publication, but existing settings use those citation counts even for papers published less than n years after publication (Fu and Aliferis, 2008; Davletov et al., 2014; Singh et al., 2015; Abrishami and Aliakbary, 2019; van Dongen et al., 2020). The use of future citation counts that are not actually available in the existing settings may lead

¹<https://arxiv.org/list/cs.CL/recent>

²<https://www.semanticscholar.org/>

³<https://www.biorxiv.org/>

⁴Statistics for each subset of the two datasets are provided in Appendix A.

to leakage of future research trends. Accordingly, we conducted a preliminary experiment to examine the effect of this leakage. We found that, with the same number of papers used for training, the use of future citation counts of newly published papers, which are not actually available, achieves higher performance than the use of papers published more than n years ago.⁵ Hence, we introduce a realistic citation count prediction task that prevents such leakage and is applicable to the prediction of citation counts for newly published papers.

3.2 Realistic Citation Count Prediction

Our realistic citation count prediction task restricts the citation count information used for training to information that is strictly available as of the publication of the target papers for evaluation. Specifically, in the case of predicting the citation count n years after publication, the citation count n years after publication is used for training with papers that were published more than n years after publication. On the other hand, for papers published less than n years after publication, the citation counts as of the publication of the target papers are used for training.

3.3 Target Citation Counts for Prediction

In this study, to determine an appropriate value of n for predicting citation counts, we first investigated the datasets described in Section 2. Specifically, we assumed that the citation counts five years after publication are stable, and we extracted papers published more than five years after publication from each dataset. We then calculated Spearman’s rank correlation between the citation counts m months after publication and five years after publication.⁶ As a result, we found that Spearman’s rank correlation between the citation count one year after publication against the count five years after publication was 0.86 for the CL dataset and 0.71 for the Bio dataset. This indicates that the citation count one year after publication is a good indicator of a paper’s final citation count. Hence, we adopt the citation count one year after publication as the target citation count for prediction.

4 Citation Count Complementation

We propose a method to estimate the citation count one year after the publication of papers that were

published less than one year ago. Our method uses the citation counts of those papers at the time the target paper was published to estimate the counts one year after they were published. Specifically, we estimate the citation counts of a paper m months after publication with a citation count c_m by the following two methods:

Case-based Extract all papers in the training set that have a citation counts c_m at m months after publication, and use the median of those papers’ counts one year after publication as the estimate.

Ratio-based For the training set, calculate the ratio of the average citation count m months after publication to the average count one year after publication, and multiply it by the citation count c_m to obtain the estimate.

While case-based estimation is expected to be accurate for less-cited papers, where there are many other papers with the same citation count, it is not suitable for highly-cited papers that have no or few other papers with the same citation count. Thus, if the citation count c_m is associated with a paper in the list of top 10% papers, it is estimated using the ratio-based method. Otherwise, it is estimated using the case-based method. The rank order of c_m is calculated from the distribution of citation counts m months after publication for the papers in the training set.

To confirm the appropriateness of this citation count complementation, we calculated Spearman’s rank correlation between the correct citation counts one year after publication against the predicted citation count before and after complementation (c_m and complemented citation count). For this investigation, we used the training portion of the 12 subsets to train and evaluate the model on the CL dataset, and we compared the average Spearman’s rank correlations for each subset. As a result, we found that the correlation improved from 0.88 to 0.92, which demonstrates that the citation count complementation is appropriate.

5 Degree of Early Adoption

In realistic citation count prediction, the full citation counts of papers published less than one year after publication cannot be used for training, yet papers that are frequently cited in such a short term are likely to be impactful. In addition, papers that

⁵Details of the experiment are provided in Appendix B.

⁶Detailed results are provided in Appendix C.

	Top 0–1%	1–2.5%	2.5–5%	5–10%	10–25%	25–100%	No citation
Within 3 months	15.5 (4.6%)	14.3 (3.8%)	10.6 (3.6%)	8.8 (5.0%)	7.5 (6.6%)	6.5 (4.9%)	5.0 (71.5%)
Within 6 months	14.3 (9.6%)	12.6 (7.3%)	9.8 (6.2%)	7.6 (8.8%)	6.3 (10.7%)	4.6 (9.4%)	3.7 (48.1%)
Within 9 months	13.8 (15.4%)	11.2 (10.3%)	7.7 (7.8%)	6.6 (10.1%)	5.3 (12.9%)	3.5 (12.4%)	2.5 (31.0%)
Within 12 months	12.7 (21.6%)	10.1 (12.0%)	6.4 (9.1%)	5.7 (10.5%)	4.4 (13.5%)	2.5 (12.9%)	2.0 (20.6%)

Table 1: Average citation counts one year after publication for papers citing at least one paper with the top $k_1\%$ to $k_2\%$ citation counts published within m months in the CL dataset. “No citation” indicates papers that did not cite any paper published within m months. The numbers in parentheses give the ratio of papers belonging to each group in each column.

cite such frequently cited papers earlier—i.e., papers with a high degree of early adoption—can be considered as adequately recognizing the latest trends and are likely to receive more attention in the future because of their novelty and technical contributions. To validate this hypothesis, we investigated whether papers that cite frequently cited papers at an early date tend to be cited more in the future.

Specifically, we examined the average citation count one year after publication for those papers that cite at least one paper with the top $k_1\%$ to $k_2\%$ citation counts published within m months. For this investigation, we used 15,962 papers published in arXiv’s cs.CL category between June 2015 and May 2020, which form the training portion of the subset described in Section 2. In the case of multiple citations of papers published within m months, we used the highest rank order of the citation counts among them. For (k_1, k_2) , we used 6 pairs: (0, 1), (1, 2.5), (2.5, 5), (5, 10), (10, 25), and (25, 100). For m , we used four values: 3, 6, 9, and 12. We then calculated the average citation count for each combination of (k_1, k_2) and m .

Table 1 lists the results. In the table, “no citation” indicates papers that did not cite any paper published within m months. We confirmed an overall trend that papers citing more recent papers and papers citing more frequently-cited papers have higher average citation counts. The average citation count of papers that cited papers in the top 1% of citations within 3 months of publication was 15.5, which was about 2.4 times higher than the average citation count of 6.5 for all papers. On the basis of these results, we attempted to leverage the degree of early adoption in citation count prediction, and we describe the specific methods for this in Section 6.1.

6 Experiments

We conducted experiments on the datasets described in Section 2 to validate the effectiveness of using citation count complementation and the degree of early adoption in realistic citation count prediction.

6.1 Setup

Task Following Maillette de Buy Wenniger et al. (2020), we defined the citation score as $\log(c_n + 1)$, where c_n is the citation count n years after a paper’s publication. In this study, we sought to predict the citation score one year after the publication by using the target paper’s title and abstract.

Prediction Model We adopted a model based on BERT (Devlin et al., 2019) to predict the citation scores. We treated the paper’s title as the first sentence of the input and the abstract as the second sentence. For the output of BERT, we used the vector representation of a special token [CLS]. The [CLS] vector was then passed through a fully connected layer and linearly transformed to obtain a prediction of the citation score. During training, we applied dropout (Srivastava et al., 2014) to the [CLS] vector and minimized the mean squared error (MSE) between the predicted and actual citation scores.

We also represented the degree of early adoption via a special token sequence, which was inserted at the beginning of the input sentence to BERT. Specifically, we created seven special tokens: “top 0–1%,” “top 1–2.5%,” “top 2.5–5%,” “top 5–10%,” “top 10–25%,” “top 25–100%,” and “no citation.” This enabled us to represent the degree of early adoption by arranging the four special tokens corresponding to the highest-ranking citation counts of the papers cited by the target paper within 3, 6, 9, and 12 months, respectively. For example, if a paper cited no paper published within 3 months, a paper published within 6 to 9 months with a top 5–

10% citation count, and a paper published within 12 months with a top 0–1% citation count, the special token sequence would be “[no citation][top 5–10%][top 5–10%][top 0–1%].”

Experimental Setting We used two BERT-based pre-trained language models (PLMs): BERT⁷ pre-trained on a general-domain corpus such as Wikipedia, and SciBERT⁸ pre-trained on a scientific-domain corpus built from a large number of papers. All models were trained with 3 epochs, a batch size of 32, the AdamW optimizer (Loshchilov and Hutter, 2019), and a learning-rate schedule with warm-up at 10% of the total training steps and linear decays in the remaining steps. Following Devlin et al. (2019), the learning rate was set to 2e-5, which achieved the highest Spearman’s rank correlation for all models on the development set, after searches conducted at rates of 2e-5, 3e-5, and 5e-5. We experimented with three different random seeds for each model and calculated the mean and standard deviation of the evaluation scores.⁹

Compared Methods We compared the following five methods to validate the effectiveness of using citation count complementation and leveraging the degree of early adoption.

- **Baseline:** A method that used only papers more than one year after publication for training.
- **+CCC:** A method that used all papers in the training set, including those published less than one year after publication, with Citation Count Complementation.
- **+CCC*:** A method that used the same number of papers as the Baseline model, in order from the newest in the training set, with Citation Count Complementation.
- **+DEA:** A method that was based on the Baseline model but used the Degree of Early Adoption.
- **+CCC+DEA:** A method that used all papers in the training set with Citation Count Complementation and the Degree of Early Adoption.

We also considered applying the proposed method to the existing citation count prediction models based on deep learning such as NNCP (Abrihami and Aliakbary, 2019), BIL_A (Ma et al.,

⁷<https://huggingface.co/bert-base-uncased>

⁸https://huggingface.co/allenai/scibert_scivocab_uncased

⁹Training took about 10 minutes per epoch and inference took a few seconds per evaluation set on a single GV100 GPU.

2021), and SChuBERT (van Dongen et al., 2020), but discarded the idea for the following reasons. First, NNCP and BIL_A were designed under the assumption that citation counts several years after a target paper’s publication are available, and thus these models were not applicable to our setting. SChuBERT was excluded from the experiments because preliminary experiments showed that its performance was equal to or lower than the Baseline, even though it is a model that predicts citation counts using the entire body of a paper. The low performance of SChuBERT is probably due to the fact that it does not perform fine-tuning since it would be computationally expensive to perform fine-tuning for SChuBERT.

Evaluation We evaluated the models with three metrics: Spearman’s rank correlation (ρ) to assess the overall ranking quality, the mean squared error (MSE) to assess the amount of error, and a metric defined as the percentage of the actual top n% of papers in the top k% of the output (n%@k%) to intuitively understand the results.

As mentioned in Section 2, because the average number of papers for evaluation in each subset of the datasets was not large, the evaluation scores would not have been stable if each subset were evaluated individually. Therefore, to yield stable results, we computed each metric across all subsets of the papers. That is, while each subset was used to train the prediction model and the citation counts of the papers for evaluation were predicted by using the model for each subset, the evaluation scores were calculated by combining the predictions for all 12 subsets.

6.2 Experimental Results

Table 2 summarizes the experimental results. For both the CL and Bio datasets, the models based on BERT and SciBERT improved the citation count prediction performance by leveraging either the citation count complementation or the degree of early adoption. The performance was further improved by using both. The SciBERT-based model outperformed the BERT-based model, which demonstrated the effectiveness of pre-training on a scientific-domain corpus for citation count prediction.¹⁰

By comparing the Baseline and +CCC* models,

¹⁰We also experimented with domain-specific models such as PubMedBERT (Gu et al., 2021) on the Bio dataset, but we could not confirm further performance improvement.

Dataset	PLM	Method	ρ	MSE	5%@5%	5%@25%	10%@10%	10%@50%
CL	BERT	Baseline	36.6 \pm 0.4	1.504 \pm 0.022	21.1 \pm 1.7	63.7 \pm 2.3	28.1 \pm 0.9	83.2 \pm 0.4

Table 2: Experimental results from comparing methods that use papers published less than one year after publication in realistic citation count prediction. Each score besides the MSE is multiplied by 100.

BERT for Coreference Resolution: Baselines and Analysis	
Abstract: We apply BERT to coreference resolution, achieving strong improvements on the OntoNotes (+3.9 F1) and GAP (+11.5 F1) benchmarks. A qualitative analysis of model predictions indicates that, compared to ELMo and BERT-base, BERT-large is particularly better at distinguishing between related but distinct entities (e.g., President and CEO). However, there is still room for improvement in modeling document-level context, conversations, and mention paraphrasing. Our code and models are publicly available.	Ground truth: top 0.9%
	Baseline: top 14.5%
	+CCC: top 2.8%
	+DEA: top 7.1%
	+CCC+DEA: top 0.8%

Figure 2: Example of a paper for which the citation count complementation and degree of early adoption improved the prediction. The left part shows the papers title and abstract (Joshi et al., 2019), and the right part shows the relative position of the citation count one year after publication of the target paper (ground truth) and the relative positions predicted by SciBERT-based models.

which used the same number of papers for training, we can see that the +CCC* model performed better on both datasets; thus, we confirmed the effectiveness of using papers published less than one year after publication with citation count complementation for training. We had predicted that the +CCC model, which used a larger number of papers for training, would perform better than the +CCC* model. This was true for the Bio dataset, but surprisingly for the CL dataset, the +CCC* model performed better. We speculate that older papers could serve as noise if the number of papers is sufficiently large, but we leave further investigation of this point to a future work. From the result for the Baseline, +CCC, and +CCC* models on the Bio dataset, we confirmed performance improvement due to the increased number of papers for training

and the leverage of newer papers. In particular, the performance gains from using new papers for training were considerable.

As for the actual predictive performance, the SciBERT-based model using both citation count complementation and the degree of early adoption achieved a score of 90.3 for the 5%@25% metric on the Bio dataset. This means that if we read only the top 25% of the papers predicted by the model for a given set of papers, we could cover 90.3% of the papers expected to have future citation counts within the top 5%. Hence, we believe that this method is highly useful from a practical viewpoint.

Figure 2 shows an example of a paper for which the citation count complementation and degree of early adoption improved the prediction. Although the citation count one year after the paper’s publi-

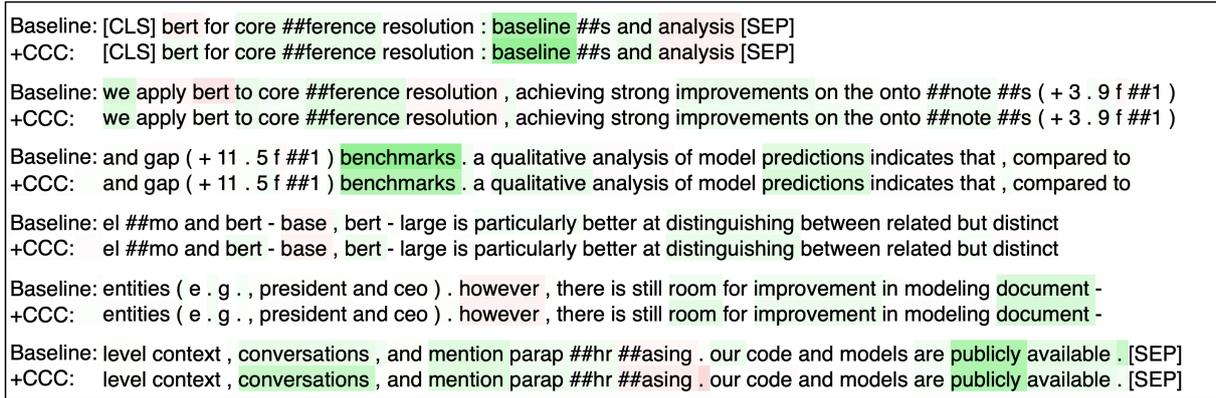

Figure 3: Visualization of the contribution of each token in predicting the citation count of the paper shown in Figure 2. Darker green represents a higher contribution to the prediction, while darker red represents a lower contribution.

citation was in the top 0.9% in the evaluation set, the Baseline model underestimate the citation count. This is likely because the paper was published 10 months after the original paper on BERT, and the Baseline model thus could not leverage the “latest” information that BERT was going to get enormous attention. The prediction was improved by applying either of the two proposed methods, and it was quite accurate when both methods were applied. The use of papers published less than one year after publication for training by citation count complementation would enable the model to use information about BERT for prediction. In addition, this paper cited the top 5% to 10% of papers within 3 months of publication and the top 0% to 1% of papers within 6 months of publication, which indicates that it captured the latest trends. We believe that the proposed method successfully incorporated these properties of the paper into citation count prediction by leveraging the degree of early adoption.

6.3 Analysis and Discussion

To investigate what words the model came to emphasize by leveraging papers shortly after publication for training, we performed an analysis using Integrated Gradients (Sundararajan et al., 2017). The Integrated Gradients method computes each input feature’s contribution to a deep network’s prediction by integrating gradients; thus, it enables analysis of each input token’s contribution to a prediction by BERT. Similar to Schwarzenberg et al. (2021) and Bharadwaj and Shevade (2022), we used a sequence of [PAD] tokens as the baseline input for Integrated Gradients to estimate the contribution of each token.

Figure 3 shows a visualization of the contribu-

tion of each token in predicting the citation count of the example paper shown in Figure 2, for the Baseline model, which does not use papers published after the BERT paper for training, and the +CCC model, which uses papers published after the BERT paper for training. The darker green represents a higher contribution to the prediction, while the darker red represents a lower contribution. The figure shows that the Baseline model did not know about BERT, and the token *bert* had a negative impact, whereas the +CCC model knew that BERT was a state-of-the-art model, and the token had a positive impact. We also observed that both models emphasized tokens that are intuitively important, such as the higher contribution of *publicly available*, which is thought to facilitate subsequent research and growth in citation counts when codes and models are made publicly available.

Furthermore, we quantitatively analyzed the tokens whose contribution to the prediction was increased by using papers shortly after publication for training. To extract these tokens, we calculated each token’s contribution in the +CCC model and its contribution in the Baseline model for the same paper. Then, we took the difference to obtain the score increase due to the use of papers published less than one year after publication. We computed this increase by using all the papers for evaluation in each of the two datasets, took the average for each token, and extracted the top 10 tokens for that average. If a word was divided into subwords, its contribution was determined by summing the subwords’ contributions. In addition, stop words, tokens containing symbols, and tokens with a document frequency of less than 10 were deleted.

Table 3 lists the extracted words. In the CL

Rank	CL	Bio
1	trec	coronavirus
2	coronavirus	coronaviruses
3	revisiting	sars
4	semeval	cov
5	rethinking	computationally
6	finnish	tumors
7	wmt	nucleocapsid
8	bert	hydroxychloroquine
9	propaganda	cannabis
10	specaugment	pandemic

Table 3: Tokens that the model came to emphasize by using papers shortly after publication for training by citation count complementation.

dataset, the conference names *trec*, *semeval*, and *wmt* were at the top of the list. This could mean that more and more papers have evaluated models on datasets that were published at those conferences in recent years. Other words such as *revisiting* and *rethinking* may be associated with an increase in the number of papers that have revised existing models and methods in recent years. In fact, the number of papers published at ACL that included these words in their titles increased from three (0.15%) in 2013-2018 to 15 (0.53%) in 2019-2022. The model also increasingly focused on technologies that have gained attention in recent years, such as *bert* and *specaugment*. In particular, SpecAugment (Park et al., 2019) is a high-profile technology in the speech-processing field that has been cited more than 2,000 times since it was published in April 2019, and the model was able to capture it here as an important technology.

As for the Bio dataset, a number of COVID-19-related words appeared at the top of the list. This indicates that the model captured the increasing number of relevant papers and increasing overall citation counts due to the COVID-19 pandemic. Also, we attribute the large performance improvement with citation count completion on the Bio dataset to the capability to focus more on COVID-19-related words.

7 Related Work

Early works on citation count prediction formulated the task and explored effective features. Castillo et al. (2007) formulated citation count pre-

diction as a regression problem and used author reputation to predict the citation count. Fu and Aliferis (2008) formulated citation count prediction as a classification problem and investigated several features that are effective for such prediction, including a paper’s title, abstract, and author information.

Other studies have sought to improve the prediction performance by using various features. One such feature is a citation graph constructed from citation relationships among papers. Davletov et al. (2014) proposed a method to use the graph’s temporal and topological features. Pobiedina and Ichise (2015) achieved high prediction performance by mining frequent graph patterns. Singh et al. (2015) proposed a method to use the citation context, which is the text in a paper that mentions other cited papers. Bhat et al. (2015) found that the interdisciplinarity of authors is effective in predicting citation counts. Li et al. (2019) proposed a method to use peer-reviewed text from multiple aspects.

Several studies have focused on aspects other than features. Chakraborty et al. (2014) and te Li et al. (2015) found several patterns in the growth of citation counts by analyzing a large number of papers, and they proposed a two-step prediction method, first classifying papers into each pattern and then predicting counts for each pattern. Xiao et al. (2016) proposed a method to predict the citation count at an arbitrary point in time from the publication of a paper, with the aim of predicting its future potential impact.

In recent years, there has been research on the use of deep learning techniques to predict citation counts. Abrishami and Aliakbary (2019) proposed an RNN-based method to predict a paper’s future citation count by using the citation counts for each elapsed year since its publication. van Dongen et al. (2020) proposed a method to predict the citation count by dividing a paper’s text into chunks and encoding the paper’s entire body with BERT. Ma et al. (2021) proposed a method to predict the citation count by extracting semantic features from a paper’s title and abstract via Doc2Vec and Bi-LSTM with an attention mechanism.

8 Conclusion

In this paper, we introduced a realistic citation count prediction task that is applicable to newly published papers, by using only citation count information that is strictly available at the time of pub-

lication of a target paper for training. We further proposed two methods to use papers published less than one year after publication for citation count prediction, as these papers cannot be directly used for training because their citation counts one year after publication are unknown. The first method is citation count complementation, which uses recent papers for training by estimating their citation counts one year after publication. The second method is to leverage the degree of early adoption, which incorporates the tendency for papers that cite highly cited papers earlier to have higher average citation counts. Through experiments using papers collected from arXiv and bioRxiv, we demonstrated that the use of papers published less than one year after publication improves the performance of realistic citation count prediction. For future work, we intend to build models that incorporate information from papers that was not used in this study, such as the body, figures, tables, and author information.

Limitations

Both methods proposed in this paper focus on fields in which technology is rapidly evolving and the latest research results are increasingly important. Because of this, these methods' effectiveness could be limited in fields for which the latest research results are not particularly important. Also, the model in this study only uses the titles and abstracts of papers as inputs, and it does not leverage the body, figures, or tables.

A Detailed Dataset Statistics

Table 4 lists the numbers of papers for training and evaluation for each subset in the CL and Bio datasets described in Section 2.

Dataset	Subset	Training	Evaluation
CL	6/2019	10,459	620
	7/2019	11,026	404
	8/2019	11,404	479
	9/2019	11,854	720
	10/2019	12,529	550
	11/2019	13,031	564
	12/2019	13,552	345
	1/2020	13,820	260
	2/2020	14,049	326
	3/2020	14,339	334
	4/2020	14,617	747
	5/2020	15,305	713
Bio	6/2020	15,962	440
	5/2020	4,451	292
	6/2020	4,743	303
	7/2020	5,046	286
	8/2020	5,331	268
	9/2020	5,597	233
	10/2020	5,827	261
	11/2020	6,088	221
	12/2020	6,307	219
	1/2021	6,524	245
	2/2021	6,769	246
	3/2021	7,012	258
4/2021	7,264	252	

Table 4: Numbers of papers for training and evaluation for each subset in the CL and Bio datasets. The subset names correspond to the year and month of publication of the papers that a subset used for evaluation.

B Details of Leakage Investigation in Existing Settings

To investigate the impact of leakage in the existing setting on the performance of citation count prediction, we conducted an experiment using the CL dataset described in Section 2. The experiment basically used the Baseline model described

PLM	Setting	Avg. train size	ρ	MSE	5%@5%	5%@25%	10%@10%	10%@50%
BERT	w/ future citation count	13,277	40.5 \pm 0.3	1.373 \pm 0.010	28.7 \pm 2.0	72.8 \pm 1.0	34.6 \pm 0.1	87.1 \pm 0.3
	w/ future citation count	8,571	39.0 \pm 0.2	1.358 \pm 0.030	26.0 \pm 0.2	73.5 \pm 1.0	33.7 \pm 1.2	85.1 \pm 0.4
	w/o future citation count	8,571	36.6 \pm 0.4	1.504 \pm 0.022	21.1 \pm 1.7	63.7 \pm 2.3	28.1 \pm 0.9	83.2 \pm 0.4
SciBERT	w/ future citation count	13,277	41.8 \pm 0.3	1.220 \pm 0.024	31.1 \pm 1.1	73.5 \pm 1.5	37.1 \pm 0.8	87.9 \pm 0.4
	w/ future citation count	8,571	40.4 \pm 0.9	1.232 \pm 0.019	31.3 \pm 2.1	72.6 \pm 1.0	35.8 \pm 0.7	86.2 \pm 1.1
	w/o future citation count	8,571	38.3 \pm 0.3	1.390 \pm 0.042	27.4 \pm 1.2	67.5 \pm 1.5	32.0 \pm 1.0	84.7 \pm 0.7

Table 5: Experimental results of the investigation of the leaks in the existing setting (w/ future citation count). Each score besides the MSE is multiplied by 100.

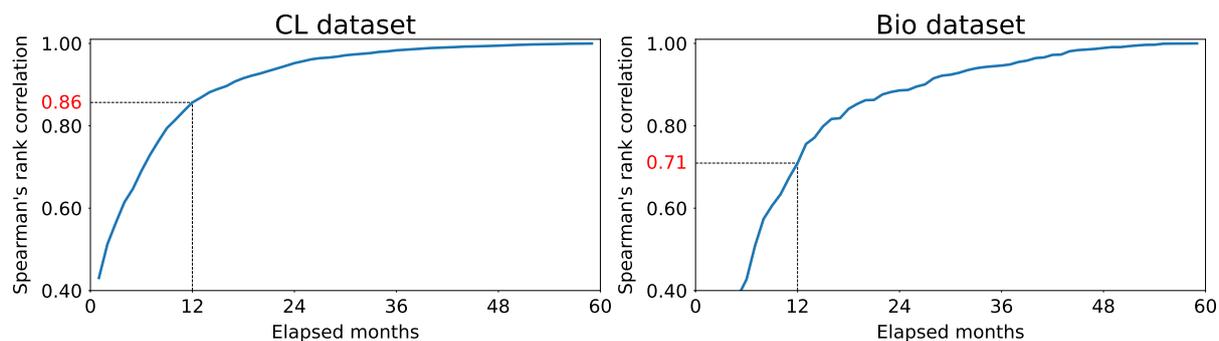

Figure 4: Spearman’s rank correlation between the citation counts m months after publication against the citation count five years after publication. The left part shows the results on the CL dataset and the right part shows the results on the Bio dataset.

in Section 6.1, and only the papers for training were changed. We compared settings that used future citation counts with those that do not. In the setting that did not use future citation counts (*w/o future citation count*), only papers published more than one year after publication as of the target paper’s publication were used for training. For example, if the subset that used papers published in June 2020 for evaluation, papers published between July 2019 and May 2020 were excluded from the training set, and only papers published between June 2015 and June 2019 were used for training. This reduced the average number of papers for training from 13,227 to 8,571. In the setting that used future citation counts (*w/ future citation count*), we used the citation counts one year after publication for all papers in the training set, including papers published less than one year after publication as of the target paper’s publication.

In the *w/ future citation count* setting, the number of papers that can be used for training was larger than in the *w/o future citation count* setting, and thus the impact of the leakage could not be fairly investigated. For a fair comparison, we also experimented with settings that align the number of papers for training used in the *w/ future citation count* setting with the *w/o future citation count* set-

ting. The number of papers for training was aligned by grouping the papers for training by year and month of publication and randomly reducing the papers in each group by the same ratio. By aligning the number of papers, we could fairly compare *w/* and *w/o future citation count* settings.

Table 5 shows the experimental results. For all metrics, the *w/ future citation count* setting, which was trained using all citation count that was actually unavailable, outperforms the *w/o future citation count* setting, which was trained using only available information. The results show that the existing setting improperly improves the performance of the prediction model. In particular, even when the number of papers for training was aligned, the *w/ future citation count* setting outperformed the *w/o future citation count* setting. This demonstrates that the future citation count of papers published close to the target causes leakage of research trends that grow in citation count in the future.

C Transition of Spearman’s Rank Correlation

Figure 4 shows Spearman’s rank correlation between the citation counts m months after publication and five years after publication in the CL and Bio datasets.

“Why do I feel offended?” Korean Dataset for Offensive Language Identification

Abstract

Warning: This paper contains some offensive expressions.

Offensive content is an unavoidable issue on social media. Most existing offensive language identification methods rely on the compilation of labeled datasets. However, existing methods rarely consider low-resource languages that have relatively less data available for training (e.g., Korean). To address these issues, we construct a novel KOrean Dataset for Offensive Language Identification (KODOLI). KODOLI comprises more fine-grained offensiveness categories (i.e., not offensive, likely offensive, and offensive) than existing ones. A likely offensive language refers to texts with implicit offensiveness or abusive language without offensive intentions. In addition, we propose two auxiliary tasks to help identify offensive languages: abusive language detection and sentiment analysis. We provide experimental results for baselines on KODOLI and observe that pre-trained language models suffer from identifying "LIKELY" offensive statements. Quantitative results and qualitative analysis demonstrate that jointly learning offensive language, abusive language and sentiment information improves the performance of offensive language identification.

1 Introduction

Data-driven approaches for detecting and measuring offensive content have steadily grown from statistical methodologies to deep learning models for natural language processing (Balayn et al., 2021). Although various methods for detecting offensive language have been proposed, most of them rely on composing training datasets to determine whether a statement is offensive (Fortuna and Nunes, 2018; Mishra et al., 2019; Vidgen and Derczynski, 2020). In South Korea, most of the population actively

* These authors contributed equally to this work.

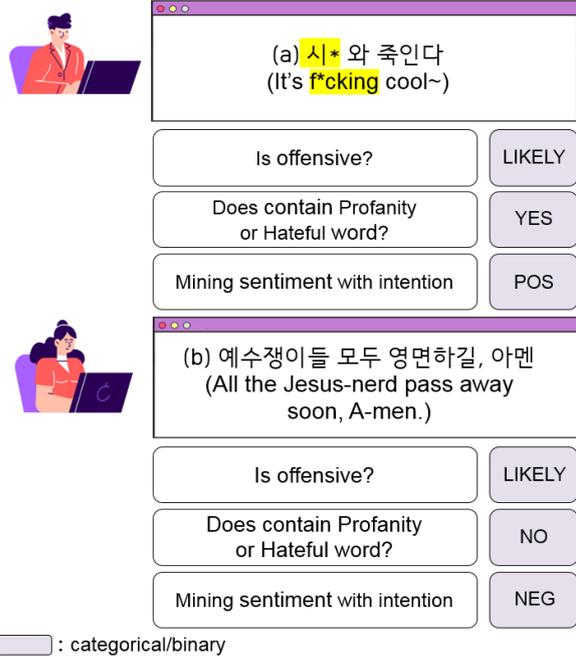

Figure 1: Understanding offensive text (a) and (b) in real-world scenarios considering three questions: identification of offense, existence of abusive language, and underlying sentiment with intention. We supplement the description with examples.

uses the Internet, and the size of online communities is large compared with the population (Park et al., 2021b). The social problems caused by offensive comments have also increased (BBC, 2022). Therefore, we need to analyze and discuss Korean texts and their offensiveness.

Recent approaches have been studied to understand offensive language based on the typology of (Waseem et al., 2017), which differentiates whether the abusive language is directed to a specific individual or group, and whether it is explicit or implicit (Zampieri et al., 2019a; Caselli et al., 2020). This typology helps to identify the offensive language from the statement. However, most existing studies (Sigurbergsson and Derczynski, 2019; Zampieri et al., 2019b) have considered the offens-

ive language detection problem as a binary classification task for distinguishing offensive languages. Although a few studies distinguish profanity and insults under offense (Wiegand et al., 2018), they are limited in classifying various types of offensive language. For instance, offensive intention can be hidden under rhetorical expressions or abusive language can be used without offensive intentions. In particular, in online communities, users freely express their opinions without self-censorship. For instance, users often emphasize emotions with profanity without any offensive intention, as shown in Figure 1(a). In addition, comments on news media (i.e., strictly regulated platforms) are sophisticated in their expressions (i.e., sarcasm or twists) to avoid blocking, as shown in Figure 1(b)¹.

To address these issues, we propose a novel offensive language identification (OLI) task that has three classes: not offensive, likely offensive, and offensive (we extend the existing OLI task by adding a likely offensive class). Moreover, we analyze the attributes of the offensive language. Offensiveness is closely associated with abuse (Caselli et al., 2020). Several studies (Alorainy et al., 2018; Rodriguez et al., 2019) have revealed that negative sentiment messages occur frequently in offensive languages. Therefore, we propose two auxiliary tasks to effectively identify offensive languages: abusive language detection (ALD) and sentiment analysis (SA). The ALD task aims to detect literally abusive language, whereas the SA task extracts the speaker’s subjectivity beyond the sentence. A combination of tasks can be useful for detecting various offensive cases and interpreting the attributes of offensiveness.

We use KODOLI to build classifiers using pre-trained language models (PLMs) (Park, 2020; Park et al., 2021c) and feature-based models (Schuster and Paliwal, 1997; Kim, 2014). We observe that these models struggle to identify likely offensive comments. We utilize a multi-task learning (MTL) technique to utilize related tasks (i.e., ALD and SA). In a qualitative analysis, models that integrate information from offensive language, abusive language, and sentiment exhibit consistent and better-contextualized predictions than those that use only offensive language information.

The contributions of this study are as follows:

- We introduce KODOLI (Korean Dataset for Offensive Language Identification), a new

dataset annotating offensive language, abusive language, and sentiment. We provide a fine-grained annotation scheme for each class to analyze offensive texts in Korean.²

- We find that the PLMs struggle to identify "LIKELY" offensive comments, including implicitly offensive comments and abusive with no intention.
- Quantitative and qualitative analyses demonstrate that learning offensive language, abusive language, and sentiment information improves the performance of OLI.

2 Related Work

Offensive language datasets Offensive language is correlated with several other linguistic and social phenomena including abusive and aggressive language, cyberbullying, racism, extremism, radicalization, toxicity, profanity, and hate speech (Caselli et al., 2020). As hate speeches increased, the number of corpora annotating offensive languages increased (Fortuna and Nunes, 2018; Poletto et al., 2021; Sigurbergsson and Derczynski, 2019; Moon et al., 2020). A previous study (Zampieri et al., 2019a) proposed a novel dataset that provides a scheme for classifying the type and target as well as offensive language. Other studies (Waseem et al., 2017; Sap et al., 2020a; Caselli et al., 2020; Wiegand et al., 2021) have been categorized into explicit and implicit offensive instances. However, none of the aforementioned studies handles the Korean offensive language. To the best of our knowledge, the present study is one of only a few studies that address the Korean offensive language by introducing related auxiliary tasks. Most recently, the concurrent study (Jeong et al., 2022) has proposed Korean offensive language dataset that includes target group, offensive span, and target span annotations as well as offensiveness annotation. They focus on justifying the decision for offensiveness through auxiliary tasks (i.e., target of insult, offensive span). In this study, we focus on subdividing the degree of offensiveness by adding the likely offensive category and auxiliary tasks (i.e., ALD and SA).

Abusive language detection Abuse encompasses many types of fine-grained negative expressions. For instance, Nobata et al. used the term ‘abuse’ to refer collectively to hate speech, derogatory

¹ Blasphemy using phonetic similarity

² <https://github.com/cardy20/KODOLI>

language, and profanity, whereas Mishra et al. considered racism and sexism as abuse. We follow the definition of abusive language suggested by Park et al.: (i) *Profanity* is a word or phrase that insults or curses others; (ii) *Hate speech* is an act of hostile expression based on negative prejudice against a group that has been historically discriminated against because of race, ethnicity, religion, gender, sexual orientation, and gender identity (Cho and Moon, 2020; Madukwe et al., 2020).

Sentiment analysis SA identifies and measures opinions, specifically in determining whether a writer’s attitude toward a particular topic is positive, negative, or neutral (Pang and Lee, 2008; Rodriguez et al., 2019; Liu, 2020). Recent studies have investigated the benefits of using sentiment features in OLI. For instance, Rodriguez et al. applied SA to detect posts suspected of instigating hatred containing highly negative tones. In addition, Plaza-del Arco et al. demonstrated that polarity knowledge can be useful for detecting hate speech and offensive languages more accurately across datasets in Spanish tweets. Inspired by the prior studies, we propose KODOLI, which contains ALD and SA tasks as auxiliary tasks.

3 Task Description

We provide a comprehensive overview of the three tasks for framing the offensive language phenomenon as follows: (i) whether a comment is offensive, likely offensive or not, (ii) whether it contains abusive language (profanity and hate speech), and (iii) whether it has sentiment with intention.

3.1 Main Task: Offensive Language Identification

This task recognizes whether a comment includes offensive language. We consider two factors from previous studies for offensive comments (Wiegand et al., 2018) as follows: (i) Is offensive language directed toward a specific individual or group? (ii) Is an offensive comment explicit or implicit? Unlike previous studies (Zampieri et al., 2019a,b), we establish three categories as follows:

- **Offensive (OFFEN):** Comments that contain surface evidence of non-acceptable language (e.g., profanity) and a targeted offense (i.e., group or individual). This category can be direct or generalized and includes insults, threats, and sexual harassment.

- **Likely offensive (LIKELY):** Comments that could be likely offensive, as they can hide the offensive intention behind sarcasm, irony, and backhanded rude jokes based on stereotypes. The LIKELY class also includes abusive language without malicious intent (additional guidelines that draw a borderline for the likely offensive class can be found in Appendix A.1.).
- **Not offensive (NOT):** Comments that do not contain direct or indirect offense. They do not have profanity or hate speech.

We construct a dataset following the aforementioned guidelines (Appendix A.1 provides details). Owing to the nature of the real-world data collected, many cases in which abusive words expressed intimacy or vitality are observed.

3.2 Auxiliary Task 1: Abusive Language Detection

Auxiliary Task 1 seeks to detect explicit expressions such as profanity and hate speech (see the definition in Section 2). These remarks can be offensive and cause discomfort and conflict within the group. Excessively explicit sexual and obscene expressions are also annotated as abusive language.

- **Abuse (ABS):** Comments that contain profanity and hate speech.
Profanity: e.g., “개같은 *들... , *들 자*하는 이유도 모름?” (you guys are *b*tches*... I do not know why you are masturbating *assh*l*s*?)
Hate speech: e.g., “시* 페미들 너무 싫다.” (I don’t like *f*cking feminist*.), “와 지금 맥날에 백인여자랑 한남 왔는데 존* 이쁘다.” (Wow, a white woman and a *f*cking Korean man* came to McDonald’s right now, and she’s freaking pretty.)
- **Non-abuse (NON):** Comments that do not contain any profanity or hate speech.

3.3 Auxiliary Task 2: Sentiment Analysis

Auxiliary Task 2 analyzes the polarity and intention of the documents and sentences, following the criteria used in the previous sentiment analysis studies (Patwa et al., 2020; Plaza-del Arco et al., 2021).

- **Positive (POS):** Comments that express happiness and support for a person, group, country,

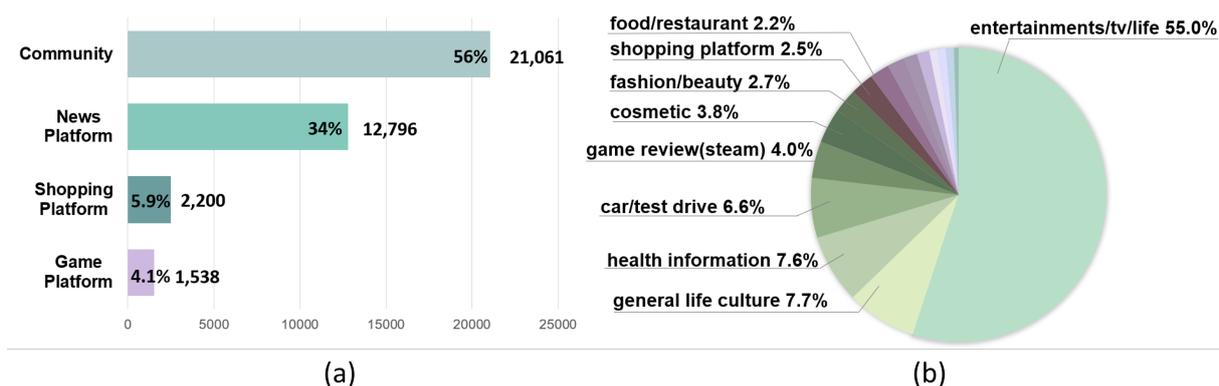

Figure 2: (a) and (b) show the KODOLI’s source and domain, respectively.

or product. e.g., “얼굴 오지게 잘 생겼네” (Your face looks f*cking good.)

- Negative (NEG): Comments that attack a specific target such as a person, group, product, or country. These make people uncomfortable and unhappy. e.g., “현기차 티비 광고보면 성능 품질관련 내용은 별로없고 오로지 감성팔이 ㅋㅋㅋ 개 극혐” (There is not much content related to performance and quality in Hyundai Motor’s TV commercials, only sentimentality haha. It is very hateful.)
- Neutral (NEU): Comments that state a fact or convey news. In general, those that do not fall into these two categories. They also exclude emotional words. e.g., “야채는 건강에 도움이 되니 우리 모두 먹도록 권장합니다.” (Vegetables are good for our health; thus, we encourage you to eat them.)

4 KODOLI

4.1 Data Collection

KODOLI aims to enhance the ability of a system to recognize offensive comments. We collect comments that convey opinions and feelings in explicit and implicit forms. Our dataset is primarily collected and sampled from online communities and news articles, as shown in Figure 2(a). Comments from popular online Korean communities, such as DC-inside³ (from October 2020 to December 2020). The comments on DC-inside contain profanity, hateful speech, and sexual harassment through sub-communities. Therefore, KODOLI is practically similar to a raw representation. We also collect comments from articles from July 2021

³ <https://www.dcinside.com/>

to September 2021. The data are collected from various fields on the Naver news platform⁴. We collect comments from top-ranked articles on pages to ensure contentiousness. To diversify the collected comments, articles are randomly selected from the topic categories of the platform, and from each article, a maximum of 500 comments are collected. Approximately 15 domains are shown in Figure 2(b). Entertainment, TV shows, and life domains constitute the majority of the sample. Although the collected comments are distributed unevenly among domains, they reflect the interests of real-world users.

Duplicates and unnecessary special characters are removed. In addition, during comment collection, special attention is paid to preventing bias on specific topics. For instance, we first count the words that frequently appear by topic. We then replace a certain percentage of comments containing a specific word to comments with the same label collected from a new domain to match the proportions⁵. Comments with sentiment polarity are supplemented by sampling reviews from open-source databases⁶ collected from the game community⁷ and Naver shopping platforms⁸. Finally, 39,589 comments are retained.

4.2 Annotation

We collect at least three annotators per post and attempt to balance gender and diversify educational backgrounds. During the annotation process, we

⁴ <https://news.naver.com/>

⁵ We found after applying this technique, the difference in occurrence between the most frequent (except for stopwords) and least frequent words was about 2%.

⁶ <https://github.com/bab2min/corpus/tree/master/sentiment>

⁷ <https://store.steampowered.com/>

⁸ <https://shopping.naver.com/>

OLI	Abusive Language Detection		Sentiment Analysis			Total
	NON	ABS	POS	NEU	NEG	
NOT	22,453	2,513	10,548	10,865	3,553	24,966 (65.4%)
LIKELY	2,461	3,122	207	1,436	3,940	5,583 (14.6%)
OFFEN	751	6,875	99	1,164	6,363	7,626 (20.0%)
TOTAL	25,665 (67.2%)	12,510 (32.8%)	10,854 (28.4%)	13,465 (35.3%)	13,856 (36.3%)	38,175

Table 1: Distribution of label combinations in the KODOLI. Herein OLI denotes Offensive Language Identification. ABS and NON denote the abuse and non-abuse for the abuse class. POS, NEU, and NEG denote positive, neutral, and negative, respectively, for the sentiment class.

contact undergraduate and graduate students. Even Korean speakers are selected using crowdsourcing. For each comment, the annotators indicate whether a comment is offensive, likely offensive, or not. Thereafter, they categorize whether the comment contains abusive language, such as profanity and hate speech in Korean, and simultaneously annotated intention in terms of sentiment polarity (Cho and Moon, 2020; Park et al., 2021a; Sohn et al., 2012). If the comments are free of profanity and hate speech, the participants are asked to judge the intended support or attack nature within the comments, following abusive language and sentiment guidelines.

Inter-annotator agreement The inter-annotator agreement is calculated based on Krippendorff’s alpha (α) (Krippendorff, 2011), a reliability coefficient developed to measure agreement among annotators. Annotators agree on an offensive comment at a rate of 82.8% (Krippendorff’s $\alpha=0.42$). In particular, we compute Krippendorff’s α using only the LIKELY label, which is 0.41. Sentiment indicates an average Krippendorff’s α of 0.45, indicating moderate agreement (Hughes, 2021; Sap et al., 2020b). For the ALD task, we obtain Krippendorff’s α of 0.72. The final dataset consists of 38,525 Korean comments.

4.3 Data Statistics

Table 1 presents the statistics of comments per task. Comment counts are provided for six and nine combinations. In our corpus, we observe the tendency of each class in terms of offensive language. For example, many comments with abusive language in ALD (6,875) and negative labels in SA (6,363) are offensive. We observe 2,513 comments with abusive language but non-offensive. These use swear words to lay emphasis and to express enthusiasm with positive sentiment, for example, ‘썩간지’ (f*ck cool), ‘존나 잘한다’(damn good). Most of the comments with LIKELY have a negative sen-

timent. They relatively have the abusive language with no target; for instance, they express their emotion with the abusive language ‘술처먹으면 감수성더예민해져서 *같음’(If I drink alcohol, I will become more sensitive and I hate this shit).

Table 1 also shows the distribution of each label. Comments are categorized to binary depending on the abusive content and two ternary classes for identifying offensive language: NOT, LIKELY, and OFFEN, and sentiment polarity: POS, NEU, and NEG. Our corpus’s offensive and abusive category distributions are skewed, whereas the sentiment distribution is balanced. Each task’s label distribution also follows the real-world comments’ nature (i.e., about two-thirds of the comments contain no profanity and are not offensive).

We analyze the frequency of comments tagged as abusive. We observe the obscene and identity terms for demographic groups (e.g., gender, race, and political orientation). We guide more in detail in A.2.

5 Modeling

Preprocessing We randomly shuffle and split the dataset into training (26,967), validation (5,778), and testing (5,780) sets. We apply the morpheme-level pre-tokenization, which is effective for character-rich languages (Park et al., 2021c). Specifically, we select Mecab-ko⁹ (Kudo, 2006), a pre-tokenizer adapted for Koreans. In the case of BERT-family models, we apply the WordPiece tokenizer following the work (Devlin et al., 2019).

Multi-task learning MTL has been widely used to train with data from multiple tasks, and we use the hard parameter sharing technique (Crawshaw, 2020). This is the practice of sharing model weights between related tasks; therefore, each weight is trained to minimize multiple loss func-

Table 2: Results for offensive language identification task on the KODOLI test set. We report the precision (P), recall (R) and F1-score for the classifiers (best in bold).

tions jointly. We construct two kinds of parts: a shared part and task-specific parts. We share the encoder layer and construct a task-specific layer for each task based on the shared encoder.

Let $x_1, x_2, \dots, x_k \in U$ be the given text with k words from input sentence U . In PLMs, we add a special symbol [CLS] at the beginning of the text and add the [SEP] symbol at the end. The embedding layer transforms a fixed-length sequence into an embedding matrix. The embedding matrix is fed to each shared encoder. The hidden states, h_1, h_2, \dots, h_k , are obtained from the encoder. We obtain the output vector \mathbf{h} from the max-pooling layer in feature-based models while using the special token [CLS] to construct the pooled output \mathbf{h} in the PLMs. After feeding the output vector into each task-specific layer, we obtain the output logit, \mathbf{z} . It passes through the softmax layer to calculate the cross-entropy loss. L_{OLI}, L_{ALD} , and L_{SA} denote cross-entropy losses for OLI, ALD, and SA tasks, respectively. $L_{CE}(U)$ is the weighted sum of the joint objective functions L_{OLI}, L_{ALD} and L_{SA} ,

$$L_{CE}(U) = \lambda_o L_{OLI}(U) + \lambda_a L_{ALD}(U) + \lambda_s L_{SA}(U), \quad (1)$$

where λ_o, λ_a and λ_s denote the weights for the OLI, ALD, and SA tasks, respectively.

6 Experimental Results

We first experiment with the single-task learning (STL) method for the OLI task using our dataset, KODOLI, in the popular and powerful NLP models (the implementation details are described in Appendix A.4). Further, we experiment with the MTL method by combining the OLI task with auxiliary task 1 (ALD) or auxiliary task 2 (SA), which are our proposed approaches. We evaluate the experimental performance using the following metrics: precision (P), recall (R), F1-score (F1) for each class and macro-averaging scores.

6.1 Experimental Settings

- BiLSTM (Schuster and Paliwal, 1997): This model consists of two layers of bidirectional long short-term memory initialized randomly. The outputs of the second layer are max-pooled to predict the result using a multi-layer perceptron.
- CNN (Kim, 2014): This model takes individual token representations as the input and then transforms sequence representations for the output using 1D convolution and max-over-time pooling.
- KLUE-BERT (Park et al., 2021c): This model follows the BERT (Devlin et al., 2019) structure. It is designed to pre-train language representation from unlabeled Korean texts¹⁰.
- KLUE-RoBERTa (Park et al., 2021c): This model follows the RoBERTa (Liu et al., 2019) architecture, which uses dynamic masking strategy and whole-word masking. It is pre-trained using the same corpora as KLUE-BERT.
- KoELECTRA (Park, 2020): This model follows the ELECTRA (Clark et al., 2020) architecture¹¹ trained with masked language modeling and replaced token detection objectives.

6.2 Results of Offensive Language Identification Task

Table 2 presents the results of the experiments with the five baseline models for the OLI task. KoELECTRA performs best in most evaluation metrics, in-

¹⁰ It was pre-trained on five Korean corpora of approximately 62GB consisting of formal documents, such as news and books, colloquial texts, multilingual web pages, encyclopedia, and petitions.

¹¹ It is trained with 34GB of crawled news data and the MODU corpus (<https://corpus.korean.go.kr/>).

Model	NOT			LIKELY			OFFEN			Macro Average		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
KoELECTRA _{OLI}	91.81	89.90	90.84	37.90	43.92	40.69	77.91	75.68	76.78	69.21	69.83	69.44
KoELECTRA _{OLI+ALD}	92.48	89.64	91.04	38.50	47.38	42.48	78.16	75.04	76.57	69.71	70.68	70.03
KoELECTRA _{OLI+SA}	92.15	90.45	91.29	38.14	45.30	41.41	78.62	74.48	76.49	69.64	70.08	69.73
KoELECTRA _{OLI+ALD+SA}	92.73	89.27	90.97	38.03	48.48	42.62	79.03	75.44	77.19	69.93	71.06	70.26

Table 3: The MTL results on the KODOLI test set using KoELECTRA. *OLI* means a model that trained only OLI task in the STL method. *OLI+ALD* and *OLI+SA* mean models trained in MTL for OLI task with ALD task or SA task, respectively. *OLI+ALD+SA* means a model jointly trained on OLI, ALD, and SA tasks in the MTL method.

cluding precision, recall, F1-score for all classes and macro-averaging scores. CNN and BiLSTM show similar results for the macro average F1-score, both of which have lower performance than the PLMs (i.e., KLUE-BERT, KLUE-RoBERTa, and KoELECTRA). These results indicate that the PLM series outperforms the non-PLM series in the OLI task. We observe that performance for the LIKELY class has a significantly lower F1-score compared to not offensive and offensive classes in all models. These results indicate that existing models suffer from the LIKELY class. In particular, the non-PLMs (i.e., CNN and BiLSTM) perform poorly in LIKELY class. We observe that models tend to predict ‘non-offensive’ about comments that hide the offensive intention and have no lexical cues regards to be patterned easily (i.e. f*ck). For example, “센텀시티는 바벨탑이라. 전부 무너져내릴 것이다.” (Centum City is the Tower of Babel. Someday it will completely collapse.) In addition, models easily predict ‘offensive’ if there is abusive language in a sentence. The results of the offensive class show higher precision, recall, and F1-score, which is interpreted as high consistency and sensitivity compared to the likely offensive instances.

6.3 Results on Multi-task Learning

Does training with auxiliary tasks improve the performance of OLI? We evaluate the performance of the MTL based on KoELECTRA (which performed best on the STL) in the OLI task. Table 3 summarizes the experimental results of KoELECTRA trained on the combination of all tasks, including the OLI. First, when learning the OLI, ALD, and SA tasks simultaneously, we observe the best precision, recall, and F1-score in most classes and the macro average. In addition, all the MTL models outperform the STL framework in all metrics except recall in OFFEN. In particular, MTL models with auxiliary tasks are effective in the LIKELY class. We observe a 1.79-point F1-

score improvement in the LIKELY class when we jointly learn ALD and OLI. The LIKELY class contains instances of abusive language but no targeted offense. In the case of jointly learning the OLI and the SA tasks, it shows 0.72 points up F1-score performance in the LIKELY class. This indicates that sentiment features are also effective for KODOLI, including the LIKELY class. We also observe that MTL outperforms STL in the other baseline models (Appendix A.5). We can see that the ALD and SA tasks complement each other to help the model identify offensive languages.

6.4 Qualitative Analysis

We qualitatively examine the model’s ability to understand various offensive cases more effectively. Models that integrate information from offensive languages, abusive terms, and sentiment show consistent and better-contextualized predictions than those that only use offensive language information. In particular, the model trained jointly on OLI and ALD is more effective in the LIKELY examples. In Table 4, although profanity or derogatory language in comments (a) and (b) are not used for offensive purposes, they can cause discomfort and shame. A model trained using offensive language with sentiment performs better in qualitative analysis. For instance, example (c) illustrates a sarcastic case without abusive terms that is implicitly offensive. The model trained with offensive and abusive language and sentiment information correctly predicts all examples (a) ~ (f), which are misclassified in the model trained with the OLI task. These results indicate that training the model with two auxiliary tasks provides a more delicate and accurate identification of offensive language.

6.5 Error Analysis

For further investigation into closing the gap, we inspect approximately 750 instances misclassified as false positives and false negatives from the MTL

Class	Comment	OLI	OLI+ALD	OLI+SA	OLI+ALD+SA
LIKELY	(a) 졸려시발 (Sleepy sh*t)	✗	✓	✗	✓
	(b) 근데 앵창 살빼면 돈도모이고 건강해지고 존나좋은데 (Losing weight saves money and makes you healthier, so that's great. Or, my mother is a wh*re.)	✗	✓	✗	✓
	(c) 기자 참 아무나한다 (It seems that anyone can easily become a journalist.)	✗	✗	✓	✓
OFFEN	(d) 힙합이새끼들은 힙합을 제발 음악이라고 포장하지마라 (Hip-hop b*st*rds, please don't treat hip-hop as music.)	✗	✓	✓	✓
	(e) 골빈 특등 머저리의 헛 소리 누가 믿나 그리고도 밥은 목구멍에 잘 넘어 갈꺼야 더러운 (Who believes this b*llsh*t of the special grade idiot with an empty skull? Do you get up each morning, too?)	✗	✗	✓	✓
	(f) 범죄자 10 8 새들...저것들부터 불태워버리자!! (Puc b*s-crim-tard Let's burn them down!!)	✗	✗	✗	✓

Table 4: Qualitative examples comparing offensive language only, and offensive language with the auxiliary tasks combination models.

model (KoELECTRA). In false positive cases, the model struggles to predict comments as offensive or likely offensive for not offensive comments. The opposite is true for false negatives. We additionally analyze likely offensive class in Appendix (A.6).

False positive types :

- The mixture of swearing but the opposite intention: e.g., *물싸개는 ㄹㅇ 별로 심한욕처럼 안느껴지는데. (I do not sound s*men excreter like a very harsh insult.)
- Using abusive language as an expression of emphasizing emotion: e.g., 와 씨* 테이블에 있는데 창문에 자꾸 하얀게 지나가는거야 (Wow, f*cking I'm at the table and something white passes repeatedly.)

False negative types :

- Implicitly offensive: e.g., 여고생이 맛있나요 여대생이 맛있나요? (How do you feel that high school girls are more tasty? or female college students?¹²)
- Modified profanity: e.g., 야 이 뿔신아 ㅋㅋ (Hey, you bbastard haha), 닥치고 일본가서 살어.. (Shudd¹³ up and live in Japan.)

¹² Sexual harassment expressions

¹³ Similar pronunciation

7 Conclusion

In this paper, we introduced KODOLI, a new Korean dataset for OLI. To this end, we collected various offensive comments from online communities and news articles in diverse domains. In particular, we expanded a fine-grained label called 'likely offensive' to distinguish the implicitly offensive and abusive comments with no targeted offense. We proposed two auxiliary tasks to help models identify offensive languages: ALD and SA. Finally, we released 38k comments annotated with offensive language, abusive language, and sentiment information. Using KODOLI, we demonstrated that modeling offensive language using abusive language and sentiment was effective in quantitative and qualitative analyses. We expect our research will benefit further studies that analyze offensiveness in Korean.

Limitations

Risk in annotation Perceptions of "offensiveness" can vary from person to person. Therefore, we outsourced our data. In addition to typical offensive norms, which refer to expert opinions, the majority decided on annotations. Eleven annotators participated in this study. The definitions in our guidelines are not representative of all possible perspectives. It is important to include the opinions of the targeted minorities when dealing with the an-

notation of offensive language. We tried to balance gender among annotators (57% men, 43% women); however, another specific target demographic remains challenging. For the consistency and quality of the data, when the concordance rate was lower than the threshold 0.5, examples were put on hold in favor of consistency. For instance, if 2 NOT, 4 LIKELY, and 5 OFFEN for a sample, the OFFEN label got the most voted, but $5/11 = 0.45 \leq 0.5$, so it is excluded from the dataset. In the future, these examples should be further studied and dealt with.

Coverage Although we collected data from various sources, we acknowledge that the data do not represent all of them. In addition, there could be bias depending on the collection period, and it could be difficult to cover neologisms.

Ethics Statement

To protect the privacy, we only collected comments rejecting all personally identifiable information, including the user IDs. Subsequently, we removed comments containing personal information, such as phone numbers and emails. Our dataset contains real-life examples of abusive language obtained from actual web data. Therefore, we notified the dangers of the postings in advance. To mitigate the risks, we limited the number of maximum comments workers worked per day, and they were given sufficient time to work. We paid workers above minimum wage. We are aware that our topics could have side effects, such as KODOLI's potential malicious use such as generating bad words. Nevertheless, we urge the practical use of KODOLI, such as filtering offensive comments explicitly and identifying potentially offensive content from multiple points of view. This can prevent the negative influence of users intentionally leaving malicious comments.

A Supplemental Material

A.1 Guidelines Detail

We have established additional guidelines for offensive language that workers can refer to when distinguishing offensive areas from likely offensive areas during the crowdsourcing process. Especially the clearer the expression of hate, profanity, and obscenity, and the more specific the target is, the closer it is to the OFFEN label. Therefore, harassment and threats are also classified as the OFFEN.

- A comment where profanity and hate speech appears explicitly and the target is clear : e.g., 노라주다 저*깁 ㄹㅇ *패고싶게생겼노. (Norajuda that bas*ard’s face really makes me want to beat him.)

- A comment which reveals a hostile attitude toward an individual or group : e.g., 이런 *게이새*들 보면 쥐패서 죽*버리고싶은데. (When I face these f*cking g*y bas*ards, I want to beat up and kill them.)
- A comment in which an expression of direct threat is present : same as second example.
- A comment which contains expressions that sexually harass or humiliate : e.g., 이 짤보고 고로상 빙의됐다 애* 존맛겠다. (After seeing this meme, I was possessed with Goro and wanted to f*ck your m*ther.)

We define the terms in the guidelines to the participants well before the annotation work, and the annotators were trained follow them precisely. Through the pilot study, we analyze the types and set the following guidelines with examples to draw a borderline for the LIKELY class.

- A comment judged to have offensive intent due to intrinsic bias: e.g., 장애인들 몸비틀고 잘 노내. (Disabled people twist their bodies and play well.)
- A comment with disrespectful expressions (reproaching, admonishing, etc.): e.g., 신이 있어? 그만건 없음. 정신차리고 사세요. (Did you say that there is a god? Nothing like that. Calm down.)
- A comment may cause shame: e.g., 섹*할때 필수용품.. (A must-have item for s*x.)
- A comment with a cynical tone: e.g., 조각일 보 다운 기사네.. (It is an article from a daily forgery..)
- A comment considered to be implicitly disparaging: e.g., 근데 화*는 왜 빠는거야? (Why did you suck Hw*s*¹⁴?)
- A comment with abusive language but judged to be acceptable: e.g., 와 미친 개잘한다. (Wow, it’s crazy, you are doing f*cking great!)

A.2 Abusive Language in KODOLI

We analyze comments with abusive labels, extract the profane term and hate term based on the frequency, and organize them into a bag of words.¹⁵

A.3 Experimental Results on Each Auxiliary Task in the STL Settings

We evaluate both the auxiliary tasks, ALD and SA. Table 5 and Table 6 summarize the baseline results of the STL setup.

Model	Abusive Language Detection		
	P	R	F1
BiLSTM	89.03	87.27	88.05
CNN	90.53	88.22	89.22
KLUE-BERT	88.60	88.22	88.41
KLUE-RoBERTa	88.96	88.61	88.78
KoELECTRA	90.96	90.02	90.47

Table 5: Precision, recall, F1-score of abusive language detection

Model	Sentiment Analysis		
	P	R	F1
BiLSTM	73.31	72.16	72.61
CNN	74.32	73.46	73.81
KLUE-BERT	77.02	76.78	76.85
KLUE-RoBERTa	76.88	76.51	76.68
KoELECTRA	77.70	77.69	77.64

Table 6: Precision, recall, F1-score of sentiment analysis

A.4 Implementation Details

- a. Hyperparameters: We used a batch size of 32 examples for each model and a fixed sentence length of 128. We used the AdamW optimizer (Loshchilov and Hutter, 2017). We set 48 seed and explored the learning rate to obtain the best results for each model. For CNN and BiLSTM, the learning rate was searched for between 1e-04, 2e-04, 3e-04, 4e-04, 5e-04, 6e-04, 7e-04. We searched for the following learning rates: 7e-06, 9e-06, 1e-05, 2e-05, 3e-05, 4e-05, for KLUE-BERT, KLUE-RoBERTa, and KoELECTRA. In the case of MTL, we initially set all lambda weights to 1.0. We searched for an appropriate lambda weight by using a grid search.
- b. Training conditions: We implemented the model using PyTorch (Paszke et al., 2019) and used an NVIDIA GeForce RTX 3090 with 24 GB of VRAM to train all baseline models. We used the HuggingFace library for our BERT-family models¹⁶.

¹⁶ <https://huggingface.co/klue/bert-base>

Model	Task	Macro Average		
		P	R	F1
CNN	OLI	66.30	64.50	65.06
	OLI + ALD + SA	67.42	67.03	66.33
BiLSTM	OLI	65.86	64.61	65.12
	OLI + ALD + SA	66.98	65.06	65.91
KLUE-BERT	OLI	67.19	68.21	67.65
	OLI + ALD + SA	68.12	69.17	68.53
KLUE-RoBERTa	OLI	66.94	68.99	67.82
	OLI + ALD + SA	68.10	70.22	68.67
KoELECTRA	OLI	69.21	69.83	69.44
	OLI + ALD + SA	69.93	71.06	70.26

Table 7: STL(OLI) vs MTL(OLI+ALD+SA)

A.5 Experimental Results on the Baseline Models in the MTL Settings

Table 7 presents the experimental results obtained using KODOLI on the STL method for the OLI task and the MTL method combining the OLI task with auxiliary task 1 (ALD) and auxiliary task 2 (SA) in the five baseline models. This result indicates that the performance is improved when two auxiliary tasks are jointly learned in all baseline models.

A.6 Error Analysis Details

We conduct an in-depth analysis of the LIKELY class, which shows relatively low performance on classifiers, with auxiliary labels. Of the 718 examples of the LIKELY class in the validation set, 208 examples misclassified LIKELY as NOT and 197 LIKELY examples as OFFEN. Among the cases misclassified as NOT, 136 cases are labeled as non-abusive language, which means that they have no explicit expression (i.e., hate words, profane). We find that a large portion of the cases is sarcastically or twisted as considering the context of the sentence. Especially, if a comment is likely offensive under the social and cultural background (e.g., first and fourth examples in A.1), the distribution of prediction scores tends to appear evenly. In addition, most misclassified cases as OFFEN (72%) contain an explicit and emphasized expression. We conjecture that classifiers predict OFFEN by looking at the specific word itself. However, humans take it differently in feeling offended.

Empirical Investigation of Neural Symbolic Reasoning Strategies

Abstract

Neural reasoning accuracy improves when generating intermediate reasoning steps. However, the source of this improvement is yet unclear. Here, we investigate and factorize the benefit of generating intermediate steps for symbolic reasoning. Specifically, we decompose the reasoning strategy w.r.t. step granularity and chaining strategy. With a purely symbolic numerical reasoning dataset (e.g., $A=1$, $B=3$, $C=A+3$, $C?$), we found that the choice of reasoning strategies significantly affects the performance, with the gap becoming even larger as the extrapolation length becomes longer. Surprisingly, we also found that certain configurations lead to nearly perfect performance, even in the case of length extrapolation. Our results indicate the importance of exploring effective strategies for neural reasoning models.¹

1 Introduction

Artificial intelligence researchers have been attempting neural-symbolic integration for a long time (d’Avila Garcez and Lamb, 2020; Hamilton et al., 2022). Neural models tend to perform better when generating intermediate reasoning steps in addition to the answer. This phenomenon was seen across various reasoning tasks, such as math word problems (Wei et al., 2022; Cobbe et al., 2021; Kojima et al., 2022; Recchia, 2021; Lewkowycz et al., 2022), commonsense reasoning (Wei et al., 2022; Wang et al., 2022), and symbolic reasoning (Wei et al., 2022; Kojima et al., 2022). However, it is yet unclear which factors in the intermediate step generation bring the benefit. Previous studies often used different strategies for step generation in an ad-hoc manner. To investigate this, we break down the neural reasoning process into two strategies: *output strategy* and *chaining strategy* (Figure 1). The output strategy (§2.1) determines the granularity of

¹Code available at: <https://github.com/ao1neko/reasoning-strategy>

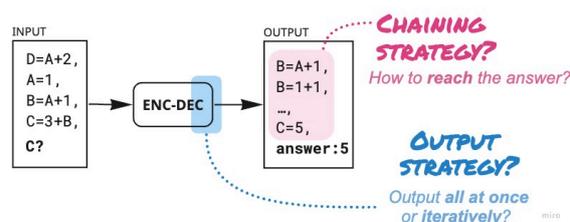

Figure 1: In a controlled setting, we found that output and chaining strategy choice significantly impact performance when conducting multi-step reasoning.

intermediate reasoning step generation (all at once vs. step-by-step vs. token-by-token). Some studies trained the models to generate reasoning steps and a conclusion derived from them at once (Nye et al., 2021; Lewkowycz et al., 2022; Wei et al., 2022; Kojima et al., 2022; Wang et al., 2022; Recchia, 2021), some generated a single reasoning step given the input and iterated this process until achieving a conclusion (Sanyal et al., 2022; Picco et al., 2021; Tafjord et al., 2021), and others iteratively generated sub-goals as well as reasoning steps (Liang et al., 2021; Shwartz et al., 2020).

In turn, the chaining strategy (§2.2) defines the reasoning path direction (shortest path vs. exhaustive path vs. backward path). For example, some studies used a backward chaining process (Picco et al., 2021; Rocktäschel and Riedel, 2017; Cingillioglu and Russo, 2019), while others adopted exhaustive searches (Tafjord et al., 2021; Liang et al., 2021; Yang et al., 2022).

To compare the strategies, we prepared a test bed of numerical reasoning problems in a simplified language (Figure 1). This format allows for more controlled testing while serving as a necessary condition—should a model fail to solve it, it cannot be expected to adequately generalize to more complex math word problems.

We found that both strategies substantially affect the symbolic reasoning performance of neural seq2seq learners. Overall, iterative generation

 $B=2, C=3+2, C=5, \text{answer}: 5$

(b) The graph nodes represent variables and edges their dependencies. *Shortest path*: a minimal chain starting from the first necessary equation. *Exhaustive*: greedily solve all equations until the target is reached. *Backward*: start from the target's equation, backtrack over dependencies until a known value is reached, then solve each equation in order.

Figure 2: Overview of (a) output and (b) chaining strategies given the INPUT: $D=A+2, A=1, B=A+1, C=3+B, C?$

outperformed all-at-once outputting, and roughly granular reasoning steps (i.e., shortest-path chaining) lagged behind finely granular steps (i.e., exhaustive and backward chaining). Surprisingly, some settings had near-perfect performance even in generalization tests which extrapolate over greater reasoning depths and unseen numbers during training.

2 Experimental settings

Problem definition. We evaluated the models' ability to iteratively perform arithmetic operations over given symbols. Given a series of equations, the task is to answer the value of a target variable (Figure 1). Each question also has a certain reasoning depth—the number of *necessary* equations to reach the answer. For example, the depth of the question $A=1, B=2+A, C=3+B, D=2, C?$ is 3 ($A=1, B=2+A, C=3+B$).

Each equation defines either an assignment (e.g., $A=1$) or a modular addition and an assignment (e.g., $B=3+1$). The addition is mod 100. The question contexts also contain distractors that are not necessary to calculate the answer (e.g., $D=A+2$ in Figure 1). A value assigned to a particular variable is typically referred to in different equations (e.g., $A=1, B=A+1$). Numbers, variables, and the ordering of equations are randomly assigned.

Motivation for using artificial data There are mainly three advantages to this dataset. First, the

symbolic format allows easier control of reasoning depth for generalization tests. Specifically, we trained a model using instances with shallow (1-5) depths and evaluated them with instances with shallow/deep (1-12) depths. On the other hand, math word problems are harder to control for reasoning depth (e.g., it is not easy to come up with various instances which have a reasoning depth of 10). Second, we wanted to avoid the "spurious bias" that natural (math word) texts implicitly bring into the model (Gururangan et al., 2018; Gupta et al., 2021; Al-Negheimish et al., 2021; Sugawara et al., 2018; Jia and Liang, 2017; McCoy et al., 2019). Third, we assume that our setting is the necessary condition for solving math word problems. It is unreasonable to expect that a model that can't solve this pure numerical reasoning task can solve more complex tasks.

In total, we prepared 5K instances for training and 2.4K for testing.

2.1 Output strategies

We compared three configurations: all-at-once, step-by-step, and token-by-token (Figure 2a).

All-at-once: The model outputs the entire reasoning chain and the final answer in a single call (i.e., *chain-of-thought* style) (Wei et al., 2022; Cobbe et al., 2021; Yavuz et al., 2022; Schwartz et al., 2020). In this setting, the more reasoning steps, the longer the sequence the decoder must generate at once.

Step-by-step: The model outputs a single reasoning step per call. Each generated step is concatenated to the past input, and the model again generates the next step (i.e., *proofwriter* style) (Liang et al., 2021; Sanyal et al., 2022; Picco et al., 2021; Tafjord et al., 2021; Shwartz et al., 2020). This process is iterated until the model outputs the answer or until a set maximum number of iterations is reached (100). **Token-by-token:** This is the same as step-by-step chaining, but the decoder outputs only a single *token* per call. We set the maximum number of steps to 500.

Comparing *all-at-once* and the others reveals the effect of changing the sequence length that the decoder outputs in a single call. In addition, comparing *step-by-step* and *token-by-token* quantifies the advantage of breaking a problem into meaningful units.

2.2 Chaining strategies

Particular variables sometimes depend on another variable; the key to reaching the correct answer is determining the order in which the equations are referred to. Regarding existing studies, we compared three chaining strategies: *shortest-path*, *exhaustive*, and *backward* chaining (Figure 2b).

Shortest-path chaining: The model straightforwardly solves the equations starting from the first solvable one (i.e., involving a known value) and ending with the target (Wei et al., 2022; Cobbe et al., 2021; Yavuz et al., 2022; Shwartz et al., 2020). Here, the reasoning behind determining the shortest path is not outputted by the model.

Exhaustive chaining: The model greedily solves all given equations until the target value is reached (Tafjord et al., 2021; Liang et al., 2021; Yang et al., 2022). Specifically, the model calculates the left-most solvable equation in each step. Note that this strategy typically derives a long reasoning chain; from an engineering perspective, this strategy is inefficient.

Backward chaining: The model starts from the equation for the target variable and backtracks over the dependent equations until it reaches a known value (Picco et al., 2021; Rocktäschel and Riedel, 2017; Cingillioglu and Russo, 2019). Then, it solves each equation in order by inserting known or calculated values until the target one is reached.

No chaining: As a baseline, we also examined the setting where the model was trained to directly output the answer.

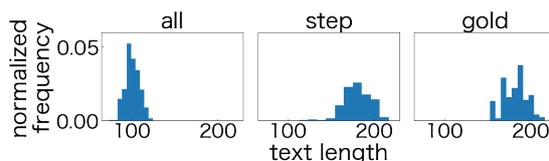

Figure 3: Distributions of the total reasoning chain length (num. characters). The all-at-once and step-by-step generate those at depth 12.

3 Results

Models: We used the pre-trained T5-base, T5-large² (Raffel et al., 2020), and BART-base³ (Lewis et al., 2020). Results of BART-base are in Appendix C.

Note that their pre-defined tokenizers have all the numbers from 0 to 9, and the numerical values in our dataset are divided into digits (e.g., “12” should be “@@1 @@2”) in advance, following Kim et al. (2021).

Training: The models were first pre-trained using a 10K *simple* dataset for 30 epochs, then trained with the 5K training set (1K training instances for each reasoning depth.) for 2000 epochs. The experiment setting details are in Appendix A. In addition, we prepared 0.2K test instances for each reasoning depth. This pre-training is intended to teach the models primitive operations (i.e., assignment, reference, and addition). The pre-training dataset contains two types of single-depth instances: *assign-refer* type (e.g., A=1, A?) and *operate-assign-refer* type (e.g., A=1+3, A?). All the results in the paper are averages of the results on three different seeds.

3.1 Output strategies

We compared the output strategies while fixing the chaining strategy to the shortest path. Figure 4a shows the accuracy per reasoning depth. Note that the accuracy score here denotes whether the answer (e.g., C=6) is correct. We observed the following: (i) **generating intermediate reasoning steps enhance the performance**, and (ii) among the output strategies, **step-by-step works the best**, and **all-at-once works the worst**. The format of the dataset in this study is simple. Therefore, this result indicates the low symbolic reasoning ability of neural models and the necessity of the choice of

³https://huggingface.co/docs/transformers/model_doc/bart

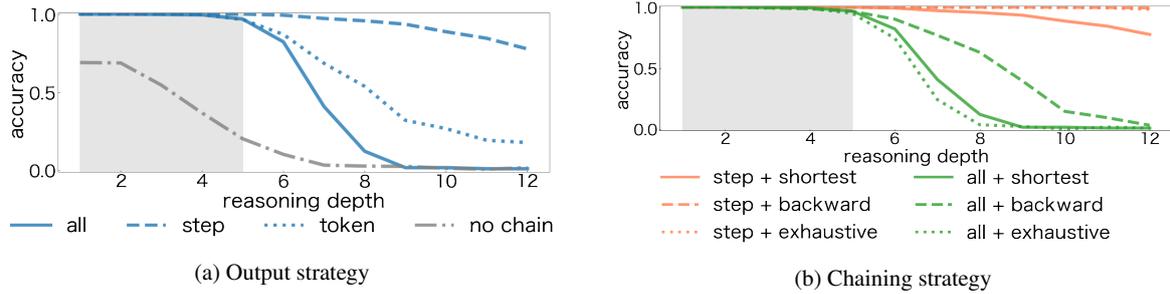

Figure 4: Accuracy changes of the models against reasoning depth. The gray range represents the training data domain (1-5 depth). Figure (4a) shows the performance degradation with the increase of reasoning steps when using the all-at-once strategy. Figure (4b) shows that the combination of step-by-step output and backward/exhaustive chaining leads to successful generalization.

Depth	Shortest	Backward	Exhaustive
6	99.3/99.3	100/ 100	99.7/99.7
8	95.5/95.7	100/ 100	99.8/99.8
12	76.7/77.7	99.5/99.5	98.2/98.3

Table 1: Accuracy of the T5-base model with the step-by-step output strategy at each depth (chain/answer).

Question: $A=1$, $B=2+A$, $B?$		
Error types	Gold	Prediction
Copying error	$B=2+A$, $B=2+1$, $B=3$	$B=6+A$, $B=6+1$, $B=7$
Hasty assignment	$B=2+A$, $B=2+1$, $B=3$	(skip step) $B=2+2$, $B=4$

Table 2: Illustrative examples of the errors under the step-by-step, shortest-path chaining settings. (skip step) denotes that the reasoning steps is accidentally skipped.

an appropriate reasoning strategy.

We hypothesized that the source of all-at-once’s inferiority was that the decoder overfitted to output a similar length of reasoning steps as those in the (shallower) training data. In fact, the models generated relatively shorter reasoning steps in the out-of-domain (e.g., depth of 12) setting when using the all-at-once strategy (Figure 3); this supports our hypothesis.

The advantage of step-by-step over token-by-token suggests the advantage of breaking the problem into meaningful units (reasoning step) and modeling each step in a single call of the encoder-decoder.

3.2 Chaining strategies

Figure 4b and Table 1 show the results on each depth with a fixed step-by-step output strategy.

Note that the accuracy of the chain (left side of the scores) was measured based on not an exact match but mathematically. For example, even if the order of generated equations is different, it is correct. The results of a fixed token-by-token output strategy are in Appendix B.

While the performance dropped in the shortest-path setting as the reasoning depth increased, with either the exhaustive or backward chaining, models successfully solved the task even when extrapolating to depths 6-12. The models correctly generated the intermediate steps (nearly perfect) as well as the final answer in the exhaustive and backward chaining settings (Table 1). Note that these strategies were ineffective with all-at-once outputting.

Gontier et al. (2020) compared chaining strategies and concluded that models that *didn’t* generate reasoning steps had better generalization performance than models that did when the reasoning chains were long. However, our results suggest that the choice of the appropriate output strategy improves the reasoning ability of the model.

We considered that the source of shortest-path inferiority was the rough granularity of the given reasoning steps. The models don’t know the shortest path before outputting the reasoning steps. Therefore, both the exhaustive and shortest path chaining approaches must search for variables other than those on the shortest path. As shown in Figure 2b, the exhaustive chaining approach is taught this process explicitly. On the other hand, the shortest-path chaining approach must be learned that by training data that don’t include this process. We thought this difference affected the accuracy and concluded that **the accuracy is higher when the granularity of given intermediate steps is**

finer, even though they are long.

Therefore, we concluded that **the accuracy is higher when the granularity of intermediate steps is finer**, even though they are long.

3.3 Error analysis

We also analyzed the errors of the depth-12 instances under the shortest-path strategy.⁴ We observed two types of errors: (i) copying errors and (ii) hasty assignment. Table 2 shows an illustrative example of each error type and the percentage of these errors. The most frequent one (53%) was a simple copying error, where the model failed to accurately copy an original equation into the reasoning chain. This erroneous copying ability is consistent with Xu et al. (2020) and supports the advantage of introducing a copy mechanism to the model (Ontanon et al., 2022). Second, a hasty assignment is the model skipping the step to copy the equation from context and instead assigned it a random value. Note that these errors were almost addressed in the other strategies; this could stem from the difficulty of the implicit calculation of the shortest path.

3.4 Models' scalability

To investigate the scalability, we compared T5-large with T5-base. Figure 5 shows the result. T5-large had a similar trend but slightly lower accuracy on all-at-once and step-by-step compared to T5-base. The reason may be that T5-large needs more data for updating the weights of the entire model. On the other hand, the accuracy of T5-large is higher than T5-base on token-by-token. It's because the data size of token-by-token is as token lengths of output sequence times as the data size of all-at-once, as shown in Figure 2a. This result indicates that the parameter size of the model needs to be larger to output token-by-token.

4 Conclusions

We investigated and factorized the reasoning strategy in symbolic numerical reasoning with neural seq2seq models. We found that the combination of step-by-step output and finely granular reasoning leads to successfully performing symbolic reasoning. Our results support the potential of neural models for symbolic reasoning.

⁴In total, 32 instances were analyzed. That is the total number of incorrect answers on one seed.

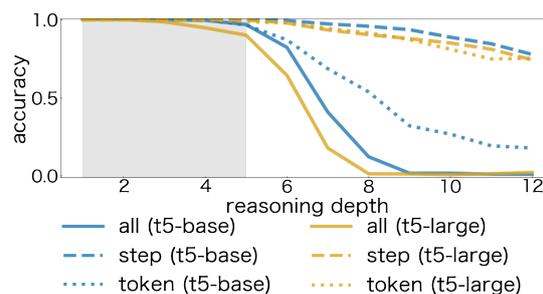

Figure 5: Accuracy changes of the T5-base and T5-large against reasoning depth. The gray range presents the training data domain (1-5 depth). This figure shows that the accuracy of T5-large with token-by-token is higher.

Limitations

We found that even simple symbolic reasoning requires the appropriate selection of reasoning strategy. It is unclear whether our findings generalize to more complex symbolic reasoning and/or problems written in natural language. If our findings do not generalize in these different settings, we must address the gap in future work. For example, we start with one of the simplest tasks and find out when models fail as we add complexity to tasks one by one.

From the engineering perspective, the iterative strategies are limited to the input length of the model. For example, in our experiments, when adopting the setting where reasoning depths are greater than 13, the input length of step-by-step and token-by-token became longer than the input length limit of T5 (i.e., 512 tokens).

In addition, gigantic language models (e.g., GPT-3) have recently been used. Including these models in our study is one of our future works.

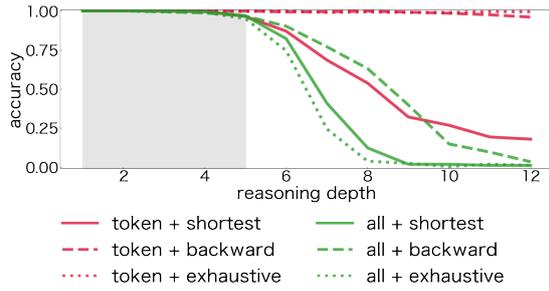

Figure 6: Accuracy changes of token-by-token per reasoning depth. The gray range presents the training data domain (depths 1-5).

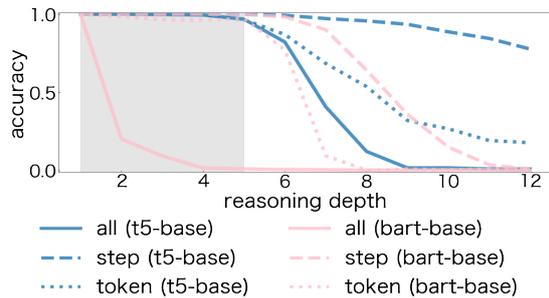

Figure 7: Accuracy changes of the T5-base and BART-base models per reasoning depth. The gray range presents the training data domain (depths 1-5). T5 seems to outperform BART.

A Details on Experimental Settings

We first examined the learning rate from 10^{-3} , 10^{-4} , and 10^{-5} ; among them, we used the largest rate at which the loss converged. After training models, we used the model with the lowest validation loss among the per-epoch checkpoints during the training reported. We used four NVIDIA V100 GPUs for NVLink 16GiB HBM2.

B Results of Token-by-token

Figure 6 shows the results on each depth with a fixed token-by-token output strategy. Like step-by-step, the performance drops in the shortest-path setting as the reasoning depth increases. In addition, the exhaustive or backward successfully solves the task even when extrapolating to depths 6-12.

C Different Architectures

We also tested BART-base (Lewis et al., 2020) as a baseline to investigate the effectiveness of the NLP-task-oriented objectives used in the T5-style pre-training. Figure 7 shows this result. In this

particular setting, T5 was superior to BART. This suggests that the NLP-task-oriented objectives benefit symbolic reasoning.

D Other errors

We analyzed the cases where the answer is correct and the chain is wrong. Table 3 shows examples of chain errors. Ignoring the incorrect step is an example of the model outputting the correct reasoning step after outputting an incorrect one. Correct assignment is an example in which the assignment accidentally makes the model output the correct step. Finally, Non-affecting error is an example in which a variable not on the shortest path is wrongly assigned a value.

Question: $A=1$, $C=5+B$, $B=2+A$, $D=3+A$, $C?$

Chain error types	Gold	Prediction
Ignoring the incorrect step	$A=1$, $B=2+A$, $B=2+1$, $B=3$, $C=5+B$, $C=5+3$, $C=8$	$A=1$, $B=2+D$, $B=2+A$, $B=2+1$, $B=3$, $C=5+B$, $C=5+3$, $C=8$
Correct assignment	$A=1$, $B=2+A$, $B=2+1$, $B=3$, $C=5+B$, $C=5+3$, $C=8$	$A=1$, $B=2+D$, $B=2+1$, $B=3$, $C=5+B$, $C=5+3$, $C=8$
Non affecting error	$A=1$, $B=2+A$, $B=2+1$, $B=3$, $C=5+B$, $C=5+3$, $C=8$	$A=1$, $B=2+A$, $B=2+1$, $B=3$, $D=3+A$, $D=3+2$, $D=5$, $C=5+B$, $C=5+3$, $C=8$

Table 3: These instances are examples of chain errors. Note that the final answers are correct.

Analyzing the Effectiveness of the Underlying Reasoning Tasks in Multi-hop Question Answering

Abstract

To explain the predicted answers and evaluate the reasoning abilities of models, several studies have utilized underlying reasoning (UR) tasks in multi-hop question answering (QA) datasets. However, it remains an open question as to how effective UR tasks are for the QA task when training models on both tasks in an end-to-end manner. In this study, we address this question by analyzing the effectiveness of UR tasks (including both sentence-level and entity-level tasks) in three aspects: (1) QA performance, (2) reasoning shortcuts, and (3) robustness. While the previous models have not been explicitly trained on an entity-level reasoning prediction task, we build a multi-task model that performs three tasks together: sentence-level supporting facts prediction, entity-level reasoning prediction, and answer prediction. Experimental results on 2WikiMultiHopQA and HotpotQA-small datasets reveal that (1) UR tasks can improve QA performance. Using four debiased datasets that are newly created, we demonstrate that (2) UR tasks are helpful in preventing reasoning shortcuts in the multi-hop QA task. However, we find that (3) UR tasks do not contribute to improving the robustness of the model on adversarial questions, such as sub-questions and inverted questions. We encourage future studies to investigate the effectiveness of entity-level reasoning in the form of natural language questions (e.g., sub-question forms).¹

1 Introduction

The task of multi-hop question answering (QA) requires a model to read and aggregate information from multiple paragraphs to answer a given question (Figure 1a). Several multi-hop QA datasets have been proposed, such as QAngaroo (Welbl et al., 2018), HotpotQA (Yang et al., 2018), and

MuSiQue (Trivedi et al., 2022). In HotpotQA, the authors provide sentence-level supporting facts (SFs) to test the reasoning ability and explainability of the models. However, owing to the design of the sentence-level SFs task (binary classification) and the redundant information in the sentences, Inoue et al. (2020) and Ho et al. (2020) show that the sentence-level SFs are insufficient to explain and evaluate multi-hop models in detail. To address this issue, R⁴C (Inoue et al., 2020) and 2WikiMultiHopQA (2Wiki; Ho et al., 2020) datasets provide an entity-level reasoning prediction task to explain and evaluate the process of answering questions. Entity-level reasoning information is defined as a set of triples that describes the reasoning path from question to answer (Figure 1b).

Several previous studies (Chen et al., 2019; Fu et al., 2021a) utilize sentence-level SFs and/or entity-level reasoning information to build explainable models by using question decomposition (Min et al., 2019b; Perez et al., 2020) or predicting sentence-level SFs. The advantages of these pipeline models are that they can exploit the underlying reasoning (UR) process in QA and their predicted answers are more interpretable. However, the question remains as to how effective training on UR tasks is for the QA task in an end-to-end manner. Although a few end-to-end models have also been introduced (Qiu et al., 2019; Fang et al., 2020), these models are not explicitly trained on entity-level and answer prediction tasks.

In addition to the triple form, the sub-question form is another way to utilize entity-level reasoning information. Specifically, Tang et al. (2021) utilize question decomposition as an additional sub-question evaluation for bridge questions (there are two types of questions: bridge and comparison) in HotpotQA. They only use sub-questions for evaluation and do not fine-tune the models on them. In addition, Ho et al. (2022) use sub-questions for both evaluation and training. However, they only

a) Standard QA task format	b) UR tasks and three aspects	c) Debiased and Adversarial examples

Figure 1: Example of (a) a standard multi-hop question, (b) two underlying reasoning tasks in the QA process and three aspects in our analysis, ‘+’ and ‘-’ indicate that the UR tasks have a positive and negative impacts, respectively, and (c) debiased and adversarial examples that are used in our study.

focus on comparison questions for date information. In contrast, we focus on the triple form of the entity-level information and conduct experiments using two datasets, 2Wiki and HotpotQA-small (obtained by combining HotpotQA and R⁴C), which include both types of questions.

In this study, we analyze the effectiveness of UR tasks (including both sentence-level and entity-level) in three aspects: (1) *QA performance*, (2) *reasoning shortcuts*, and (3) *robustness*. First, QA performance is the final objective of the QA task. We aim to answer the following question: **(RQ1)** *Can the UR tasks improve QA performance?* For the second aspect, previous studies (Chen and Durrett, 2019; Jiang and Bansal, 2019a; Min et al., 2019a; Trivedi et al., 2020) demonstrate that many questions in the multi-hop QA task contain biases and reasoning shortcuts (Geirhos et al., 2020), where the models can answer the questions by using heuristics. Therefore, we aim to ask the following: **(RQ2)** *Can the UR tasks prevent reasoning shortcuts?* For the final aspect, to ensure safe development of NLP models, robustness is one of the important issues and has gained tremendous amount of research (Wang et al., 2022). In this study, we aim to test the robustness of the model by asking modified versions of questions, such as sub-questions and inverted questions. Our question is **(RQ3)** *Do the UR tasks make the models more robust?*

There are no existing end-to-end models that can perform three tasks simultaneously (sentence-level SFs prediction, entity-level prediction, and answer prediction); therefore, we first build a multi-hop BigBird-base model (Zaheer et al., 2020) to perform these three tasks simultaneously. We then evaluate our model using two multi-hop datasets: 2Wiki and HotpotQA-small. To investigate the ef-

fectiveness of the UR tasks, for each dataset, we conduct three additional experiments in which the model is trained on: (1) answer prediction task, (2) answer prediction and sentence-level prediction tasks, and (3) answer prediction and entity-level prediction tasks. We also create four debiased sets (Figure 1c) for 2Wiki and HotpotQA-small for **RQ2**. We create and reuse adversarial questions for 2Wiki and HotpotQA-small for **RQ3**.

The experimental results indicate that the UR tasks can improve QA performance from 77.9 to 79.4 F1 for 2Wiki and from 66.4 to 69.4 F1 for HotpotQA-small (**RQ1**). The results of the models on the four debiased sets reveal that the UR tasks can be used to reduce reasoning shortcuts (**RQ2**). Specifically, when the model is trained on both answer prediction and UR tasks, the performance drop of the model on the debiased sets is lower than that when the model is trained only on answer prediction (e.g., 8.9% vs. 13.4% EM). The results also suggest that the UR tasks do not make the model more robust on adversarial questions, such as sub-questions and inverted questions (**RQ3**). Our analysis shows that correct reconstruction of the entity-level reasoning task contributes to finding the correct answer in only 37.5% of cases. This implies that using entity-level reasoning information in the form of triples does not answer adversarial questions, in this case, the sub-questions. We encourage future work to discover the effectiveness of the entity-level reasoning task in the form of sub-questions that have the same form as multi-hop QA questions.

2 Background

Reasoning Tasks in Multi-hop QA In this study, we consider UR tasks in multi-hop QA including two levels: *sentence-level* and *entity-level*. The

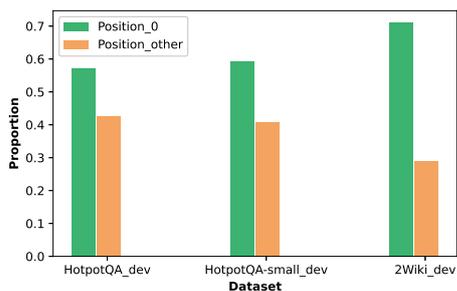

Figure 2: Information on the position of sentence-level SFs in the dev. sets of the three datasets.

sentence-level SFs prediction task was first introduced by Yang et al. (2018). This task requires a model to predict a set of sentences that is necessary to answer a question (Figure 1).

To evaluate the UR process of the models, derivation and evidence information were introduced in R⁴C and 2Wiki, respectively. Both derivation and evidence are sets of triples that represent the reasoning path from question to answer. The difference is the form; derivation in R⁴C uses a semi-structured natural language form, whereas evidence in 2Wiki uses a structured form. We conduct experiments with both R⁴C (HotpotQA-small) and 2Wiki. For consistency, we use the term *entity-level reasoning prediction task* to denote the derivation task in R⁴C and the evidence task in 2Wiki.

Reasoning Shortcuts and Biases In this study, we consider both reasoning shortcuts and biases to be similar. These are spurious correlations in the dataset that allow a model to answer the question correctly without performing the expected reasoning skills, such as comparison and multi-hop reasoning. Following previous studies (Jiang and Bansal, 2019a; Ko et al., 2020), we use the terms *word overlap shortcut* and *position bias*.

To check whether the UR tasks can prevent reasoning shortcuts, we first identify the types of shortcuts that exist in HotpotQA-small and 2Wiki. We use heuristics to identify the word overlap shortcut (Appendix A). We find that the word overlap shortcut is common in HotpotQA-small, but not in 2Wiki. The small sample size of HotpotQA-small (Section 4) increases the uncertainty of the obtained results. Therefore, within the scope of this study, we mainly experiment with position bias.

We observe that many examples in 2Wiki contain answers in the first sentence. Therefore, we divide every sentence-level SF in each gold para-

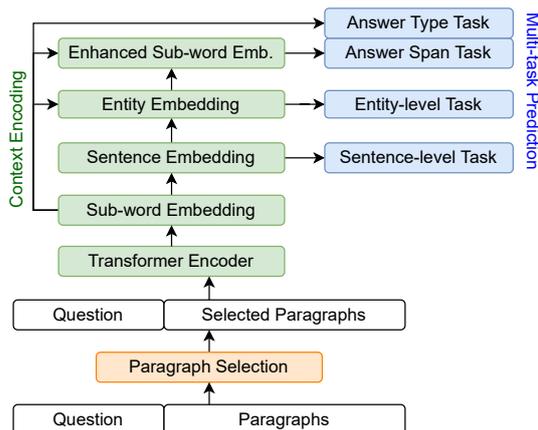

Figure 3: Our model has three main steps: paragraph selection, context encoding, and multi-task prediction.

graph into two levels: the first sentence (position_0) and the remaining sentences (position_other). Subsequently, we obtain the percentage of each level by dividing the total number of each level (e.g., position_0) by the total number of SFs. Figure 2 illustrates the information on the position of sentence-level SFs in dev. sets of three datasets. We find that all three datasets have a bias toward the first sentence. We also find that 2Wiki has more position biases than HotpotQA and HotpotQA-small.

3 Our Multi-task Model

To investigate the usefulness of UR tasks for the QA task, we jointly train the corresponding tasks: sentence-level SFs prediction, entity-level prediction, and answer prediction. Figure 3 illustrates our model. To handle long texts, we use the Big-Bird model (Zaheer et al., 2020), which is available in Hugging Face’s transformers repository.² Our model comprises three main steps: (1) paragraph selection, (2) context encoding, and (3) multi-task prediction. We use the named entity recognition (NER) models of Spacy³ and Flair (Akbik et al., 2019) to extract all entities in the context and use them for the entity-level prediction task.

Paragraph Selection Following previous models (Qiu et al., 2019; Fang et al., 2020; Tu et al., 2020), instead of using all the provided paragraphs, we first filter out answer-unrelated paragraphs. We follow the paragraph selection process described in Fang et al. (2020). First, we retrieve first-hop

²https://huggingface.co/transformers/model_doc/bigbird.html

³<https://spacy.io/>

paragraphs by using title matching or entity matching. We then retrieve second-hop paragraphs using the hyperlink information available in Wikipedia. When we retrieve paragraphs, we reuse a paragraph ranker model⁴ from the hierarchical graph network (HGN) model (Fang et al., 2020) to rank input paragraphs using the probability of whether they contain sentence-level SFs.

Context Encoding To obtain vector representations for sentences and entities, we first combine all the selected paragraphs into one long paragraph and then concatenate it with the question to form a context C . Specifically, $C = [[\text{CLS}], q_1, \dots, q_m, [\text{SEP}], p_1, \dots, p_n, [\text{SEP}]]$, where m and n are the lengths of the question q and the combined paragraph p (all selected paragraphs), respectively. The context C is then tokenized into l sub-words before feeding into BigBird to obtain the contextual representation C' of the sub-words:

$$C' = \text{BigBird}(C) \in \mathbb{R}^{l \times h}, \quad (1)$$

where h is the hidden size of the BigBird model. Next, we obtain the representation $s_i \in \mathbb{R}^{2h}$ of the i -th sentence and the representation $e_j \in \mathbb{R}^{4h+d_t}$ of the j -th entity, as follows:

$$\begin{aligned} s_i &= C'_{S_{\text{start}}^i}; C'_{S_{\text{end}}^i} \\ e_j &= C'_{E_{\text{start}}^j}; C'_{E_{\text{end}}^j}; t_j; s_k, \end{aligned} \quad (2)$$

where $[\cdot]$ denotes the concatenation of the two vectors, $C'_{S_{\text{start}}^i}$ and $C'_{E_{\text{start}}^j}$ denote the first sub-word representations of the i -th sentence and j -th entity, respectively. $C'_{S_{\text{end}}^i}$ and $C'_{E_{\text{end}}^j}$ denote the last sub-word representations of the i -th sentence and j -th entity, respectively. We enrich the entity embedding e_j by concatenating it with a d_t -dimensional type embedding t_j and a sentence embedding s_k , where k is the index of the sentence containing the j -th entity.

We also leverage the entity information to improve the contextual representation of sub-words C' as it is mainly used for the answer prediction task, which will be described in the next section. Thus, the enhanced sub-word representation C''_i of the i -th sub-word is calculated as follows:

$$C''_i = C'_i; e_k \in \mathbb{R}^{5h+d_t}, \quad (3)$$

where e_k is the embedding of the k -th entity containing the i -th sub-word. Otherwise, e_k is a null vector with the same dimension.

⁴<https://github.com/yuwfan/HGN>

Multi-task Prediction After context encoding, we train our model on three main tasks together: (1) sentence-level prediction, (2) entity-level prediction, (3) and answer prediction. We split the answer prediction task into two sub-tasks, similar to previous studies (Yang et al., 2018; Fang et al., 2020), including answer type prediction and answer span prediction. We train our model by minimizing the joint loss for all tasks, as follows:

$$\begin{aligned} L_{\text{joint}} &= \lambda_{\text{sent}} L_{\text{sent}} + \lambda_{\text{ent}} L_{\text{ent}} + \\ &\lambda_{\text{ans}} (L_{\text{start}} + L_{\text{end}} + L_{\text{type}}), \end{aligned} \quad (4)$$

where λ_{sent} , λ_{ent} , and λ_{ans} are the hyper-parameters for three tasks: sentence-level prediction, entity-level prediction, and answer prediction (details are given in Appendix B.1).

For the sentence-level prediction task, we use a binary classifier to predict whether a sentence is a supporting fact. For the answer type prediction task, we use a 4-way classifier to predict the probabilities of *yes*, *no*, *span*, and *no answer*. Two linear classifiers are used for the answer span prediction task to independently predict the start and end tokens of the answer span.

Different from existing end-to-end models (Qiu et al., 2019; Fang et al., 2020), our model is explicitly trained on the entity-level prediction task. We formalize the entity-level reasoning prediction task as a relation extraction task (Zhang and Wang, 2015). The input is a pair of entities, and the output is the relationship between two entities. From all named entities obtained by using the NER models, we generate a set of entity pairs; for example, given N entities, we obtain $N \times (N - 1)$ pairs. For each pair, we predict a relationship in a set of predefined relationships obtained from the training set. We then use cross-entropy as the learning objective.

4 Datasets and Evaluation Metrics

We mainly experiment with 2Wiki and HotpotQA-small. We also train and evaluate our model on the full version of HotpotQA. We reuse and create debiased and adversarial sets for the evaluation. Table 1 presents the statistics for 2Wiki, HotpotQA-small, and additional evaluation sets. The details of HotpotQA and 2Wiki are presented in Appendix B.2. It should be noted that all datasets are in English.

4.1 HotpotQA-small

R⁴C (Inoue et al., 2020) is created by adding entity-level reasoning information to the samples

Split	2Wiki	HotpotQA-small
Train	167,454	3,671
Dev.	12,576	917
Test	12,576	-
Debiased	12,576 (x4)	917 (x4)
Adversarial	12,576	659 & 134

Table 1: Statistics for 2Wiki and HotpotQA-small. There are four debiased sets in 2Wiki and HotpotQA-small. There are one adversarial set in 2Wiki and two adversarial sets in HotpotQA-small.

in HotpotQA. We obtain HotpotQA-small by combining HotpotQA (Yang et al., 2018) with R⁴C. HotpotQA-small comprises three tasks as in 2Wiki: (1) sentence-level SFs prediction, (2) entity-level prediction, and (3) answer prediction. First, we re-split the ratio between the training and dev. sets; the new sizes are 3,671 and 917 for the training and dev. sets, respectively (the original sizes are 2,379 and 2,209, respectively). In R⁴C, there are three gold annotations for the entity-level prediction task; in 2Wiki, there is only one gold annotation. For consistency in the evaluation and analysis, we randomly choose one annotation from the three annotations for every sample in R⁴C.

The entity-level reasoning in R⁴C is created by crowdsourcing. We observe that there are many similar relations in the triples in R⁴C, and these relations can be grouped into one. For example, *is in*, *is located in*, *is in the*, and *is located in the* indicate location relation. We also group the relations by removing the context information in the relations; for example, *is a 2015 book by* and *is the second book by* are considered similar to the relation *is a book by*. After grouping, the number of relations in R⁴C is 2,526 (it is 4,791 before).

4.2 Debiased Dataset

The objective of our debiased dataset is to introduce a small perturbation in each paragraph to mitigate a specific type of bias, in our case, the position bias shown in Figure 2. For both 2Wiki and HotpotQA-small, we use the same method to generate four debiased sets: ADDUNRELATED, ADDRELATED, ADD2, and ADD2SWAP. The differences between these four sets are whether the sentence is related or unrelated to the paragraph and whether we add one or two sentences into the paragraph. The details of each set are as follows.

ADDUNRELATED: One sentence unrelated to the paragraph is added. In our experiment, we use a list of sentences in the sentence-level revision dataset (Tan and Lee, 2014). We randomly choose one sentence that has a number of tokens greater than eleven but less than twenty-one.

ADDERELATED: One sentence that does not have an impact on the meaning or flow of the paragraph is added. In our experiment, we write multiple templates for each entity type (e.g., for a film entity, “#Name is a nice film”, where #Name is the title of the paragraph), then randomly choose one template, and add it to the paragraph. To detect the type of the paragraph, we use the question type information in 2Wiki and HotpotQA-small, the results of the NER model, and the important keywords in the question (e.g., who, magazine, album, and film).

ADD2: ADDRELATED and ADDUNRELATED are combined in order.

ADD2SWAP: The order of ADDRELATED and ADDUNRELATED in ADD2 is swapped.

4.3 Adversarial Dataset

The objective of our adversarial dataset is to check the robustness of the model by asking modified versions of questions. For HotpotQA-small, we reuse two versions of adversarial examples in Geva et al. (2022). The first one is automatically generated by using the ‘Break, Perturb, Build’ (BPB) framework in Geva et al. (2022). The BPB framework performs three main steps: (1) breaking a question into multiple reasoning steps, (2) perturbing the reasoning steps by using a list of defined rules, and (3) building new QA samples from the perturbations in step #2. The second version is a subset of the first version and is validated by crowd workers. We only use the examples in these two versions that the original examples appear in HotpotQA-small.

For 2Wiki, no adversarial dataset is available. Based on the idea of the BPB framework in Geva et al. (2022), we apply two main rules from BPB for 2Wiki: (1) replace the comparison operation for comparison questions, and (2) use the prune step for bridge questions. For the first rule, we replace the operation in the comparison questions (e.g., “Who was born first, A or B?” is converted to “Who was born later, A or B?”). For the second rule, we use a sub-question in the QA process as the main question (e.g., for Figure 1, we ask, “Who is the father of Joan of Valois?”).

Dataset	Task Setting	Answer		Sentence-level		Entity-level	
		EM	F1	EM	F1	EM	F1
2Wiki	(1) Ans	72.03	77.87	-	-	-	-
	(2) Ans + Sent	72.82	78.65	78.06	92.38	-	-
	(3) Ans + Ent	72.33	78.21	-	-	46.11	76.65
	(4) Ans + Sent + Ent	73.60	79.37	78.46	92.68	45.97	76.69
HotpotQA-small	(1) Ans	52.89	66.43	-	-	-	-
	(2) Ans + Sent	54.42	69.03	75.35	91.00	-	-

	(4) Ans + Sent + Ent	54.74	69.44	75.14	90.88	6.43	31.05

Table 2: Ablation study results (%) of our model in the dev. sets of 2Wiki and HotpotQA-small. *Ans*, *Sent*, and *Ent* represent the answer prediction task, sentence-level SFs prediction task, and entity-level prediction task, respectively. ‘Task Setting’ represents the tasks that the model is trained on. ‘-’ indicates the tasks the model is not trained on.

4.4 Evaluation Metrics

Each task in HotpotQA and 2Wiki is evaluated by using two metrics: exact match (EM) and F1 score. Following the evaluation script in HotpotQA and 2Wiki, we use joint EM and joint F1 to evaluate the entire capacity of the model. For HotpotQA, they are the products of the scores of two tasks: sentence-level prediction and answer prediction. For 2Wiki and HotpotQA-small, they are the products of the scores of three tasks: sentence-level prediction, entity-level prediction, and answer prediction.

5 Results

Currently, there are no existing end-to-end models that explicitly train all three tasks together; therefore, in this study, we use our proposed model for analysis. We also compare our model with other previous models on the HotpotQA and 2Wiki datasets. In general, the experimental results indicate that our model is comparable to previous models and can be used for further analyses. We focus more on the analysis; therefore, the detailed results of the comparison are presented in Appendix B.3.

5.1 Effectiveness of the UR Tasks

To investigate the effectiveness of the UR tasks, we train the model in four settings: (1) answer prediction only, (2) answer prediction and sentence-level SFs prediction, (3) answer prediction and entity-level prediction, and (4) all three tasks together.

QA Performance (RQ1) Our first research question is whether the UR tasks can improve QA performance. To answer this question, we compare the

results of different task settings described above. The results are presented in Table 2. For 2Wiki, using sentence-level and entity-level separately (settings #2 and #3), the QA performance does not change significantly. The improvement is significant when we combine both the sentence-level and entity-level (setting #4). Specifically, the scores when the model is trained on the answer prediction task only (setting #1) and on both the answer prediction task and UR tasks (setting #4) are 77.9 and 79.4 F1, respectively. In contrast to 2Wiki, using sentence-level and entity-level separately, there is a larger QA performance improvement in HotpotQA-small. Specifically, the F1 scores of settings #2 and #3 are 69.0 and 69.1, respectively, whereas, the F1 score of the first setting is 66.4. Similar to 2Wiki, there is a large gap between the two settings, #1 and #4 (66.4 F1 and 69.4 F1, respectively).

In summary, these results indicate that both sentence-level and entity-level prediction tasks contribute to improving QA performance. These results align with the findings in Yang et al. (2018), which shows that incorporating the sentence-level SFs prediction task can improve QA performance. We also find that when combining both sentence-level and entity-level prediction tasks, the scores of the answer prediction task are the highest.

Reasoning Shortcuts (RQ2) To investigate whether explicitly optimizing the model on the UR tasks can prevent reasoning shortcuts, we evaluate the four settings of the model on the four debiased sets of 2Wiki and HotpotQA-small. The generation of the debiased sets includes stochastic steps. To minimize the impact of randomness on our re-

Table 3: Average performance drop from five times running (smaller is better) of the four settings on the four debiased sets of 2Wiki and HotpotQA-small. The best and worst scores are boldfaced and underlined, respectively.

ported results, we generate the debiased sets five times and report the average evaluation scores. The average performance drops are presented in Table 3 (detailed scores are given in Appendix B.4).

Overall, for 2Wiki, when the model is trained on only one task (#1), the drop is the largest (except for ADDRELATED, which is the second largest). When the model is trained only on the answer prediction task, the drops are always higher than those when the model is trained on three tasks. Specifically, the gaps between the two settings, #1 (only answer task) and #4 (all three tasks), are 4.5%, 0.4%, 3.2%, 4.5% (EM score) for ADDUNRELATED, ADDRELATED, ADD2, and ADD2SWAP, respectively. These scores indicate that the two tasks, sentence-level and entity-level, positively affect the answer prediction task when the model is trained on three tasks simultaneously.

For HotpotQA-small, we observe that the effectiveness of the UR tasks is inconsistent. For example, for ADDUNRELATED, when training the model on the three tasks (setting #4), the reduction is larger than that when training on answer task only (setting #1) (5.1 vs. 3.0 EM). However, for ADDRELATED, the reduction on setting #4 is smaller than that on setting #1 (1.3 vs. 4.0 EM). One possible reason is that the performance of the entity-level task is not good (6.4 EM), which affects the answer prediction task when the model is trained on the three tasks together. Another possible reason is that the position bias in HotpotQA-small is not sufficiently large. We present a detailed analysis in Section 5.2 to explain this case.

Robustness (RQ3) To test whether the UR tasks can help to improve the robustness of the model,

Task Setting	Dev-adver		Reduction %	
	EM	F1	EM	F1
Ans	37.09	46.07	48.51	40.84
Ans + Sent	34.26	43.64	52.95	44.51
Ans + Ent	32.67	39.43	54.83	49.58
Ans + Sent + Ent	34.19	42.74	53.55	46.15

Table 4: Results of our model in the dev-adversarial set of 2Wiki and the performance drop.

we evaluate the four settings of the model on the adversarial sets. For 2Wiki, the results are presented in Table 4. The scores for all four settings decrease significantly on the adversarial set. The reduction is the smallest when the model is trained on the answer task only. The UR tasks do not make the model more robust on this adversarial set. For HotpotQA-small, we observe the same behavior, that is, when the model is trained on the answer task only, the reduction is the smallest. All results are presented in Table 5. These results indicate that both sentence-level and entity-level prediction tasks do not contribute to improving the robustness of the models on adversarial questions, such as sub-questions and inverted questions. We analyze the results in Section 5.2.

5.2 Analyses

Details of RQ2 To investigate the results concerning RQ2 in more depth, we first analyze the position biases of different types of questions in 2Wiki and HotpotQA-small. We find that the comparison questions have more position biases than the bridge questions in both 2Wiki and HotpotQA-

Task Setting	Dev		Dev-Adver		Adver↓ (%)		Dev-Adver-val		Adver-val↓ (%)	
	EM	F1	EM	F1	EM	F1	EM	F1	EM	F1
(1) Ans	52.89	66.43	40.36	51.23	23.69	22.88	37.31	46.69	29.46	29.72
(2) Ans + Sent	54.42	69.03	41.73	52.50	23.32	23.95	34.33	43.86	36.92	36.46
(3) Ans + Ent	54.74	69.08	42.79	52.16	21.83	24.49	27.61	36.86	49.56	46.64
(4) Ans + Sent + Ent	54.74	69.44	40.52	51.14	25.98	26.35	31.34	38.22	42.75	44.96

Table 5: Results of our model in the dev. and two dev-adversarial sets of HotpotQA-small. ‘Adver’ denotes adversarial and ‘Adver-val’ denotes the adversarial set that was validated by crowd workers.

Task Setting	Correct Ans	Correct Ent	Correct Both Ans & Ent
(3) Ans + Ent	4,109	6,851	2,249 (32.8%)
(4) Ans + Sent + Ent	4,300	6,450	2,420 (37.5%)

Table 6: Number of correct predicted answers, number of correct predicted entity-level reasoning, and number of examples that have both correct predicted answers and correct predicted entity-level reasoning.

small (Appendix B.5). To evaluate the effectiveness of the position bias for each type of question, we evaluate the four settings of the model on the four debiased sets for each type of question in both datasets. All the results are presented in Appendix B.5.

For 2Wiki, we find that most of the answers are in the first sentences in the comparison questions. This large bias is the main reason for the significant reduction in the scores in the comparison questions. 2Wiki has 46.0% of comparison questions. The reduction in comparison questions contributes to the reduction in the entire dataset. In other words, the results of 2Wiki are affected by those of the comparison questions. HotpotQA-small has only 22.0% of comparison questions, and the position bias in the comparison questions was not sufficiently large. Therefore, the position bias does not have a significant impact on the main QA task. In other words, the UR tasks do not have a significant effect.

Details of RQ3 The adversarial questions used in RQ3 are the sub-questions in the QA process for bridge questions and the inverted questions for comparison questions. We observe that the triple in the entity-level task is helpful in answering the sub-questions. For example, the triple is: (*Charles of Valois, father, Philip III of France*) and the sub-question is “Who is the father of Charles of Valois?”. To understand more on the behaviors of the model, we analyze the results from 2Wiki in two

settings: (3) Ans + Ent and (4) Ans + Sent + Ent. Table 6 presents the detailed results for these two settings. We find that correct reconstruction of the entity-level reasoning task contributes to finding the correct answer only in 32.8% of cases in setting #3 and only in 37.5% of cases in setting #4. Entity-level reasoning in the form of triples has no significant effect on the main QA process. Several examples are presented in Appendix B.5.

We conjecture that there are three possible reasons why the UR tasks cannot contribute to the adversarial dataset. The first one is the difference in the form and design of the tasks. Specifically, the entity-level reasoning task is formulated as a relation extraction task; the input is a pair of entities, and the output is a relation label. Meanwhile, the adversarial dataset is formulated as a QA task; the input is a natural language question, and the output is an answer. The second reason is the incompetence of the entity-level reasoning information. As discussed in Ho et al. (2022), the entity-level reasoning in the comparison questions does not describe the full path from question to answer, and other reasoning operations are required to obtain the answer. The final reason is the manner in which we utilize the entity-level reasoning information. Our model does not consider the order of the triples in the reasoning chain. For example, we do not consider the order of the two steps in Figure 1b. We hope that our research will inspire future studies to investigate the effectiveness of the UR tasks in the form of a natural language question, which has the same form as a multi-hop QA question.

6 Related Work

Multi-hop Datasets and Analyses To test the reasoning abilities of the models, many multi-hop QA datasets (Welbl et al., 2018; Talmor and Berant, 2018; Yang et al., 2018) have been proposed. Recently, Trivedi et al. (2022) introduced MuSiQue, a

multi-hop dataset constructed from a composition of single-hop questions. The reason why do we not conduct experiments on MuSiQue is explained in the limitations section.

In addition to Tang et al. (2021) and Ho et al. (2022), the most similar to our research mentioned in the Introduction, there are some other existing studies (Chen and Durrett, 2019; Jiang and Bansal, 2019a; Min et al., 2019a; Trivedi et al., 2020) on the analysis and investigation of the multi-hop datasets and models. However, most of them do not utilize the internal reasoning information when answering questions.

Multi-hop Models Various directions have been proposed for solving multi-hop datasets, including question decomposition (Talmor and Berant, 2018; Jiang and Bansal, 2019b; Min et al., 2019b; Perez et al., 2020; Wolfson et al., 2020; Fu et al., 2021a), iterative retrieval (Feldman and El-Yaniv, 2019; Asai et al., 2020; Qi et al., 2021), graph neural networks (Song et al., 2018; De Cao et al., 2019; Ding et al., 2019; Qiu et al., 2019; Tu et al., 2019; Fang et al., 2020), and other approaches such as single-hop based models (Yang et al., 2018; Nishida et al., 2019) or transformer-based models (Devlin et al., 2019; Zaheer et al., 2020). Our model is based on the BigBird transformer model.

Other QA Reasoning Datasets In addition to multi-hop reasoning datasets, several other existing datasets also aim to evaluate the reasoning abilities of the models. Some of them are: DROP (Dua et al., 2019) for numerical reasoning; CLUTRR (Sinha et al., 2019), ReClor (Yu et al., 2020), and LogiQA (Liu et al., 2020) for logical reasoning; Quoref (Dasigi et al., 2019) for coreference reasoning; CommonsenseQA (Talmor et al., 2019), MCScript2.0 (Ostermann et al., 2019), and CosmosQA (Huang et al., 2019) for commonsense reasoning. Many of these datasets consist of only a single paragraph in the input or lack explanation information that describes the reasoning process from question to answer. However, our focus is on multi-hop reasoning datasets that contain multiple paragraphs in the input and provide explanatory information for the QA process.

7 Conclusion

We analyze the effectiveness of the underlying reasoning tasks using two multi-hop datasets: 2Wiki and HotpotQA-small. The results reveal that the

underlying reasoning tasks can improve QA performance. Using four debiased sets, we demonstrate that the underlying reasoning tasks can reduce the reasoning shortcuts of the QA task. The results also reveal that the underlying reasoning tasks do not make the models more robust on adversarial examples, such as sub-questions and inverted questions. We encourage future studies to investigate the effectiveness of the entity-level reasoning task in the form of sub-questions.

Limitations

Our study has two main limitations. The first one is the small size of HotpotQA-small. Currently, there are no other multi-hop datasets that contain a large number of examples with the entity-level reasoning prediction task. MuSiQue is the most potential option. The entity-level reasoning information in MuSiQue includes two types of formats: triple format and natural language question format. We do not experiment with MuSiQue because the number of examples that have entity-level reasoning information in the form of a triple is small: 2,253 out of 19,938 in the training set and 212 out of 2,417 in the dev. set.

The second limitation is that our model does not consider the order of the triples in the entity-level reasoning prediction task. As shown in Figure 1b, the two triples are ordered. However, our model formulates the entity-level prediction task as a relation extraction task. We predict a relation given the two entities detected by the NER models. Therefore, the order of the triples is not considered. We conjecture that this may be one of the reasons why the entity-level reasoning prediction task (e.g., a triple (*Film A*, *director*, *D*)) does not support the model when answering sub-questions (e.g., *Who is the director of Film A?*) using the same information.

A Word Overlap Shortcut

Using adversarial methods, Jiang and Bansal (2019a) show that examples in HotpotQA often contain word overlap shortcut, where the models can answer the questions by performing word-matching between the question and a sentence in the context.

Based on this finding, we automatically calculate the word overlap shortcut for 2Wiki and HotpotQA-small. We observe that the word overlap shortcut is common in bridge questions; therefore, we only calculate the word overlap shortcut for bridge questions in 2Wiki and HotpotQA-small. To check whether a sample contains the word overlap shortcut, we do the following steps:

- Obtain a set of surrounding words S by getting the five words immediately to the left and right of the answer span, then remove stopwords in S .
- Obtain a set of overlapping words (O) between S and a question.
- We consider a sample containing the word overlap shortcut if there are at least two words in O and $\frac{|O|}{|S|} \geq 0.65$. These numbers (threshold) are chosen based on the evaluation of 40 examples that are manually annotated by the authors.

We find that there are 56 out of 5,791 and 151 out of 715 examples (5,791 and 715 are the numbers of bridge questions in 2Wiki and HotpotQA-small) in the dev. sets of 2Wiki and HotpotQA-small containing the word overlap shortcut.

It is noted that there is another type of shortcut, namely, entity-type matching shortcut. Based on the experimental results and human performance, Min et al. (2019a) reveal that examples in HotpotQA contain the entity type matching shortcut, where the models can answer the questions by using the first five tokens in the questions; meanwhile, humans can answer the questions by using the entity type of the paragraphs. Currently, there is no dataset that can prevent the entity-type shortcut; therefore, we do not use this type of shortcut in our experiments.

B Experimental Details

B.1 Implementation Details

We use Pytorch (Paszke et al., 2017) and Hugging Face when building our model. For the context encoding step, we use a pre-trained BigBird model as the encoder; the hidden dimension is 768. For the entity-level reasoning prediction task, we obtain 33 relations for 2Wiki and 2,526 relations for R⁴C, from all triples in the training set, including a non-relation type. We use entity type embedding d_t of

50. We fine-tuned our model with a total batch size of 32 on a single GPU (NVIDIA A100 80GB) using mixed precision and a gradient accumulation step of 8. Following the hyperparameters in the BERT model (Devlin et al., 2019), for optimization, we use the Adam Optimizer (Kingma and Ba, 2015) with a learning rate of 3e-5, weight decay of 0.01, learning rate warmup over the first 10% of the total number of training steps, and linear decay of the learning rate. We also use a dropout probability of 0.1 on all layers.

For multi-task prediction, we use λ_{sent} as 4, λ_{ent} as 15, and λ_{ans} as 1 for 2Wiki and HotpotQA-small; we use λ_{sent} as 7 and λ_{ans} as 1 for HotpotQA. We do not run all experiments with different values of λ_{sent} , λ_{ent} , and λ_{ans} ; instead we run several experiments, based on the results, we then adjust the parameters. We find that when running with λ_{sent} as 4 for 2Wiki and 7 for HotpotQA, λ_{ent} as 15, and λ_{ans} as 1, it produces the best results. We fix the random seed for the reproducibility of the results. We observe that the final epoch often produces the best scores, and its scores are stable on adversarial datasets; therefore, we choose the final epoch for all settings in our experiment.

B.2 Datasets

HotpotQA HotpotQA was created by crowdsourcing. Due to the design of the dataset, there are only two tasks in HotpotQA: sentence-level SFs prediction and answer prediction. R⁴C was created based on HotpotQA and contained 4,588 questions. The dataset requires systems to provide an answer and derivation in a semi-structured natural language form. There are two types of questions in HotpotQA: bridge and comparison.

2Wiki 2Wiki was constructed by utilizing a Knowledge Base and Wikipedia, and the questions were created by using templates. There are three different tasks in the dataset: (1) sentence-level SFs prediction, (2) evidence generation (for consistency, we use the term *entity-level prediction*), and (3) answer prediction. The context consists of ten paragraphs, including two or four gold paragraphs and eight or six distractor paragraphs. The gold paragraph contains the information required to find the answer. Meanwhile, the purpose of the distractor paragraph is to distract the models. There are four different types of questions in the dataset: comparison, inference, compositional, and bridge-comparison. Inference and compositional

<p>Question: Who was born first, Albert Einstein or Abraham Lincoln?</p> <p>Paragraph A: Albert Einstein</p> <p>[1] Albert Einstein (14 March 1879 – 18 April 1955) was a ...</p> <p>Paragraph B: Abraham Lincoln</p> <p>[2] Abraham Lincoln (February 12, 1809 – April 15, 1865) was a ...</p> <p>Answer: Abraham Lincoln</p> <p>Sentence-level supporting facts: 1, 2</p> <p>Entity-level reasoning prediction (Evidence):</p> <p>Step 1: ("Albert Einstein", "date of birth", "14 March 1879") &</p> <p>Step 2: ("Abraham Lincoln", "date of birth", "February 12, 1809")</p> <p>Adversarial question: Who was born later, Albert Einstein or Abraham Lincoln?</p>
--

Figure 4: Example of a comparison question from the 2Wiki dataset.

questions are two sub-types of the bridge question. For the convenience of analysis, we consider comparison and bridge-comparison questions as comparison questions. Figure 4 presents an example of a comparison question from the 2Wiki dataset.

2Wiki was designed to focus on the entire reasoning process from question to answer. The entire capacity of the model is evaluated by using two metrics: joint EM and joint F1. To obtain the joint F1 score, they first calculate the joint precision and joint recall as follows: $P^{joint} = P^{ans} P^{ent} P^{sent}$ and $R^{joint} = R^{ans} R^{ent} R^{sent}$. (P^{ans}, R^{ans}) , (P^{ent}, R^{ent}) , (P^{sent}, R^{sent}) represent the precision and recall for three tasks: answer prediction, entity-level reasoning prediction, and sentence-level SFs prediction. The joint EM is 1 when all three tasks achieve an exact match and otherwise 0.

B.3 Results Comparison

We compare our results with three previous models: BiDAF, CRERC, and NA-Reviewer. BiDAF is a baseline model in Ho et al. (2020). CRERC (Fu et al., 2021a) is a pipeline model that includes three modules: relation extractor, reader, and comparator. NA-Reviewer (Fu et al., 2021b) is an improved version of CRERC, as it addresses the error accumulation issue. It is noted that both CRERC and NA-Reviewer models are evaluated on only 2Wiki.

Table 7 presents the results of our model and previous models in the dev. set of HotpotQA and in the test set of 2Wiki. It also shows the performance of our model in the dev. set of HotpotQA-small and human performance in Ho et al. (2020).

Results on HotpotQA Our score is comparable to the BERT-base version of two strong models, SAE (Tu et al., 2020) and HGN (Fang et al., 2020)

in the dev. set of the distractor setting in HotpotQA. Specifically, our joint F1 is 67.8, while for SAE-BERT, it is 66.5, and for HGN-BERT, it is 66.9. However, our score is smaller than the RoBERTa-base of SAE and HGN. They are 72.8 and 74.4 F1 for SAE-RoBERTa and HGN-RoBERTa, respectively. It is noted that we use the BigBird-ITC version in our model. Although the BigBird-ETC version performs better than the BigBird-ITC version, it is not available in Hugging Face. We do not use SAE and HGN for our analyses because these models are not designed to train on the entity-level reasoning prediction task.

Results on HotpotQA-small The scores on HotpotQA-small are lower than those on HotpotQA in the answer prediction task. This result may be explained by the fact that the training size of HotpotQA-small is smaller than HotpotQA (3,671 vs. 90,564). Due to the small size, we only use the gold paragraphs for experiments. That is why the scores on HotpotQA-small are higher than those on HotpotQA in the sentence-level task. For the entity-level task, the EM score is quite low (6.4 EM). A possible reason for this is that there are many relations in HotpotQA-small (2,526 relations); meanwhile, there are only 33 relations in 2Wiki. We observe that the F1 score (31.1 F1) is much better than the EM score. Therefore, we keep using HotpotQA-small for analyses.

Results on 2Wiki Our model significantly outperforms BiDAF in all tasks. Our results are comparable to CRERC. The EM score of our model in the entity-level task is lower than that of CRERC. A possible explanation for this might be that the relation extractor module in CRERC is fine-tuned on 2Wiki; therefore, it can extract entities better than the NER models from Spacy and Flair that are used in our model. However, the F1 score of our model in the entity-level task is higher than that of CRERC. This indicates that our model can correctly obtain a few triples in a set of gold triples for many samples. All our scores (except the F1 score of the entity-level task) are lower than those on NA-Reviewer. Our target is to analyze the UR tasks in an end-to-end model. Although the pipeline models (CRERC and NA-Reviewer) are easy to interpret, we cannot determine how the UR tasks affect answer prediction in an end-to-end model. Therefore, we use the design of our model to perform the analyses in this study.

Dataset	Model	Answer		Sentence-level		Entity-level		Joint	
		EM	F1	EM	F1	EM	F1	EM	F1
HotpotQA	HGN-BERT [‡] (Fang et al., 2020)	<i>N/A</i>	74.76	<i>N/A</i>	86.61	×	×	<i>N/A</i>	66.90
	HGN-RoBERTa (Fang et al., 2020)	68.93	82.18	63.09	88.59	×	×	46.46	74.34
	SAE-BERT (Tu et al., 2020)	61.32	74.81	58.06	85.27	×	×	39.89	66.45
	SAE-RoBERTa (Tu et al., 2020)	67.70	80.75	63.30	87.38	×	×	46.81	72.75
	Our BigBird-base	61.90	76.09	58.54	86.93	×	×	39.39	67.81
HotpotQA-small	Our BigBird-base	54.74	69.44	75.14	90.88	6.43	31.05	4.25	21.69
2Wiki	BiDAF (Ho et al., 2020)	36.53	43.93	24.99	65.26	1.07	14.94	0.35	5.41
	CRERC (Fu et al., 2021a)	69.58	72.33	82.86	90.68	54.86	68.83	49.80	58.99
	NA-Reviewer (Fu et al., 2021b)	76.73	81.91	89.61	94.31	53.66	70.83	52.75	65.23
	Our BigBird-base	74.05	79.68	77.14	92.13	45.75	76.64	39.30	63.24
	Human UB (Ho et al., 2020)	91.00	91.79	88.00	93.75	64.00	78.81	62.00	75.25

Table 7: Results (%) of our model and previous models in the dev. set of HotpotQA and in the test set of 2Wiki. We also show the performance of our model in the dev. set of HotpotQA-small. *Answer*, *Sentence-level*, and *Entity-level* represent the answer prediction task, sentence-level prediction task, and entity-level prediction task, respectively. For HGN-BERT, the scores that we obtained (from left to right: 58.93 73.18 54.64 85.34 35.11 64.24) are lower than the reported scores in HGN (Fang et al., 2020); therefore, we show the reported F1 scores in HGN.

B.4 Effectiveness of the UR Tasks

Reasoning Shortcuts (RQ2) Table 8 presents the performance drop (smaller is better) for five times running of the four settings of the model on the four debiased sets of 2Wiki and HotpotQA-small. As depicted in the table, for 2Wiki, the gap between two settings #1 (answer prediction task only) and #4 (all three tasks) is consistent in all five times running. Meanwhile, for HotpotQA-small, the gap between two settings #1 (answer prediction task only) and #4 (all three tasks) is inconsistent in all five times running. This observation supports our explanation in Section 5.2 that the position bias in HotpotQA-small does not have a large impact on the main QA task.

B.5 Analyses

Details of RQ2 Figure 5 illustrates the information on the position of sentence-level SFs of comparison and bridge questions in the dev. sets of the two datasets: 2Wiki and HotpotQA-small. As shown in the Figure, the comparison questions have more position biases than the bridge questions in both 2Wiki and HotpotQA-small. Furthermore, we observe that the position bias in the comparison questions in HotpotQA-small is smaller than that in 2Wiki.

Table 9 presents the performance drop for two types of questions, comparison and bridge questions, in 2Wiki and HotpotQA-small.

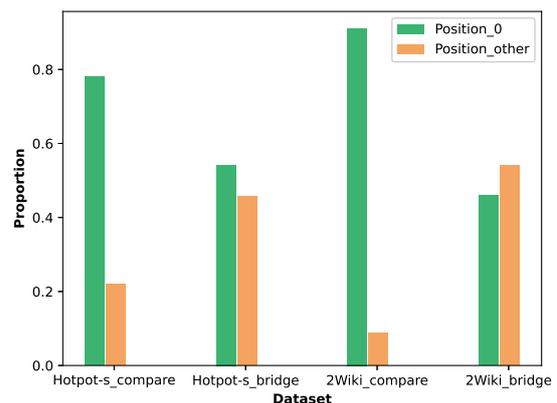

Figure 5: Information on the position of sentence-level SFs of comparison and bridge questions in the dev. sets of the two datasets: 2Wiki and HotpotQA-small.

Details of RQ3 Table 10 presents examples of the outputs predicted by our model, which is trained on three tasks simultaneously.

PubMedCLIP: How Much Does CLIP Benefit Visual Question Answering in the Medical Domain?

Sedigheh Eslami, Christoph Meinel, Gerard de Melo

{sedigheh.eslami, christoph.meinel, gerard.demelo}@hpi.de

Abstract

Contrastive Language–Image Pre-training (CLIP) has shown remarkable success in learning with cross-modal supervision from extensive amounts of image–text pairs collected online. Thus far, the effectiveness of CLIP has been investigated primarily in general-domain multimodal problems. In this work, we evaluate the effectiveness of CLIP for the task of Medical Visual Question Answering (MedVQA). We present PubMedCLIP, a fine-tuned version of CLIP for the medical domain based on PubMed articles. Our experiments conducted on two MedVQA benchmark datasets illustrate that PubMedCLIP achieves superior results improving the overall accuracy up to 3% in comparison to the state-of-the-art Model-Agnostic Meta-Learning (MAML) networks pre-trained only on visual data. The PubMedCLIP model with different back-ends, the source code for pre-training them and reproducing our MedVQA pipeline is publicly available at <https://github.com/sarahESL/PubMedCLIP>.

1 Introduction

Medical visual question answering (MedVQA) seeks answers to natural language questions about a given medical image. The development of MedVQA has considerable potential to benefit healthcare systems, as it may aid clinicians in interpreting medical images and obtaining more accurate diagnoses by consulting a second opinion. Thus, it has become a very active area of research, with competitive benchmarks and yearly competitions (Abacha et al., 2021). Yet, visual question answering in the medical domain in particular remains non-trivial, as we suffer from a general lack of large balanced training data, in part due to privacy concerns. To solve the multimodal task of MedVQA, a system must understand both medical images and textual questions and infer the associations between them sufficiently well to produce a correct answer (An-

tol et al., 2015). Thus, the success of these solutions is tied to the effectiveness of their visual and question encoders. Current approaches for MedVQA adopt deep artificial neural network encoders to interpret the image and the question. Previous studies in MedVQA (Nguyen et al., 2019; Zhan et al., 2020; Pan et al., 2021; Gong et al., 2022) commonly exploit the Mixture of Enhanced Visual Features (MEVF) model (Nguyen et al., 2019) as their visual encoder to overcome data limitations. However, MEVF is custom-tailored for the particular challenges encountered in the VQA-RAD (Lau et al., 2018) dataset, i.e., specifically designed for the organs present in this dataset, limiting its generalizability to other settings.

In non-medical settings, recent work (Su et al., 2019; Zhang et al., 2020; Cho et al., 2021; Wang et al., 2021; Radford et al., 2021; Yu et al., 2022) has shown improvements of visual encoders when learning from multimodal image–text pairs in comparison to learning from just visual images. Among these approaches, the contrastive pre-training of language–image data in OpenAI’s CLIP (Radford et al., 2021) has been particularly prominent. CLIP is trained using a vast number of image–text pairs acquired from the Internet with close to zero additional human annotation. We argue that this is particularly promising for the medical domain, since data annotation requires expert medical knowledge, making it expensive and time-consuming. Following CLIP, we investigate to what extent learning from publicly available medical image–text pairs without any further annotation can aid in the MedVQA task. To this end, we use image–text pairs obtained from PubMed articles to train a new version of CLIP called PubMedCLIP. We then examine the outcomes when incorporating PubMedCLIP into state-of-the-art MedVQA methods, investigating whether CLIP benefits MedVQA.

To the best of our knowledge, this is the first study introducing a PubMed-optimized CLIP and

assessing the effectiveness of its visual and textual encoders for VQA. Unlike prior work on MedVQA, PubMedCLIP is trained using medical images from a diverse range of body regions and is not restricted to only a few organs. We conduct extensive experiments on two MedVQA benchmark datasets and employ diverse back-end visual encoders in PubMedCLIP. Our experiments show that using PubMedCLIP as a pre-trained visual encoder improves previous models by up to 3%. Our experiments further reveal question type distributional differences in the two MedVQA benchmark datasets that have not been imparted in previous work and cause different back-end visual encoders in PubMedCLIP to exhibit different behavior on these datasets.

2 Related Work

Shen et al. (2021) showed the benefits of CLIP for general-domain visual question answering. However, MedVQA approaches generally need to be able to learn from small amounts of training data and be able to pick up fine-granular details such as subtle medical abnormalities. Recent MedVQA approaches typically employ deep pre-trained neural encoders and consist of four main components: a visual encoder, question encoder, attention-based fusion of vision and text features, and an answer classifier (Nguyen et al., 2019; Vu et al., 2020; Zhan et al., 2020; Pan et al., 2021; Liu et al., 2021a; Gong et al., 2022). Skip-thought vectors, LSTM, and GRU recurrent neural networks have been popular question encoders in prior work. Due to the lack of diversity in the semantics of the questions in the ImageCLEF VQA-Med 2021 Challenge (Abacha et al., 2021), the winning teams (Gong et al., 2021; Eslami et al., 2021) were able to treat MedVQA as a multi-class image classification task, without any need to encode and interpret the questions. Bilinear attention networks (Kim et al., 2018), multimodal compact bilinear pooling (Fukui et al., 2016), stacked attention networks (Yang et al., 2016), and element-wise production are popular as multimodal pooling approaches in MedVQA. With regard to the visual encoder, the winning teams in the ImageCLEF VQA-Med Challenges (Abacha et al., 2020, 2021) often fine-tune an ensemble of pre-trained VGG (Simonyan and Zisserman, 2014) and various ResNet (Lei et al., 2018) encoders. A notable number of papers (Nguyen et al., 2019; Zhan et al., 2020; Pan et al., 2021; Gong et al., 2022) employ the Mixture

of Enhanced Visual Features (MEVF; Nguyen et al. 2019) in order to overcome image data limitations. MEVF consists of two modules: 1. the pre-trained meta-learning module, which uses Model-Agnostic Meta-Learning (MAML; Finn et al. 2017) with the objective of solving a k -shot n -way classification problem with the abnormality status of chest, abdomen, and brain organs as classes, 2. the Convolutional Denoising Autoencoder (CDAE; Masci et al. 2011) module in order to have a robust visual encoder for noisy medical images. The pre-training of MEVF is custom-tailored for the particular organs that are present in the VQA-RAD (Lau et al., 2018) dataset, i.e., chest, brain, abdomen. Another study (Do et al., 2021) similarly trained multiple meta-models confined to these three body regions, combined with a scoring mechanism to select the n most robust and accurate encoders and concatenate their outputs to represent the visual features. Liu et al. (2021a) also restricted the objective of their visual encoding to chest, brain, and abdomen, and pre-trained three separate visual encoder teacher models for these respective body regions. They distilled the three teacher models into a smaller student model by contrastive representation distillation. As opposed to previous work, which learns from just visual data, we design an alternative encoder, PubMedCLIP, which not only uses natural language as supervision for visual representation learning, but also learns features in medical images of various modalities and diverse body organs, and hence, is not limited to only a few body regions.

3 PubMedCLIP

Our first step is to fine-tune the original general-domain CLIP using medical image–text pairs. We refer to the fine-tuned version as PubMedCLIP. Figure 1 (A) shows an overview of the training procedure for PubMedCLIP. Texts and images are encoded separately using CLIP, which we denote by $\mathbf{e}_t \in \mathbb{R}^{b \times d}$, $\mathbf{e}_v \in \mathbb{R}^{b \times d}$, respectively, for a batch of size b . For each image–text pair, a label $y \in \mathbb{R}$ represents the correspondence of the pairing of image and text. The cosine similarities between text and image features are computed to represent the respective visual and textual logits \hat{y}_v , \hat{y}_t , i.e.,

$$\hat{y}_v = \frac{\mathbf{e}_v^\top \mathbf{e}_t}{\|\mathbf{e}_v\| \|\mathbf{e}_t\|}, \quad \hat{y}_t = \frac{\mathbf{e}_t^\top \mathbf{e}_v}{\|\mathbf{e}_t\| \|\mathbf{e}_v\|}. \quad (1)$$

As formulated in Eq. 2, a weighted sum of the vision and language loss values is computed to

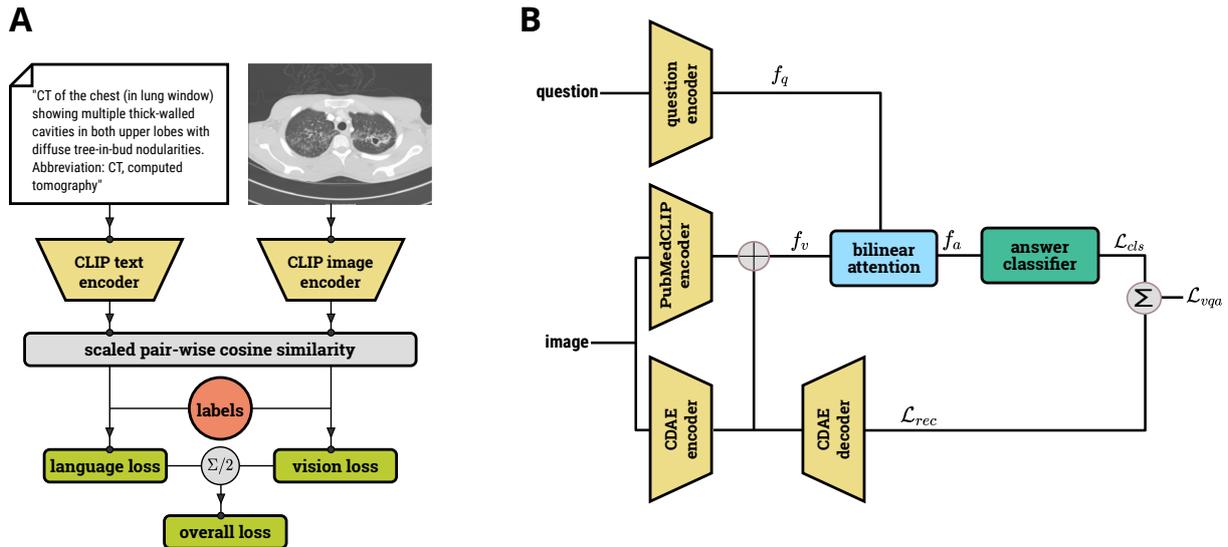

Figure 1: (A) Overview of how PubMedCLIP is pre-trained. (B) Schematic of MedVQA backbone with PubMedCLIP pre-trained visual encoder.

represent the overall loss. $Y \in \mathbb{R}^b$ denotes the set of labels y for a total of b image–text pairs in the batch. In this work, we use the cross-entropy loss

$$\mathcal{L} = \lambda H(\hat{y}_v, Y) + (1 - \lambda)H(\hat{y}_t, Y). \quad (2)$$

Following CLIP, we set $\lambda = 0.5$ to obtain the average of vision and language losses.

For training PubMedCLIP, we drew on the Radiology Objects in COntext (ROCO) dataset (Pelka et al., 2018). Previous work (Rajpurkar et al., 2017; Wang et al., 2017; Irvin et al., 2019; Johnson et al., 2019a) also proposes large-scale multi-modal datasets in the medical domain. However, they include images of only one imaging modality, i.e., X-ray, for a very limited number of body regions. In contrast, ROCO includes over 80K samples of diverse imaging modalities such as ultrasound, X-rays, PET scans, CT scans, MRI, angiography, from various human body regions, e.g., head, neck, spine, chest, abdomen, hand, foot, knee, and pelvis. Learning visual representations of diverse organs with various imaging modalities is valuable for a MedVQA system, as it is expected to interpret images given such diversities. The image–text pairs in ROCO stem from PubMed articles. The texts are taken from the relatively short captions (average length of 20 words) associated with images in the articles, which provide rich explanatory information about the content of images. In this work, the training and validation data splits from the original paper (Pelka et al., 2018) were used to train PubMedCLIP, with ViT-B/32 Vision

Transformer (Dosovitskiy et al., 2021), ResNet RN-50 (He et al., 2016), and RN-50x4 visual encoder back-ends. With respect to the maximum text length accepted by CLIP, which is 76, we trimmed any longer captions, while zero-padding shorter ones. PubMedCLIP was trained for 50 epochs with a batch size of 64, and Adam optimization (Kingma and Ba, 2014) with a learning rate of 10^{-5} . The trained models, source code as well as further implementation details are available online at <https://github.com/sarahESL/PubMedCLIP>.

Figures 2 and 3 show PCA visualizations of the caption and image embeddings, respectively, for the ROCO validation set. Comparing CLIP and PubMedCLIP embeddings, PubMedCLIP appears to obtain more semantic-aware visual and textual features with regard to body locations. For instance, looking at chest, abdomen, and head body locations, the corresponding embeddings form clusters for PubMedCLIP. However, the original CLIP embeddings are scattered without much separation.¹

4 PubMedCLIP for MedVQA

Given a MedVQA training dataset represented as $T = \{(v_i, q_i, a_i)\}_{i=1}^D$ of size D , where v_i is a medical image, q_i is the corresponding natural language question, and a_i is natural language answer, our goal is to learn to emit correct answer a_i given

¹In Appendix A, we provide more information on our approach for proxy-labeling the unannotated captions from the ROCO dataset. The proxy-labels have been merely used for the purpose of visualisations in this paper.

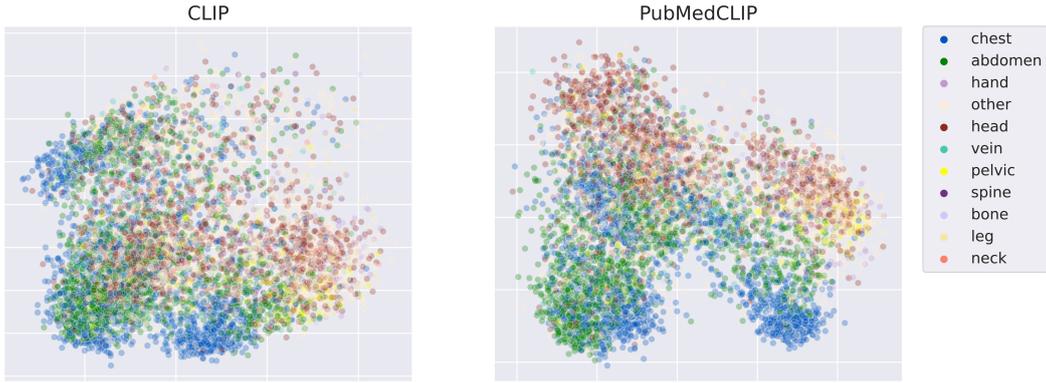

Figure 2: PCA visualizations of image embeddings.

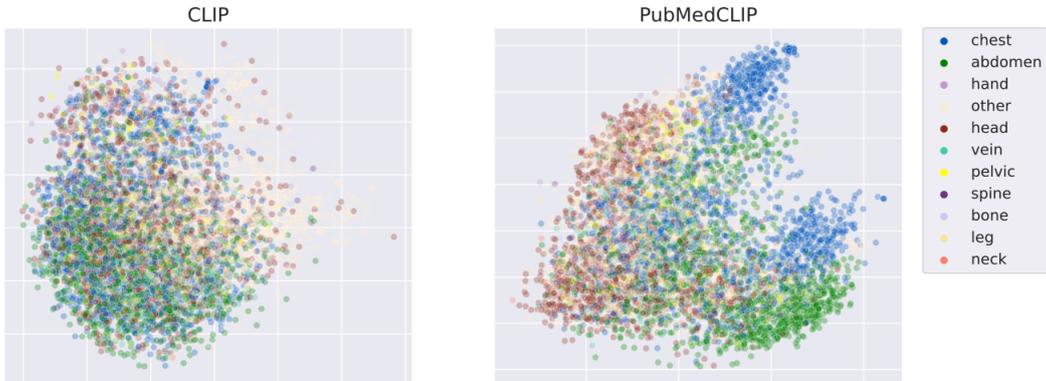

Figure 3: PCA visualizations of text embeddings.

image-question pair (v_i, q_i) . For this, we assume appropriate encoding functions to obtain $\mathbf{f}_v \in \mathbb{R}^n$ as an n -dimensional vector encoding for image v_i and the sequence embedding of $\mathbf{f}_q \in \mathbb{R}^{m \times l}$ for the question q_i with length l . We then cast MedVQA as a multi-label classification function $F : \mathbb{R}^n \times \mathbb{R}^{m \times l} \rightarrow \{0, 1\}^{|A|}$ where A is the overall set of possible answers and $F(\mathbf{f}_v, \mathbf{f}_q) = \mathbf{a}_i$ for the one-hot encoded answer \mathbf{a}_i .

Our goal is to investigate the effect of employing PubMedCLIP as the pre-trained visual encoder in MedVQA. To this end, we considered two prominent MedVQA methods, MEVF (Zhan et al., 2020) and QCR (Nguyen et al., 2019), that adopt MAML as their pre-trained visual encoder and GloVe word embeddings followed by a Recurrent Neural Network (RNN) as their question encoder. We substitute the pre-trained MAML module in MEVF and QCR with the pre-trained visual encoder from PubMedCLIP. A schematic architecture of our pipeline is shown in Figure 1 (B). The representative visual feature \mathbf{f}_v in this solution is the concatenation of the outputs of the PubMedCLIP network and the CDAE encoder. The objective of CDAE’s encoder

is to robustly encode the noisy version v'_i of an image v_i while the decoder learns to reconstruct the original non-noisy images. Denoting the reconstructed image as v_i^{rec} , Equation 3 defines the image reconstruction loss of CDAE as the mean squared error.

$$\mathcal{L}_{\text{rec}} = \|v_i - v_i^{\text{rec}}\|^2 \quad (3)$$

The multimodal pooling mechanism for combining \mathbf{f}_v and \mathbf{f}_q is BAN (Kim et al., 2018) to obtain the answer feature vector \mathbf{f}_a , as illustrated in Figure 1 (B). For answer prediction, which is a classification task in our case, a sigmoid layer preceding a binary cross-entropy loss is utilized in order to allow multiple correct answers per question. Eq. 4 formulates the answer classification loss function.

$$\mathcal{L}_{\text{cls}} = -\frac{1}{D} \sum_{i=1}^D \sum_{c=1}^A a_{i,c} \log(\hat{a}_{i,c}) + (1 - a_{i,c}) \log(1 - \hat{a}_{i,c}) \quad (4)$$

Here, $\hat{a}_{i,c} = \sigma(\mathcal{M}(\mathbf{f}_a))$, where σ represents the sigmoid function. Following BAN (Kim et al., 2018), the answer classifier \mathcal{M} is a two-layer feed-forward network with ReLU activation.

The objective of MedVQA is to simultaneously minimize the error of answer classification and image reconstruction, denoted as:

$$\mathcal{L}_{\text{vqa}} = \mathcal{L}_{\text{cls}} + \mathcal{L}_{\text{rec}}. \quad (5)$$

5 Experiments

5.1 Datasets and Setup

We conducted our experiments using two well-known MedVQA datasets:

1. **VQA-RAD** (Lau et al., 2018) consists of 315 images and 3,515 English language question-answer pairs. Following previous work, we adopt the data split proposed in MEVF (Nguyen et al., 2019). We notice that all the images in the test dataset are also present in the training set. However, the set of question-answer pairs for these images in the test set are unseen in the training set.
2. The **SLAKE** (Liu et al., 2021b) dataset consists of English and Chinese questions. In this work, we utilize the English subset of the dataset, comprising 642 images and more than 7,000 question-answer pairs. Using the original data split, we observe that in contrast to VQA-RAD, all the images in the test set of SLAKE are unseen in the training set.

To ensure a fair comparison, our experiments followed the same setups used in the original MEVF and QCR studies. MEVF was trained for 20 epochs, QCR for 200, both with Adam optimization. When using PubMedCLIP as either the pre-trained visual encoder or the text encoder, we set the learning rate to 1×10^{-3} and 2×10^{-3} and the batch size to 16 and 32 in QCR and MEVF, respectively. All implementations are based on the PyTorch framework (Paszke et al., 2019). We ran the original MEVF and QCR on our machine and report the results here to have a fair comparison. Due to the non-deterministic behaviour of the cuDNN library in CUDA convolution operations (Pham et al., 2020), we observed non-deterministic results in different runs of the original MEVF and QCR. For a more robust comparison, we repeated all experiments 10 times and report the average accuracy scores.

5.2 Results and Analysis

The results of our experiments using PubMedCLIP’s visual encoder are given in Table 1. In

order to see the effectiveness of PubMedCLIP in comparison to the general domain CLIP, we also report the results when using CLIP. We provide the overall accuracy along with the accuracy of answering only open-ended or closed-ended questions.

When using CLIP and PubMedCLIP as the pre-trained visual encoder only, it is observed that the results of both the MEVF and QCR approaches improve. Furthermore, PubMedCLIP yields an absolute improvement of up to 1% in comparison with the original CLIP. On the VQA-RAD dataset, PubMedCLIP with the ResNet-50 backend achieves the best results, improving the overall accuracy of MEVF up to 6% and for QCR up to 3%. Results on the SLAKE dataset show that PubMedCLIP with ViT-B/32 Vision Transformer encoder back-end attains the best accuracy. It enhances MEVF by up to 3% and QCR up to 2%. We witness the same trend of improvement among overall, open-ended, and closed-ended accuracy scores.

In Figure 4, a comparison of image embeddings when using MAML as apposed to PubMedCLIP’s visual encoder is shown using PCA analysis for the VQA-RAD dataset. We find that in contrast to the MAML encoder, PubMedCLIP’s visual encoding results in organ-aware visual embeddings i.e., images of head, chest, and abdomen form more coherent and distinct clusters.

In Table 2, we compare the performance of PubMedCLIP with the recent state-of-the-art models in MedVQA. All the models use BAN as the fusion mechanism. In Table 2, PubMedCLIP refers to using PubMedCLIP as the pre-trained visual encoder in QCR. The comparison shows that PubMedCLIP achieves the best results on open-ended, closed-ended, and overall accuracies.

Behavior of visual encoder back-ends. The fact that PubMedCLIP with ResNet-50 back-end achieves the best results for VQA-RAD, while PubMedCLIP with ViT performs best on the SLAKE dataset points us to underlying differences in the question type distribution in these datasets. As Figure 5 shows, the majority of the questions in the VQA-RAD ask about the presence of an abnormality in the images. This requires the visual encoder to detect local features and local abnormalities. Thus, the CNN-based ResNet model with better visual localization outperforms the Vision Transformer. However, on SLAKE, the majority of questions are of the type “organ”, asking which organ is present in the image. For such cases, the

MedVQA Model	Question Encoder	Visual Encoder	VQA-RAD Accuracy			SLAKE Accuracy		
			Open	Closed	Overall	Open	Closed	Overall
MEVF	GloVe+RNN	MAML + AE (*)	42.1%	73.2%	60.8%	74.1%	77.5%	75.5%

Table 1: Accuracy scores on VQA-RAD and SLAKE datasets. (*) denotes the original MEVF (Nguyen et al., 2019) and (+) denotes the original QCR (Zhan et al., 2020). Bold numbers represent the rows that achieved best overall accuracy. Light cyan, yellow, and green highlight correspond to the results when using MAML, CLIP and PubMedCLIP as the visual encoder only, respectively.

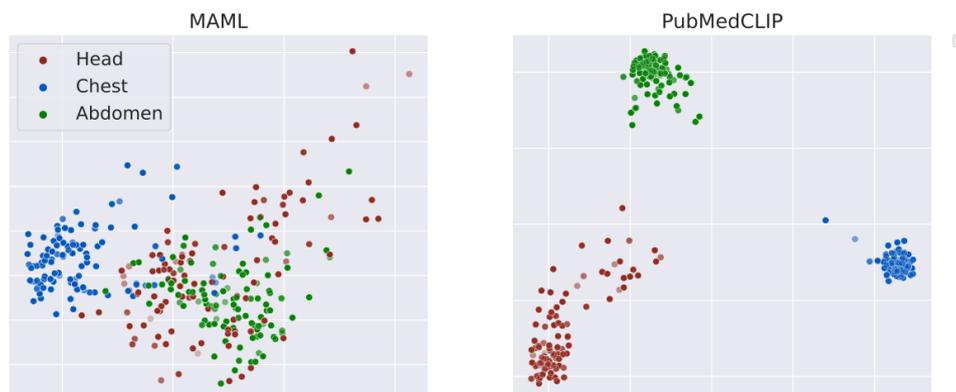

Figure 4: PCA visualizations of MAML and PubMedCLIP image embeddings for VQA-RAD dataset.

MedVQA Model	VQA-RAD Accuracy			SLAKE Accuracy		
	Open	Closed	Overall	Open	Closed	Overall
MEVF (Nguyen et al., 2019)	42.1%	73.2%	60.8%	74.1%	77.5%	75.5%
QCR (Zhan et al., 2020)	56%	77.9%	69.2%	76.8%	80.6%	78.3%
MMQ (Do et al., 2021)	53.7%	75.8%	67%	—	—	—
VQAMix (Gong et al., 2022)	56.6%	79.6%	70.4%	—	—	—
PubMedCLIP + BAN (ours)	60.1%	80%	72.1%	78.4%	82.5%	80.1%

Table 2: Comparison of PubMedCLIP with state-of-the-art MedVQA models. Results for the SLAKE dataset are not reported in the MMQ and VQAMix papers.

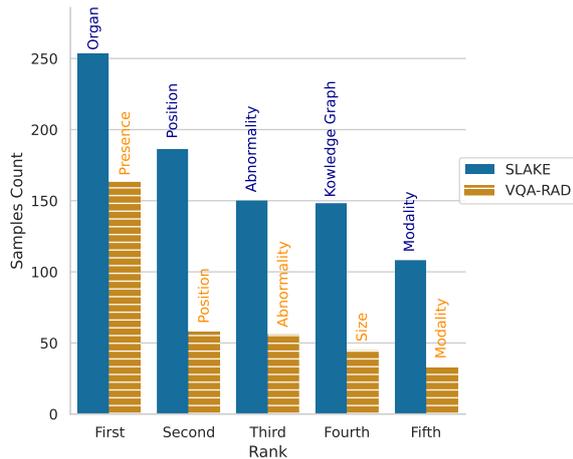

Figure 5: Distribution of top 5 most frequent question types in VQA-RAD and SLAKE.

visual encoder needs to be able to acquire a holistic overall understanding of the image and thus capture long-range dependencies of image patches. Vision Transformers indeed are capable of accounting for such features (Yu et al., 2021), and hence perform better on the SLAKE dataset.

PubMedCLIP as the text encoder. We expanded our experiments to investigate the effects of PubMedCLIP’s text encoder in MedVQA. To this end, we replaced the question encoder in the MEVF model with PubMedCLIP’s text encoder, i.e., instead of using GloVe word embeddings and an RNN network to model the question, we use PubMedCLIP’s text tokenizer and encoder, which receives the question q_i with l words and outputs a sequence-level embedding $\mathbf{f}_q \in \mathbb{R}^m$. Note that the size of image and text embeddings when using PubMedCLIP is equal. The results of our experiments in Table 3 suggest that invoking PubMedCLIP to encode questions in MedVQA is not as successful as using it for images. Furthermore, Table 3 shows that using both the visual and textual encoders of PubMedCLIP achieves absolute improvements of up to 5% in comparison to the original MEVF model. However, the best results are achieved with PubMedCLIP as the visual encoder together with GloVe+RNN for encoding questions.

In order to have a better understanding of the PubMedCLIP’s text encoder, a PCA visualization of the question embeddings is provided in Figure 6. The top row shows the embeddings when annotated according to their respective body location and the bottom row depicts them when labeled with question types, i.e., whether the question asks

Visual Encoder	Question Encoder	VQA-RAD Accuracy		
		Open	Closed	Overall
MAML	GloVe+RNN(*)	42.1%	73.2%	60.8%
	PubMedCLIP	26.5%	72.9%	54.3%
PubMedCLIP	GloVe+RNN	48.6%	78.1%	66.5%
	PubMedCLIP	48%	77.4%	65.6%

Table 3: Accuracy of PubMedCLIP as text encoder in the MEVF model. (*) denotes the original MEVF.

about the *Presence* of abnormality, *Position* of abnormality, type of *Abnormality*, etc. For having a comprehensible analysis, we visualize the top five frequent question types shown in Figure 5. Observations from Figure 6 suggest that PubMedCLIP’s text encoder emits organ-aware textual embeddings in contrast to GloVe+RNN. However, PubMedCLIP does not separate embeddings based on the question type, while GloVe+RNN results in better question type clusters. These findings suggest that question type awareness when encoding questions might be more beneficial than organ awareness for the MedVQA task. Based on our experiments, exploiting PubMedCLIP as the visual encoder in the QCR model is the most effective solution.

Furthermore, we sampled a few questions from the VQA-RAD test set and compared their pairwise cosine similarities when using GloVe+RNN versus PubMedCLIP encoding. We seek to examine the power of PubMedCLIP text encoder in identifying semantic differences. Figure 7 reports the cosine similarities when using PubMedCLIP in contrast to GloVe+RNN embeddings. As can be seen, when using PubMedCLIP text encoder, different questions about “lung abnormality” and “image plane” are equally similar to the “rib fracture” question, i.e., 0.77, and the encoder does not distinguish them. However, the cosine similarities are more intuitive when using GloVe+RNN. For instance, questions “Is there a rib fracture?” and “Describe the lung abnormalities?” have a small similarity of 0.27, while questions “Which plane is this image taken?” and “What is the plane of this image?” have a high similarity of 0.86.

In addition, it is observed that PubMedCLIP generally results in embeddings that are highly close to each other, with cosine similarities of more than 0.7 for different questions on disparate topics. In contrast, similarities of GloVe+RNN encoding are spread in the range of $[-0.09, 1]$, meaning that these embeddings are scattered over the m -

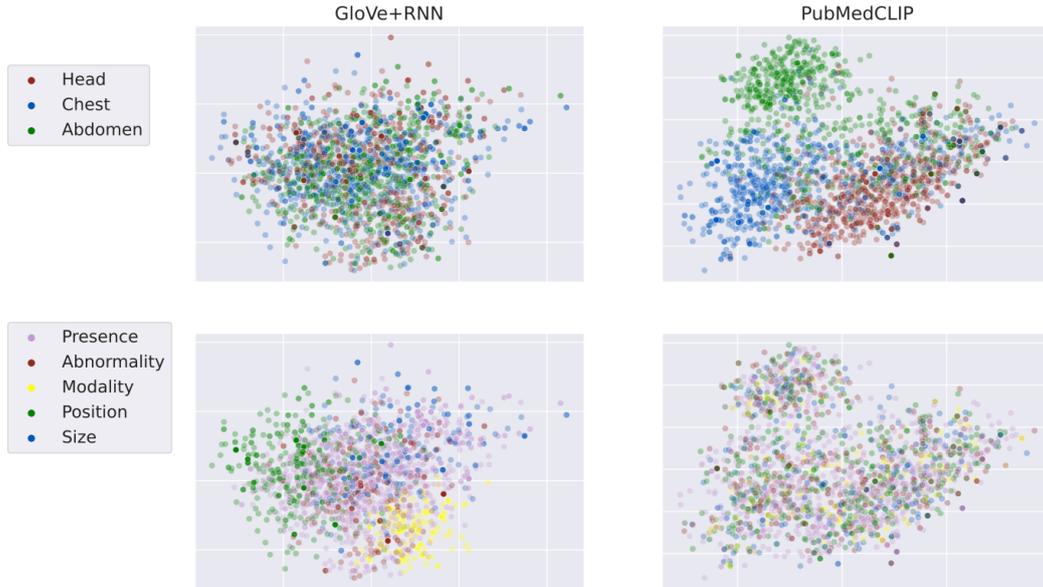

Figure 6: PCA of question embeddings. (Top) Labeled with body locations. (Bottom) Labeled with question types.

dimensional embedding space. We conclude that GloVe+RNN distinguishes the semantics of questions more effectively in comparison to PubMedCLIP’s text encoder for the MedVQA task.

CLIP versus PubMedCLIP. In order to better see the impact of fine-tuning PubMedCLIP, we additionally looked into the intermediate task of image–text matching using nearest neighbors vector retrieval. Considering that the pre-training objective in CLIP and PubMedCLIP is to minimize the cosine distance between paired image and text embeddings while maximizing this distance for non-paired image–text combinations, we argue that with a rich representation learning model, a nearest neighbor approach using the cosine distance metric should be fairly successful in retrieving matching image–text pairs. We randomly selected a subset of $D' = 10,000$ samples from the ROCO training data and used them to compare the outcomes of image–text matching in the medical domain. We exploit the text encoder as well as the visual encoder in CLIP and PubMedCLIP. Using Faiss (Johnson et al., 2019b) for vector retrieval, we investigated KNN with $K = 1$ on batches of size b . For each batch, the objective was to find the closest encoded text for a given encoded image, using the cosine distance metric. The evaluation metric for this setting is the overall accuracy of image–text matching over all batches:

$$\text{acc} = \frac{\sum_{i=1}^S \# \text{ correct matches in batch } i}{D'}, \quad (6)$$

V-L encoder	Batch size	ViT-B/32	RN50	RN50x4
CLIP	8	58.1%	49.1%	57.7%
	16	44%	36.1%	45.1%
	32	21.6%	25.5%	33.1%
PubMedCLIP	8	93.1%	89.2%	92.2%
	16	87.6%	81.1%	85.7%
	32	80.1%	70.6%	76.2%

Table 4: Accuracy scores of image-text matching using CLIP and PubMedCLIP vision–language encoders.

where $S = \lceil \frac{D'}{b} \rceil$. Table 4 summarizes the results for batch sizes of 8, 16, and 32. PubMedCLIP achieves over 40% improvement in comparison to CLIP across all batch sizes, with the ViT-B/32 back-end achieving the best results. This shows the effectiveness of our fine-tuning in PubMedCLIP.

Comparison of qualitative examples. In Figure 8, examples from the VQA-RAD and SLAKE datasets are provided that illustrate the performance of the original MEVF and QCR in comparison with PubMedCLIP, used here as either the visual or question encoder for QCR. PubMedCLIP_TE_VE, PubMedCLIP_TE and PubMedCLIP_VE refer to the scenarios of PubMedCLIP as both visual and textual encoders, as textual encoder only, and as the visual encoder only, respectively.

We find that the MEVF model often has difficulties discerning which organ is depicted in the image. For instance, regardless of the asked ques-

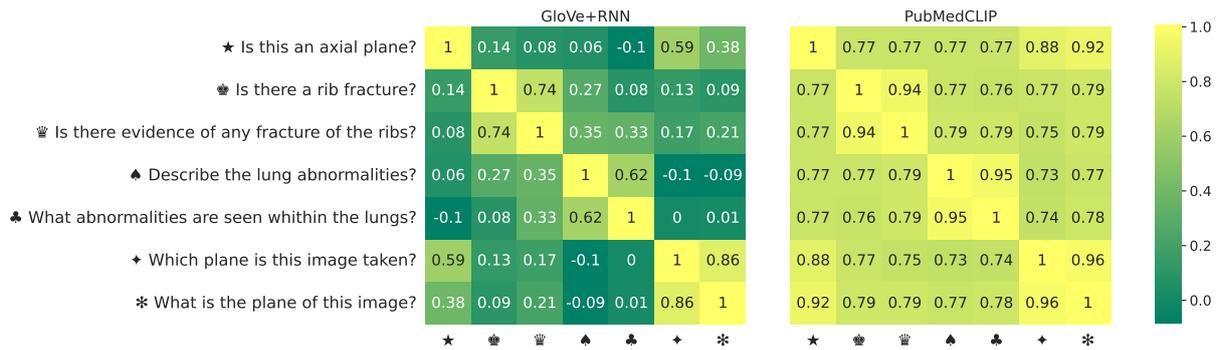

Figure 7: Pair-wise cosine similarities of questions from VQA-RAD encoded with GloVe+RNN compared with PubMedCLIP. Each question is associated with a symbol and represented only by the symbol on the horizontal axis.

	A	B	C
Question:	What are the bright white, structures, almost forming an X?	Where does the image represent in the body?	Are there multiple or just 1 metastatic focus?
Answer:	lateral ventricles	chest	one
MEVF:	chest tightness ... ✗	atelectasis, effusion ✗	right chest ✗
QCR:	extremities ✗	lower left lung ✗	no ✗
PubMedCLIP_TE_VE:	diffuse ✗	no ✗	yes ✗
PubMedCLIP_TE:	extremities ✗	no ✗	both sides ✗
PubMedCLIP_VE:	lateral ventricles ✓	chest ✓	yes ✗

Figure 8: (A) Example from VQA-RAD dataset. (B) Example from SLAKE dataset. (C) Example from VQA-RAD dataset that all models fail to answer correctly.

tion in Figure 8 (A), MEVF provides an answer related to the chest region, while the image is of the brain. This behaviour is also seen in Figure 8 (B) and 8 (C). From this perspective, QCR appears to be providing answers that are at least relevant to the given image. As Figure 8 (B) shows, the answer provided by QCR is related to the chest X-ray, although it is not a correct answer. Furthermore, it is observed that when PubMedCLIP is used as the question encoder, the model has difficulties providing the correct answers and often misinterprets open-ended questions as close-ended. In contrast, PubMedCLIP as the visual encoder successfully yields the correct answers.

Figure 8 (C) shows an example from the VQA-RAD that all models fail to answer correctly. MEVF again provides irrelevant answers about body organs not present in the image. QCR and PubMedCLIP misinterpret the question as a yes/no one. In spite of this, the fact that PubMedCLIP_VE answers with “yes” may illustrate that it has at least

detected the “one” metastatic focus in the image. In comparison, QCR answers with “no”, showing its troubles in interpreting the image and recognizing the metastatic focus. Figure 8 (C) reveals that these models still have shortcomings in understanding questions and correctly relating them to the images.

6 Conclusion

This work introduces PubMedCLIP, a pre-trained vision–language encoder for the medical domain trained via contrastive learning of medical image–caption pairs from PubMed articles. We demonstrated that PubMedCLIP results in organ-aware vision and language embeddings and evaluated its effectiveness for the task of MedVQA in comprehensive experiments across two heterogeneous MedVQA benchmarks. While PubMedCLIP’s text encoder is found to be less powerful for MedVQA, we showed that PubMedCLIP’s visual encoder outperforms previously used pre-trained visual encoders by up to 3%, leading to state-of-the-art results.

Limitations

Although we envision that in the long term, MedVQA systems can be sufficiently successful and trustworthy to aid medical practitioners towards better interpreting medical images and providing better healthcare, we emphasize that the development of these systems is still in its infancy stage and they are not yet ready for fully automated and unsupervised use in real-world clinical settings. Despite the notable improvement of accuracy in MedVQA brought by PubMedCLIP, further evaluations of these models from the vantage points of scalability, trustworthiness, explainability, and generalizability are required before they can be deployed for sensitive clinical tasks. In future work, we plan to perform further analysis of these models using explainable AI techniques such as Grad-CAM visualizations to assess the regions of focus within the image from the class activation maps. Furthermore, due to a lack of suitable data to train large-scale models for other languages, our current experiments are limited to English language MedVQA, so different findings may be observed for typologically different languages. By releasing PubMedCLIP, we hope to enable further research investigating these aspects as well as its effectiveness in other use cases, e.g., image classification for medical diagnosis and radiology report generation.

Discussions on Ethics

As remarked above, MedVQA models are still in their early stages of development and have limitations that should be considered before being used in any real-world scenarios.

A Proxy-labeling ROCO dataset for visualization purposes

In order to have a better analysis of the PCA visualizations when comparing CLIP and PubMedCLIP encodings, we created proxy body location labels by identifying organ-specific keywords in ROCO captions. The complete list of keywords used for each body location is provided in Listing 1. Furthermore, the distribution of these proxy labels in the ROCO validation dataset is shown in Figure 9.

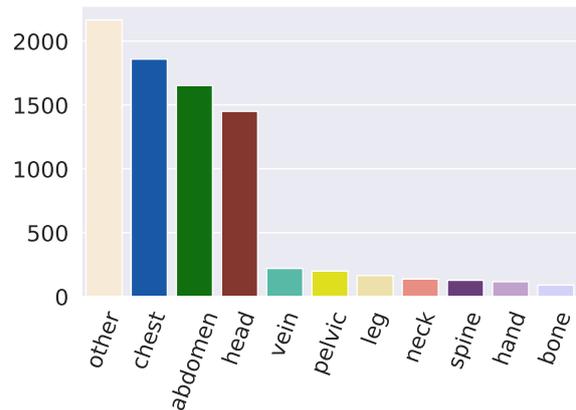

Figure 9: Distribution of proxy labels in ROCO.

Multilingual BERT has an accent: Evaluating English influences on fluency in multilingual models

Isabel Papadimitriou* and Kezia Lopez* and Dan Jurafsky

Computer Science Department

Stanford University

{isabelvp,keziak1,jurafsky}@stanford.edu

Abstract

While multilingual language models can improve NLP performance on low-resource languages by leveraging higher-resource languages, they also reduce average performance on all languages (the ‘curse of multilinguality’). Here we show another problem with multilingual models: grammatical structures in higher-resource languages bleed into lower-resource languages, a phenomenon we call *grammatical structure bias*. We show this bias via a novel method for comparing the fluency of multilingual models to the fluency of monolingual Spanish and Greek models: testing their preference for two carefully-chosen variable grammatical structures (optional pronoun-drop in Spanish and optional Subject-Verb ordering in Greek). We find that multilingual BERT is biased toward the English-like setting (explicit pronouns and Subject-Verb-Object ordering) as compared to our monolingual control language model. With our case studies, we hope to bring to light the fine-grained ways in which multilingual models can be biased, and encourage more linguistically-aware fluency evaluation.

1 Introduction

Multilingual language models share a single set of parameters between many languages, opening new pathways for multilingual and low-resource NLP. However, not all training languages have an equal amount, or a comparable quality of training data in these models. In this paper, we investigate if the hegemonic status of English influences other languages in multilingual language models. We propose a novel method for evaluation, whereby we ask if model predictions for lower-resource languages exhibit structural features of English. This is similar to asking if the model has learned some languages with an “English accent”, or an English *grammatical structure bias*.

We demonstrate this bias effect in Spanish and Greek, comparing the monolingual models BETO

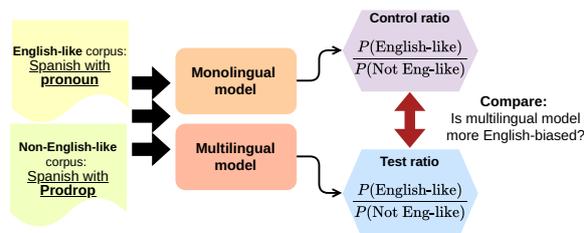

Figure 1: Our method for evaluating English structural bias in multilingual models. We compare monolingual and multilingual model predictions on two sets of natural sentences in the target language: one which is structurally parallel to English, and one which is not.

(Cañete et al., 2020) and GreekBERT (Koutsikakis et al., 2020) to multilingual BERT (mBERT), where English is the most frequent language in the training data. We show that *mBERT prefers English-like sentence structure in Spanish and Greek* compared to the monolingual models. Our case studies focus on Spanish pronoun drop (pro-drop) and Greek subject-verb order, two structural grammatical features. We show that multilingual BERT is structurally biased towards explicit pronouns rather than pro-drop in Spanish, and subject-before-verb order in Greek: the structural forms parallel to English.

Though the effect we showcase here is likely not captured by the downstream classification tasks often used to evaluate multilingual models (Hu et al., 2020), it demonstrates the type of fluency that can be lost with multilingual training — something that current evaluation methods miss. In fact, though we choose two clear-cut syntactic features to investigate, there are many less-measurable features that make language production fluent: subtleties in lexical choice, grammatical choice, and discourse expression, among many others. With this paper, beyond showing a trend for two specific grammatical features, we wish to highlight fluency discrepancies in multilingual models, and also call for more evaluations focused on fluency.

S_{parallel} : English-like structure	$S_{\text{different}}$: Different structure
Spanish explicit pronoun (pron in orange, verb in blue)	Spanish prodrop (verb in blue)
Yo <u>volveré</u> para averiguarlo I will return to figure it out El 2004, <u>ella</u> <u>hizo</u> doblaje a el Inglés [...] In 2004, <u>she</u> <u>did</u> dubbing to English [...] <u>Ella</u> <u>decide</u> pasar sus vacaciones en la granja <u>She</u> <u>decides</u> to spend her vacation in the country	Jamás <u>dan</u> soluciones y siempre [...] [They] Never <u>give</u> solutions and always [...] <u>Jugó</u> de centrocampista en el Real Zaragoza [He/She/You] <u>Played</u> as a midfielder in Real Zaragoza <u>Habita</u> en Perú. Greek Subject-Verb (subject in orange, verb in blue)	Greek Verb-Subject (subject in orange, verb in blue)
<u>Πηγές</u> της Αντιπολίτευσης <u>αναφέρουν</u> ότι [...] Sources of the Opposition <u>mention</u> that [...] Σε άλλες πλευρές ο <u>ποταμός</u> <u>κυλά</u> από ψηλούς βράχους On other sides, the <u>river</u> <u>flows</u> from tall boulders Η <u>εκπαίδευση</u> και η μόρφωση <u>απέκτησαν</u> επιτέλους προτεραιότητα Training and education have finally <u>acquired</u> priority	Το σκορ του αγώνα <u>άνοιξε</u> ο Γουέν Ρούνι The score of the game <u>opened</u> Wayne Rooney Εδώ πρέπει να <u>γίνουν</u> μεγαλύτερες <u>προσπάθειες</u> . Here must <u>happen</u> bigger <u>efforts</u> Απασχόληση στο εξωτερικό <u>ψάχνουν</u> οι μισοί Έλληνες σε παραγωγική ηλικία Employment in foreign countries <u>search</u> half of <u>Greeks</u>

Table 1: Examples from our dataset for S_{parallel} and $S_{\text{different}}$ in Spanish and Greek, along with roughly word-by-word gloss translations in English. In all cases, we’ve underlined $w(x)$, the word we use to represent the construction in our calculations. These examples are not randomly selected and have been chosen to be significantly shorter than the average sentence in our datasets in order to be presentable in a table.

Our proposed method can be expanded, without the need for manual data collection, to any language with a syntactic treebank and a monolingual model. Since our method focuses on fine-grained linguistic features, some expert knowledge of the target language is necessary for evaluation. Multilingual evaluation so far has been largely translated or automatically curated, and the methods for creating such datasets have allowed for the creation of resources in many languages for which there were none. Fluency evaluation requires some linguistic expertise to set up, and as such is more restricted in the languages the research community can reach. Nevertheless, such evaluation has been missing from the multilingual NLP literature, and our work bridges this gap by proposing fluency testing for multilingual models.

Our work builds off of a long literature on multilingual evaluation which has until now mostly focused on downstream classification tasks (Conneau et al., 2018; Ebrahimi et al., 2022; Clark et al., 2020; Liang et al., 2020; Hu et al., 2020; Raganato et al., 2020; Li et al., 2021). With the help of these evaluation methods, research has pointed out the problems for both high- and low-resource languages that come with adding many languages to a single model (Wang et al., 2020; Turc et al., 2021;

Lauscher et al., 2020, inter alia). Methods for creating more equitable models have been proposed, through identifying or reserving language-specific parameters for each language (Ansell et al., 2022; Pfeiffer et al., 2022), through training models without typologically distant languages that dominate the training data (Ogueji et al., 2021; Virtanen et al., 2019; Ògúnrèmí and Manning, 2023), as well as through adding model capacity (Conneau et al., 2020; Xue et al., 2021; Lepikhin et al., 2021; Liang et al., 2023). We hope that our work can add to these analyses and methodologies by pointing out issues beyond downstream classification performance that can arise with multilingual training, and aid towards building and evaluating more equitable multilingual models.

2 Method

Our method relies on finding a variable construction in the target language which can take two structural surface forms: one which is parallel to English (S_{parallel}) and one which is not ($S_{\text{different}}$). Surface forms parallel to English are those which mirror English structure. For example, English has strict Subject-Verb-Object word order, and so a *parallel* structure in another language is one where the verb

and its arguments appear in Subject-Verb-Object order, while a *different* structure is one where the verb appears before the subject (see Table 1 for examples).

Once we have identified such a construction in our target language, we can ask: are multilingual models biased towards S_{parallel} ? For a native speaker of the target language, structural, semantic, and discourse features determine whether they will use S_{parallel} or $S_{\text{different}}$ in a given context — with the alternative option usually being less fluent. We assume that a BERT-sized monolingual model in the target language will have a sufficiently accurate representation of this fluent variation between S_{parallel} and $S_{\text{different}}$ without being influenced by other languages. Therefore, to understand if multilingual models have an English structural bias, we now just have to answer: do multilingual models prefer S_{parallel} over $S_{\text{different}}$ *more* than the fluent distribution defined by a monolingual model?

2.1 Collecting model judgements

By design, both S_{parallel} and $S_{\text{different}}$ are constructions that occur naturally in the target language. Therefore, we should be able to use the syntactic treebank annotations to pick out sentences that exhibit the structures S_{parallel} or $S_{\text{different}}$. We can put these extracted sentences into two corpora, C_{parallel} and $C_{\text{different}}$. Note that the sentences in C_{parallel} and $C_{\text{different}}$ are unrelated and not paired, and that the two corpora can have different sizes. Crucially, we have to use natural sentences for both of our corpora: we cannot artificially alter sentences from S_{parallel} to $S_{\text{different}}$, or use templates to create sentences. This is because our evaluation is about the subtleties of fluency, while altered or templated stimuli are not naturally produced and are therefore often awkward, confounding any effect we might want to measure.

Each model gives us a ratio r_{model} : the average probability of a sentence in C_{parallel} divided by the average probability of a sentence in $C_{\text{different}}$ according to the model. That is:

$$r_{\text{model}} = \frac{\sum_{x \in C_p} P_{\text{model}}(x) / |C_p|}{\sum_{x \in C_d} P_{\text{model}}(x) / |C_d|} \quad (1)$$

We want to compare judgements on these corpora from two models: a monolingual model `mono` and a multilingual model `multi`. Our experimental question then boils down to asking if r_{multi} is significantly larger than r_{mono} .

2.2 From model outputs to construction probability

How can we calculate $P_{\text{model}}(x)$ for a given sentence x , focusing on the probability of a specific construction in x ? Looking at model judgements over long natural sentences introduces a lot of noise that is unrelated to the structural construction in question, reducing the statistical power of our experiment. Furthermore, since we are looking at encoder-only bidirectional models, there is no canonical or controlled way of extracting the probability of a whole sentence. To get a better model judgement for each sentence, we can extract the probability of *one word* in each sentence that best represents the construction. For example, if we are looking at pronoun drop, it makes sense to use main verb of the sentence as the target word, as this is the syntactic head of the pronoun that is present or dropped. Using a carefully chosen word as a proxy for the probability of a construction is a methodological choice also made in reading time psycholinguistics experiments (Levy, 2011; Levy and Keller, 2013).

Going back to our problem of calculating $P_{\text{model}}(x)$, we define w to be a function that returns the structurally-relevant word from each sentence. Using this, we approximate $P_{\text{model}}(x)$ in Eq. (1) with $P_{\text{model}}(w(x)|x)$. The probability $P(w(x)|x)$ is simple to calculate for BERT-style masked language models: it is simply the logit of the word $w(x)$ when we encode the sentence x using `model`.

2.3 Extending to more languages

Extending our fluency evaluation to a new language requires three language-specific steps: (1) decide on an appropriate construction with two structural forms S_{parallel} and $S_{\text{different}}$, (2) decide on an appropriate $w(x)$: which word in each structural form can represent the form, and (3) use treebank annotations to pull out sentences which exhibit S_{parallel} or $S_{\text{different}}$, and identify the relevant word. Below, we detail these steps for our two case studies.

2.4 Case Study: Spanish Pro-drop

In Spanish, the subject pronoun is often dropped: person and number are mostly reflected in verb conjugation, so the pronoun is realized or dropped depending on semantic and discourse factors. English, on the other hand, does not allow null subjects except in rare cases, and expletive syntactic subjects like “there” are even added when there

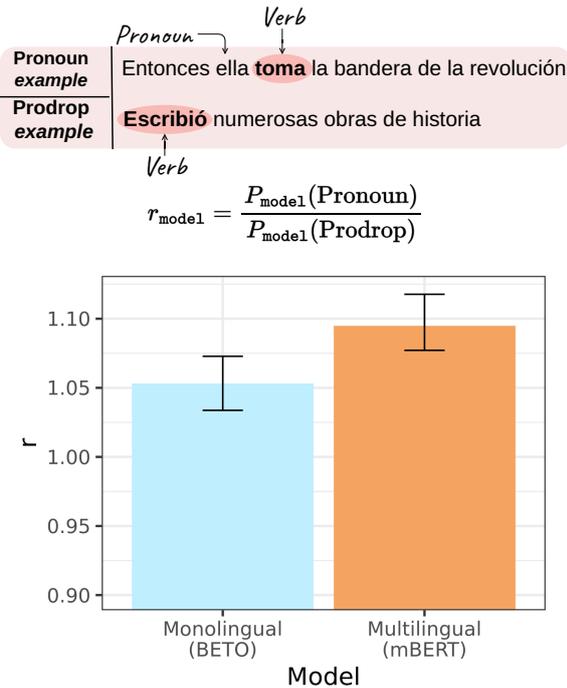

Figure 2: Results from our experiment on the Spanish GSD treebank, along with two examples from the treebank to illustrate S_{parallel} (with pronoun) and $S_{\text{different}}$ (pro-drop). We compare model logits for the main verb of the sentence, which is bold and highlighted in the examples. Error bars represent 95% bootstrap confidence intervals. We find that r_{mono} is significantly smaller than r_{multi} (bootstrap sampling, $p < 0.05$).

is no clear subject. For our Spanish experiment, we define S_{parallel} to be sentences which have the subject pronoun of the main verb, as is necessary in English, and $S_{\text{different}}$ to be pro-drop sentences which have a main verb with no realized subject. We define w to be the main verb of the sentence, which is always present in our extracted examples.

To extract our corpora C_{parallel} and $C_{\text{different}}$, we use the Spanish GSD treebank from the Universal Dependencies dataset (De Marneffe et al., 2021). We ignore all sentences not verb-rooted (i.e. noun phrases), those rooted with “haber” (which in its copula-like existential form cannot take an explicit subject, “There is” in English), and those using the impersonal-“se” passive construction (e.g. “se nos fue permitido”, “it was permitted of us”). We then take all sentences with a pronoun subject (i.e. a pronoun dependent of the root verb) and add them to C_{parallel} and all sentences where there is no nsubj relation to root verb and add them to $C_{\text{different}}$. We always pick the main root verb of the sentence as our w . We collect 283 sentences in C_{parallel} and 2,656 sentences in $C_{\text{different}}$.

2.5 Case Study: Greek Subject-Verb order

English is a fixed word order language: with few exceptions, the order of a verb and its arguments is Subject-Verb-Object. Greek, on the other hand, has mostly free word order (Mackridge, 1985), meaning that the verb and arguments can appear in any order that is most appropriate given discourse context. For our experiment, we define S_{parallel} to be cases in Greek when the subject precedes the verb, as is the rule in English. $S_{\text{different}}$ is then the cases when the verb precedes the subject, which almost never happens in English.

We define w to be the first element of the subject and verb: the subject when the subject comes first or the verb when the verb comes first. This first element is closer to the surrounding context, and so gives us a word-order-sensitive measurement of how the subject-verb construction is processed as a whole within the context. Though this choice means that our w is a noun in S_{parallel} and a verb in $S_{\text{different}}$, this does not constitute a confounder between models: we are comparing the same noun-verb probability ratio between different models.

To extract our corpora C_{parallel} and $C_{\text{different}}$, we use the Greek Dependency Treebank, the Universal Dependencies treebank for Greek (Prokopidis and Papageorgiou, 2017). We take all sentences where the main verb has a lexical subject, and we add to C_{parallel} if the subject appears before the verb and to $C_{\text{different}}$ if it appears after. We collect 1,446 sentences in C_{parallel} and 425 sentences in $C_{\text{different}}$.

3 Results

Results are shown in Figures 2 and 3, showing for both of our case studies that multilingual BERT has a greater propensity for preferring English-like sentences which exhibit S_{parallel} . Multilingual BERT significantly prefers pronoun sentences over pro-drop compared with monolingual BETO (bootstrap sampling, $p < 0.05$), and significantly prefers subject-verb sentences over verb-subject sentences over GreekBERT (bootstrap sampling, $p < 0.05$).

4 Discussion

In this paper, we proposed fluency evaluation as a further way of understanding the curse of multilinguality: what can be lost when we train many languages together. The discrepancies that we point out in these experiments are not going to seriously affect multilingual LM performance, especially in the more coarse-grained classification tasks that

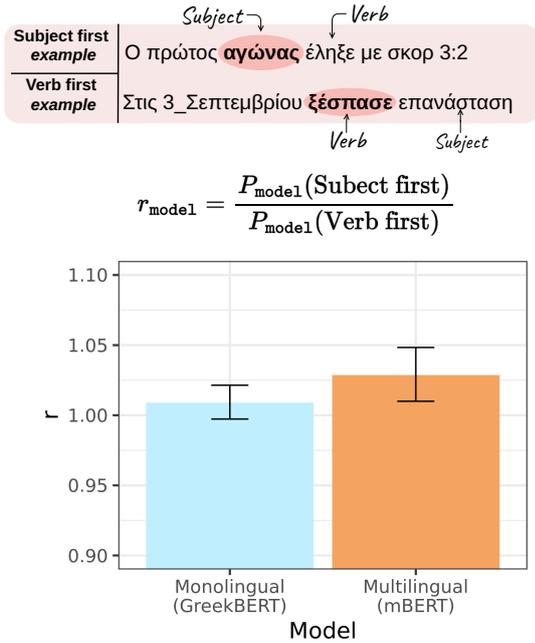

Figure 3: Results from our experiment on the Greek Dependency Treebank, along with two examples from the treebank to illustrate S_{parallel} (Subject-Verb) and $S_{\text{different}}$ (Verb-Subject). We measure and compare model logits for the bold words: the subject in subject-verb sentences and the verb in verb-subject sentences. Error bars represent 95% bootstrap confidence intervals. r_{mono} is significantly smaller than r_{multi} (bootstrap sampling, $p < 0.05$).

are most commonly used for evaluation. But, as we demonstrate here, not all levels of language learning can be evaluated from such datasets.

Our experiments do not pinpoint the reasons behind the effects that we measure: there are different possible explanations for the English-like trends that we showcase. On the one hand, the effects we measure might stem from training with a language that’s more dominant in the training data, like English is for many multilingual models. Such training could lead to an English-biased representation space which the representations of other languages conform to. On the other hand, the effects we show might be down to the data: the non-English datasets used to train a multilingual model may be more limited in domain, may contain a high proportion of data that’s actually been translated from English (Multilingual Wikipedia is often translated, Adar et al., 2009), or might be more polluted with irrelevant or non-linguistic elements. Domain limitations and translationese stemming from the data are separate, but related issues to fluency: fluency can be grammatical, but

also involves proficiency in a range of registers or possibilities. It is also possible that the effects we show are due to a combination of both multilingual representation learning artifacts, and training data quality. Further controlled fluency experimentation on the limits and abilities of multilingual models is needed to disentangle these effects. We hope the case studies in this paper can inspire more fine-grained evaluation of multilingual models, so that we understand the “accent”-like effects of hegemonic languages more fully.

5 Limitations

This study is meant to highlight the kinds of modeling flaws that have so far gone undetected and that can arise for lower-resource languages in multilingual models. However, our study does not focus on languages that are truly low-resource. In fact, as designed it could not do so: our methodology relies on having an available monolingual model, which of course requires a large amount of training data. This is because our method requires a control: we can only judge multilingual models against what we can believe to be a non-biased language model in the language. There are ways to test for fluency in low-resource languages that would not require a monolingual model as a control, but would require dataset collection in the target language for features that reflect fluency and linguistic acceptability (similar to what Warstadt et al. (2019) achieve with the CoLA dataset for English). We hope our study can create motivation for such work in linguistically-aware, fine-grained multilingual evaluation for languages of all resource levels.

Our experiments focus on BERT-style models, since this is mostly the size of model available for monolingual, non-English models (in our case BERT and GreekBERT). However, it is not necessary from these experiments that our findings extrapolate to larger models that are commonplace at the time of writing.

Lastly, both pro-drop and subject-verb order are largely discourse-dependent constructions. For example, pro-drop is more likely when the subject of the sentence is very clear from the discourse, while subject-verb order in Greek is changed to achieve different discourse focus, similar to how intonation changes the focus of a sentence in English (e.g., stressing the verb in “Mary helped John” puts the focus on the verb, which in Greek can be done by putting the verb first). Despite this, all of our ex-

periments are done on isolated sentences from the UD treebanks and do not contain discourse content. Though this means that the models do not have the full relevant context for each input, we do not expect that having more context should favor one model more than another for our evaluation. Since this work compares models on the same inputs, we did not consider this a significant confounder.

Abstract

Vision-and-language (V&L) models pre-trained on large-scale multimodal data have demonstrated strong performance on various tasks such as image captioning and visual question answering (VQA). The quality of such models is commonly assessed by measuring their performance on unseen data that typically comes from the same distribution as the training data. However, when evaluated under out-of-distribution (out-of-dataset) settings for VQA, we observe that these models exhibit poor generalization. We comprehensively evaluate two pretrained V&L models under different settings (i.e. classification and open-ended text generation) by conducting cross-dataset evaluations. We find that these models tend to learn to solve the benchmark, rather than learning the high-level skills required by the VQA task. We also find that in most cases generative models are less susceptible to shifts in data distribution compared to discriminative ones, and that multimodal pretraining is generally helpful for OOD generalization. Finally, we revisit assumptions underlying the use of automatic VQA evaluation metrics, and empirically show that their stringent nature repeatedly penalizes models for correct responses.

1 Introduction

Visual Question Answering (VQA) is the task of automatically answering natural language open-ended questions about images. Tackling VQA involves multiple skills, such as language and visual understanding, integrating information between the two (vision and language) modalities, and commonsense and knowledge based reasoning. One of the goals of the VQA research has been fostering the development of systems that are able to answer *any open-ended question about any image*. This

motivation has inspired a fruitful line of research in designing VQA benchmarks (e.g., Malinowski and Fritz, 2014; Antol et al., 2015; Krishna et al., 2017; Goyal et al., 2017; Hudson and Manning, 2019) and models (e.g., Yang et al., 2015; Anderson et al., 2018; Lu et al., 2019; Cho et al., 2021).

In this work, we investigate if recent pretrained VQA models can indeed answer any open-ended question about images or if they are mostly suitable for answering questions from the VQA benchmarks they are optimized for. In other words, *are models learning to solve the task or learning to solve the datasets?* We believe the former is more aligned with the goal of building real-world VQA systems.

To measure whether models learn to solve the task of VQA, we believe we need to examine their *out-of-distribution (OOD)* generalization capabilities: how they perform on examples drawn from a distribution other than that of the training set. In this work, we extensively evaluate OOD generalization of current pretrained V&L models by conducting cross-dataset evaluations (without any adaptation to the test domain).

Through our extensive experiments, we provide in-depth discussion on the following questions:

- *How well do recent models generalize under OOD settings?* We observe a notable drop in performance from IID to OOD settings across models and benchmarks, demonstrating that models mostly learn to solve specific benchmarks as opposed to learning general skills for answering questions about images. This result is not simply due to a mismatch between the set of answers between the training and test VQA datasets, nor due to poor representation of test answers in VQA training data.
- *Is multimodal pretraining beneficial for OOD generalization?* We find that while image-text pretraining is helpful in most OOD settings, it is not always more useful than in IID ones. Moreover, it is least useful for OOD evalua-

^{*}denotes equal first author contribution. [†] denotes equal contribution. [‡] denotes equal senior contribution. Detailed contributions follow at the end of the paper.

tion on the VIZWIZ benchmark, highlighting the challenges of a real-world benchmark.

- *Is generative modeling more robust to distribution shifts?* In most cases, we observe that generative models—which are not bound to predictions over a fixed set of answers curated from the training data—are more robust to OOD evaluation than discriminative (*i.e.*, classification-based) ones. Moreover, we quantify what the limitations of discriminative models are for real-world VQA applications (*e.g.*, answering questions of visually-impaired users), where the answers a deployed model needs to produce cannot be predetermined.
- *Are current automatic VQA metrics too stringent for OOD evaluation?* We examine if the performance of our pretrained models is negatively impacted by the current standard VQA accuracy metrics, which match predicted answer strings to a limited number of ground-truth answers. Human evaluation reveals the stringent nature of such accuracy metrics, which is especially pronounced in the OOD settings. Nevertheless, while the IID-to-ODD performance gap is reduced after human evaluation, models still exhibit poor generalization to OOD VQA benchmarks.

We believe our OOD evaluations and supporting analyses expose the shortcomings of current models, and recommend future work to adopt these evaluation practices to provide real-world, robust assessment of VQA systems.

2 Related Work

Beyond IID evaluation in VQA. Previous work has evaluated VQA models beyond the IID setting for robustness to *specific and controlled* aspects – novel compositions of seen concepts (Agrawal et al., 2017; Johnson et al., 2017; Hudson and Manning, 2019), change in prior distributions of answers per question type (Agrawal et al., 2018; Gokhale et al., 2020; Niu et al., 2021), adversarial examples provided by humans (Sheng et al., 2021; Li et al., 2021b), consistency, negation, and simple perturbation in questions (Jimenez et al., 2022), counter-examples (Dancette et al., 2021), and controlled shifts in language and vision modalities (Akula et al., 2021). Our focus, however, is to evaluate for *overall* robustness to OOD data without controlling for specific aspects, by testing our

models on different OOD benchmarks. We believe our experimental setting more closely emulates the expected experience of deployed VQA systems. Moreover, when the exact nature of distribution shift between train and test splits is known (such as in (Agrawal et al., 2018)), approaches developed to tackle such shifts tend to rely on the explicit knowledge of construction of such OOD splits resulting in inflated sense of progress (Teney et al., 2020).

Similar to us, Zhang et al. (2021); Hudson and Manning (2019) also present some experimental results on VQA OOD evaluation, however they do it in limited manner (*e.g.*, do not consider all pairs of datasets, do not evaluate the effect of multimodal pretraining, etc.). To our best knowledge, ours is the first work to extensively quantifying the extent of IID to OOD performance drops in current VQA models and study the effect of several factors: answer overlap, multimodal pretraining, generative vs. discriminative modeling, and stringent evaluation metric.

Domain adaptation in VQA. Some studies (Jabri et al., 2016; Chao et al., 2018; Zhang et al., 2021) have explored domain adaptation of VQA models from one VQA benchmark to another. Our focus, instead, is on evaluating *zero-shot* cross-benchmark generalization *without* any adaptation. This allows us to assess the robustness of current models towards unforeseen distribution shifts. Our work is similar to that of Torralba and Efros (2011) and Hendrycks et al. (2020), who study OOD generalization in vision and text.

Zero-shot VQA with pretrained models. In an emerging line of research (Tsimpoukelli et al., 2021; Alayrac et al., 2022; Song et al., 2022; Piergiovanni et al., 2022), large-scale pretrained unimodal models (Brown et al., 2020; Radford et al., 2021) are repurposed to tackle VQA in zero-shot or few-shot fashion. While such zero-shot VQA evaluations are a better test of generalization than IID evaluations, our focus, differently, is on investigating whether models can generalize to unseen datasets *upon being taught the task by showing examples from one dataset*. Moreover, this line of work does not focus on a thorough analysis of models in OOD settings (which is hard to define for these models due to the massive amount of data they are pretrained on).

3 Experimental Setup

In this section, we present our framework to examine OOD generalization in VQA. We examine two pretrained Transformers across five benchmarks.

3.1 Models

We evaluate the performance of two representative, widely-used pretrained models that have achieved strong performance in various V&L tasks in the last few years: ViLBERT (Lu et al., 2019) and ALBEF (Li et al., 2021a). We evaluate these models in a broad range of settings (generative/discriminative, w/wo pretraining, and multiple benchmarks), resulting in 128 experiments. We chose these models as they include components shown to be important in the literature: cross-attention (ViLBERT and ALBEF), and contrastive learning (ALBEF). We note that our goal is to study trends that hold across different models, and we leave for future work controlled comparisons across architectures.

ViLBERT is one of the first, yet strong models in the recent pretrain–fine-tune paradigm in V&L. Its inputs are a sequence of sub-word tokens (Wu et al., 2016), and a set of regions of interest given by a Faster R-CNN (Ren et al., 2015; Anderson et al., 2018). The authors fine-tune it on VQAV2 by learning a classifier over the most frequent answers. We first re-implement this model successfully, and then extend it to a generative setting by pretraining and fine-tuning a Transformer decoder (more details in App. A). We denote the discriminative/generative version as ViLBERT_{DISC}/ViLBERT_{GEN}. Unless otherwise specified, results for ViLBERT_{DISC} are from our code base for direct comparison with ViLBERT_{GEN}.

ALBEF is a state-of-the-art V&L encoder whose visual inputs are image patches encoded by a vision Transformer (Dosovitskiy et al., 2021; Touvron et al., 2021) that is jointly trained with the rest of the model. Li et al. (2021a) fine-tune ALBEF on VQAV2 by adding a 6-layer Transformer decoder to generate answers (ALBEF_{GEN}). We use the official implementation,¹ and furthermore train a discriminative variant (ALBEF_{DISC}) by learning a multi-answer classifier, as in ViLBERT_{DISC}.

In our analysis, we investigate the role of multi-modal pretraining. ViLBERT was pretrained on 3M image–text pairs from Conceptual Captions (CC; Sharma et al. 2018). Li et al. (2021a) re-

Dataset	# Train (imgs / qns)	# Val (imgs / qns)	# Classes	Coverage [%]
VQAV2	82,783 / 443,757	40,504 / 214,354	3,129	98.07 / 98.07
GQA	72,140 / 943,000	10,234 / 132,062	1,533	99.78 / 99.79
VG	59,635 / 868,259	39,645 / 577,063	3,449	76.55 / 76.55
VIZWIZ	20,523 / 20,523	4,319 / 4,319	3,112	96.76 / 97.01

Table 1: Datasets statistics. #classes is the number of classes we use for the discriminative models; coverage is the percentage of questions that can be answered with our selected classes in train/validation splits.

leased two checkpoints for ALBEF: one pretrained on 4M images from CC, MS-COCO (Lin et al., 2014), SBU (Ordonez et al., 2011) and Visual Genome (Krishna et al., 2017); the other one is further pretrained on Conceptual 12M (Changpinoy et al., 2021) for a total of 14M images.²

3.2 Datasets and Evaluation Metrics

Datasets. We ground our analysis on five diverse VQA datasets: VQAV2 (Goyal et al., 2017), GQA (Hudson and Manning, 2019), VISUAL GENOME (VG; Krishna et al. 2017), VIZWIZ (Gurari et al., 2018) and VQA-CP (Agrawal et al., 2018). VQAV2 is the most commonly used VQA dataset to date. VQA-CP re-splits it such that, for every question type, train and test sets have different prior distributions of answers. VG includes questions centered around either the full image or a specific region. GQA is a large-scale dataset that focuses on compositionality of template-generated questions. Finally, VIZWIZ is the only real-world VQA dataset, collected from visually-impaired people. VG and GQA have one answer per question, while the other datasets include 10 answers per question. See Tab. 1 and App. A for more details.

There are several differences among these datasets. Both VQAV2 and GQA mostly have one-word answers (89% and 81%, respectively) whilst there are fewer in VG (57%) and VIZWIZ (67%). The type of questions also varies: VG does not contain binary ‘yes/no’ questions, but rather spans 6 WH-questions. By design, GQA questions require more compositional skills but do not test for counting; while VIZWIZ questions are more conversational as they were collected through a speech interface and has a significant proportion of OCR questions (21%). Moreover, a significant number of VIZWIZ questions (28%) are *unanswerable* due to the challenges faced by the visually-impaired users in taking pictures, resulting in poor focus,

²We also conducted experiments with ViLBERT pretrained on same datasets as the 4M ALBEF checkpoint. We found no significant difference compared to the results presented throughout this paper.

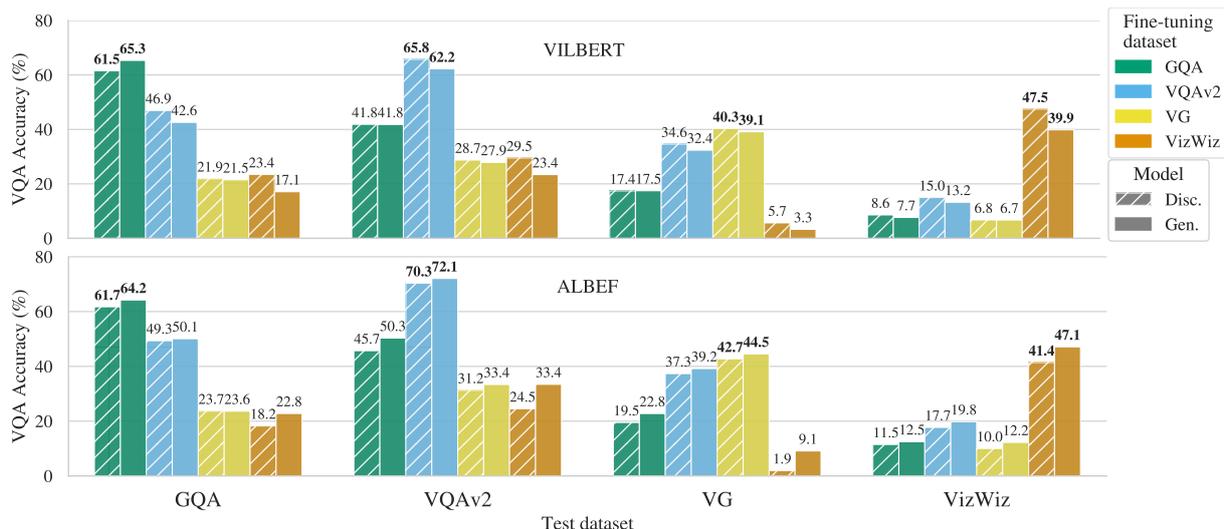

Figure 1: IID (highlighted in bold) vs. OOD performance. Top: ViLBERT pretrained on CC. Bottom: ALBEF pretrained on CC, VG, SBU, MS-COCO and C12M datasets. All models are initialized with BERT weights.

poor lighting or entirely missing the entity of interest. As such, the distribution of images in VIZWIZ is different from other datasets.

Evaluation metrics. These VQA benchmarks compute model accuracy between its prediction and the ground-truth answer(s) by string matching (after simple pre-processing). VQAV2 and VIZWIZ, each with 10 answers per question, account for diversity in ground-truth answers by scoring a given model answer as $\min\{1.0, 0.3 \times \text{count}\}$, where count is the number of annotators that used that answer. For GQA and VG, both with one answer per question, we use top-1 accuracy.³

3.3 Training Details

Following common practice, for discriminative models, we select the top- k most frequent answers as the set of answer classes to perform classification over. Here k is a dataset-dependent variable, chosen to cover most of the questions (see Tab. 1). All models are trained on the respective training sets and evaluated on the validation sets. For VG, we randomly split the data into training and validation (60%/40%) with no image is in both splits.

4 Out-of-Distribution Generalization

We examine to what extent our models learn to solve a specific VQA benchmark by latching on dataset-specific correlations, as opposed to learning

³We note that GQA and VG propose top-5 accuracy. We, instead, opt for top-1 accuracy to keep a consistent setup with VQAV2 and VIZWIZ. And we believe top-5 accuracy is impractical for many applications, such as answering questions for visually-impaired users.

more general skills required in VQA. We fine-tune a pretrained model on the train split of one benchmark (e.g., GQA) and evaluate it on the validation split of a different one (e.g., VG). Overall, we evaluate models by fine-tuning them on each benchmark and testing them against all benchmarks. If pretrained models are indeed learning the VQA skill, we expect to see a small drop in performance between the IID and OOD settings.

The results are presented in Fig. 1, with different evaluation benchmarks grouped on the x -axis. First, across all models and for each benchmark, we see a notable drop in the VQA accuracy from the IID to the OOD setting. While such a drop might be anticipated, we found the extent of the drop surprising given the impressive performance of current pretrained VL models. For all models shown, the largest drops are observed when evaluating models on the VIZWIZ benchmark. Moreover, even the smallest performance drop, which happens when fine-tuning models on VQAV2 and evaluating them on VG, remains relatively large (i.e., 5.3 points for ALBEF_{GEN}). These results show that *pretrained models are largely learning the fine-tuning benchmark without learning to solve the VQA task.*

Second, we observe that fine-tuning on VQAV2 results in the lowest drop in IID to OOD performance across all conditions—the VQAV2 bar (shown in blue in Fig. 1) is the closest to the IID one for GQA, VG, and VIZWIZ. We conclude that fine-tuning on VQAV2 yields a model that best generalizes to OOD settings in our benchmarks. This result is not simply due to the size of the fine-tuning benchmark as VG is larger than VQAV2.

Similarly, all the models achieve highest OOD performance on VQAV2. We conjecture that VQAV2 is the most diverse benchmark of our selection.

4.1 Evaluating on Shared Answer Sets

Discriminative models treat VQA as a multi-answer classification task over the set of top- k most frequent answers in the fine-tuning data. This limits their performance: if a certain answer is not frequent in the fine-tuning data, a discriminative model will perform poorly for such an answer during test time. While this limitation also affects IID evaluation, we expect it to have a stronger effect in OOD generalization (due to potentially different answer distributions between the fine-tuning and test sets). We next examine to what extent this limitation affects OOD performance by controlling for the mismatch in answer sets between the fine-tuning and test sets. We do so by considering only the test questions whose answers are included in the top- k answers of a given fine-tuning dataset (for more details, see App. B).

Fig. 2 shows the improvement in the VQA accuracy over the IID and OOD evaluation accuracy (in Fig. 1) when controlling for the shared answer set. For IID evaluation, only one intersection of answer sets is reported, corresponding to the smallest gap between IID and OOD evaluation, with remaining numbers reported in Tab. 10 (App. B). Thus, the difference between the height of the IID bar (#) and the OOD bar (*) with respect to which answer intersection between IID and OOD is computed, represents the best case scenario for OOD generalization, *i.e.*, the least drop from IID to OOD.

We observe a similar pattern across the models: in most cases, using a shared answer set improves the performance. *Overall, we still observe a notable gap between the OOD and IID settings for the best case OOD generalization scenario, showing that a shared answer set does not circumvent the difficulty of OOD generalization for these models.* A few cases where IID evaluations with a shared answer set hurt performance are discussed in App. B. When evaluating on the shared answer set, we further examine if the drop in accuracy from IID to OOD is due to the low frequency of the test answer classes in the OOD fine-tuning set. The details of the correlation computation and the results are explained in App. B and Tab. 9, respectively. This result indicates that frequency of the answer class is a contributing factor to the weak OOD generalization, but we also explore other causes in Sec. 7.

	VQAV2	GQA	VG	VIZWIZ
VQAV2	92.9	96.7	65.1	43.6
GQA	73.5	99.9	44.8	36.6
VG	52.7	62.4	74.2	32.3
VIZWIZ	79.4	82.5	40.9	86.2

Table 2: Maximum achievable accuracy for all test answers based on the top- k answers present in the respective fine-tuning sets. Rows correspond to fine-tuning datasets, columns correspond to the test benchmarks

4.2 The Case for the Generative Evaluation

A discriminative model cannot correctly answer questions for which the answers lie outside the predefined top- k classes; therefore, by treating VQA as a classification task, we can define the upper-bound performance of discriminative models on VQA by computing the accuracy given all answers in the test set being answered correctly. The upper-bound VQA accuracy is shown in Tab. 2; we observe a large drop from IID to OOD evaluations for most conditions. VIZWIZ has the lowest achievable accuracies in OOD evaluation.

However, our ALBEF_{DISC} and ViLBERT_{DISC} models still perform notably worse than maximum achievable accuracy in all settings (smallest gap of 21.5% across all conditions, see Fig. 7 in App. B); *as a result, the poor OOD performance in the discriminative setting is not simply due to the low maximum achievable accuracy.* We conclude that the common practice of modeling VQA as a classification task severely limits the generalization capability of models to new datasets. On the other hand, generative models do not suffer from a fixed class set. They can generate a larger set of answers—all words for which the tokens occur in the pretraining data, including those that are out-of-vocabulary for the given VQA fine-tune datasets. We argue that generative modeling is a more promising solution for real-world application of VQA; similarly, recent work has identified text generation as a way to unify various V&L tasks (*e.g.*, Cho et al., 2021; Wang et al., 2022; Alayrac et al., 2022).

We next ask *whether our ViLBERT_{GEN} and ALBEF_{GEN} models are more successful in OOD generalization compared to their discriminative counterparts.* For each model (*i.e.*, generative/discriminative ALBEF/ViLBERT), we first calculate the gap between the IID setting and each OOD setting (*i.e.*, Δ OOD), resulting in three values per benchmark. For instance, for the VQAV2 benchmark, Δ OOD numbers are calculated between the model fine-tuned on VQAV2 and those

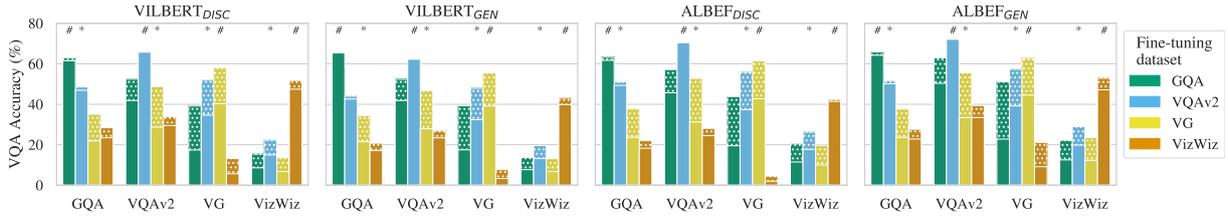

Figure 2: IID (#) vs OOD performance when controlling for the shared answer set. Solid bars are as in Fig. 1; stacked dotted bars are improvements when evaluating on questions with shared answer sets between IID and OOD settings. For IID, the shared answer set is computed with respect to a dataset denoted with *.

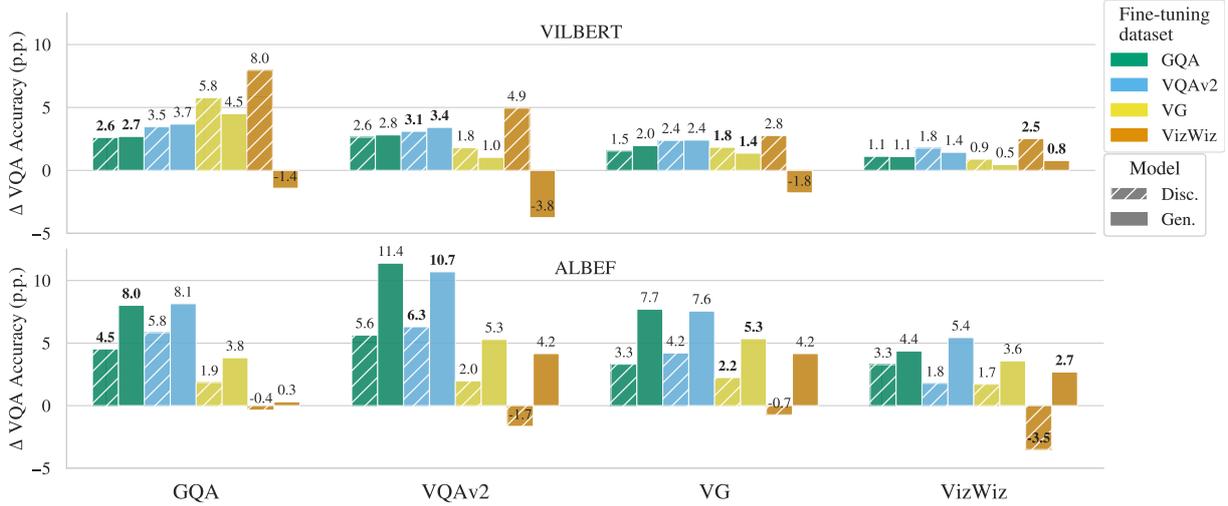

Figure 3: Percentage point difference in VQA accuracy between models with and without multimodal pretraining, for OOD and IID (highlighted in bold) evaluations. All models are initialized with BERT weights.

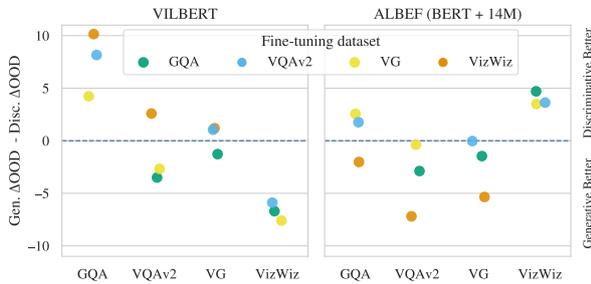

Figure 4: Difference in Δ OOD values between discriminative and generative models.

fine-tuned on VG, GQA, and VIZWIZ. Note that the higher the Δ OOD value, the poorer a model is in OOD generalization. We then compute the difference between the Δ OOD values of the generative and discriminative models. Fig. 4 visualizes this result; the benchmarks are shown on the x -axis and each circle represents the difference in Δ OOD values between the generative and discriminative model for a given fine-tuning dataset. If a generative model is more robust to OOD evaluation, we expect to see smaller Δ OOD value for that model compared to its discriminative counterpart: when the circles are below the x -axis (depicting negative values), the generative model is more robust than the discriminative one. We observe ALBEF_{GEN}

models often outperform their discriminative counterparts with respect to OOD generalization.

5 The Effect of Multimodal Pretraining

Previous work has shown that pretraining on multimodal (*i.e.*, image–text) data improves IID performance (*e.g.*, Lu et al., 2019; Li et al., 2021a); here, we ask if multimodal pretraining can help in OOD settings as well. We repeat the experiments in Sec. 4 without pretraining our models on multimodal data; instead we train the models on the train split of one benchmark and test it on the validation split of another. Fig. 3 shows the difference between the VQA accuracy of models with and without multimodal pretraining: each bar shows the gap between a bar in Fig. 1 and the equivalent experiment without multimodal pretraining.

We observe that multimodal pretraining is helpful in almost all conditions, since the majority of values displayed in Fig. 3 are positive. Pretraining is improving OOD performance likely because it can reduce the gap between the train and OOD test data by potentially exposing the model to a more diverse set of data points during pretraining. In our

Model	MM PT	VQAv2	VQA-CP	Drop
CF-VQA	–	53.6	63.5	9.9
VILBERT _{DISC}	no	66.7	42.5	24.2
VILBERT _{DISC}	yes	67.0	42.9	24.1
ALBEF _{DISC}	no	64.0	40.1	23.9
ALBEF _{DISC}	yes (4M)	70.0	44.4	25.6
ALBEF _{DISC}	yes (14M)	70.3	45.2	25.1
ALBEF _{GEN}	no	61.4	36.6	24.8
ALBEF _{GEN}	yes (4M)	71.0	49.2	21.8
ALBEF _{GEN}	yes (14M)	72.1	49.6	22.5

Table 3: Performance of models on VQAv2 (IID) and VQA-CP (OOD). The last column shows drop in performance from VQAv2 to VQA-CP. MM PT: Multimodal Pretraining.

experiments, the maximum gain from multimodal pretraining is indeed observed in OOD settings for both VILBERT (fine-tune on VIZWIZ; test on GQA) and ALBEF (fine-tune on GQA; test on VQAv2); however, *multimodal pretraining is not always more useful in OOD settings compared to IID ones*. For example, when evaluating VILBERT on VQAv2, pretraining helps the IID setting more than some of the OOD ones. Lastly, multimodal pretraining is detrimental for some cases where models are fine-tuned on VIZWIZ.

We observe that multimodal pretraining is more effective for the generative ALBEF compared to the discriminative ALBEF (cf. the shaded and solid bar with the same color in Fig. 3 bottom). For the VILBERT model, we generally do not observe such a pattern—discriminative and generative models mostly show comparable improvements due to multimodal pretraining. We observe only small improvements when increasing the size of the multimodal pretraining dataset for the ALBEF model (see Fig. 8 in App. B for more details).

6 Evaluation on VQA-CP

In this section, we evaluate the models⁴ on the VQA under Changing Priors dataset (VQA-CP; Agrawal et al. 2018). This dataset is designed such that, for every question type, train and test splits have different prior distributions of answers. Thus, models that overfit to answer priors in training data and lack sufficient visual grounding show poor generalization on the VQA-CP test set. For comparison, we also evaluate the performance of Counterfactual VQA (CF-VQA; Niu et al. 2021), a state-of-art method on VQA-CP, which does not use either the Transformer architecture nor multi-

⁴ALBEF and VILBERT_{DISC} (using the official codebase).

modal pretraining. However, it explicitly tackles the language (*i.e.*, question and answer) biases in VQA-CP.

Tab. 3 shows that for all the Transformer-based models, there is a large drop in the performance (at least 22%) from VQAv2 to VQA-CP. Thus, in spite of advances in the Transformer architecture and pretraining on diverse datasets, models are still overfitting to answer priors in the training data and lack sufficient visual grounding (Agrawal et al., 2018). However, the drop is much less for CF-VQA (10%), suggesting that *incorporating inductive biases specific to the generalization problem (i.e., modeling language bias) helps more than the Transformer architecture or scaling up the amount of pretraining data*. We also observe that the drop from VQAv2 to VQA-CP is often lower for the generative ALBEF than the discriminative ALBEF (except for ALBEF without any multimodal pretraining). Thus, *generative models are more robust than the discriminative ones*, especially when they are pretrained (similarly to the observations made in Sec. 4.2). As for the effect of pretraining, for generative ALBEF, pretraining helps reduce the drop from VQAv2 to VQA-CP. However, for discriminative models, pretraining does not seem to help generalization (in fact, it worsen ALBEF).

7 Qualitative Analysis

To dig deeper into the potential causes of the poor OOD generalization of our pretrained models, we perform a qualitative study. To this end, we randomly sample and manually examine failure cases in top-30 answer classes with the highest performance drop when moving from IID to OOD evaluation. We only focus on answer classes that are present in both the train and test splits, ensuring that performance drop is not due to the absence of answer classes in the training set. We report the top-5 classes that contribute the most to the drop in performance for each OOD setting in Tab. 11 (App. C). We notice that the following answer classes appear frequently across different OOD settings: yes/no answers, directions (left/right), colors, and numbers. In the following, we discuss a few major potential causes for the poor OOD generalization, and mention VILBERT_{DISC} responses as examples in the discussion, although similar observations hold for other models.

Poor reasoning skills. Models evaluated on GQA, but fine-tuned on another dataset, show the

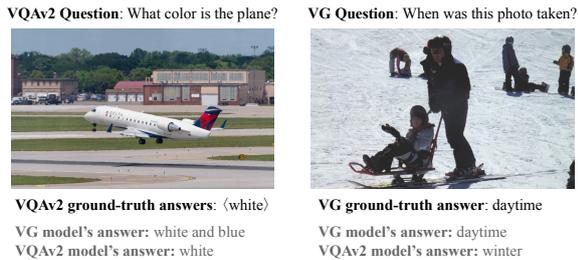

Figure 5: Examples where models’ prediction are correct but not accounted for in the ground-truth set. ⟨ ⟩ denotes a list of unique (out of 10) ground-truth answers. VG (VQAV2) model refers to a ViLBERT_{DISC} fine-tuned on VG (VQAV2).

highest performance drop on classes such as “yes”, “no”, “right”, “left”, “top”, and “bottom”. For instance, ViLBERT_{DISC} fine-tuned on VQAV2, and evaluated on GQA underperforms ViLBERT_{DISC} that has been both fine-tuned and evaluated on GQA by 24% for the answer class “no.” Upon qualitative examination, we find that for many of such failure cases, the GQA questions are more compositional and hence require more complex reasoning (e.g., “Are there both bison and zebras in the image?”, “Is the cheese to the right or to the left of the empty plate?”) than the questions for the same answer classes in other datasets (e.g., from VQAV2 train set: “Is the TV turned on?”, “Which hand is the man holding up?”). This study re-affirms previous findings that VQA models lack sufficient logical, spatial, and compositional reasoning skills (Johnson et al., 2017; Hudson and Manning, 2019) but for the more recent, pretrained Transformer models.

Overfitting to the answer priors. Previous studies have shown that VQA models tend to be biased towards the prior distribution of answers in the training set (per question type) (Agrawal et al., 2018). We find that this limitation exists in the more recent pretrained models as well, and it is especially hurtful in the OOD settings because the priors need not be the same across train and test sets, unlike in the IID settings. For instance, ViLBERT_{DISC} fine-tuned on VQAV2 predicts “2” for a lot of questions with target answer “1” in the VG test set. Similarly, sometimes ViLBERT_{DISC} fine-tuned on VG incorrectly predicts “helmet” for VQAV2 test questions such as “What is the skateboarder wearing to protect his head?”, “What protective gear is he wearing?” when the skateboarder is not wearing anything. This indicates that the model is relying on answer priors rather than visual grounding. Our experimental results on VQA-CP

(Sec. 6) directly quantify the extent of such limitations in current models.

Overfitting to the question format. We observe instances of models failing to correctly answer questions when the format of the questions changes between the fine-tuning and test sets. For instance, questions about “chair” in the VQAV2 fine-tuning set are mostly of the form “What is ... sitting on?” whereas in the GQA test set, they are mostly of the form “What kind of furniture is ...?”. Thus, the “chair” class accuracy of ViLBERT_{DISC} fine-tuned on VQAV2 drops from 48% when tested on VQAV2 to 38% on the GQA test set. Similarly, ViLBERT_{DISC} fine-tuned on GQA fails terribly for “dog” and “cat” classes on the VG test set (accuracy drops of 47% and 43% respectively between GQA–GQA (fine-tuned on GQA, tested on GQA) and GQA–VG). GQA questions are mostly of the form “What animal ...?” or “What kind of animal ...?” whereas VG questions often do not mention the word “animal” and are of the form “Who is ...?” or “What is ...?” (e.g., “Who is holding the Frisbee?”, “What is on the leash?”). To the best of our knowledge, no previous work has reported such behavior of VQA models (i.e., they tend to overfit to the question format).

Finally, we observe cases where correct model responses are evaluated as incorrect by the VQA evaluation metric, as such responses differ from the ground-truth answers. In the next section, we provide examples of such cases and examine the impact of **stringent evaluation metric** on poor OOD generalization by engaging human raters to evaluate responses.

8 Human Evaluation

In our qualitative study, we observed that the stringent nature of the standard VQA evaluation metrics (i.e., performing string matching of model responses with a small set of ground-truth answers) repeatedly penalizes models for correct responses because those responses do not exist in the set of ground-truth answers (Fig. 5). For example, the evaluation metric fails to take into account differences (between model response and ground-truth) due to specificity of the answers (e.g., “on table” vs. “table”, “pizza slices” vs. “pizza”), synonyms, and different interpretations of the question (e.g., Fig. 5 right).

In this section, we aim to quantify how robust standard VQA metrics are by performing human

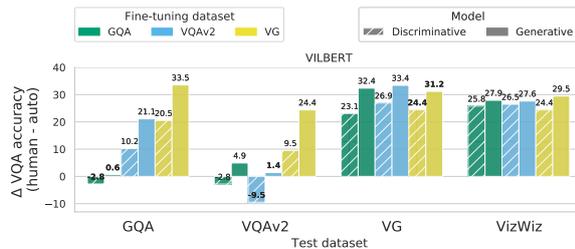

Figure 6: Difference in human and automatic accuracy of $VILBERT_{DISC}$ (shaded bars) and $VILBERT_{GEN}$ (plain bars) for GQA, VQAV2, VG and VIZWIZ. Accuracies in bold denote the IID settings.

evaluation of our models for both IID and OOD settings. The details of the setup and in-depth results are provided in App. D. Below we present our main findings.

Human evaluation yields notably higher accuracies than the automatic evaluation. This is shown in Fig. 6, where the increase can be up to 33.5% when moving from automatic to human evaluation.⁵ This implies the current automatic metrics miss out on a lot of correct responses due to their stringent nature. Interestingly, this increase in model accuracy from automatic to human evaluation is higher for $VILBERT_{GEN}$ than $VILBERT_{DISC}$ for all the benchmarks. This is expected because the generative model is more likely to produce longer, more varied answers, which might not be awarded using automatic metric but are still correct responses. Moreover, human evaluation helps OOD settings more than the IID settings for most of the benchmarks (*e.g.*, GQA, VQAV2). This is also expected, because in the OOD settings, a model might not learn the format of the test answer (“on table” vs. “table”, “clear vs. sunny”) from the train set (unlike in the IID settings) and hence it is more likely to be penalized by the automatic accuracy metric. Thus, we conclude that the currently used accuracy metrics for VQA are not robust, especially for generative models and OOD evaluation settings. Hence, to more accurately evaluate the goodness of our models, *we need to develop better evaluation metrics for VQA.*

Even after human evaluation, models still exhibit poor OOD generalization. Although human evaluation improves the models’ accuracies and more so for the OOD than the IID settings, we observe that the models’ performance in OOD settings is still worse compared to that of IID set-

⁵In some cases, human evaluation yields lower accuracy than the automatic evaluation. We discuss this in App. D.

tings, albeit with reduced margin (see App. D for quantitative results). We also note that while $VILBERT_{DISC}$ usually outperformed $VILBERT_{GEN}$ with the automatic evaluation, $VILBERT_{GEN}$ outperforms $VILBERT_{DISC}$ for all the test sets under human evaluation. This reinforces the observations in Sec. 4.2 regarding stronger OOD generalization of generative models over discriminative ones.

9 Conclusion

In this study, we show that, despite their impressive performance when evaluated on test data drawn from the same distribution as the training data, recent V&L models perform poorly in out-of-distribution (OOD) settings. We conclude that these models learn to solve specific benchmarks as opposed to the skill of visual question answering (VQA). Interestingly, in most cases, we observe that the generative models are more robust to OOD generalization compared to the discriminative ones. Moreover, pretraining the models on large image-text data often helps in OOD generalization. Our results also highlight the importance of human evaluation for a more accurate assessment of model performance: we find that the current VQA automatic metrics miss out on a notable number of correct model responses. Human evaluation is especially important as the community is shifting towards generative VQA models which, unlike discriminative ones, can produce answers that go beyond those seen in a training/fine-tuning dataset. Finally, to make progress towards more capable models, we need more rigorous evaluation protocols that shed light on models’ strengths and short-comings. We believe testing models in OOD settings is a step towards this direction as it helps evaluate models for general skills required to solve the task as opposed to benchmark-specific correlations.

Limitations

We list some limitations of our work which could benefit from future investigations.

First, when exploring potential factors for poor OOD generalization, our quantitative analysis focused only on differences in answer distributions between fine-tuning and test datasets. However, future work should investigate differences in question distribution, image distribution and combinations of these three variables.

Second, it would be interesting to conduct further investigation to understand why multimodal

pretraining does not help in certain cases. A correlation analysis between improvement in accuracy (due to multimodal pretraining), and between pretraining and fine-tuning/test data could be useful.

Third, the models investigated in our study (ViLBERT and ALBEF) are pretrained on a relatively small number (millions) of data points compared to language-only pretrained transformers, such as BERT, trained on billions of tokens. Such large-scale pretraining has been shown to improve OOD robustness for language-only models (Hendrycks et al., 2020). Hence, we leave for future work to investigate multimodal models trained on billions of image–text pairs (for instance, LAION-5B; Schuhmann et al. 2021).

Lastly, in this study, we only focus on standard VQA evaluation metrics for each benchmark. However, it would be interesting to also evaluate the robustness of metrics such as WUPS (Malinowski and Fritz, 2014) that compute answer similarities based on the distance between them in the WordNet (Miller, 1995) tree and are expected to be more robust than the standard metrics.

Ethics Statement

Below we present some considerations related to the ethical and broader impact of our work.

First, all datasets used in our study are from published work and are publicly available, including the VIZWIZ data (Gurari et al., 2018) which has been curated from visually impaired users and released publicly after proper filtering to preserve the privacy of the users.

Second, for human evaluation of our models, we collected human data via the Amazon Mechanical Turk platform. We detail the data collection process and measures taken to control the quality of collected data in App. D. As for the ethical considerations related to collecting data from human subjects, our data collection campaign was approved by an ethics review board in our institution. Human subjects were paid at the rate of 0.15 USD per HIT (Human Intelligence Task) resulting in an hourly payment well above minimum wage.

Third, by testing models on a data distribution different from the training one, the OOD evaluation setting studied in our work has the following broader impacts: it highlights (1) the challenges of generalizing to real-world VQA datasets such as VIZWIZ, and (2) the kind of biases learned (and also potentially amplified) by the models.

Lastly, we discuss both potentially beneficial and harmful applications of the task of Visual Question Answering studied in our work. VQA has many potential applications beneficial for society:

- Aiding visually impaired users in understanding their surroundings (Human: What is on the shelf above the microwave? AI: Canned containers.)
- Teaching children through interactive demos (Kid: What animal is that? AI: That is Dall Sheep. You can find those in Alaska.)
- Aiding analysts in processing large quantities of visual surveillance data (Analyst: What kind of car did the man in red shirt leave in? AI: Blue Toyota Prius.)
- Interacting with in-home physical robots (Human: Is my laptop in my bedroom upstairs? AI: Yes. Human: Is the charger plugged in?)
- Making visual social media content more accessible (AI: Your friend Bob just uploaded a picture from his Hawaii trip. Human: Great, is he at the beach? AI: No, on a mountain.)

But like most other technology, VQA could also be used for potentially harmful applications such as:

- Invasion of individual’s privacy by using VQA to query streams of video data being recorded by CCTV cameras at public places.
- Visually impaired users often need assistance with parsing data containing personal information (Ahmed et al., 2015), such as credit cards, personal mails, etc. Such VQA systems could be configured to leak/retain personally identifiable information.

Contributions

Aishwarya Agrawal initiated and designed the project, ran experiments and analyses on the official codebase of ViLBERT, contributed significantly to paper writing, and provided project support and advice. *Ivana Kajić* was responsible for the project’s technical infrastructure for the re-implementation of ViLBERT, ran experiments and analyses, and contributed significantly to paper writing. *Emanuele Bugliarello* co-led the data preparation, ran experiments and analyses on ALBEF, and contributed significantly to paper writing.

Elnaz Davoodi co-lead the data preparation, and helped setting up and running re-implementation experiments. *Anita Gergely* led the human evaluation experiments, and contributed to paper writing. *Phil Blunsom* provided project advice. *Aida Nematzadeh* provided significant project support and advice, helped running experiments, and contributed significantly to paper writing.

Acknowledgements

We are grateful to Antoine Miech, Lisa Anne Hendricks and Chris Dyer for their constructive feedback. ■ During this project, *Emanuele Bugliarello* was supported by the funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 801199.

A Experimental Setup Details

In this section, we report additional details regarding our experimental setup.

A.1 Models

We evaluate the performance of two strong models, ViLBERT (Lu et al., 2019) and ALBEF (Li et al., 2021a). These models belong to the family of pretrained Transformer that has recently achieved state-of-the-art performance on several V&L tasks, and are specifically instances of dual-stream architectures (Bugliarello et al., 2021). In this paradigm, models are first pretrained on a large collection of image–caption pairs, and then fine-tuned to solve specific downstream tasks. ViLBERT is pretrained using three objectives, masked language modeling (MLM; Devlin et al. 2019), masked region modeling and image–text matching (ITM; Chen et al. 2020). ALBEF is pretrained using MLM, ITM and an image–text contrastive loss (Li et al., 2021a). We refer the reader to Sec. 3 for an overall description of these models. Tab. 4 lists pretraining and architecture details for both models. All the models were fine-tuned using the AdamW (Loshchilov and Hutter, 2019) optimizer, with model-specific hyperparameters in Tab. 6.

ViLBERT. In this model, the textual inputs are first processed through 6 Transformer layers, before being combined with visual inputs through inter- and intra-modal attention layers. We re-implement this architecture, and confirm comparable performance by reproducing its results with the ones obtained through the official codebase⁶ (see Tab. 5 for IID performance of both implementations). A key difference between the two implementations is in the image features: while the official model uses 10–100 regions of interest (RoIs) from a ResNeXt-152 (Xie et al., 2017), our re-implementation relies on 100 RoIs extracted by Faster R-CNN (Ren et al., 2015) trained on VG.

We then extend our codebase to implement a generative version of ViLBERT by replacing the discriminative decoder with an autoregressive decoding head.⁷ The decoder is trained with teacher-forcing, and in datasets with several responses, the

⁶<https://github.com/facebookresearch/vilbert-multi-task/>.

⁷Our implementation of the generative decoder follows that of TransformerDecoder available at <https://github.com/pytorch/pytorch/blob/master/torch/nn/modules/transformer.py>.

most frequent response is used as the ground truth response. Pretraining on CC, when used, is done by generating text. We also examine the effect of pretraining on both the encoder and decoder, and find the learning to be more stable when using only pretrained encoder, although further hyperparameter exploration could mitigate this difference. We study the effects of multimodal pretraining on the Conceptual Captions dataset (Sharma et al., 2018) with 3M images.

ALBEF. Like ViLBERT, ALBEF is a dual-stream encoder but with two main differences: first, the visual inputs are image patches that are processed through a vision Transformer (Dosovitskiy et al., 2021); and second, the cross-modal interactions happen through standard Transformer cross-attention at each layer (whereas ViLBERT uses co-attention layers specifically designed for intra- and inter-modal interactions). In addition, the model is trained with pseudo-targets that are generated from a moving-average version of its weights. We run experiments using the official codebase.⁸ The visual backbone is a DeiT-B/16 (Touvron et al., 2021) pretrained on ImageNet-1k (Deng et al., 2009) at resolution 224×224 , and further trained during the multimodal pretraining phase. For the downstream VQA benchmarks, we follow the authors and resize input images to 384×384 and apply random augmentation during fine-tuning. Li et al. (2021a) formulated the VQA task as generative by adding a 6-layer Transformer decoder initialized from the pretrained encoder. We follow this approach and also evaluate a discriminative version by learning a two-layer MLP with ReLU (Agarap, 2018) non-linearity in between, following the authors’ setup for the Visual Entailment benchmark (Xie et al., 2019). We found the hyperparameters proposed by Bugliarello et al. (2021) to work better. During inference, we evaluate ALBEF in two ways: first, following the authors, we rank the in-domain candidate answers based on their likelihood; second, we let the model generate any possible answer in an open-ended fashion through greedy decoding. We found these two approaches to minimally affect final performance (see Tab. 7). Unless otherwise specified, we report results given by generation as it reflects open-ended question answering.

Model	# Params	Pretrain data	# Images	# Captions
VILBERT	240M	CC	3.3M	3.3M
ALBEF (4M)	450M	+COCO+SBU+VG	4M	5M
ALBEF (14M)	450M	+C12M	14M	15M

Table 4: Pretrained models details. ALBEF size includes both the main model and its moving average. Pretraining data: CC (Sharma et al., 2018), COCO (Lin et al., 2014), SBU (Ordonez et al., 2011), VG (Krishna et al., 2017), C12M (Changpinyo et al., 2021).

Model	VQAv2	GQA	VG	VIZWIZ
Official codebase	67.04	66.78	40.69	44.46
Re-implementation	65.75	61.51	40.31	47.46

Table 5: Comparison between the official and our codebases for VILBERT_{DISC} in the IID setting.

A.2 Datasets

Tab. 1 lists statistics for each dataset in our study. VQAv2 (Goyal et al., 2017) is the most commonly used VQA dataset to date, it consists of 265K images and 1.1M question-image pairs, each with 10 ground-truth answers. VQA-CP (Agrawal et al., 2018) re-splits the VQAv2 dataset such that, for every question type, train and test sets have different prior distributions of answers. VG (Krishna et al., 2017) includes 108K images and 1.7M questions, each paired with a single answer, centered around either the full image or a specific region within it. GQA (Hudson and Manning, 2019) is another large-scale effort (22M questions, each with one answer) that focuses on compositionality of template-generated questions for real-world images (from VG). Following prior work, we use the GQA *balanced* subset (1.5M questions). Finally, VIZWIZ (Gurari et al., 2018) is the only real-world VQA dataset as it was collected from visually impaired people. It consists of 31K image-question pairs, each paired with 10 answers.

A.3 Training Details

Following common practice, for discriminative models, we select the top- k most frequent answers from the fine-tuning dataset, as the set of answer classes to perform classification over. Here k is a dataset-dependent variable. For VQAv2 and GQA, we use the same answer sets as VILBERT (3,129 and 1,533, respectively). For VIZWIZ, we select the answers that appear at least 8 times in training and validation sets, for a total of 3,112 answers that cover 97% of the data. For VG, we select the answers that appear at least 29 times in the dataset, for a total of 3,449 answers that cover 76.5% of the data. Importantly, combined with the VQA accu-

Benchmark	Qn len	# Classes	BS	LR	# Epochs
VQAv2	16	3,129	256	4e-5	20
GQA	26	1,533	256	4e-5	20
VG	16	3,449	256	4e-5	20
VIZWIZ	40	3,112	256	4e-5	20

(a) Parameters used for VILBERT models. The internal codebase uses LAMB optimizer with the initial LR of 1e-3, with the best checkpoint selected on eval dataset.

Benchmark	Qn len	# Classes	BS	LR	# Epochs
VQAv2	16	3,129	256	1e-4	20
GQA	26	1,533	256	1e-4	20
VG	16	3,449	256	1e-4	20
VIZWIZ	40	3,129	256	1e-4	20

(b) Discriminative ALBEF.

Benchmark	Qn len	Answer len	BS	LR	# Epochs
VQAv2	16	6	256	2e-5	20
GQA	26	5	256	2e-5	20
VG	16	8	256	2e-5	20
VIZWIZ	40	11	256	2e-5	20

(c) Generative ALBEF.

Table 6: Hyperparameters used in our experiments. Question and answer lengths are in tokens, BS is the batch size, LR is the learning rate.

racy metric defined above, this results in an upper-bound to the accuracy that discriminative models can achieve in each dataset (see Tab. 2).

All models are trained on the respective training sets and evaluated on the validation sets, which lets us conduct in-depth analyses that would otherwise be impossible to carry out on private test sets. As there is no official split of VG, we randomly sample the data into training (60%) and validation (40%) such that no image appears in both splits.

B Additional Results

Evaluation with Shared Answer Sets While different answer sets are an apparent issue for discriminative models, they also impact the performance of generative models, as the number of data points for each answer class seen by the generative model during fine-tuning varies: data-points in top- k answer set are more frequent than others (by definition of top- k). In other words, even though a tokenizer used to produce an answer could generate it, it is unlikely (or less likely) to do so if it has not seen (or seen rarely) that combination of tokens during fine-tuning. Thus, even for generative models, we consider performance on top- k most frequent classes for each benchmark.

Thus, we report the accuracy on the subset of

	VQAV2	GQA	VG	VIZWIZ
VQAV2	72.37	50.56	38.94	19.81
GQA	50.32	64.26	22.80	12.51
VG	33.40	24.99	43.35	12.60
VIZWIZ	34.17	22.73	8.89	48.44

(a) Ranking-based evaluation of ALBEF_{GEN}.

	VQAV2	GQA	VG	VIZWIZ
VQAV2	72.09	50.10	39.20	19.81
GQA	50.33	64.24	22.79	12.50
VG	33.39	23.64	44.55	12.25
VIZWIZ	34.44	22.80	9.13	47.14

(b) Generation-based evaluation of ALBEF_{GEN}.

Table 7: Performance of ALBEF_{GEN} (14M) when tested via ranking (top) and generation (bottom). Rows correspond to the fine-tuning datasets, columns correspond to the test benchmarks. The model performs similarly in both setups. We found similar results for ALBEF_{GEN} (4M).

test questions whose answers are shared between *both* the IID and the OOD models. For instance, when comparing the performance of the VQAV2 and VG fine-tuned models on the VQAV2 test set, we compute the average accuracy on those VQAV2 questions whose ground truth answers are present in the top- k answers from VQAV2 as well as the top- k answers from VG: we extract the common answer labels (between VQAV2 and VG top- k answers) and compute performance on test questions belonging to these shared answer labels only.

For IID evaluations, there are several possible ways to define shared answer sets based on OOD vocabs. While a subset is shown in Fig. 2, Tab. 10 lists the VQA accuracy of each model in the IID settings when evaluated on the questions in the test sets whose answers are shared between the top- k answers in both the IID and the OOD settings (see Sec. 4.1 for more details).

In some IID cases, restricting the answer set to common answers hurts the performance (indicated as a lack of dotted bar in Fig. 2). Interestingly, this pattern is observed across all models for some IID evaluations where the shared answer set is computed with respect to the VG benchmark only: VQAV2 for ViLBERT_{DISC} (-7.65 pp drop), VQAV2 (-8.65 pp drop) and GQA (-8.00 pp drop) for ViLBERT_{GEN}, VQAV2 (-6.86 pp drop) for ALBEF_{DISC}, and VQAV2 (-6.89 pp drop) for ALBEF_{GEN}. This seems to indicate that the GQA and VQAV2 questions corresponding to shared answer set with VG are more difficult than the average difficulty of these test sets.

	VQAV2	GQA	VG	VIZWIZ
VQAV2	–	0.41	0.51	0.11 [^]

Table 8: Spearman’s rank correlation between drops in test accuracy (from IID to OOD) and the differences in proportion of answer classes between IID and OOD fine-tune sets. Unless otherwise specified with a [^] character, ρ values are significant with $p < .05$. Rows correspond to the fine-tuning datasets, columns correspond to the test benchmarks.

	VQAV2	GQA	VG	VIZWIZ
VQAV2	–	0.43	0.51	0.25
GQA	0.27	–	0.43	0.19
VG	0.26	0.36	–	0.13
VIZWIZ	0.47	0.55	0.48	–

Table 9: Spearman’s rank correlation between drops in test accuracy (from IID to OOD) and the differences in proportion of answer classes between IID and OOD fine-tuning sets for ALBEF_{GEN}. $p < .05$ for all ρ . Rows correspond to the fine-tuning datasets, columns correspond to the test benchmarks.

Answer Frequency Correlation In order to examine the relationship between accuracy drop for less frequent classes, we first compute per answer-class accuracy (average accuracy of all test questions belonging to the same answer class) for answers in shared answer set. We then sort the shared answer classes based on their weighted drop in per-class accuracy from IID to OOD (IID accuracy - OOD accuracy), *i.e.* absolute drop in per-class accuracy weighted by number of data points belonging to that class in the test set. We then compute the Spearman’s rank correlation of these weighted drop in per-class accuracies with difference in percentage frequencies of the answer classes between IID

and OOD fine-tuning sets (percentage frequency of an answer class in IID minus its percentage frequency in OOD).

Tab. 8 list Spearman’s rank correlations of IID-to-OOD drops in test accuracy vs. proportion of answer classes in respective (IID and OOD) fine-tuning sets for ALBEF_{DISC}, ViLBERT_{GEN} and ViLBERT_{DISC} (see Sec. 4.1 for more details). As a simple baseline test, we also compute correlations and p-values for a permuted dataset to confirm their lack of significance, or correlation values close to zero.

Maximum Achievable Scores Table 2 lists maximum achievable accuracies, and Figure 7 shows the difference between those scores and bar values shown in Figure 1. In our analyses, we also noted that differences in answer pre-processing strategies can result in slightly different numbers than those reported in Tab. 2. However, those differences did not change the conclusion of our findings.

Effect of pretraining data size on ALBEF For the ALBEF model, while we often observe improvements by increasing the size of the multi-modal pretraining dataset (4M vs. 14M), the improvements are small. When pretraining on the smaller dataset (4M, see Fig. 8), we observe a median improvement (over no pretraining) of 1.9% for the discriminative and 4.9% for the generative ALBEF, while the median additional improvements due to larger pretraining dataset (14M) are 0.1% and 0.6% respectively (refer to Fig. 3). Surprisingly, there are also dataset pairs for which larger pretraining has a negative effect when compared to the performance with a smaller pretraining set (e.g., ALBEF model fine-tuned on VIZWIZ and tested on VQAV2).

C Potential Causes of Poor OOD Generalization: A Qualitative Study

In section 4, we observe that our pretrained models exhibit poor OOD generalization for the task of VQA. We also noted that this poor generalization is not entirely explained by the absence or poor representation of test answer classes in the training data. Here, we perform a qualitative study to dig deeper into the potential causes of the poor OOD generalization. We manually examine 20 randomly-sampled qualitative examples of failure cases on top-30 answer classes contributing the most to the drop in performance from IID to OOD.

We only focus on answer classes that are shared between the train and test splits to make sure the performance drop is not due to the absence of answer classes in the training dataset. We report the top-5 classes that contribute the most to the drop in performance for each OOD setting in Tab. 11. Below, we describe four major potential causes⁹ for the poor OOD generalization that we can infer from our qualitative study on ViLBERT_{DISC}¹⁰ and ALBEF_{GEN}. The specific examples reported below are for ViLBERT_{DISC}.

Poor reasoning skills. In Tab. 11, we can see that a model fine-tuned on VQAV2, VG, or VIZWIZ and evaluated on GQA shows the highest performance drop on classes such as “yes”, “no”, “right”, “left”, “top”, and “bottom”. For instance, VQAV2–GQA (fine-tuned on VQAV2, evaluated on GQA) model underperforms GQA–GQA model by 24% for “no.” Upon qualitative examination, we find that for many of such failure cases, the GQA questions are more compositional and hence require more complex reasoning (e.g., “Are there both bison and zebras in the image?”, “Is the cheese to the right or to the left of the empty plate?”) than the questions for the same answer classes in other datasets (e.g., from VQAV2 train set: “Is the TV turned on?”, “Which hand is the man holding up?”). This study re-affirms previous findings (Johnson et al., 2017; Hudson and Manning, 2019) – VQA models lack sufficient logical, spatial, and compositional reasoning skills – for the more recent, pretrained Transformer models.

Overfitting to the answer priors. Previous studies have shown that VQA models tend to be biased towards the prior distribution of answers in the training set (per question type) (Agrawal et al., 2018). We find that this limitation exists in the more recent pretrained models as well, and it is especially hurtful in the OOD settings because the priors need not be the same across train and test sets, unlike in the IID settings. For instance, ViLBERT_{DISC} fine-tuned on VQAV2 predicts “2” for a lot questions with target answer “1” in the VG test set. Similarly, sometimes ViLBERT_{DISC} fine-tuned on VG incorrectly predicts “helmet” for

⁹For poor OOD generalization on the VIZWIZ benchmark, one of the reasons could be difference in image distributions between VIZWIZ (that contains many blurry pictures, or pictures with poor lighting conditions) and other three datasets (that contain clear pictures).

¹⁰We use the model trained with the official codebase.

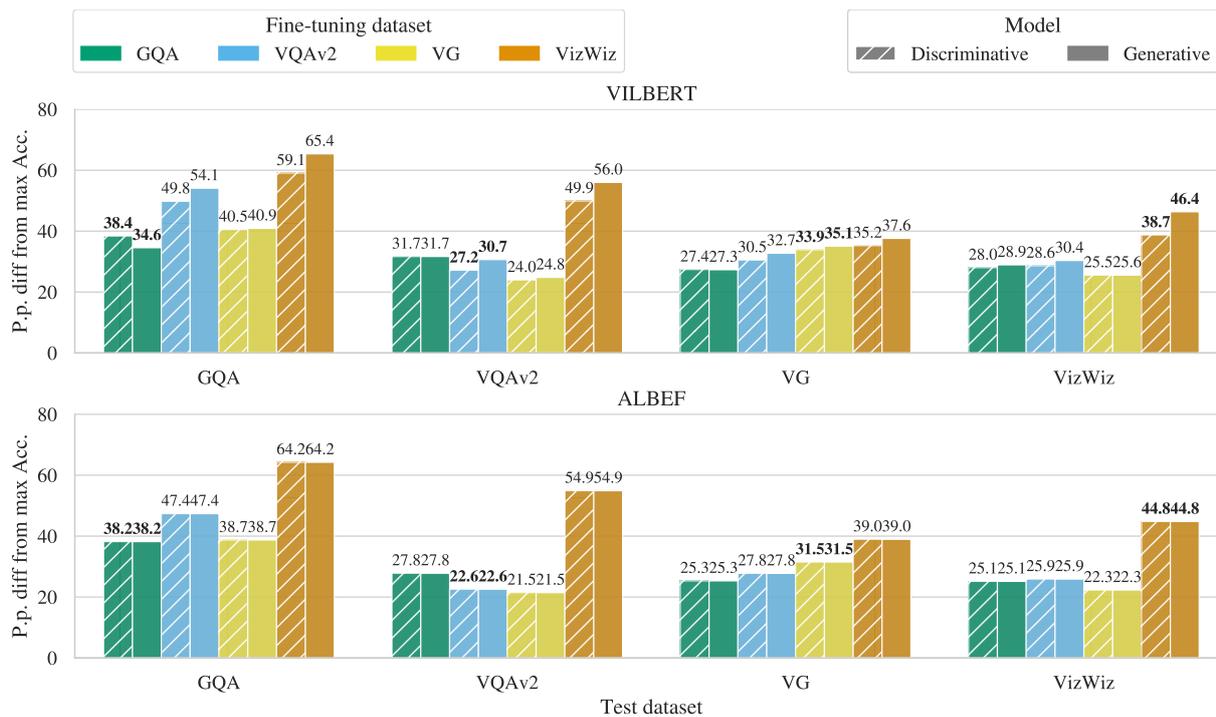

Figure 7: Percentage point difference between maximum achievable accuracies in Table 2 and accuracies in Figure 1. Results for VILBERT pretrained on the same data as ALBEF 4M are also shown.

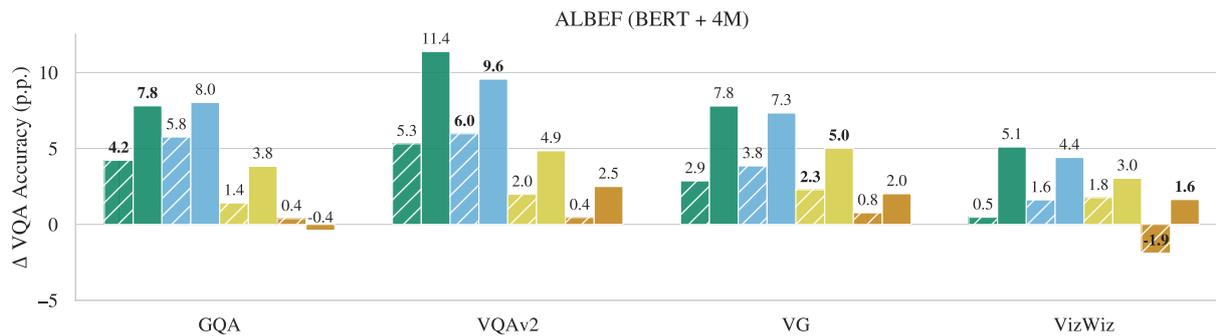

Figure 8: Difference in VQA accuracy (p.p.) for ALBEF that has and has not been pretrained on the 4M dataset.

VQAv2 test questions such as “What is the skateboarder wearing to protect his head?”, “What protective gear is he wearing?” when the skateboarder is not wearing anything. This indicates that the model is relying on answer priors rather than visual grounding. Our experimental results on VQA-CP (Sec. 6) directly quantify the extent of such limitations in current models.

Overfitting to the question format. For each answer class, there is usually a limited variation in the format of questions in the fine-tuning set. For some of the answer classes showing poor OOD generalization, we found that certain question formats are quite dominant in the fine-tuning set, and that these dominant formats are different between the OOD fine-tuning and test sets. Thus, we conjecture

that models are likely overfitting to such dominant formats in fine-tuning data and hence fail to generalize at test time when the format changes. For instance, questions about “chair” in the VQAv2 fine-tuning set are mostly of the form “What is ... sitting on?” whereas in the GQA test set, they are mostly of the form “What kind of furniture is ...?”. Thus, the “chair” class accuracy of VILBERT_{DISC} fine-tuned on VQAv2 drops from 48% when tested on VQAv2 to 38% on the GQA test set. As another example, VILBERT_{DISC} trained on GQA fails terribly for “dog” and “cat” classes on VG test set (accuracy drops of 47% and 43% respectively, where drop is between GQA–GQA and GQA–VG). GQA questions are mostly of the form “What animal ...?” or “What kind of animal

Model	Test	Fine-tune	Answer Set	VQA Acc. (IID)	VQA Acc. (OOD)	Difference

Table 10: VQA accuracy of each model in the IID settings (see column VQA Acc. (IID)) when evaluated on the questions in the test sets whose answers are shared between the top- k answers in both the IID and the OOD settings. Please refer to Sec. 4.1 for more details. Answer Set: OOD benchmarks with respect to which IID shared answer set accuracy is computed. VQA Acc. (OOD): OOD accuracy on questions corresponding to the shared answer set, *i.e.* when fine-tuned on the OOD dataset mentioned in Answer Set column and tested on the benchmark mentioned in the Test column. Difference: VQA Acc. (IID) - VQA Acc. (OOD). Gray bands highlight the OOD benchmarks with respect to which IID shared answer set accuracy is computed in Fig. 2.

...?” whereas VG questions often do not mention the word “animal” and are of the form “Who is ... ?” or “What is ... ?” (*e.g.*, “Who is holding the Frisbee?”, “What is on the leash?”). Similarly, for the answer class “pizza”, ViLBERT_{DISC} fine-tuned

on VG has mostly seen questions of the format “What food is this?”, “What is the man eating?”, “What is on the plate?”, “What’s in the box?” in VG fine-tuning set. However, when evaluated on the VQAv2 test set, the model fails to respond cor-

rectly for questions about “pizza” such as, “What snack is this?” (model response: “pineapple”), “What recipe this will become?” (model response: “cheese”), “What’s in the bowl” (model response: “tomato sauce”). For the last example, perhaps the model is not expecting pizza to be in a bowl.

Related to above, we observed that sometimes VILBERT_{DISC} fails to produce the correct answer type for a given question. For instance, VILBERT_{DISC} fine-tuned on VG responds with “woman” to the question “Is the person who is cutting these carrots right handed or left handed?”. So it appears as if the VG model does not understand the question structure in this example, *i.e.* the response is expected to be either “right” or “left”. Similarly, for the question “Are there more blue or black shirts?”, VG model responds with “rolled up”. Similarly, it answers “1 on right” to the question “What type of apple is shown?”, instead of describing some attribute of apple such as “green”.

Stringent evaluation metric. We notice that sometimes the models’ responses are correct but they are evaluated as incorrect because those responses do not exist in the ground-truth answers. For instance, VQAV2–VG model gets penalized for answering “table” instead of “on table”¹¹ (Q: “Where is . . . ?”) or “sunny” instead of “clear” (Q: “How is the weather?”). More examples in Fig. 5. This effect is expected to be more pronounced for the OOD evaluation than IID, because in IID a model can learn the format of the test answer (“on table” vs. “table”, “clear vs. sunny”) from the train set, whereas in OOD the format in the train set can be different from the test set. Also, such stringent evaluation (*i.e.*, performing string matching with a small set of ground-truth answers) is expected to hurt generative models more than discriminative ones because they show more variations in the form of the answers as they are not limited by a fixed answer vocabulary (*e.g.*, “pizza slices” instead of “pizza” (Q: “What are these?”), “pizzeria” instead of “pizza” (Q: “What kind of restaurant is this?”)). We observed that, VG model (model fine-tuned on VG) evaluated on GQA answers questions about “man” with “snowboarder”, “man on left” (*i.e.* more descriptive referring expressions) than just saying “man” but it does not get any credit

¹¹Note that before computing the accuracy, both the predicted and the ground truth answers are pre-processed for answer normalization but such pre-processing is very basic. More details of the pre-processing can be found at <https://visualqa.org/evaluation.html>

because GQA ground truth is “man”. To quantify the extent of this issue and measure its effect on discriminative vs. generative models, IID vs. OOD settings, we perform human evaluation of machine generated answers and provide additional insights in Sec. 8.

Poor performance of GQA model on color questions (both IID and OOD): VILBERT_{DISC} fine-tuned on GQA does not seem to be transferring well to color questions in the VQAV2 and VG test sets (and even in IID GQA test set). In Tab. 11, we can see that the top-5 answer classes with highest drop in IID-to-OOO performance for GQA model have quite a few colors. For instance, for the answer class “red” in the VG test set, GQA model fails to correctly answer simple questions (given the kind of questions GQA model is fine-tuned on) such as “What is the primary color of the sign on the right?”, “What is the main color of the strawberry?”, “What color is the pull luggage of the woman?”, “What color are the pepperonis?”. It is not clear why GQA model does not perform well on color questions.

D Human Evaluation

Method. We used Amazon Mechanical Turk to collect human judgment about model responses on a random subset of 10K questions for each of the test sets—VQAV2, GQA and VG. Since the size of VIZWIZ test set is less than 10K, we collected human judgment on all the VIZWIZ test questions. However, we dropped the questions that were tagged as “unanswerable” or “unsuitable” (more details are provided below under “Filtering VizWiz data”). The total number of VIZWIZ test questions for which we collected human judgment is 1440 (per model). We performed human evaluation of the responses from the following models – VILBERT_{DISC}¹² and VILBERT_{GEN} trained on the VQAV2, GQA, VG datasets. We did not collect human judgements for models *fine-tuned* on VIZWIZ, because a significant proportion of the responses from these models tend to be “unanswerable” or “unsuitable” (35% on VQAV2, 39% on GQA, 65% on VG, and 64% on VIZWIZ). Collecting human feedback about such responses would

¹²For VILBERT_{DISC}, we had initially collected human judgements for the version trained using the official codebase, and we did not collect annotations again for our reimplementation due to time constraints. Given our results above, we do not expect significant differences between the two versions.

Table 11: Top-5 answer classes with highest performance drop from IID to OOD (for the same test set) for all OOD configurations. The answer classes are sorted by drop in weighted (wtd) accuracy, i.e. drop in absolute (abs) accuracy weighted by the # test questions for that answer class.

not provide useful insights, because all questions in VQAv2, GQA and VG should be answerable, therefore all cases of “unanswerable” should be incorrect. Such responses are just a side effect of a model’s priors caused by all the unanswerable training points in the VIZWIZ fine-tuning set.

For each response, we asked 5 raters to evaluate the question, image, and a given model response, and indicate through a binary choice whether they considered the model response a correct answer to the question or not. To control the quality of the data, we filtered out low quality data using different heuristics such as distribution of yes/no answers for each worker, their mean submission times, average agreement with their fellow workers, or average alignment with the automatic accuracy.¹³ In each of these cases, we looked at random samples from the outliers to qualitatively confirm our hypothesis. More details about the human evaluation interface are presented in the next paragraph.

To compute human accuracy of a model response (for a given question and image), we considered a response correct if at least 4 raters voted it is correct, and incorrect otherwise. We decided so in order to decrease noise introduced by cases where there was low agreement between raters.

Data collection interface. Fig. 10 shows a sample of the interface the MTurk raters used to submit their responses. The workers were shown some examples, but in order not to bias them, we did not give them detailed guidance as to what should be considered correct for not - rather we asked them to rely on common sense, and consider an answer correct if it seems both factually accurate and natural in the context. See Fig. 11 for details.

Filtering VizWiz data. For human evaluation we filtered out all image-question pairs for which the ground truth answer indicates it is *unanswerable*. That is, we have not collected human feedback for questions for which the ground truth answer appears in the following list:

- "unanswerable", "unsuitable"
- "insufficient image"
- "unknown", "unsure", "not clear"
- "blurry", "too blurry"

¹³How frequently a worker’s response (yes/no) aligns with the automatic accuracy computed (100.0/0.0) More specifically, we equate the worker’s *yes* response with 100.0 and *no* with 0.0 and look at the average difference between the worker’s response and the automatic accuracy

- "i don’t know", "don’t know", "i don no", "no idea"
- "unusable image", "unsuitable image", "unstable image", "insufficient image quality", "unreadable"
- "i can’t tell", "can’t tell", "can’t see"
- "0" ¹⁴

In particular, this left us with 1440 questions for the VIZWIZ dataset.

Results. We report the human accuracies for VILBERT_{DISC} and VILBERT_{GEN} in Fig. 9 (bottom). We also report the accuracies obtained using automatic metrics (please see Sec. 3.2 for description of automatic metrics for each dataset) computed over the same random subset of test questions as that used for human evaluation in Fig. 9 (top). Please refer to Sec. 8 for discussion of results.

Qualitative examples of questions being incorrectly penalized by automatic evaluation Tab. 12 shows some examples for responses which were awarded 0.0 accuracy using automatic metrics but were marked as correct by all 5 raters during human evaluation.

Discussion on VQA data quality For the collected human judgement data, we find that for a significant number of questions (32%) there was low agreement between the 5 raters, i.e. either 3/5 answered *correct* while the remaining 2/5 answered *incorrect*, or vice-versa. Note that this is after we already filtered out low quality judgements. We have to recognize that, despite our best efforts to control data quality using our heuristics, there might still be low quality data in our dataset. Low quality annotations can be misleading and might distort the results of our analysis. Yet, we believe that we have collected a large enough sample to dampen the effect of these on the reported results. Upon examining some examples from such low agreement questions, we find that many such cases highlight the quality of the VQA data. For instance, questions not being sufficiently objective but up for interpretation, questions phrased poorly that make it difficult to understand what the question is asking about, *etc.* We discuss these further below.

- **Low agreement due to ambiguity.** One reason why human raters might give different feedback stems from ambiguity and subjectiv-

¹⁴Qualitative examples have suggested that often this was used to indicate *unanswerable*.

Figure 9: Human evaluation of $\text{ViLBERT}_{\text{DISC}}$ (shaded bars) and $\text{ViLBERT}_{\text{GEN}}$ (plain bars) and comparison with automatic evaluation on a random subset (10K) of test questions for each test dataset – GQA, VQAV2, VG and VIZWIZ. Accuracies in bold denote the IID settings. Top: accuracies obtained using automatic evaluation. Bottom: accuracies obtained using human evaluation.

ity around the question and the contents of the image. In these cases it is up to the raters subjective opinion to judge whether the answer is acceptable or not. Find some qualitative examples in Tab. 13.

- **Low agreement due to poor quality question.** Some questions in the original dataset are of rather poor quality which makes it near impossible for the rater to provide a valuable response. Find some qualitative examples of such questions in Tab. 14.

Also surprisingly, from Fig. 6, we see that for models fine-tuned on VQAV2 or GQA and tested on VQAV2, and models fine-tuned on GQA and tested on GQA, human evaluation yields lower accuracy than automatic evaluation! This is not as expected. Upon examining some examples for responses with 100.0 automatic accuracy but marked as *incorrect* by at least 4 human raters, we again find some noise in the ground-truth answers. Tab. 15 shows some examples. Below we report the number of questions where at least 4 human raters voted incorrect even though the automatic metric indicated ≥ 90.0 accuracy. Generative case: {GQA \rightarrow GQA (fine-tuned on GQA, tested on GQA): 86, GQA \rightarrow VQAV2: 49, VQAV2 \rightarrow VQAV2: 48}, Discriminative case: {GQA \rightarrow GQA: 128, GQA \rightarrow VQAV2: 52, VQAV2 \rightarrow VQAV2: 76}.

Question: What are the people standing on?

Response: sand

Is the displayed **response** a correct answer to the above **question** about the image?

- Correct
- Incorrect

Figure 10: Sample of the MTurk interface the raters used to annotate data.

Instructions

You will see a question and a corresponding, short response displayed next to the image. The question and response both concern the contents of the image. Based on the image, is the provided response a correct answer to the question?

Your task: Please indicate whether the response is correct by selecting **Correct** or **Incorrect**.

A response should be considered **correct** if:

1. It is relevant to the question and answers the question in a direct, grammatically correct way, AND
2. It accurately reflects the contents of the displayed image.

A response should be considered **incorrect** if:

1. It is not a coherent, natural response to the question, OR
2. It does not accurately reflect the contents of the displayed image.

Note: We expect the responses to be short and concise, not full sentences. Thus a response should **not** be considered incorrect solely on the basis that it is brief.

Please see the examples below to understand the task better:

- **Example 1:** This response is correct.

Question: What colour is the flip-flop?

Response: red

Is the displayed **response** a correct answer to the above **question** about the image?

- Correct
- Incorrect

- **Example 2:** This response is correct.

Question: Is this a cat?

Response: no

Is the displayed **response** a correct answer to the above **question** about the image?

- Correct
- Incorrect

- **Example 3:** This response is incorrect. Although the response addresses the question, it does not accurately reflect the image's contents. A correct response would be 'baseball'.

Question: What are they playing?

Response: basketball

Is the displayed **response** a correct answer to the above **question** about the image?

- Correct
- Incorrect

- **Example 4:** This response is incorrect. Although it is true that the scene is at the zoo, the response does not directly address the question. A correct response would be 'no'.

Question: Is this at a museum?

Response: at zoo

Is the displayed **response** a correct answer to the above **question** about the image?

- Correct
- Incorrect

Abstract

This paper investigates the identification of populist rhetoric in text and presents a novel cross-lingual dataset for this task. Our work is based on the definition of populism as a "communication style of political actors that refers to the people" but also includes anti-elitism as another core feature of populism. Accordingly, we annotate references to *The People* and *The Elite* in German and English parliamentary debates with a hierarchical scheme. The paper describes our dataset and annotation procedure and reports inter-annotator agreement for this task. Next, we compare and evaluate different transformer-based model architectures on a German dataset and report results for zero-shot learning on a smaller English data. We then show that semi-supervised tri-training can improve results in the cross-lingual setting. Our dataset can be used to investigate how political actors talk about *The Elite* and *The People* and to study how populist rhetoric is used as a strategic device.

1 Introduction

The rise of populism in Europe and throughout the world has been noted not only in politics and the media but also has been the subject of many studies in political science and related areas (see, among others, [Mudde \(2007\)](#)). The concept of populism, however, is complex and vague and eludes a strict definition. So far, only limited agreement exists on the exact properties of the construct, despite numerous efforts to provide a clear definition.

In the literature, populism has been described as an ideology ([McRae, 1969](#); [Mudde, 2004](#)), a rhetoric ([Abts and Rummens, 2007](#)) or style ([Moffitt, 2016](#)), as a political strategy ([Weyland, 2001, 2021](#); [Hawkins and Kaltwasser, 2017](#)) and as a discourse ([Laclau, 1977](#); [Aslanidis, 2016](#)), amongst others (see [Aslanidis \(2018\)](#) for a short overview). The *Oxford Handbook on Populism* ([Rovira Kaltwasser et al., 2017](#)) groups existing work into three

dominant approaches to analyzing populism, i.e., (i) the ideational approach of [Mudde \(2004\)](#), (ii) the socio-cultural approach ([Ostiguy, 2017](#)), and (iii) the political-strategic approach ([Hawkins and Kaltwasser, 2017](#)), each one capturing a different view on populism.

Nevertheless, most studies agree that *anti-elitism* and *people-centrism* are amongst the core dimensions of populist rhetoric, and the two dimensions are therefore included as features in most survey tools used to measure the degree of populism of political parties and actors ([Polk et al., 2017](#); [Rooduijn et al., 2019a](#); [Meijers and Zaslove, 2020](#)). One major drawback of surveys, however, is that they only provide us with one score for each party or actor and can not be used to study how populist rhetoric is used as a strategic tool in different contextual settings.

As a result, more and more efforts have been made recently to measure populist and anti-elitist attitudes directly from text ([Rooduijn and Pauwels, 2011](#); [Dai, 2018](#); [Aslanidis, 2018](#); [Ernst et al., 2019](#); [Hawkins et al., 2019](#); [di Cocco and Monechi, 2021](#); [Vaughan and Heft, 2022](#)). This has the advantage of providing us with more fine-grained and context-dependent measures that enable us to investigate when and how anti-elitist rhetoric is used as a strategic tool in party competition ([Vaughan and Heft, 2022](#)). In addition, it has been suggested that populist rhetoric targeting political elites might function "as a form of ethnoracial dog-whistle politics" ([Bonikowski and Zhang, 2023, p.2](#)). Evidence for this claim comes from the frequent co-occurrence of right-wing populism with nativist messages, as shown in Example 1.1 below, taken from a parliamentary speech of a far-right politician in the German Bundestag.

Ex. 1.1 *Because the Merkel government has lied to the people about how long refugees and illegal migrants will actually be with us [...] (N. Kleinwächter, AfD, 15/11/2019)*

This example illustrates the different dimensions of populist rhetoric where anti-elitism is combined with a Manichean worldview that separates society into two antagonistic camps, *the corrupt elite* and *the pure people* (Mudde, 2004). This divide into *Us-versus-Them*, also known as *Othering*, is a well-known strategy for creating in- and outgroups, used to conceptualize specific groups as outsiders and to depict them as inferior or even as dangerous. Example 1.1 uses *Othering* to transfer the message that “refugees and illegal migrants” are not part of *The People* and that an immoral political elite is acting against *The People*’s general interest (“the Merkel government has lied to the people”).

While there is no shortage of studies on various aspects of populism, only a few works have tried to develop robust and reliable measures of populism that can be used for empirical research at scale to quantify the degree of populism expressed by political actors, such as politicians and parties. Being able to assess populism from a quantitative standpoint using large amounts of data, e.g., text, has the potential, in turn, to help us understand the causes and consequences of populism by allowing us to track its spatial and temporal distribution.

In the paper, we provide a methodology to detect and quantify references to *The People* and *The Elite* in large amounts of text. We present a novel dataset of German and English political debates where instances of *The People* and *The Elite* have been manually annotated and use this data to learn to predict those references in monolingual and cross-lingual settings. We then show that these predictions align with the results of expert surveys for measuring populism but, crucially, provide us with *more fine-grained and context-sensitive* information that can be used to study left- and right-wing populism in parliamentary debates at large scale. We make all data and models available at <https://github.com/umanlp/mope.git>.

2 Related Work

2.1 Defining Populism

Defining populism is an intellectual challenge *per se*. Most scholars, however, agree that populism is a multi-dimensional construct and that *anti-elitism* and *people-centrism* are two of the core characteristics of populist discourse (Mudde, 2004; Hawkins, 2009; Dai, 2018; Schulz et al., 2017). Many studies have adapted Mudde’s view of populism as “a thin-centered ideology that considers society to be

ultimately separated into two homogeneous and antagonistic camps, ‘the pure people’ versus ‘the corrupt elite’” (Mudde, 2004, p. 543).

Another influential view distinguishes between *thin* and *thick* populism, where the former is considered as a “communication style of political actors that refers to the people” (Jagers and Walgrave, 2007, pp.322). *Thick* populism, on the other hand, is similar to Mudde’s definition and combines people-centrist references with anti-elitism and the exclusion of certain minority groups from *The People*. Our operationalization of populist rhetoric is most similar to Jagers and Walgrave (2007)’s *thin populism*. Still, it can also be used within other conceptual frameworks that rely on people-centrism and anti-elitism as defining features of populism.

So far, a variety of approaches have been proposed for analyzing populism. Some works rely on **expert opinions and surveys** (Rooduijn et al., 2019b; Meijers and Zaslove, 2021a) to obtain theoretically grounded measurements of populism. This approach, however, only yields scores on the level of parties or organizations but defies a more fine-grained or graded analysis on the text or sub-text level (Aslanidis, 2018). **Text-based approaches**, on the other hand, have the potential to identify context-sensitive manifestations of populism and its characteristics and, in turn, profile political actors along multiple dimensions.

2.2 Measuring populism in text

Text-based methods for measuring populism can be classified into four main approaches. The first is based on **manual content analysis** where a larger text is segmented into smaller units, and trained human coders inspect each unit and search for populist cues (Jagers and Walgrave, 2007; Hawkins, 2009, *inter alia*). While this approach can obtain high content validity, it is also extremely time-consuming and, depending on the categories in the codebook, does not necessarily generalize well across different topics, geographical and cultural specificities, or time periods.

A second approach, called **holistic coding**, also involves human annotation where trained coders read the document and, based on the comparison to a small set of anchor texts, decide whether the text as a whole should be considered as populist or not (Hawkins and Castanho Silva, 2018; Hawkins et al., 2019, *inter alia*). Document-level analysis is less fine-grained, and often it is not evident why a

Table 1: Hierarchical annotation of references to *The People* and *The Elite*.

particular text has been coded as populist. Furthermore, assigning scores to documents offers limited interpretability for analysis.

The third approach for measuring populism applies **computer-assisted content analysis**, based on dictionaries that contain cue words related to populist rhetoric, such as *people*, *elite*, *establishment*, *corrupt*, etc. (e.g. Jagers and Walgrave (2007); Caiani and della Porta (2011); Vasilopoulou et al. (2014); March (2017); Pauwels (2011); Rooduijn and Pauwels (2011); Bonikowski and Gidron (2016)). While dictionary-based approaches are fast and scale easily, they are less valid and reliable than manual content analysis (Grimmer and Stewart, 2013). This is partly due to the arbitrariness in the selection of the dictionary entries or keywords, where (potentially biased) choices made in the creation of the dictionary can impact the analysis. Another reason for the often low content validity is that dictionary-based methods are not context-sensitive. For instance, Rooduijn and Pauwels (2011) have tried to capture notions of *people-centrism* and *anti-elitism* in text using a dictionary-based approach, and found a reduced content validity compared to manual coding, especially for people-centrism.

The fourth approach uses **supervised machine learning (ML)** for populism detection. First steps in this direction have been taken by Dai (2018); di Cocco and Monechi (2021) and Huguet Cabot et al. (2021). Dai (2018) presents an approach based on document embeddings and SVMs to predict

whether a text is populist or not. The reported performance is quite high (95% acc.), but merely due to the choice of evaluation metric and the highly skewed class distribution (i.e., only 4% of the instances in the dataset are labeled as populist).

In contrast, di Cocco and Monechi (2021) do not rely on manual annotations but approximate populism by party affiliation. They consider all sentences uttered by members of a populist party as populist and show that their measure of populism, based on the predictions of a classifier trained on the weakly supervised data, correlates with party membership and, thus, with the experts’ ratings of populism. However, the approach does not capture the defining features of the construct, and it is unclear what has been learned by the classifier.

Huguet Cabot et al. (2021) present a dataset of Reddit comments annotated for stance (Discriminatory, Critical, Neutral, Supportive) and emotions towards six social groups (Conservatives, Liberals, Immigrants, Refugees, Jews, Muslims). While they also aim at detecting *Us vs. Them* rhetoric, in their work, the groups are given. In contrast, we explicitly model the building blocks of populism, i.e., references to *The People* and *The Elite*, and detect all mentions of either group in text. The advantage of our approach is threefold. First, our representations are contextualized, thus overcoming the shortcomings of dictionary-based approaches. Second, by manually coding all mentions to *The People* and *The Elite* in text, we can overcome the problem of incomplete or biased keyword lists, which is

party	speeches	speakers	tokens
CDU/CSU	76	57	72,113
SPD	58	44	48,988

another weakness of dictionary-based approaches (Grimmer and Stewart, 2013). Finally, our approach yields more fine-grained results that allow us to study differences in populist rhetoric, e.g., for actors from different ideological backgrounds.

3 MoPE: Annotating Mentions of the People and the Elite

We now present MoPE, our new data set with annotated mentions of *The People* and *The Elite*.

The People versus The Elite. According to Mudde (2017), the difference between the two camps in populist rhetoric is not based on issues of class or nationality, but rather on *morality*. *The People* are an artificial construct of a (non-existing) homogeneous community whose defining criteria are self-ascribed and depend on the specific ideology that serves as the carrier for the *thin-centered ideology*, i.e., populism (see §2.1). *The Elite*, on the other hand, can be seen as the anti-thesis of the *The People* and also obtains its defining features based on the situational context.

To operationalize the two concepts, we use a hierarchical schema where we encode instances of the two classes on the first level (Table 1). Level 2 then distinguishes individuals and groups of persons from elite organizations, while Level 3 encodes fine-grained information about the individual actors. Our schema builds upon and extends the categories in the codebook of Wirth et al. (2019, p.12)¹. Additionally, Level 3 encodes geo-political entities (GPE) as they provide important information for many applications. Following Jagers and Walgrave (2007) and Wirth et al. (2019), we use the

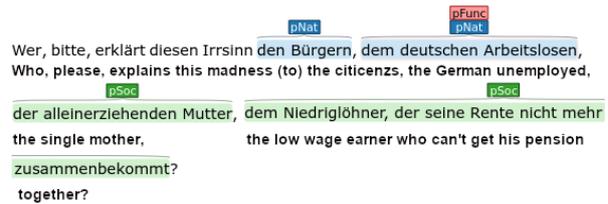

Figure 1: Annotations of references to *The People* (PNAT: people by nationality; PFunc: people by function; PSOC: social variables like gender, class).

term *Elite* in a broad sense as referring to persons, groups, organizations or institutions with a disproportionate amount of power, wealth, privilege or skills through which they can have an impact on politics and society. As instances of *The People*, we consider (a) unspecified groups of people and (b) individuals that denote common members of the public, such as John Q. Public.

German Bundestag data. We extracted a dataset of German parliamentary debates for the 19th legislative term (2017–2021), controlled for topic and party membership of the speakers.² The time frame was selected because of its relevance for the rise and consolidation of populist rhetoric in German politics. Our data set includes 267 speeches by 196 different speakers from 6 German parties (Table 2). Figure 1 shows an example annotation from our data, with references to different mentions of *The People*. Please note that while our task has some similarities to Named Entity Recognition (NER), there are also crucial differences. Most importantly, only some of our mentions are proper names, while many of them are noun phrases that include subordinated clauses like relative clauses (e.g., “the low wage earner who can’t get his pension together” in Figure 1). This means that the average span length of our mentions is considerably longer than for NER, which introduces additional ambiguity for annotation and prediction.³ We will come back to this issue in §3.2. Annotations can (and often do) include embedded mentions. Entities can belong to more than one class (see, e.g., *the German unemployed* in Figure 1, which belongs to the classes “People by Nation” and “People by Function”).

²We follow best practices and provide a datasheet (Bender and Friedman, 2018; Gebru et al., 2021) with details on corpus creation and sampling in the supplementary materials.

³For example, some of the ambiguities arise from PP attachment ambiguities for longer mention spans.

English Europarl-UdS data. We additionally compile an English data set to enable testing for the generalization capabilities of our models not only across languages but also beyond recent debates and topics. The English data was extracted from the EuroParl-UdS corpus (Karakanta et al., 2018), a multilingual (En, De, Es) parallel corpus of parliamentary debates from the European parliament, with speeches from 1999–2018. We randomly selected speeches from three different years (1999, 2014, 2015), with 70 different speakers from 18 countries (for details, see Appendix, Tables 12, 10).

Annotation process. The data was double annotated by two student assistants with background in political/social science. During the annotation process, we had weekly meetings to discuss ambiguous cases. The final version was adjudicated by one of the authors (a linguist by training), who also corrected inconsistent span annotations: it includes 9,297 annotated mentions (German subcorpus). In our experiments, we ignore all mentions where the speakers refer to themselves (Label EPOWN) using

the pronouns *I/me*, since this label can be assigned based on a simple string match. This results in a set of 7,422 mentions with 22,479 annotated tokens that we divide into training, dev and test set (see Appendix B, Table 11 for more details on the size and distribution of the different splits).

The English data set includes 29,584 tokens with 1,423 annotated mentions (1,074 w/o EPOWN) and 3,567 annotated tokens (3,218 w/o EPOWN).

3.1 Inter-annotator agreement (IAA)

Since our data includes multi-label annotations, we cannot report Cohen’s κ . We follow Hripcsak and Rothschild (2005) and compute F1, treating the annotations of one annotator as the ground truth and the other as the predicted annotations. We then switch roles and report averaged micro F1 on the mention level for the fine-grained labels (level 3).⁴ Table 3 reports micro F1 on the mention level for German, using a strict measure that only considers a mention as correct when all tokens that belong to that mention have been identified correctly. The last column shows the average number of tokens annotated by our two coders (i.e., the number of in-

⁴Also see the discussion in Hripcsak and Rothschild (2005) why chance-corrected measures are not optimal for NER and other sequence-level tasks where the number of negative entities is unknown.

stances *before* adjudication). As the exact mention metric is rather strict and punishes spans that have been identified correctly by both coders but where the span boundaries slightly disagree, we also report a measure based on token overlap that has been introduced for the evaluation of opinion role spans (Katiyar and Cardie, 2016). Here we consider a mention as correct if the annotations overlap and both annotators have assigned the same label. Micro F1 for exact match is 0.69, while the overlap measure is much higher with an F1 of 0.80.

Table 4 shows IAA for the English data from the EU parliament. As for German, references to the people seem to be the most difficult class.

3.2 Error analysis

We notice a high variance in F1 for the different classes. In particular, we can see that F1 for the frequent label types is much higher than IAA for the low-frequency labels. Looking at the data, we see that our domain expert annotators often disagree on the exact span of the mentions. In particular, one annotator often failed to include complement clauses which strongly impacts exact IAA.

The F1 scores for overlapping annotation spans (Table 3) show a substantial increase for many classes, confirming our assumption that the annotators did not so much disagree on the *class labels* but on the *span boundaries* of the mentions. As mentioned above, at times, the domain experts also struggled with PP attachment decisions, as illustrated in Example 3.1 where “at age 63” should not be included in the mention span.

Ex. 3.1 *So why should professional soldiers at age 63 no longer be able to meet the physical demands of service [...] (E. Brecht, SPD, 9/6/2021)*

In addition, the confusion matrix (Appendix B, Table 7) suggests that recall is a problem, showing a considerable number of instances that have been coded by one annotator only. We confirm this problem by looking at individual classes. Especially generic mentions of *The People* have been annotated mostly by one of the two annotators (263 instances have been identified as PGEN by A1 while A2 annotated 111 instances only). This recall problem has been discussed by Beigman Klebanov et al. (2008) for the metaphor detection task where the authors distinguish between *genuine disagreements* and *slips of attention*, which is a common phenomenon, especially for rare classes where the units of analysis are not given, and the annotators

first have to detect them in longer texts before they can assign the labels.

We also notice some systematic disagreements for the classes in our schema. Examples are, for instance, the classes PEOPLE BY NATION and PEOPLE BY ETHNICITY, where A1 shows a bias for the first label while A2 preferred the second. This happened for mentions like *the population of X*, which can be interpreted as ‘citizens of X’ (PNAT) or as referring to all people who live in the country and thus share the same cultural background (PETH). Another systematic disagreement concerns PEOPLE BY FUNCTION and GENERIC mentions, illustrated in Example 3.2. Here, A1 interpreted the mention (“the people who...”) as a generic reference (PGEN) while A2 focused on the function of the people (rebuilding the country) and assigned the label PFUNC.

Ex. 3.2 *I am proud of our country and of [the people who, through the economic miracle, have made it a country that is treated with respect and appreciation _{pFunc/pGen}]. (J. Juratovic, SPD, 28/5/2020)*

In general, we notice that IAA for mentions of *The Elite* is higher than for references to *The People*. We suggest that this is due to two reasons. First, mentions to *The People* are, per definition, more abstract and vague, and second, the average mention length for instances of *The People* is longer than for *The Elite* (elite person: 2.3, elite organization: 2.7, people: 3.1 tokens).

4 Experiments

We use our data set from §3 to benchmark the task of predicting mentions of *The Elite* and *The People* from text sentences. Our task can be decomposed into two separate sub-tasks: (i) mention *detection* (MD) and (ii) mention *classification* (MC). We present experiments where we compare different transformer-based model architectures (Vaswani et al., 2017; Devlin et al., 2019) for those tasks. Specifically, we compare (i) a pipeline approach (MD→MC) with (ii) an end-to-end token classification model (E2E-Tok) and (iii) semi-supervised tri-training (TRI) (Zhou and Li, 2005).

Mention detection. Our MD model is a token classification model, similar to the NER model of Devlin et al. (2019), and predicts the span boundaries for mentions of *The People* and *The Elite* on the token level. We use the BIO schema to encode

Task & model architecture			dev set			test set		
			Prec	Rec	F1	Prec	Rec	F1
	<i>span detect.</i>	MD	82.0 ± 1.00	83.0 ± 0.80	82.4 ± 0.86	79.5 ± 1.21	80.4 ± 1.91	80.0 ± 1.34

	End-to-end	E2E-Tok	83.0 ± 0.31	80.7 ± 0.80	81.9 ± 0.55	79.2 ± 0.89	78.3 ± 0.74	78.7 ± 0.39
Level 3	Pipeline	MD→MC	68.7 ± 3.0	72.3 ± 3.16	70.4 ± 3.08	63.8 ± 3.85	67.9 ± 4.10	65.8 ± 3.97
	End-to-end	E2E-Tok	80.6 ± 1.38	79.6 ± 0.88	80.1 ± 0.49	73.6 ± 2.00	74.8 ± 1.21	74.2 ± 0.48

Table 5: F1 (micro), precision and recall for the different models on the German dev and test sets. **Bold** indicates the best performing end-to-end scores for each annotation level and \pm shows stdev over the three runs.

the span boundaries and, for each token, predict whether it belongs to a specific mention.

Mention classification. Our next model architecture tries to predict the label for a given mention using sequence classification. For this, we concatenate the input sentence with the respective mention, separated by a [SEP] token, and input the sequence to the model, which then predicts a label for the entire sequence. Please note that this model relies on gold spans as input and provides an upper bound for determining the correct class of a mention.

Pipeline. When performing mention classification, the span-based MC model needs to know the span boundaries to predict a mention’s label. Therefore, we test a pipeline approach where we first use the MD model to detect the spans of the mentions and then predict the label, using the MD output as input to the MC model.

End-to-end token classification. We compare the pipeline results to an end-to-end token classification model. The architecture is similar to the MD model, but in addition to span boundary detection, we also predict the labels of the mentions on the token level. We use the BIO schema as prefixes to the class labels to encode the span boundaries *and* class for each mention and, for each token, predict whether it belongs to a specific span *and* class (including the None class).

Cross-lingual tri-training with disagreement. Semi-supervised approaches have successfully improved model performance, especially in low-resource scenarios. We, therefore, test the potential of *tri-training* (Zhou and Li, 2005) in a cross-

lingual setting to improve results for knowledge transfer from German to English. Tri-training is an iterative process where we use the predictions of two classifiers c_1, c_2 to assign labels to unlabeled instances and expand the training set of a third classifier. Previous work has shown that *tri-training with disagreement*, i.e., adding only those instances to the training data of c_3 where c_1 and c_2 agree with each other’s predictions but disagree with the prediction of c_3 , can filter out uninformative instances and improve the efficiency of the training process (Chen et al., 2006; Zhou, 2008; Sjøgaard, 2010).

Specifically, we use the end-to-end architecture (E2E-Tok) to train three multilingual classifiers based on bert-base-multilingual-cased with different seeds on the German train set. For each seed, we select the model that performed best on the dev set. We then use the three classifiers to predict labels for new, unlabeled data points from the English part of the EuroParl-UdS corpus and, for each classifier c_i , select new instances based on *disagreement* and add them to c_i ’s training set. Please note that this results in different training sets for each classifier. We then continue fine-tuning the classifiers on the expanded training data for m iterations, followed by n iterations of supervised training on gold data. We repeat this process until the results on the dev set stop improving. Then we use the three semi-supervised classifiers to predict labels for the test set based on majority voting.

In contrast to previous work (Ruder and Plank, 2018), we do not share parameters between learners but encourage the diversity of the models by keeping them separate. For efficiency, we do not fully retrain the models on the expanded data but

Level	Model	German test _{de}			English test _{en}

simply add $m + n$ epochs of fine-tuning in each iteration. For details on model setup and parameter settings, see Appendix B.1, B.4 and B.2.

4.1 Results for German

In all experiments, we report results averaged over three runs with different initializations. All models are implemented with the Huggingface transformers library (Wolf et al., 2020) and PyTorch (Paszke et al., 2017). For evaluation, we use seqeval (Nakayama, 2018), a python implementation of the well-known CoNLL 2000 evaluation script for sequence tagging tasks (Tjong Kim Sang and Buchholz, 2000), and report precision, recall and F1 (micro) in *strict* mode on the mention level for the different levels of our hierarchical annotations (see Appendix B.3 for details).

We first report results for the token-based **mention detection** task (Table 5). F1 on the development and test set are close with around 80%. The upper bound for **mention classification** of gold mention spans is very high for the coarse-grained levels where we distinguish between mentions of *The People* and *The Elite* (Level1/2), with an F1 of around 96%. For the fine-grained classes, the upper bound is around 92% for dev and 88% for test (Table 5, MC, Level3).

We now turn to the end-to-end architectures (MD→MC, E2E-Tok) where we predict the span boundaries *and* the class labels. While the MC model performs well on gold mentions, it visibly struggles to predict labels for automatically determined spans, and F1 decreases by around 20% for all levels (Table 5). On the other hand, our end-to-end token-based model is much better suited for this task, with an F1 over 74% for L3 and around 80% for the coarse-grained prediction of mentions of *The People* and *The Elite*.

4.2 Cross-lingual transfer to English

Zero-shot transfer. Lauscher et al. (2020) have shown that results for *zero-shot cross-lingual transfer* do not decrease much for lower-level tasks like PoS and NER if source and target language are typologically close. This observation encourages us to try zero-shot transfer learning for our task, which is closely related to NER. We use the E2E-Tok architecture from our previous experiments and initialize it with a pretrained multilingual transformer (mBERT). We then train mBERT on the German data and use it to detect instances of *The People* and *The Elite* in the English debates. The experiments are meant to investigate how well we can transfer information from German to English without annotating *any* English data.

Table 6 shows results for the mBERT model on the German test set and zero-shot learning, using the same model to predict labels for the English benchmark data. We can see that F1 for the fine-grained Level-3 predictions on the English test set is only slightly lower than for German (71.7% vs. 71.4% F1). However, the gap between precision and recall is more substantial than in the monolingual setting, and the trend is reversed, showing higher recall with much lower precision. Not surprisingly, results for mBERT on the German test set are lower than the ones for the German BERT model (cf. Table 5).

Looking at the tri-training results, we observe another increase of around 1% for the English data. Interestingly, training the classifier on unlabeled English data also yields an improvement of >2% F1 on the German test set (L3) for mBERT, closing the gap between the mBERT and German BERT results. Overall, the results indicate a successful transfer, considering that the model did not see *any* hand-labeled English data during training.

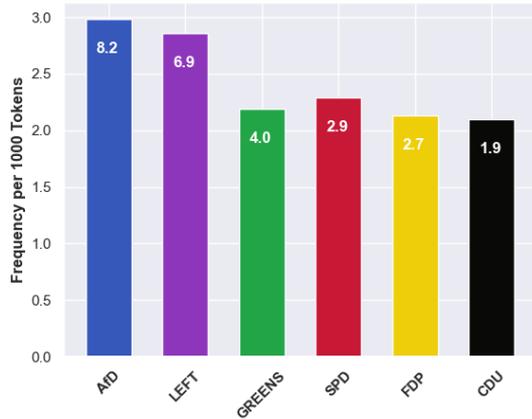

Figure 2: Distribution of references to *The People* in the German Bundestag (2017-2021). Numbers in the bar show POPPA scores for people-centrism.

5 Measuring *thin populism* from text

We are now able to investigate Jagers and Walgrave (2007)’s concept of *thin populism* by looking at how often political actors refer to different subsets of *The People*. For that, we use our three monolingual classifiers described in §4 and predict labels for all debates from the German Bundestag from the 19th legislative term (2017–2021) (> 16 million tokens). We take the majority vote of the three classifiers to determine the final predictions. Figure 2 shows the distribution of the aggregated counts for all references to *The People* for each party. ⁵

We can now validate how well our operationalization of *thin populism* in text correlates with expert ratings. For that, we compute Spearman’s rank correlation between the normalized counts for each party and the party’s score for people-centrism in the Populism and Political Parties Expert Survey (POPPA) (Meijers and Zaslove, 2021b) (also see Table 9 in the Appendix, C). We observe a very strong positive correlation ($\rho = .94$, $p = .005$) between the expert ratings for people-centrism and our predicted counts (Level 1), where both left and right-wing populist parties show a substantially higher amount of people mentions.

However, when looking at the fine-grained predictions for different subgroups of *The People*

⁵We excluded the CSU from the analysis. While the party is forming a joint parliamentary group with the CDU in the Bundestag, it is only running for election in a single German province, Bavaria. This results in a conflict between the party’s “Bavaria first!” policy on the province level and the need to accommodate their sister party’s policies on the federal level (Frymark, 2018, pp.2-3). We, therefore, expect that the governing faction is not representative of the party as a whole.

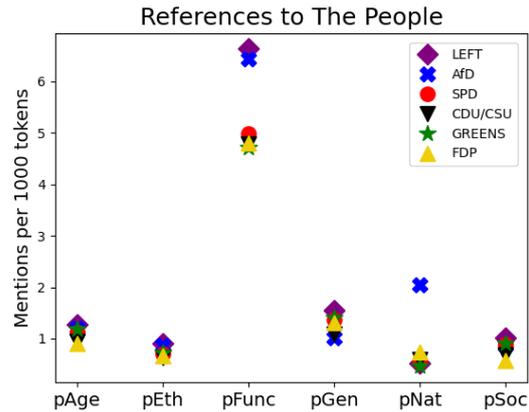

Figure 3: Distribution of group mentions in the 19th legislative term of the German Bundestag (2017-2021).

(Level 3, Figure 3), we also notice interesting differences. For example, both populist parties use a higher amount of references to PEOPLE BY FUNCTION than the mainstream parties. At the same time, only the far-right AfD shows excessive use of PEOPLE BY NATION, often as a dog-whistle to send the message that some people are not “our kind of people”.⁶

Overall, our approach of predicting references to *The People* is able to successfully identify populist rhetoric in large amounts of text and agrees well with expert ratings. However, our results also highlight the importance of a more fine-grained operationalization of *thin populism* that distinguishes between different subgroups of *The People*.

6 Conclusions

In this paper, we presented MOPE, a novel data set for detecting mentions of *The People* and *The Elite* in political text. Our data set includes more than 9,000 annotated mentions for German and an English benchmark set with around 1,600 mentions for cross-lingual transfer learning. We evaluated different transformer-based model architectures on our new data set and explored zero-shot cross-lingual transfer and cross-lingual tri-training.

In future work, we will combine references to *The Elite* with stance detection, which will allow us to model and quantify the different dimensions of populism separately, i.e., *people-centrism* and *anti-elitism*, thus enabling large-scale studies of populism from left- and right-wing political actors in different contextual settings.

⁶This observation is consistent with the AfD’s high POPPA score for nativism (9.7 of 10).

7 Limitations

We would like to point out some limitations of our work. First, in this paper, we do not yet provide measures of populist rhetoric but release a data set and method for detecting instances of *The People* and *The Elite* in text, which we see as a prerequisite for a theoretically grounded, multi-dimensional model of populism that captures the core features of the construct, i.e., *anti-elitism* and *people-centrism*. While our results correlate with expert ratings from survey tools for German, the validity of the English annotations still needs to be tested, and the accuracy for infrequent classes needs to be improved. In addition, further work needs to investigate the robustness of our models on data from different domains and text types.

Supplementary Material

A Inter-annotator agreement (IAA)

Table 7 shows the confusion matrix for our two human annotators (A1, A2) for the fine-grained classes (Level 3) in the German Bundestag debates. Due to space limitations, only the most frequent classes are shown. The **prefixes** of the labels are EP: Elite-Person, EO: Elite-Organisation, P: People. The **domains of the labels** are FIN: finance, MIL: military; POL: politics; ECO: economy; AGE: people by age; ETH: people by ethnicity; FUN: people by profession/function; GEN: Generic mentions; NAT: people by nation; SOC: social variables (gender, class); GPE: geo-political entities.

B Training details

B.1 Setup and parameters

For all experiments, we report results averaged over three runs. In each run, we initialise the model with a different seed: {18, 23, 44}. As optimizer, we use AdamW (Loshchilov and Hutter, 2019). The initial learning rate was set to 2.69^{-05} , with a weight decay of 0.0198. We did not freeze any layers but fine-tuned the whole model in all experiments. For tri-training, we experimented with $m = \{3, 5\}$ and $n = \{1, 5\}$ and found that $n=3$ and $m=1$ were robust across different levels. A more principled hyperparameter search might further improve results.

B.2 Training/dev/test splits

Table 11 shows the distribution of labels in the different data splits (train/development/test) for each level in our hierarchical annotation schema. We ensure that none of the agenda items in the test set are included in the training set. This results in a much more challenging and realistic setting compared to distributing speeches from the same agenda item into training and test sets.

B.3 Sequence tagging evaluation

As noted by Lignos and Kamyab (2020), many evaluation scripts for sequence tagging tasks will produce non-replicable results due to inconsistent handling of “improper label sequences”, i.e., mentions that have been labeled with the correct class but have been assigned an incorrect prefix. This results in an inconsistent number of entities in the gold standard and thus produces results that are not

comparable. To avoid this problem, we report results for the *strict* mode where prefixes are included in the evaluation.

For illustration, consider the following two sequences:

- GOLD: ['B-ELI', 'O', 'B-ELI', 'I-ELI', 'O', 'B-ELI']
- PRED: ['B-ELI', 'O', 'O', 'I-ELI', 'O', 'B-ELI']

In *strict* mode, the seqeval evaluation script would consider only proper mentions starting with 'B' for calculation (precision $\frac{2}{2} = 1.00$):

- GOLD: ['**B-ELI**', 'O', 'B-ELI', 'I-ELI', 'O', '**B-ELI**']
- PRED: ['**B-ELI**', 'O', 'O', 'I-ELI', 'O', '**B-ELI**']

However, in *default* mode, the seqeval evaluation first "repairs" the improper label sequences:

- PRED: ['B-ELI', 'O', 'O', '**B-ELI**', 'O', 'B-ELI']

After that, in *default* mode, all three mentions are used for calculation, even if they do not start in the original sequence with a starting token (precision $\frac{2}{3} = 0.67$):

- GOLD: ['**B-ELI**', 'O', '**B-ELI**', 'I-ELI', 'O', '**B-ELI**']
- PRED: ['**B-ELI**', 'O', 'O', '**B-ELI**', 'O', '**B-ELI**']

B.4 Tri-training with disagreement

We use a sample of 20,000 instances (sentences) from the EuroParl-UdS corpus as unlabelled data for tri-training. The data size was determined to extract a sufficient number of data points for tri-training while keeping the additional time for training and prediction low. From the 20,000 instances, between 950 to 1,500 instances have been selected for each classifier during tri-training (see Table 8 for exact numbers).

We loaded the checkpoints for the three best baseline classifiers (E2E) and continued training for 5 epochs on the newly extracted instances. Finally, we trained each classifier for another 5 epochs on the original training set. Then we used the three classifiers to predict labels for the test instances based on a majority vote.

C Populism and Political Parties Expert Survey (POPPA)

Table 9 shows expert ratings from the 2018 Populism and Political Parties Expert Survey (POPPA) (Meijers and Zaslove, 2021b) for all six German parties that participated in government in the 19th legislative term (2017–2021). The first column lists scores for people-centrism, a core feature of populism strongly related to Jagers and Walgrave (2007)’s concept of *thin populism*, and the second column shows the mean populism score for each party, aggregated over all relevant dimensions of populism in the survey. The ratings were collected between April 2018 and July 2018 from 294 country experts and include survey items for populism, political style, party ideology, and party organization in 28 European countries.⁷

SharPT: Shared Latent Space Prompt Tuning

Bo Pang Semih Yavuz Caiming Xiong Yingbo Zhou
Salesforce Research

{b.pang, syavuz, cxiong, yingbo.zhou}@salesforce.com

Abstract

Prompt tuning is an efficient method for adapting large language models, and Soft Prompt Transfer (SPoT) further narrows the gap between prompt tuning and full model tuning by transferring prompts learned from source tasks to target tasks. It is nevertheless difficult and expensive to identify the source task that provides optimal prompts. In this work, we propose to learn a shared latent space which captures a set of basis skills from a mixture of source tasks. Given an instance, its embedding queries the latent space, yielding a basis skill vector. This vector generates soft prompts, via a lightweight prompt generator, which modulates a frozen model. The latent space and prompt transformation are learned end-to-end by training on source tasks. Transfer learning from source tasks to a target task simply amounts to finetuning the prompt generator, accounting for roughly 0.3% parameters of the frozen backbone model, while the shared latent space is also frozen in finetuning. Our approach outperforms prior soft prompt methods by a significant margin on a variety of tasks such as NLI, sentence completion, QA, conference resolution, word sense disambiguation. We also find, on various model scales, our method achieves competitive performance compared to finetuning the full model.

1 Introduction

Adapting pre-trained large language models (LLMs) has advanced the progress in many NLP areas (Devlin et al., 2019; Raffel et al., 2020). This is typically done by finetuning all parameters of a model on a downstream task (i.e., MODEL TUNING). This approach is however expensive, especially given the growing sizes of SOTA LLMs.

This limitation motivates recent research on parameter-efficient methods which only tune a small amount of parameters (Houlsby et al., 2019; Brown et al., 2020; Karimi Mahabadi et al., 2021;

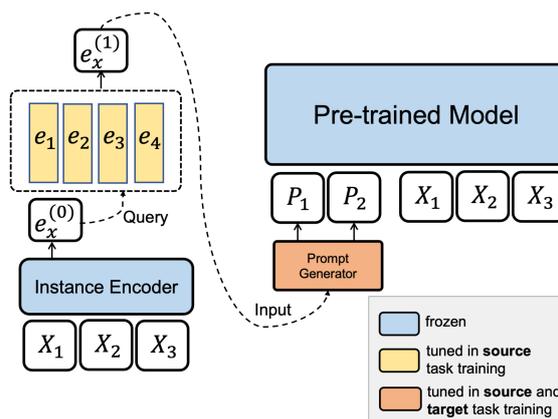

Figure 1: An illustration of SharPT. An instance, as illustrated by with three tokens $\{X_1, X_2, X_3\}$, is encoded by the instance encoder, giving $e_x^{(0)}$, and then queries the skill latent space, resulting in a skill vector $e_x^{(1)}$. The skill vector is transformed by a simple and lightweight prompt generator, outputting prompt tokens (e.g., $\{P_1, P_2\}$). They are prepended to the instance tokens and modulate the pre-trained frozen model. The instance encoder and the pre-trained model are frozen in all scenarios. The skill vectors are tuned in source task training and frozen in target task training. The prompt generator is tuned in both source task and target task training.

Lester et al., 2021; Li and Liang, 2021; Hambarzumyan et al., 2021). Among them, a line of research focus on the methods that modulate a frozen LLM via prompts (Liu et al., 2021). Brown et al. (2020) showed that prepending an input text with a prompt, which typically consists of a task description and/or several examples, can effectively adapt a frozen GPT-3. This approach nevertheless underperforms MODEL TUNING and is sensitive to the choice of prompt wordings. Instead of actual text (or hard prompt), Lester et al. (2021) proposed PROMPT TUNING, which prepends a soft prompt, consisting of k tunable tokens, to input text. The soft prompt can be optimized with gradient-based methods. PROMPT TUNING achieves competitive performance to MODEL TUNING when the model size is large (e.g., over 10B parameters) but still underperforms with smaller models.

SPoT (Vu et al., 2022) improves over PROMPT-

TUNING by leveraging knowledge from source tasks. They first learn a task-specific soft prompt for each task in a set of source tasks. Given a target task, they search over the set of source prompts and use the best one or some weighted combination to initialize the prompt for the target task and then tune the prompt. It further narrows the performance gap to MODEL TUNING on smaller models. But it is complicated and expensive to identify the source task that provides optimal prompts.

In this work, we propose a novel prompt-based transfer learning method, SHARPT (**Shared Latent Space Prompt Tuning**). Figure 1 illustrates the general idea. SHARPT assumes a shared (discrete) latent space by all source and target tasks. We call each vector in the latent space as a *skill vector*, since we assume each one captures a basis NLP capacity or skill after training on the source tasks. Given an instance (from either a source task or a target task), an instance encoder embeds it into an instance vector, which is then used to query the latent space to find the nearest neighbor, yielding a skill vector for this instance. A lightweight prompt generator then generates soft prompts as a function of the selected skill vector. The soft prompts condition a frozen LLM. The latent space and prompt generator are learned end-to-end on a mixture of source tasks. In target task training, the latent space is frozen and only the prompt generator is tuned.

SHARPT retains the key advantage of prior prompt methods, parameter-efficiency. It only updates approximately 0.1% to 0.3% parameters compared to MODEL TUNING. Different from prior methods, we add an instance encoder to encode each instance. The instance encoder is lightweight and frozen in all scenarios.

SHARPT and SPOT both exploit a generic idea, *leveraging knowledge shared across tasks*. The approaches to achieve this are however distinctly different. SPOT assumes *task-to-task transfer* based on *task-level prompts* and the knowledge is encoded in task prompts. It is not straightforward to identify a source prompt for a target task. They illustrated two approaches: (1) SPOT-Oracle and (2) SPOT-Retrieval. SPOT-Oracle involves using oracle test labels and expensive search (e.g., 48 times more expensive than regular prompt tuning in their experiments). In SPOT-Retrieval, they first tuned a task prompt for each source and target task independently and retrieved a prompt based on prompt similarity. Note that the retrieval tun-

ing is only for searching a source prompt, which is in addition to final prompt tuning on the target task. In contrast, SHARPT assumes the knowledge is encoded in a *shared latent space* and utilizes *instance-level prompts*, which are generated based on latent vectors from the shared space. These designs make source-to-target transfer simple. We learn the shared latent space with all source tasks in a single training run. Also, the tuning on the target task only requires a single run. Given an instance from a target task, we use the instance embedding to identify a skill vector, learned from all source tasks, which is then transformed to soft prompts.

In summary, we design an instance-prompt-based method by learning a shared skill latent space. We apply SHARPT to a diverse set of tasks covering diverse domains and task categories. We find that our method outperforms prior prompt-based methods and matches full-model-tuning across model scales.

2 Method

Suppose we have a task with data $T = \{(\mathbf{x}, \mathbf{y})\}$ and a pre-trained LLM P_θ . MODEL TUNING updates θ to minimize $\mathcal{L}(\theta) = -\log P_\theta(\mathbf{y}|\mathbf{x})$ ¹. PROMPT TUNING prepends to \mathbf{x} a soft prompt, $\mathbf{p} \in \mathbb{R}^{L \times d}$, which has L vectors of size d . It then optimizes \mathbf{p} by minimizing $\mathcal{L}(\mathbf{p}) = -\log P_\theta(\mathbf{y}|\mathbf{p}, \mathbf{x})$.

SHARPT assumes there exists a discrete latent space, consisting of a set of skill vectors $\mathbf{E} = \{\mathbf{e}_i \in \mathbb{R}^m\}_{i=1}^K$ with K vectors in total. The soft prompt is a simple transformation of one of the skill vectors \mathbf{e}_i , that is, $\mathbf{p} = f_\alpha(\mathbf{e}_i)$. The transformation or prompt generator (f_α) is a light-weight MLP.

$$\mathbf{e}'_i = \text{Tanh}(W_1 \mathbf{e}_i + b_1), \mathbf{p}_l = W_2(z_l + \mathbf{e}'_i) + b_2 \quad (1)$$

where $z_l \in \mathbb{R}^d$ is the position embedding for the l th token (and randomly initialized in training) and $W_1 \in \mathbb{R}^{d \times m}$, $W_2 \in \mathbb{R}^{d \times d}$. Then we have the soft prompt $\mathbf{p} = \{\mathbf{p}_l\}_{l=1}^L$.

Given \mathbf{x} , we infer its skill vector by (1) embedding it via a frozen instance encoder (e.g., SimCSE BERT-base), which yields $\mathbf{e}_x^{(0)}$; (2) querying \mathbf{E} to find the nearest neighbour. Formally, that is,

$$\mathbf{e}_x^{(1)} = \mathbf{e}_k, \quad k = \arg \min_{i \in [K]} \left\| \mathbf{e}_x^{(0)} - \mathbf{e}_i \right\|_2. \quad (2)$$

For a target task, our method is then trained with the following loss,

$$\mathcal{L}(\alpha) = -\log P_\theta(\mathbf{y}|f_\alpha(\mathbf{e}_k), \mathbf{x}). \quad (3)$$

¹Summation over the data is omitted for notation clarity.

In target task training aforementioned, \mathbf{E} is known and fixed. We next specify how to learn it from source tasks. Suppose we have N source tasks, $\{T_j^{(s)}\}_{j=1}^N$. We simply mix all tasks together, $T^{(s)} = \bigcup_{j=1}^N T_j^{(s)}$. Given $x \in T^{(s)}$ and its embedding $e_x^{(0)}$. \mathbf{E} is learned with the following loss,

$$\mathcal{L}(\mathbf{E}) = \left\| \text{sg}(e_x^{(0)}) - e_k \right\|_2, \quad (4)$$

where $\text{sg}()$ is a stop gradient operator and e_k is defined in Equation (2). The overall loss in source task learning is,

$$\mathcal{L}(\alpha, \mathbf{E}) = \mathcal{L}(\alpha) + \mathcal{L}(\mathbf{E}) \quad (5)$$

In summary, the forward pass for training on source and target tasks are exactly the same (also see Figure 1). The only difference is the loss function, Equation 5 (source) versus Equation 3 (target).

3 Experiments

High-to-Low Resource Transfer In this setting, the target tasks are low-resource tasks (less than 10K training examples), while the source tasks are high-resource tasks. It consists of 25 tasks in total. There are 15 source tasks (e.g., DocNLI, DROP) and 10 target asks (e.g., BoolQ, ColA). Please see Appendix A for the complete list or Table 1 for the target tasks. We keep the setting to be almost the same as a major experiment in Vu et al. (2022) for a fair comparison, with the exception that we exclude C4 from the source task since it is a much larger dataset than other tasks. Excluding C4 does not affect SPOT performance since it does not provide an optimal source prompt for any target task.

Transfer across Different Task Categories We here investigate the transferability from datasets in some task categories to datasets in other held-out task categories. Following Sanh et al. (2022), we assume datasets in each category measures a general NLP ability, and use the same taxonomy defined in Sanh et al. (2022). The source tasks include (1) QA tasks: ReCoRD, SQuAD, DROP, MultiRC, and RACE; (2) sentiment analysis tasks: Yelp-2 and SST-2; (3) a paraphrase detection task: QQP; (4) a semantic similarity task: CXC. The target tasks include (1) a sentence completion task: COPA; (2) NLI tasks: CB and RTE; (3) a coreference resolution tasks: WSC; (4) a word sense disambiguation task: WiC.

Training Details As in prior works (Raffel et al., 2020; Lester et al., 2021), all datasets are converted to a text-to-text format. All experiments are conducted with T5-base-LM-adapted as the backbone unless stated otherwise. We use a SimCSE (Gao et al., 2021) model (BERT-base) as the instance encoder. Since the instance encoder is always frozen, we can pre-compute the embeddings of all instances and only keep the embeddings. However, we find that memory and time saved in this approach is negligible². In source task training, the model (skill latent space and prompt generator) is simply tuned on the mixture of all source tasks for each setting. The model is tuned for 80K steps. In learning and testing on target tasks, we closely follow the procedure in Vu et al. (2022). The model is tuned for 100K on each target task. We save a checkpoint every 500 steps and report results on the checkpoint with the highest validation performance. The prompt generator generates 64 soft tokens. The following hyperparameters are shared in all target and source task training: learning rate (0.3), the number of warmup steps (4000), optimizer (Adam).

4 Results

High-to-Low Resource Transfer The results are shown in Table 1. We first compare our method, SHARPT, to methods with comparable compute- and parameter-efficiency, PROMPTTUNING and SPOT-Retrieval. Our method has a clear improvement over the two methods across most tasks and on the average performance. We next compare SHARPT with much more expensive methods, SPOT-Oracle and MODEL TUNING. Note that SPOT-Oracle is significantly more expensive than our method since it tunes on each target task with each possible task prompt (e.g., it requires roughly 48 times more training time), and utilizes oracle labels. While being much more efficient, SHARPT matches or outperforms SPOT-Oracle. Also, our method performance is on par with the MODEL TUNING performance which requires to tune the entire model. These results indicate SHARPT is an efficient and competitive approach.

Transfer across Different Task Categories The results are shown in Table 2. Our method outperforms both PROMPTTUNING and SPOT methods.

²For instance, removing the instance encoder in training (by pre-computing the instance embeddings) does not allow a larger batch size compared to including the instance encoder.

	BoolQ	CB	CoLA	COPA	CR	MRPC	RTE	STS-B	WiC	WSC	Average
ModelTuning	81.4	94.0	51.1	71.2	<u>94.1</u>	87.5	81.5	89.4	68.3	<u>80.8</u>	<u>79.9</u>
SPoT-Oracle	77.6	97.0	<u>55.6</u>	<u>69.3</u>	93.9	<u>88.7</u>	74.7	90.0	70.2	77.2	79.4
PromptTuning	73.0	92.7	52.9	56.7	93.5	86.1	68.7	88.1	63.6	71.5	74.7
SPoT-Retrieval	74.2	95.4	54.8	58.3	93.6	88.4	71.6	90.0	66.7	72.9	76.6
SHARPT	<u>78.9</u>	<u>94.6</u>	58.2	67.0	94.5	89.7	<u>79.4</u>	89.1	<u>68.8</u>	81.6	80.2

Table 1: Results on the high-to-low transfer learning setting. Methods in the upper panel are significantly more expensive than those in the lower panel. The best performance is in **bold**, and the second best is underlined.

	COPA	CB	RTE	WSC	WiC
ModelTuning	71.2	<u>94.0</u>	81.5	80.8	68.3
SPoT-Oracle	63.0	92.9	72.0	77.2	70.2
PromptTuning	56.7	92.7	68.7	71.5	63.6
SPoT-Retrieval	61.2	89.4	71.4	73.6	66.7
SHARPT	<u>65.0</u>	94.6	<u>79.4</u>	<u>79.0</u>	<u>69.8</u>

Table 2: Results on transferring across task categories.

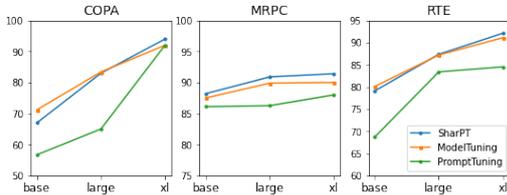

Figure 2: Results on models of different sizes.

The improvement over SPoT methods is larger in this setting than in the high-to-low transfer setting. This might be because SPoT relies more on knowledge shared by tasks in the same category, while SHARPT learns a *shared latent space across all source tasks* and is more suitable to leverage knowledge shared across datasets of different categories.

Across Model Scales In the experiments above, we show that our method can close the performance gap between full model tuning and prompt-based methods on a mid-sized model, T5-base (220M). Here conducts experiments with larger models, T5-large (800M) and T5-xl (3B), and compare SHARPT to MODEL TUNING and PROMPT TUNING. As shown in Figure 2, SHARPT matches or slightly outperforms MODEL TUNING under the three model scales. Our method also shows considerable improvements over PROMPT TUNING.

Ablations We ablate two key components of SHARPT: (1) training on source tasks; (2) skill latent space that captures shared knowledge. See the results in Table 3. Clearly, knowledge learned from source tasks and encoded in the latent space is critical for target task performance.

	BoolQ	CB	CoLA	COPA
SHARPT	78.9	94.6	58.2	67.0
No Source Task Training	64.3	89.3	10.3	58.0
No Latent Space	67.9	82.4	17.6	61.0

Table 3: Ablation results.

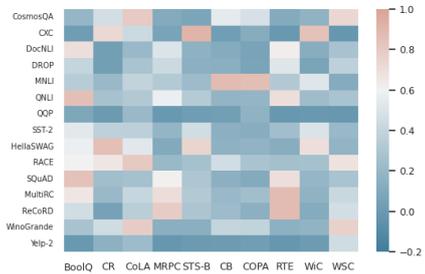

Figure 3: A heatmap of task relations based on skill vector usage of each task.

Task Relations We investigate if the latent space captures source and target task relations to allow knowledge transfer. Each instance queries the latent space and selects one latent skill. We convert this selection to a one-hot vector and treat it as an instance encoding. A task representation is the average of instance encodings in the task. The cosine similarity between two task representations is computed as their relation. The relations between source and target tasks are visualized in Figure 3. It seems that more complicated source tasks such as QA and NLI tasks transfer more knowledge to target tasks via the skill latent space.

5 Conclusion

We introduce SHARPT, which learns a shared latent space which captures a set of basis NLP capacities from a mixture of source tasks. Target instance queries this space to retrieve a skill vector, which then generates prompt tokens to condition a frozen LLM. Our approach outperforms prior soft prompt methods by a significant margin on a variety of tasks. Our method also matches full-model-tuning across model scales.

Limitations

Although our method is much simpler than SPOT, PROMPTTUNING is still arguably the simplest method for adapting LLMs to downstream tasks. It would be a fruitful research direction to design transfer learning approaches that retain (or even improve) our method’s performance and meanwhile further simplify our method, getting closer to the simplicity of PROMPTTUNING.

Abstract

With the prominence of large pretrained language models, low-resource languages are rarely modelled monolingually and become victims of the “curse of multilinguality” in massively multilingual models. Recently, AfriBERTa showed that training transformer models from scratch on 1GB of data from many unrelated African languages outperforms massively multilingual models on downstream NLP tasks. Here we extend this direction, focusing on the use of related languages. We propose that training on smaller amounts of data but from related languages could match the performance of models trained on large, unrelated data. We test our hypothesis on the Niger-Congo family and its Bantu and Volta-Niger sub-families, pretraining models with data solely from Niger-Congo languages and finetuning on 4 downstream tasks: NER, part-of-speech tagging, sentiment analysis and text classification. We find that models trained on genetically related languages achieve equal performance on downstream tasks in low-resource languages despite using less training data. We recommend selecting training data based on language-relatedness when pretraining language models for low-resource languages.

1 Introduction

Since the introduction of the large pretrained language models (Devlin et al., 2019), low-resource languages have not had the opportunity to be treated in the same way as high-resource languages such as English, French or Mandarin Chinese. Massively multilingual models trained using a mixture of high and low-resource languages such as mBERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020) or mT5, (Xue et al., 2021) have been proposed as a solution. Yet these do not work as well on low-resource languages as they do on high-resource languages due to the “curse of multilinguality” (Conneau et al., 2020), where an

increase of languages in a model leads to capacity dilution, negatively affecting performance for all languages. This makes massively multilingual models sub-optimal solutions for such languages.

The quality of the training data for low-resource languages seems to differ greatly to that of high-resource languages (Kreutzer et al., 2022). The AfriBERTa models (Ogueji et al., 2021) demonstrate the considerable success of pretrained representations when trained with a ‘small’ (1GB), high-quality dataset focused on eleven languages of a single continent – Africa. AfriBERTa Large outperforms the larger, massively multilingual models on named-entity-recognition (NER) and text classification for various African languages. While this *continental* approach is promising, it uses a mixture of different language families that are not genetically related.

Here, we propose using language relatedness in lieu of general geographic proximity of languages to pretrain transformer models. We test this hypothesis by grouping training data by language family and then testing on four tasks: NER, Part-of-Speech Tagging (POS Tagging), Sentiment Analysis and Text Classification. New models trained range from 100 to 600 MB of training data, in contrast to 1GB of data for AfriBERTa and 2395 GB for XLM-R. We find that the smallest models trained on the most closely-related languages perform as well as models trained with up to 10 times the amount of data (AfriBERTa).

In this paper we:

- Train and release¹ pretrained models on genetically grouped African languages
- Finetune and release models for NER, POS tagging, sentiment analysis and text classification on various African languages

¹Models are available to download at <https://github.com/Tolulope/mini-but-mighty>

- Find that training on genetically grouped languages performs equally to larger models, despite training on much less data.

2 Related Work

Despite a long history of work on individual NLP tasks on African languages (Adedjouma Sèmiyou et al., 2012; Dibitso et al., 2019; Schlunz et al., 2016; Pauw et al., 2006; Onyenwe et al., 2014; Hunegnaw et al., 2021; Orimaye et al., 2012; Eisenlen, 2016; Alabi et al., 2020), the lack of freely available and aggregated models made it difficult for languages to build off of each other.

The lack of adequate training data in low-resource languages, including African languages, led to multilingual pretraining transformer models such as mBERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020) and mT5 (Xue et al., 2021) using multilingual resources such as Wikipedia and the Common Crawl corpus.

In contrast, the “small data” approach, introduced with the release of the AfriBERTa models (Ogueji et al., 2021) advocates for pretraining models with small amounts of data solely in low-resource languages. The AfriBERTa Large model outperforms XLM-R and mBERT on text classification and NER for a few African languages. This is likely due to the lack of inclusion of a range of African language data and the use of unclean, crawled datasets in the original training data for the large models.

Our proposal to use small, high-quality data draws on the finding that small data perform competitively given the right quality of data (Kreutzer et al., 2022). Our work asks how far we can extend this small data approach by seeing whether large uncurated datasets can be outperformed or at least equalled by small, carefully selected high-quality datasets.

3 Method

3.1 Languages

In our work, we train models with a wide variety of African languages. To compare with AfriBERTa, we use the Afro-Asiatic languages (Amharic, Hausa, Somali, Tigrinya, and Afaan Oromoo) and when focussing on linguistic typology, we work on Niger-Congo Languages. The Niger-Congo family, introduced by Greenberg in 1949, is a genetic family of languages merging the

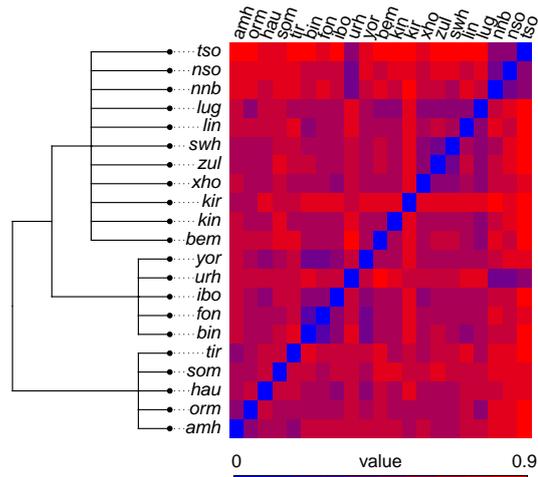

Figure 1: Heatmap displaying the average of syntactic and phonological distances queried from lang2vec between languages used to train the models along with the phylogenetic tree of the languages. Blue represents very close languages and red very distant languages. Clusters are visible for Volta-Niger languages (urh, yor, ibo, fon, and bin) and Bantu languages (nnb, nso, and tso amongst others).

Bantu and ‘Semi-Bantu’ families, due to the similarities found between both (Greenberg, 1949). It spans sub-Saharan African and is a genetic grouping. Figure 1 displays a heatmap of the average of the syntactic and phonological distances between the languages used extracted from WALS using lang2vec (Littell et al., 2017). We see clusters of similarity for the genetically grouped Volta-Niger and Bantu languages, and so our groups, while designed genetically, also are typologically coherent.

The African languages used to train models in this work are summarised with their language families in Table 1.

3.2 Training Data

When training the pretrained models, we add to the AfriBERTa corpus (Ogueji et al., 2021) by collecting various data sources online. See the list of data sources in Appendix A.1. We prioritise datasets produced solely by or in partnership with members of their communities.

3.3 Model Architecture and Training Details

We train all new models with the same architecture as AfriBERTa Large, with 6 attention heads, 768 hidden units, 3072 feedforward size, and a maximum length of 512 (Ogueji et al., 2021). Models trained from scratch are trained for 460,000

Language	ISO Code	Language Family	Branch

Nigerian Pidgin	pcm	English Creole	

Table 1: Summary of languages used for training language models with their language family, branch and ISO 639-3 code used to refer to languages in Section 4.

steps with a learning rate of $1e-4$. To compare pretrained to continued pretraining, we continue pretraining of the AfriBERTa model by 180,000 steps with all the data from the Niger-Congo family. We also compare newly trained models to monolingual and massively multilingual models trained with much more data: BERT Cased (Devlin et al., 2019), BERT Uncased, RoBERTa (Liu et al., 2019), and XLM-RoBERTa (Conneau et al., 2019).

To initially compare genetics with geography, we train two models with different subsets of the AfriBERTa corpus. *AfriBERTa (Niger-Congo)* is trained with data from the Niger-Congo languages in AfriBERTa (Gahuza, Igbo, Kiswahili and Yorùbá) and *AfriBERTa (Afro-Asiatic)* is trained with the Afro-Asiatic languages in AfriBERTa (Afaan Oromoo, Amharic, Hausa, Somali, and Tigrinya).

The Niger-Congo family has many branches. Due to data availability, we focus on the Volta-Niger and Bantu branches. We supplement the existing data in the AfriBERTa corpus with data in Bemba, Edo, Fon, isiXhosa, isiZulu, Kiswahili (Congolese variant), Lingala, Luganda, Nande, Sepedi, Setswana, Urhobo and Xistonga). Data from these languages totals roughly 364 MB of data. We call the model trained with all of these languages *Niger-Congo BERTa*. We then divide the data by language family and pretrain *BantuBERTa* and

VoltaBERTa.

To test the effects of tokenisation, we train a custom tokenizer with the training data from the Niger-Congo family with the same vocabulary size as AfriBERTa, namely 70,000. The training data for the tokenizer was sampled using the method introduced in XLM (Conneau and Lample, 2019), using an $\alpha = 0.3$.

3.3.1 Size comparison models

To test whether the data selection for the Niger-Congo BERTa models results in the models’ performance downstream, we train AfriBERTa models with the same amount of training data in Niger-Congo BERTa (364 MB), BantuBERTa (260 MB) and VoltaBERTa (107 MB). The resulting models are Afriberta 107, AfriBERTa 260 and AfriBERTa 364, which will be finetuned and directly compared to a model of the same size. To achieve this we proportionally reduce the amount of training data for each language in the AfriBERTa corpus to create three pretraining corpora with 107MB, 260MB and 364MB accordingly each with data from the eleven languages used to train AfriBERTa. The results are averaged across relevant languages for each sized model: Volta-Niger languages for AfriBERTa 107, Bantu languages for AfriBERTa 260 and all Niger-Congo languages for AfriBERTa 364.

The newly trained models along with AfriBERTa are summarised in Table 2.

3.4 Evaluation Data

We evaluate our models on four downstream tasks: named-entity recognition, part-of-speech tagging, sentiment analysis and text classification.

NER: For NER, we use the MasakaNER dataset (Adelani et al., 2021b), covering 10 African Languages covering Afro-Asiatic (Amharic, Hausa, Luo) and Niger-Congo languages. The Niger-Congo branches represented are Bantu (Kinyarwanda, Luganda, Kiswahili), Volta-Niger (Igbo, Yorùbá) and West Atlantic (Wolof).

POS Tagging: For POS Tagging, we use high-quality POS tagging data provided by Masakhane (which is not yet publicly available) covering Bambara, Hausa, Igbo, Kinyarwanda, Nyanja (or Chichewa), Nigerian Pidgin English, Kiswahili, isiXhosa, isiZulu and data from the DHASA-SACAIR 1st Joint Task on Part-of-Speech Tagging for African Languages covering isiNdebele, isiXhosa, isiZulu and Setswana.

Model	Languages	Training Data (MB)	Evaluation Data (MB)	Time to train (hrs)
<i>AfriBERTa (Ogueji et al., 2021)</i>	orm, amh, kin, kir, hau, ibo, pcm, som, swa, tir, yor	939	80	–
<i>AfriBERTa (Niger-Congo)</i>	kin, kir, ibo, swa and yor	279	23	57

Table 2: Summary of models trained and/or used in experiments. Models trained on NVIDIA TITAN RTX GPUs

Sentiment Analysis: For Sentiment Analysis, we use YOSM (Shode et al., 2022) and NaijaSenti (Muhammad et al., 2022). YOSM is a sentiment corpus of film reviews in Yorùbá. NaijaSenti is a Twitter sentiment analysis corpus covering the Nigerian languages Hausa, Igbo, Nigerian Pidgin English and Yorùbá.

Text classification: For text classification, we use a Hausa and Yorùbá news topic classification dataset (Hedderich et al., 2020) and the KINNEWS and KIRNEWS dataset (Niyongabo et al., 2020) covering Kinyarwanda and Kirundi.

4 Results

Results for our experiments are listed in Figure 2 and Tables 3 to 8. Given that datasets have data for languages in different families and branches, we select relevant models for comparison here and leave the full set of the results in the Appendix.

4.1 NER

We finetune the pretrained language models for NER using the Masakhane NER dataset. The results for the AfriBERTa model are taken from the paper (Ogueji et al., 2021). The results for our NER experiments are in Figure 2.

For Niger-Congo languages, shown in Figure 2a, *Niger-Congo BERTa* performs almost as well as AfriBERTa and AfriBERTa with continued pre-training. The difference in results is not statistically significant, but the slight increase may suggest that more training data results in better performance for the NER task.

For Afro-Asiatic languages, shown in Figure 2b, the *AfriBERTa (Afro-Asiatic)* model performs almost as well as AfriBERTa with differences in

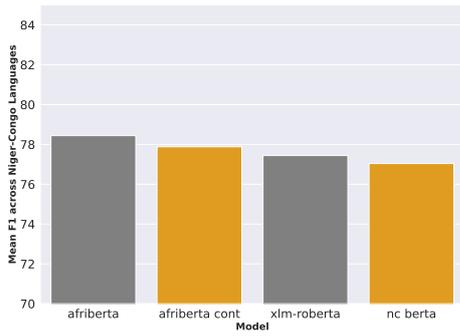

F1 that are not statistically different (less than 0.1 F1). This suggests that training data selection based on genetic grouping results in downstream performance that is not significantly different, despite the reduction in data used. XLM-RoBERTa performs best for Luo and Nigerian Pidgin. Nigerian Pidgin is an English Creole, so we can assume the abundance of English training data in XLM-RoBERTa’s training data helps performance. Luo, a language not present in the training data of any of the models has the best performance with XLM-RoBERTa. This suggests that for unseen languages and English Creoles, it may still be best to finetune massively multilingual models.

4.2 POS Tagging

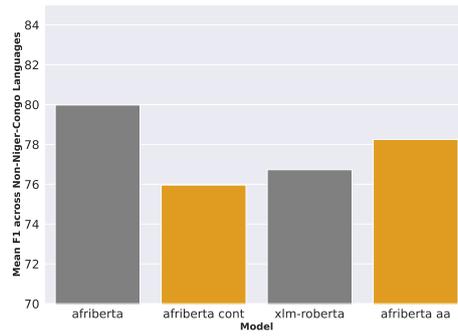

We finetune the models trained on the Part-of-Speech Tagging task, using our two datasets. With languages that have multiple datasets, we train separate models and report the mean per language.

In Table 3 we can see that *BantuBERTa* performs best on most Bantu languages, with an improvement on AfriBERTa of 1.8 F1 for isiZulu, 1.5 F1 for isiXhosa and 1.51 F1 for Chichewa, despite using roughly 25% of the training data of AfriBERTa. Despite the results not being significantly different, we see that training smaller models with higher quality data and a criterion of genetic relatedness leads to performance that is as good as larger models.

For Hausa, an Afro-Asiatic language, we see in Table 4 that *AfriBERTa (Afro-Asiatic)* does not perform significantly differently from AfriBERTa, with only a slight difference in F1 score (0.08 F1 less than AfriBERTa). This suggests that for POS Tagging, linguistically-informed data selection leads to performance that is as good as that

(a) Mean F1 of Niger-Congo languages

(b) Mean F1 of non-Niger-Congo languages

Figure 2: Plots of the mean F1 scores across languages for NER. Plot (a) shows the mean F1 for Niger-Congo languages and Plot (b) shows the mean across non-Niger-Congo languages.

lang	family	afriberta	bantu	nc berta
bam	bantu	86.65	86.70	86.8
ibo	volta-niger	80.47	78.53	80.03

nbl	bantu	80.91	80.88	81.05
nya	bantu	81.14	82.65	81.67
ssw	bantu	84.50	85.44	85.54
swa	bantu	92.06	91.79	91.51
xho	bantu	84.96	86.46	86.40
zul	bantu	82.35	84.16	83.50
mean		86.04	85.86	85.87

Table 3: F1 scores for POS Tagging models of languages that are in the Niger-Congo family. **BantuBERTa** and **Niger-Congo BERTa** perform as well as AfriBERTa across languages.

lang	afriberta	afriberta cont	afriberta aa	xlm roberta
hau	91.34	89.55	91.26	89.89
pcm	87.57	86.31	86.19	89.76
mean	89.46	87.93	88.73	89.83

Table 4: F1 scores for POS Tagging models of languages that are not in the Niger-Congo family. **AfriBERTa (Afro-Asiatic)** is performing almost as well as AfriBERTa for Hausa, despite being trained with much less data.

of larger models outside the Niger-Congo family. Nigerian Pidgin performs best with XLM-RoBERTa, an expected result given that Nigerian Pidgin is an English Creole.

4.3 Sentiment Analysis

The results for Yorùbá presented are the mean F1 scores from the YOSM and NaijaSenti models.

lang	afriberta	nc berta	afribera nc	volta niger
ibo	86.78	87.53	86.96	88.48
yor	86.09	85.92	85.93	86.42
mean	86.44	86.72	86.44	87.45

Table 5: F1 scores for Sentiment Analysis models of languages that are in the Volta-Niger family. **VoltaBERTa** performs as well as AfriBERTa, despite being trained with 10% of the data.

lang	afriberta	nc berta tok	xlm roberta	afriberta aa
hau	87.42	85.54	85.85	87.43
pcm	72.94	74.83	79.06	70.95
mean	80.18	80.19	82.46	79.19

Table 6: F1 scores for Sentiment Analysis models of languages that are not in the Volta-Niger family. **AfriBERTa (Afro-Asiatic)** is performing almost as well as AfriBERTa for Hausa, despite being trained with much less data.

For Volta-Niger languages, the model trained on only 100MB of data, **VoltaBERTa** has the best performance for both Igbo and Yorùbá, outperforming AfriBERTa by 1.7 and 0.33 F1 despite being trained on 10% of the data. Here we see the advantages of a model being trained on a smaller, yet distinct branch of the Niger-Congo family. The results imply that a smaller linguistically-selected model is as good as a larger non-linguistically-selected model, and has the advantage of being smaller and

therefore more widely usable. It is possible that the high similarity of these languages leads to the model’s increased ability learn about the languages and perform better downstream.

Hausa has the best performance with *AfriBERTa (Afro-Asiatic)* and Nigerian Pidgin English with XLM-Roberta. We also see that the English Creole performs best when finetuned on a model trained on English data, supporting our language-relatedness claim with a different set of languages. Training data from similar languages suffices for competitive performance downstream.

4.4 Text Classification

For text classification, we continue to see the trend that models trained on much less data do not have significantly different performance downstream. *AfriBERTa (Afro-Asiatic)*’s performance is almost as good as AfriBERTa’s for Hausa, *BantuBERTa* with a Niger-Congo tokenizer performs almost as well for Kinyarwanda and outperforms AfriBERTa for Kirundi for Bantu languages and *VoltaBERTa* does not perform significantly differently for Yorùbá. In yet another task, we demonstrate that linguistically-informed data selection trumps data quantity.

4.5 Is quality still relevant if we hold size constant?

In addition to comparing model performance with different amounts of training data, we also directly compare models trained with the same amount of data but with different sets of languages with varying levels of genetic similarity below.

Table 8 summarises the training data experiments with the mean F1 score for each model across languages for each task. AfriBERTa 107 is compared to the *VoltaBERTa* model as they both use 107 MB of training data, AfriBERTa 260 is compared to the *BantuBERTa* as both models use 260 MB of data and AfriBERTa 364 is compared to *Niger-Congo BERTa* as they both use 364 MB of training data. We train the *Niger-Congo BERTa* models with and without a custom tokenizer. The results from models trained with a custom tokenizer have an asterisk. We see that when size is held constant the models trained with high-quality data from closely-related languages perform at least as well as models train with data from a wider range of languages. These results highlight the importance of data selection when resources are limited and support our claim that pretraining with genetically-

related languages doesn’t result in significantly different performance downstream.

Overall, we see that across tasks and languages, models trained with data from genetically related languages alone work as well as models trained with up to 10 times the amount of data.

5 Model Visualisation

5.1 Model Visualisation

To visualise the models, we extract sentence embeddings by concatenating the weights of the last four layers of the model for 1,000 sentences in each language’s evaluation set. We use 1000 sentences for each language to ensure an even distribution across languages. For dimensionality reduction, we use Uniform Manifold Approximation and Projection (UMAP) (McInnes et al., 2018) and visualise each sentence in two dimensions. We present UMAP plots as they are not as sensitive to parameters as t-SNE.

Visualisations of models grouped by language family (specific branches when part of the Niger-Congo family) are below. All visualisations show evidence of language-specific and family-specific clustering in the models.

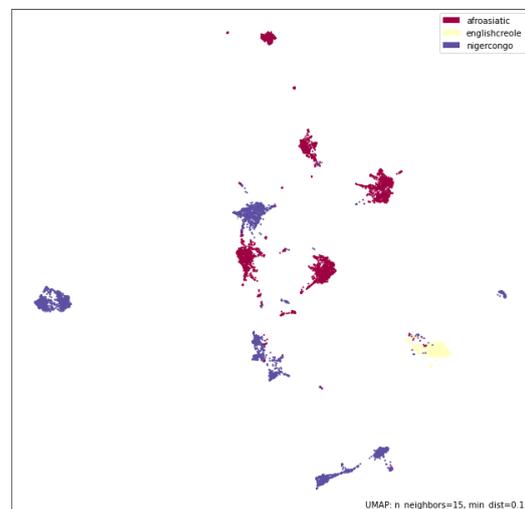

Figure 3: AfriBERTa visualised with languages in the training, coloured by language family (Afro-asiatic in pink, English Creole in yellow and Niger-Congo languages in purple). There appear to be language specific clusters.

When reduced by UMAP, AfriBERTa does not seem to cluster languages by family. Nigerian Pidgin English, is situated away from most of other languages, apart from Yorùbá (bottom right). This

lang	family	afriberta	afriberta cont	afriberta aa	bantu tok	nc berta tok	volta niger
hau	afro-asiatic	90.13	88.18	89.84	84.1	84.22	71.77
kin	bantu	73.87	74.41	70.45	73.69	73.46	68.26
kir	bantu	82.37	84.18	81.38	84.72	83.59	80.91
yor	volta-niger	79.88	80.63	70.88	70.52	78.98	79.70
mean		81.56	81.85	78.14	78.24	80.06	76.77

Table 7: F1 scores for Text Classification models

	afriberta 107	volta niger	afriberta 260	bantu	afriberta 364	nc berta
NER	79.61	82.46	78.10	79.45	76.66	77.04
POS Tagging	79.32	80.40	85.51	86.56	84.78	85.67*
Sentiment Analysis	85.30	87.45				
Text Classification	76.68	78.15	77.50	79.21*	78.11	78.68*
mean per model	80.23	82.12	80.23	81.74	79.85	80.46

Table 8: Table showing the mean F1 across languages in each sub-family compared to an AfriBERTa model trained on the same amount of data for each task. Results with an asterisk (*) are from models trained with a custom tokenizer.

is could be due to borrowing of Yorùbá words into Nigerian Pidgin English.

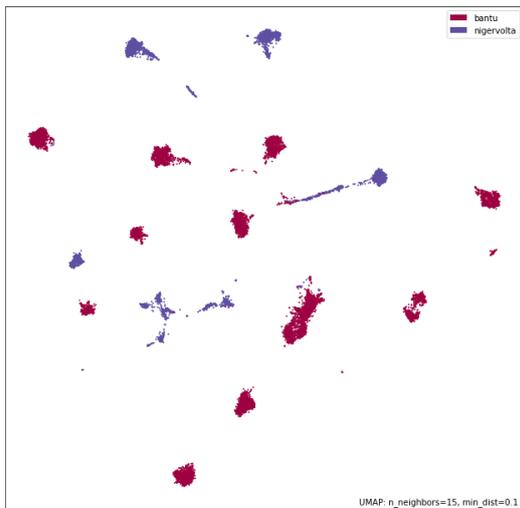

Figure 4: Niger-Congo BERTa visualised with languages in the training, coloured by language family (Bantu languages in pink and Volta-Niger languages in purple). We see language-specific clusters, but no branch-specific separation of the language clusters.

The *Niger-Congo BERTa* model does not seem to cluster languages by sub-family. This may be because all the languages are in the same larger family already.

The *VoltaBERTa* model completely splits Bantu and Volta-Niger Languages, possibly helped by the absence of Bantu languages in the training data. This could be due to the scripts of Igbo and Yorùbá

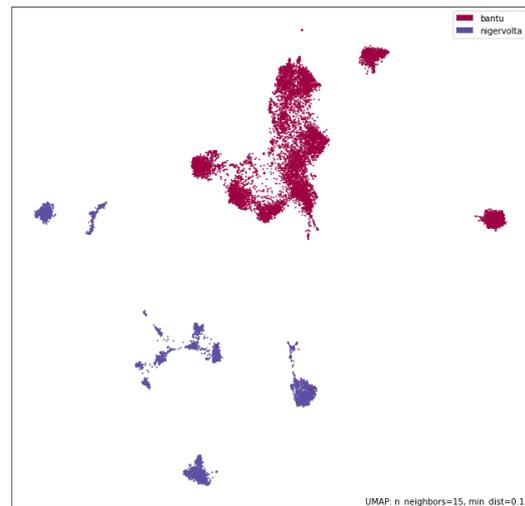

Figure 5: *VoltaBERTa* visualised with languages in the training, coloured by language family (Bantu languages in pink and Volta-Niger languages in purple). Here, Bantu languages are clearly separated from Volta-Niger languages.

(use of diacritics) and Fon (use of different characters), leading the model to internally distinguish between languages part of the Volta-Niger family and those that are not.

Overall, we see that the more closely related the languages used to train the pretrained model, the more distinct the representations of different language families or branches in the UMAP visualisations. This is most likely due to the other languages not being present in the training data, but

the results for POS Tagging and Sentiment Analysis show that this focus on closely related languages leads to improvements in performance with much less data.

6 Discussion

In this work we see that when pretraining multilingual models with closely related languages, the resulting finetuned models work just as well as models finetuned on a wider variety of languages. Sentence embeddings show that the more closely related the languages in the training data, the better the model’s ability to differentiate language families.

We do not see one model consistently outperforming others. However, we do see multilingual models of closely related languages work for those languages downstream and generalise better to unseen languages within the family. **BantuBERTa** works very well for POS Tagging of Bantu languages and **VoltaBERTa** for sentiment analysis of Volta-Niger languages. Continued pretraining of AfriBERTa with closely related languages gives the best text classification result on average. This “small data” combined with language similarity approach demonstrates that it is possible to maintain performance with fewer resources, possibly at the expense of using different models for different downstream tasks.

7 Conclusion

In this paper, we have pretrained several multilingual transformer models exclusively with low-resource languages. We have shown that the grouping of closely-related languages in training data can match or improve performance across several downstream tasks despite the reduction in training data used. We have also demonstrated that for very low-resource languages, we can exploit language similarity to improve performance of NLP tasks on these languages with models trained on similar languages only.

8 Limitations

In this work we did not have an exact overlap of downstream tasks to training data and therefore could not exactly match pretrained models to general task performance. We did not have Bantu language data for Sentiment Analysis, preventing us from making conclusions on this task with BantuBERTa. We also note that we only have data from

two branches of the Niger-Congo family. Data from a wider variety of branches would have helped us make more general conclusions.

We did not compare any of our models to finetuned large language models, nor did we fine-tune our pretrained models before finetuning them for the downstream tasks. It is possible that language-adaptive finetuning of Niger-Congo languages on these models trained exclusively on Niger-Congo languages may lead to even better performance. Given the lack of resources in these languages, one would have to determine guidelines on which data would be used for pretraining or finetuning in this case.

A Appendix

A.1 List of data sources

A.6 Training data comparisons

Language	Data Sources
Afaan Oromoo	AfriBERTa Corpus
Amharic	AfriBERTa Corpus
Hausa	AfriBERTa Corpus
Somali	AfriBERTa Corpus
Tigrinya	AfriBERTa Corpus
Bemba	Text from Bemba Speech Corpus (Sikasote and Anastasopoulos, 2022)
Gahuza	AfriBERTa Corpus
isiXhosa	Xhosa Navy Parallel Corpus (Tiedemann, 2012)
isiZulu	Umsuka English - isiZulu Parallel Corpus (Mabuya et al., 2021)
Kiswahili	AfriBERTa Corpus, Language modeling data for Swahili (Shikali and Refuoe, 2019) and Gamayun (Öktem et al., 2020) Congolese Kiswahili Medium kit
Lingala	Gamayun (Öktem et al., 2020) Lingala Kit
Luganda	Makerere MT Corpus (Mukiibi et al., 2021)
Nande	Gamayun (Öktem et al., 2020) Nande kit
Sepedi	South African News Data (Marivate and Sefara, 2020)
Setswana	Autshumato Setswana Monolingual Corpora (McKellar, 2018) and South African News Data (Marivate and Sefara, 2020)
Xitsonga	Autshumato English-Xitsonga Manually Translated Parallel Corpora (Pienaar et al., 2018)
Èdó	JW300 (Agić and Vulić, 2019)
Fon	FFR Translate Corpus (Emezue and Dossou, 2020)
Igbo	AfriBERTa Corpus and Igbo Monolingual Dataset (Ezeani et al., 2020)
Urhobo	JW300 (Agić and Vulić, 2019)
Yorùbá	AfriBERTa Corpus and MENYO-20k dataset (Adelani et al., 2021a)
Nigerian Pidgin	AfriBERTa Corpus

Table 9: List of sources for language data used to train the models in Table 2.

Abstract

Text summarization aims to condense long documents and retain key information. Critical to the success of a summarization model is the faithful inference of latent representations of words or tokens in the source documents. Most recent models infer the latent representations with a transformer encoder, which is purely bottom-up and thus does not capture long-distance context well. Also, self-attention-based models face the challenge of quadratic complexity with respect to sequence length. We propose a method to improve summarization models on these two aspects. Our method assumes a hierarchical latent structure of a document where the top-level captures the long range dependency at a coarser time scale and the bottom token level preserves the details. *Critically, our method enables token representations to be updated in both a bottom-up and top-down manner.* In the bottom-up pass, token representations are inferred with local self-attention to leverage its efficiency. Top-down correction is then applied to allow tokens to capture global context. We demonstrate the effectiveness on a diverse set of summarization datasets, including narrative, conversational, scientific documents and news. Our model achieves state-of-the-art performance on a wide range of long document summarization benchmarks, compared to recent efficient transformers. We show that our model can summarize an entire book and achieve competitive performance using 0.27% parameters and much less training data, compared to a recent GPT-3-based model. These results indicate the general applicability and benefits of the framework.

1 Introduction

An abstractive summarization system aims to generate a semantically coherent and linguistically fluent summary by conditioning on the document. The dominant approach for abstractive summarization is to use a Seq2Seq model (Sutskever et al., 2014) with an encoder-decoder architecture instantiated

with either RNNs (Hochreiter and Schmidhuber, 1997) or transformers (Vaswani et al., 2017). In such a model, an encoder computes or infers ¹ latent representations of observed tokens (words or subwords) in a document, conditioning on which a decoder generates a summary. This paper studies the problem of how to compute informative latent representations, which in turn would improve summarization.

We propose a method which *synergizes bottom-up computation with top-down computation* while assuming a multi-scale latent structure of a document. In a multi-scale structure, higher-level variables (like those representing sentences, segments) model the document at a coarser time-scale and abstract away details, and are suitable for capturing long range dependency of the document; in contrast, lower-level variables (like those representing tokens) preserve details, and prevent the summary from losing key details (such as the name of an entity). In our method, the summary is generated by conditioning on token representations (low-level variables), similar to recent abstractive summarization models (Zaheer et al., 2020; Beltagy et al., 2020). There is however a critical difference. In our method, *token representations are first bottom-up inferred and then top-down updated with high level representations, hence rendering low-level representations aware of global context.* See Figure 1 for an overview of our method.

Multi-level models have been widely studied in modeling for images (Sønderby et al., 2016), speech (Mehri et al., 2016), and language (Chung et al., 2016). It is also not new in the summarization literature. Prior summarization research has explored hierarchical models (Cheng and Lapata, 2016; Nallapati et al., 2016; Zhang et al., 2019; Xu et al., 2020; Cohan et al., 2018; Ruan et al., 2022). These works focus on the bottom-up computation

¹In this paper, "compute" and "infer" (and "computation" and "inference") are used interchangeably.

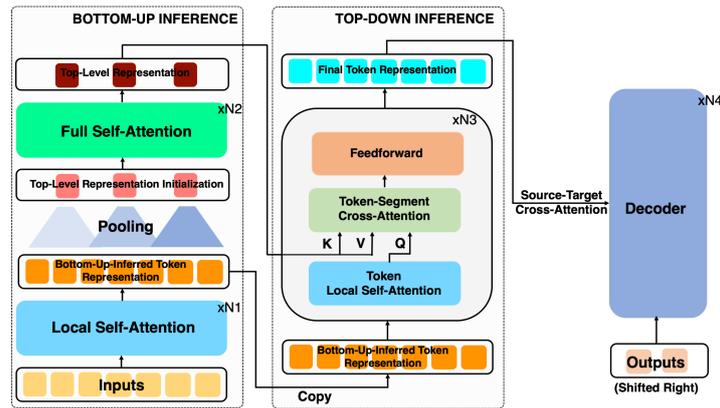

Figure 1: An overview of the top-down transformer. Suppose a document with 7 tokens is the inputs to the model, as shown on the bottom left. The bottom-up inference is achieved with local self-attention (N_1 layers) as shown in the left panel. To initialize the top-level representations, we pool bottom-up-inferred token representations with either equal weights or adaptive weights (see Section 2.3 for details). Top-level representations are then updated with full self-attention (N_2 layers) to capture global context. They are then used to update bottom-up-inferred token representations, accounting for the top-down update for token representations, as shown in the middle panel. The final token representations are attended by the decoder to generate a summary. Note that inference is used in the sense of statistical inference for latent variables and does not imply no training.

in a hierarchical model, computing higher-level representations (e.g., sentences, paragraphs) based on lower-level representations (e.g., words). In contrast, our method emphasizes the combination of bottom-up, as done in prior works, and top-down where lower-level representations are updated and enriched with higher-level representations (see the middle panel in Figure 1). This design is critical for summarization which requires global context. As shown in our ablations, removing the top-down update undermines the summarization performance.

The proposed method is agnostic to the model architecture. Due to the dominance of transformer models in NLP (Chen et al., 2018; Zhang et al., 2020; Sun et al., 2019; Martin et al., 2020), we instantiate our method with a transformer-based model. There is a bottleneck of applying transformers to long documents, because its computational and memory cost has a quadratic dependency on the sequence length. This issue is especially critical for summarization since we are more interested in summarizing long documents since short ones can be quickly read through by humans. To address this issue, a large amount of prior works have been devoted to develop efficient transformers with sub-quadratic complexity (Wang et al., 2020; Child et al., 2019; Beltagy et al., 2020; Zaheer et al., 2020; Kitaev et al., 2020; Roy et al., 2021).

Our method provides a natural way to diminish this quadratic complexity issue. In the bottom-up computation, we use local self-attention where each token only attends the tokens within a local fixed-length window, and thus the complexity does

not grow as a function of the input sequence length. The top-down correction for (local) token representations enables them to capture more global context, reducing the limitation of local attention. In prior works like Longformer (Beltagy et al., 2020), Bigbird (Beltagy et al., 2020), local attention is also used. Our method is different from these models in terms of how to inject global information to locally computed representations. Longformer and BigBird utilize a few global tokens which attend and are attended by all local tokens, whereas we use top-down correction. Our approach can better capture global information compared to prior models, as demonstrated by clear performance improvements over these models in our experiments.

In summary, our methods have two key components: (1) *local attention in bottom-up computation* and (2) *top-down correction for locally-computed-token-representations by high level representations*. The first component alleviates the computational and memory cost and allows our model to process long documents, and the second component injects global information to local tokens and improves summarization performance. We call our model as *top-down transformer*, to emphasize the importance of the top-down update. We evaluate the model on a diverse set of summarization benchmarks. They cover documents from a variety of domains, including news articles and scientific, conversational, and narrative documents, and of various lengths ranging from hundreds of words (e.g., a news article), several thousands to over ten thousands of words (e.g., a scientific paper, a book chap-

ter), to even over hundred thousands of words (e.g., an entire book). Across all long document datasets, our models achieve competitive or state-of-the-art performance. We also show that our model is able to summarize a whole book. Compared to Wu et al. (2021) using GPT-3 and requiring humans to extensively label data, our model achieves competitive performance on book summary with only 0.27% parameters and a small amount of publicly available data. The diverse and strong empirical results support the effectiveness and wide applicability of the proposed model.

Our contributions are summarized as follows: (1) we propose a method which combines bottom-up computation and top-down update for long document summarization; (2) we conduct extensive evaluations and achieve strong performance on various long document benchmarks; and (3) we adapt our method to the challenging task of summarizing an entire book and achieve GPT-3-level performance with only 0.27% parameters.

2 Methods

Figure 1 gives a graphical overview of the top-down transformer. We introduce its details in this section. Suppose a document has N tokens, $\mathbf{t} = \{t_i\}_{i=1}^N$. In our method, token representations are computed by combining top-down and bottom-up processes. This leads to effective and efficient inference for token representations. They are then attended by a decoder to generate a summary, as in a regular encoder-decoder transformer.

2.1 Bottom-Up Computation

In the bottom-up path, contextual embeddings of the tokens, $\{e_i \mid e_i \in \mathbb{R}^d\}_{i=1}^N$, are computed with N_1 layers of local self-attention. In particular, each token t_i only attends to nearby tokens within a window of size of w . The complexity is hence $O(Nw)$, in contrast to $O(N^2)$ for full self-attention models.

2.2 Top-Down Computation

The efficiency with local self-attention in the bottom-up path nevertheless comes with a limitation, that is, each e_i only captures the context within a local window instead of that of the whole document. To mitigate this issue, we propose a top-down update for token representations.

Consider a two-level multi-scale latent structure for a document. The lower level consists of token representations, $\{e_i\}_{i=1}^N$, computed by the bottom-

up computation. The top level consists of units at a coarser level. It is affordable to apply full self-attention at the top level due to its coarser granularity, allowing these top-level units to capture global document context. The self-attention mechanism for the top-level representations is the original multi-head self-attention proposed in Vaswani et al. (2017).

Denote the top level representations after self-attention update as $\{s_j \mid s_j \in \mathbb{R}^d\}_{j=1}^M$ (see Section 2.3 for details on top-level representation initialization methods). We can then update the bottom-up-inferred token representations with the top-level representations. This is achieved with N_3 top-down computation layers, as illustrated by the middle panel in Figure 1. Each layer contains three transformations on $\{e_i\}$: (1) token self-attention, (2) token-segment cross-attention, (3) feed-forward. (1) and (3) are the same as those in the bottom-up layers or regular self-attention layer with local attention. (2) implementing the cross-attention between the top and bottom levels is the critical operation. In particular, each e_i is updated with cross-attention,

$$\tilde{e}_i = e_i + \text{LayerNorm}\left(\sum_{j=1}^M \alpha_{ij} f_v(s_j)\right), \quad (1)$$

$$\alpha_{ij} = \frac{\exp(f_q(e_i)^T f_k(s_j))}{\sqrt{d} \sum_{l=1}^M \exp(f_q(e_i)^T f_k(s_l))} \quad (2)$$

where f_q , f_k , and f_v indicate query, key, and value linear mappings, respectively. For notational clarity, Equation 1 only illustrates the case with a single attention head. In practice, we use multi-heads. The cross-attention operation injects global contextual information into bottom-up-inferred token representations, e_i , and yields global-context-aware token representations, \tilde{e}_i , conditioning on which a summary can be generated by a decoder.

To instantiate the top-down computation, we need to make two choices: (1) the number of top-levels above the token level and (2) the unit representation for each top-level. We choose to use one top level since it is sufficiently coarser to apply full self-attention for a wide range of long document benchmarks we experimented on. A natural choice for top level units is sentence, paragraph, and chapter, depending on the number top level considered. Such a choice however leads to complicated implementations and reduced scalability due to the varying length of these units. We hence choose a

simpler approach, where the top level consists of fixed-length segments of the documents. While we use a single top level, multiple top levels can be simply achieved with segments with increasingly coarser granularity.

In the top-down computation, segment-level self-attention has a complexity of $O(M^2)$, and token-segment cross-attention has a complexity of $O(NM)$. Thus, together with bottom-up inference, the complexity is $O(Nw + M^2 + NM)$. In practice, we use relatively small w (window size) and M (number of segments).

2.3 Pooling Methods

As aforementioned, we use a single top level, consisting of fixed-length segments. The segment representations are initialized by pooling token representations. Following the notation above, suppose a document is divided into M segments, and the embedding of the j th segment is initialized as,

$$s_j^{(0)} = \sum_{n=1}^k p_n e_{j \times d + n} \quad (3)$$

where k is the kernel size and d is the stride. p_n is the weight for the n th token. We introduce two approaches to compute the weights. The first method is average pooling (AvgPool) and hence $p_n = \frac{1}{k}$, which is simple and convenient. In the second approach, we leverage the reference summary to define the importance of each token to assign adaptive weights (AdaPool). Particularly, we learn an importance tagger with labels constructed with the reference summaries, which involves three steps:

1. Construct training labels for the importance tagger: (1) word lemmatization for document and reference words; (2) label a document word as important if it appears in the reference word list and is a non-stopword
2. Train a top-down transformer encoder with constructed labels as the importance tagger
3. Train the summarization model with oracle weights (i.e., constructed labels from Step 1.) and test it with the adaptive importance weight assigned by the learned tagger

In our experiments, we also used OracleAdaPool where the weights are obtained from Step 1 with the reference summaries. Note that if $\{p_n\}_{n=1}^k$ does not form a valid probability distribution, s_j can be

computed with a normalized weight distribution within each pooling window as follows,

$$s_j^{(0)} = \frac{\sum_{n=1}^k \exp(p_n) e_{j \times d + n}}{\sum_{n=1}^k \exp(p_n)}. \quad (4)$$

$\{s_j^{(0)}\}_{j=1}^M$ are updated with self-attention, yielding $\{s_j\}_{j=1}^M$, which are then used in top-down inference for token representations, as discussed in Section 2.2.

3 Experiments

3.1 Overview

We thoroughly evaluate the proposed method on various summarization datasets. See Table 7 in the appendix for a summary of datasets used in the current work. Our model is first evaluated on two standard long document summarization benchmarks, PubMed and arXiv (Cohan et al., 2018). It outperforms various efficient transformers and other approaches and achieves state-of-the-art performance. Although we focus on long document summarization, models under our framework is also applicable to shorter documents. We test our model on CNN-Dailymail (See et al., 2017), the most widely used short summarization dataset. Compared to a full self-attention model, our model achieves competitive or better performance. Recently, a more challenging benchmark, SummScreen (Chen et al., 2021), is proposed, where summarization systems need to summarize TV show scripts. These documents convey plot events often indirectly and implicitly in dialogues, in contrast to news and scientific articles where statements follow a logical order and facts are offered explicitly. Moreover, a typical episode contains multiple subplots that proceed in parallel. Solving this benchmark thus requires a system to draw information from utterances spreading out through the entirety of the input and integrate them to a concise description. Our model outperforms strong baselines on this challenging benchmark by a significant margin. Another challenging dataset, BookSum (Kryściński et al., 2021), is also recently released. It covers books from the literature domain, including stories, plays, and novels. Similar to ScreenSum, it requires integrating plot events from indirectly expressed descriptions. A further challenge is to process long-form texts up to hundreds of pages or over 100,000 words. Our method does well on this challenge, achieving competitive or superior performance compared to

a GPT-3-based model (Wu et al., 2021). While the GPT-3-based model has 175 billion parameters and requires human labelers to extensively write summaries and provide reward information, our model with 464 million parameters is 380 times smaller and merely requires training on relatively minimal data. These results suggest our framework is a generally effectively for documents of various lengths, domains.

3.2 Implementation Details

We use the same encoder-decoder architecture for all datasets. The encoder has 8 bottom-up layers and 4 top-down layers for tokens, and 2 self-attention layers for segments. The decoder has 12 layers. The encoder layers for tokens (12 layers) and the decoder layers are all initialized from BART (Lewis et al., 2020) except the parameters for token-segment cross-attention in the top-down layers, which are randomly initialized. The self-attention parameters for segments are also randomly initialized. The window size is 1024 unless otherwise specified. Our settings closely follow Longformer (Beltagy et al., 2020) which has 12 layers for the encoder and decoder, is initialized from BART, and uses a local window size of 1024. Thus, comparison with Longformer is a test of the effect of top-down correction for token representations. The segment-pooling has a kernel size of 32 and a stride size of 24. The maximum number of segments is 512. The maximum document lengths for PubMed, arXiv, CNN-DM, TVMegaSite, ForeverDreaming, BookSum are 8192, 16384, 1024, 12288, 12288, 12288, respectively. The optimizer for all models is Adam with an learning rate of $5e-5$. Model performance is evaluated with ROUGE scores (Lin, 2004). Reported performance is based on the checkpoint with the best validation R-2 score. Summary samples for each dataset generated by our models are provided in the Appendix.

3.3 Scientific Documents

We first test the effectiveness of our framework on two widely used datasets based on scientific documents, PubMed and arXiv. They consist of long documents of length ranging from several thousands of words to over ten thousands words. Three variants of our model with various pooling weights are presented. AvgPool, AdaPool, and OracleAdaPool in Table 1 indicate average pooling, pooling with adaptive weights, pooling with adaptive weights determined by references, respectively (see Section 2.3 for more details).

The experiment results are displayed in Table 1. Pegasus (Zhang et al., 2020) is pretrained on a large-scale of dataset with a pretraining objective specifically designed for summarization. It uses a full self-attention encoder and thus has to truncate the source document due to the quadratic memory complexity. The summarization-oriented large-scale pre-training makes it a strong baseline. Dancer (Gidiotis and Tsoumakas, 2020) takes a divide-and-conquer approach in which the summary is divided into sections and each section is paired to the appropriate section of the document and the model is trained on short sequences and has a low memory requirement. This is a straightforward approach achieving strong performance.

TLM-I+E (Pilault et al., 2020) first extracts salient sentences and then uses a GPT-style model to generate a summary by conditioning on the introduction section and extracted sentences (instead of the whole document), thus reducing memory requirement. SSN-DM (Cui and Hu, 2021) is an extractive model and uses a sliding encoder to process segments of a document and a memory module to capture autoregressive dependency between segments. These two models bear similarities to our model in that they use a multi-scale structure. The extracted salient sentences in TLM-I+E can be considered a representation of the document at a coarser granularity since salient information

is retained. Instead of keeping the coarser representations in the latent space, TLM-I+E reads out them to the observed word space. In SSN-DM, the fixed-size memory module pooling information from each segments can also be considered a high level representation of the document. Despite these similarities, our model, synergizing bottom-up and top-down inference, clearly outperforms these prior models.

BigBird (Zaheer et al., 2020), Longformer (Beltagy et al., 2020), and LSH (Kitaev et al., 2020; Huang et al., 2021) are efficient transformers. BigBird based on Pegasus pre-training combines local attention, random attention tokens, and global attention tokens. LSH uses content-dependent sparse attention based on local sensitivity hashing. Longformer is closely related to our models. It uses the same local attention as in our bottom-up computation except it has an extra [CLS] token which is a global attention token. Longformer is also initialized from BART. The only difference is that our models compute token representations with both top-down and bottom-up processes, in contrary to pure bottom-up in Longformer. The clear performance improvement over Longformer and other efficient transformers indicates the effectiveness of the synergy of bottom-up and top-down computation.

3.4 Short Documents

CNN-DailyMail			
	R-1	R-2	R-L
BART (Reported)	44.15	21.28	40.90
BART (Re-eval)	43.93	20.81	40.79
TopDownFormer (AvgPool)	<u>44.32</u>	21.03	41.40
TopDownFormer (AdaPool)	44.85	21.31	41.15
TopDownFormer (OracleAdaPool)	63.87	38.42	59.10

Table 2: Results on CNN-DailyMail. Best performance (no oracle) is in bold, and the second best is underlined.

To demonstrate the general applicability of the proposed framework, we show its effectiveness on short document summarization and compare it to full self-attention model. We hypothesize that although the bottom-up computation uses local self-attention, our method with the top-down correction would lead to competitive or better summarization performance.

Our model parameters are initialized from BART. Hence, BART with full self-attention forms a natural baseline, allowing for direct comparison. In the bottom-up inference, the local attention window size of our models is 256. As shown in Table 2,

our models achieve slightly better performance, especially in terms of R-1 and R-L, than BART. It confirms our hypothesis that a synergy of bottom-up with local attention and top-down inference with global attention is effective and achieves on-par or better performance as full self-attention.

3.5 SummScreen

Scientific and news articles often require that facts are offered explicitly and statements follow a logical order, which might allow summarization models to exploit layout and stylistic biases. We next test the proposed method on a more challenging dataset, SummScreen, which requires a model to draw and integrate information from indirect expressions across a wide range of the document. SummScreen (Chen et al., 2021) provides two datasets, TVMegaSite and ForeverDreaming, collecting from two different TV show transcript websites. Each document is the transcript of a TV show episode and the summary is an associated recap.

Table 3 summarizes the results. Extractive oracle is an extractive method by extracting nearest neighbors based on Rouge scores. Longformer is an abstractive method and takes the whole document as input. Hybrid models first select salient sentences and then input them to BART. Our models outperform these strong baselines and even achieves comparable or superior performance than prior models having access to oracle information.

3.6 BookSum

BookSum (Kryściński et al., 2021) is another challenging dataset, consisting of books from the literature domain including stories, plays and novels. It includes examples on three levels of granularity with increasing difficulty: (1) paragraph-level with inputs with hundreds of words, (2) chapter-level, with inputs with several thousands or over ten thousands of words, (3) book-level, with inputs spanning up to hundreds of pages and over hundred thousands of words. The chapter-level examples have comparable lengths to other popular long-form summarization datasets such as PubMed, arXiv. We first test our models on the chapter level. The book-level summarization is extremely challenging. First, the number of examples (313 books) is limited. Second, a book is too long to fit in current models. We train our model in a curriculum and recursive way to address the two issues.

Table 4: Results on BookSum Chapter Level. Best performance (no oracle) is in bold, and second best is underlined.

3.6.1 Chapter Level

Table 4 displays the results. Kryściński et al. (2021) takes a divide-and-conquer approach to summarize chapters. They finetune BART, T5, and Pegasus on the paragraph level data and the chapter summary is obtained by concatenating the paragraph summary. This might miss the intra-paragraph context. Our models directly summarize the whole chapters and outperform these divide-and-conquer models. Efficient transformers, Longformer and BigBird, are also able to take in the whole chapters as inputs. But these bottom-up approaches clearly underperform our models.

3.6.2 Book Level

We first train a top-down transformer on chapter-level and then fine-tune it on book-level data. The inputs to the book-level model are (1) the concatenated chapter reference summaries in training or (2) the concatenated chapter summaries generated by the chapter-level model in testing. The chapter-to-book curriculum training is to mitigate the scarcity of book-level data. The recursive summarization of chapters and then books can be considered abstractive content selection applied to book data.

Table 5 summarizes the book-level results. The middle section shows the performance for the models with the divide-and-conquer approach (Kryściński et al., 2021), same as those for the chapter-level data. Wu et al. (2021) also attempts to summarize books using GPT-3 with reinforcement learning (RL) finetuning. The results are shown in third

BookSum Book Level

Table 5: Results on BookSum Book Level. Best performance (no oracle) is in bold, and second best is underlined.

section in Table 5. Their method shares similarity with ours in that they decompose books into shorter sequences and train the model and summarize the text segments recursively. There are three differences between our approach and theirs. First, we train our model with the limited data from BookSum, while (Wu et al., 2021) requires human labelers to write summaries, which is highly costly. Second, our model has lower complexity, allowing it to take in longer input. Thus, we only need to decompose the book one time (into chapters), in contrast to multiple recursive decomposition steps. Multiple recursive summarization steps is prone to accumulating errors. Third, GPT-3 uses bottom-up inference to infer token representations, in contrast to the synergy of bottom-up and top-down inference in our approach. The last two differences might account for our competitive performance using a much smaller model (0.46B vs. 175B) and less data.

3.7 Ablation Studies

Our method has two key components: (1) local attention in bottom-up computation, and (2) top-down update to inject global context. We conduct ablation studies on these two factors. All ablation experiments are performed with PubMed.

We first ablate top-down update (TDU). The results are summarized in Table 6. The first row shows the performance of the top-down transformer with top-down update via cross-attention and window size 1024, which is our final model. The second row shows the performance for a vari-

ant of top-down update. In this variant, to update the bottom-up inferred token representations, we concatenate the token representations with the corresponding top-level segment representations, in contrast to the cross-attention approach used in the final model. We can see a clear performance degradation, indicating the importance of the cross-attention-based top-down update. The third row displays the results without top-down update, and the decoder attends the bottom-up-inferred token representations to generate summaries. Compared to our final model, the performance is also degraded, suggesting the effectiveness of the top-down update.

The lower panel of Table 6 presents ablations on window size (WS) of local attention. As the window size increases, the performance on all metrics enhances. The effect is quite large when the window size is increased from 32 to 256. The effect becomes smaller after 256, but the model performance can still benefit from larger window size.

		R-1	R-2	R-L
TDU via cross-attention	WS - 1024	48.34	21.40	44.22
TDU via concat	WS - 1024	47.04	20.36	43.03

4 Related Work

Summarization Models Prior works have proposed extractive models (Nallapati et al., 2017; Cui and Hu, 2021), abstractive models (Nallapati et al., 2016; Zhang et al., 2020), and hybrid models combining extractive and abstractive methods (Gehrmann et al., 2018; Pilault et al., 2020), for text summarization. Although our model mostly follows the abstractive approach, it also has connections to the hybrid models. These models usually first extract salient sentences from the source document and then summarize the extracted sentences with an abstractive model. Extracted sentences can be viewed a high level representation of the document, although it is the observed space but not in the latent space as in our framework. A continuous representations in the latent space facilitates end-to-end learning. Moreover, assigning importance weight with the importance tagger in our method resembles an extractive step in a hybrid model, and

thus top down transformer with learned importance tagger can be considered a hybrid model.

Efficient Transformers Despite the effectiveness of transformers on a variety of tasks, its quadratic complexity with respect to the sequence length has limited its application to problems with long sequences. A large amount of works have attempted to address this limitation. A major line of work focuses on designing various sparse attention mechanisms. These works can be roughly categorized into two groups, depending on whether the sparsity pattern is content-dependent (Kitaev et al., 2020; Roy et al., 2021; Wang et al., 2021; Liu et al., 2021) or content-independent (Child et al., 2019; Beltagy et al., 2020; Ainslie et al., 2020; Zaheer et al., 2020). Our work is mostly related to content-independent sparse attention. A main assumption of content-independent sparse attention is that the context temporally and/or spatially proximate to the query token is more important, which is intuitively sensible and supported by empirical attention analysis (Child et al., 2019). Thus, a common sparse attention pattern is local attention, where each query token only attends to a neighborhood within a fixed temporal and/or spatial window. While this reduces the complexity to be linear, a model with only local attention cannot model long-range dependency. Prior works combine local attention with other attention patterns with wider or global receptive field such as dilated attention, random attention tokens, and global attention tokens (Beltagy et al., 2020; Zaheer et al., 2020). Our models also use local attention for its efficiency and leverage top-down inference to enable global-context awareness.

5 Conclusion

In this work, we propose a summarization method which combines bottom-up computation with top-down computation to improve token representation inference. In the bottom-up pass, token representations are inferred with local self-attention to exploit its efficiency. Top-down correction is then applied to allow tokens to capture global context. Our model achieves (1) state-of-the-art performance on a wide range of long document summarization benchmarks, and (2) competitive performance on summarizing whole books using 0.27% parameters and much less training data, compared to a recent GPT-3-based model. These results indicate the general applicability and benefits of the proposed

framework.

Limitations

In the current work, we only explore a model with a single top-level layer. It would be a fruitful research direction to study models with multiple layers, with growing level of abstraction. This might improve both the efficiency and performance of the current model, since long range dependency is mostly captured by higher-level layers and the window size at the low-level can be small.

B Qualitative Examples

PubMed Example #1: Reference

a new class of water - soluble c60 transfecting agents has been prepared using hirschbingel chemistry and assessed for their ability to act as gene - delivery vectors in vitro. in an effort to elucidate the relationship between the hydrophobicity of the fullerene core, the hydrophilicity of the water - solubilizing groups, and the overall charge state of the c60 vectors in gene delivery and expression, several different c60 derivatives were synthesized to yield either positively charged, negatively charged, or neutral chemical functionalities under physiological conditions. these fullerene derivatives were then tested for their ability to transfect cells grown in culture with dna carrying the green fluorescent protein (gfp) reporter gene. statistically significant expression of gfp was observed for all forms of the c60 derivatives when used as dna vectors and compared to the ability of naked dna alone to transfect cells. however, efficient in vitro transfection was only achieved with the two positively charged c60 derivatives, namely, an octa - amino derivatized c60 and a dodeca - amino derivatized c60 vector. all c60 vectors showed an increase in toxicity in a dose - dependent manner. increased levels of cellular toxicity were observed for positively charged c60 vectors relative to the negatively charged and neutral vectors. structural analyses using dynamic light scattering and optical microscopy offered further insights into possible correlations between the various derivatized c60 compounds, the c60 vector / dna complexes, their physical attributes (aggregation, charge) and their transfection efficiencies. recently, similar gd@c60 - based compounds have demonstrated potential as advanced contrast agents for magnetic resonance imaging (mri). thus, the successful demonstration of intracellular dna uptake, intracellular transport, and gene expression from dna using c60 vectors suggests the possibility of developing analogous gd@c60 - based vectors to serve simultaneously as both therapeutic and diagnostic agents.

PubMed Example #1: Model Output

a new class of water - soluble c60 transfecting agents with positively charged, negatively charged, or neutral chemical functionalities under physiological conditions was prepared using hirschbingel chemistry. transfection, cytotoxicity, and biophysical structure / activity studies were performed in an effort to elucidate the relationship between the hydrophobicity of the fullerene core, hydrophilicity, and the overall charge state of the c60 vectors in gene delivery / expression. only two positively charged c60 derivatives, namely, an octa - amino derivatized c60 and a dodeca - amino derived c60 vector, showed efficient in vitro dna delivery into cells. increased levels of cellular toxicity were observed for positively charged compounds relative to the negatively charged and neutral vectors, and aggregation was the major factor that negatively affected the cytotoxic profiles of these c60 - vector / dna complexes. the successful demonstration of intracellular dna uptake and gene expression from dna dna conjugates formed from c60 compounds suggests the possibility of developing analogous gd@c60 vectors to serve as both therapeutic and diagnostic agents.

PubMed Example #2: Reference

context : isolated involvement of the appendix in crohn's disease is reported to be 0.2 % to 1.8 %, and is usually associated with ileocaecal crohn's disease in 25 % of ileal and 50 % of caecal disease. while appendicitis in a patient who was previously diagnosed to have ileocaecal crohn's may be managed with appendicectomy and ileocaecal resection, appendicectomy alone when performed for appendicitis in a patient with unsuspected ileocaecal crohn's disease could lead to postoperative complications including enterocutaneous fistula.case report : a young female patient who underwent appendicectomy elsewhere for acute appendicitis presented to us with a persistent enterocutaneous fistula of 6 weeks duration. she had complained of general ill health and occasional altered bowel habits for 6 months prior to the acute appendicitis presentation. our investigations, including a ct scan, suggested the possibility of ileocaecal crohn's disease. she underwent excision of the enterocutaneous fistula and ileocaecal resection, and histopathology of the resected specimen confirmed crohn's disease. in the postoperative period she received mesasalazine. when last seen 2 years later during her regular follow - up, she was found to be in good health.conclusion : the possibility of ileocaecal crohn's disease should be considered in patients presenting with unexplained postoperative enterocutaneous fistula following appendicectomy. a high index of clinical suspicion is required to make a prompt diagnosis and institute appropriate further treatment in form of ileocaecal resection.

PubMed Example #2: Model Output

introduction : isolated involvement of the appendix in crohn's disease is reported to be 0.2 % to 1.8 %, and is usually associated with ileocaecal crohn's disease in 25 % of ileal and 50 % of caecal disease. while appendicitis in a patient who was previously diagnosed to have ileocaecal crohn's may be managed with appendicectomies, appendicectomy alone when performed for acute appendicectomy could lead to postoperative complications including enterocutaneous fistula.case report : a young female patient who underwent appendicectomy elsewhere presented to us with a persistent enterococcal fistula of 6 weeks duration. on further questioning, she informed us that she had presented to this hospital with a 2 - week history of abdominal pain, confined to the right lower abdomen. she had complained of general ill health and occasional altered bowel habits for 6 months prior to the acute appendicectomy presentation. our investigations, including a computerized tomography scan, suggested the possibility of crohn's disease. she underwent excision of the enterococcus fistula and resection of the caecum, and histopathology of the resected specimen confirmed the diagnosis. in the postoperative period she received mesasalazine. when last seen 2 years later during her regular follow - up, she was found to be in good health.conclusion : appendicectomy alone is a safe procedure in patients with suspected crohn ileocaecal involvement. while appendiceal resection will suffice in those who present subacutely and are diagnosed preoperatively by clinical signs, a high index of clinical suspicion is required to make a prompt diagnosis.

arXiv Example #1: Reference

we study experimentally the thermal fluctuations of energy input and dissipation in a harmonic oscillator driven out of equilibrium, and search for fluctuation relations. we study transient evolution from the equilibrium state, together with non equilibrium steady states. fluctuations relations are obtained experimentally for both the work and the heat, for the stationary and transient evolutions. a stationary state fluctuation theorem is verified for the two time prescriptions of the torque. but a transient fluctuation theorem is satisfied for the work given to the system but not for the heat dissipated by the system in the case of linear forcing. experimental observations on the statistical and dynamical properties of the fluctuation of the angle, we derive analytical expressions for the probability density function of the work and the heat. we obtain for the first time an analytic expression of the probability density function of the heat. agreement between experiments and our modeling is excellent.

arXiv Example #1: Model Output

we study the fluctuations of energy and dissipation in a thermostated harmonic oscillator driven out of equilibrium by an external deterministic forcing. this oscillator is very well described by a second order langevin equation. using the fluctuation dissipation theorem, we obtain fluctuation relations for the work given to the system by the external torque and for the heat dissipated by the system, by writing the first principle of thermodynamics between the two steady states. from the experimental results, we derive analytical expressions for the probability density functions of the work and the dissipated heat, and for their finite time corrections, both for a forcing linear in time and a forcing sinusoidal in time. from these expressions, we present some analytical derivations of fluctuation theorems based on experimental observations.

arXiv Example #2: Reference

the pairing hamiltonian constitutes an important approximation in many- body systems, it is exactly soluble and quantum integrable. on the other hand, the continuum single particle level density (cspld) contains information about the continuum energy spectrum. the question whether one can use the hamiltonian with constant pairing strength for correlations in the continuum is still unanswered. in this paper we generalize the richardson exact solution for the pairing hamiltonian including correlations in the continuum. the resonant and non - resonant continuum are included through the cspld. the resonant correlations are made explicit by using the cauchy theorem. low lying states with seniority zero and two are calculated for the even carbon isotopes. we conclude that energy levels can indeed be calculated with constant pairing in the continuum using the cspld. it is found that the nucleus @xmath{0} is unbound. the real and complex energy representation of the continuum is developed and their differences are shown. the trajectory of the pair energies in the continuum for the nucleus @xmath{1} is shown.

arXiv Example #2: Model Output

the exact solution of the richardson pairing hamiltonian is obtained by including the resonant and non resonant continuum through the continuum single particle level density (cspld). the gamow states, which appear in the complex energy representation, provide the main contribution from the continuum. the inclusion of the continuum has been used to study the unbound isotope @xmath{0} and beyond. it was found that the continuum pairs (pair energies with positive real components) converge to the real part of the uncorrelated pair energy and they do not appear in complex conjugate partners. as a result the total energy of the system may be complex. from the exact solutions of the pairing and pairing - like hamiltonians the cspld can be used to investigate many - body correlations.

Jake meets Tad at ConFusion where Tad is enjoying a salad. Tad doesn't believe David's story as to why he is in Gloucester. Liza joins them and serves Tad with a restraining order to stay away from the bar in Gloucester. Amanda takes Trevor for an exam at the hospital and joins Angie. David also joins them. Erica sits alone in her hotel room when Opal comes to ask if she's seen the documentary on Pine Valley. Ryan stares at a blank television when Emma comes downstairs with Corinna. Emma asks Ryan if he is going to watch the documentary. In Gloucester, Gayle comes in to check on Greenlee. Greenlee tells Gayle that she has to get home. Greenlee clinches her fist as she imagines how it would be if she were home. Erica panics as to what Ryan might have said on the documentary. Erica receives another copy of the documentary that Hayley did of Pine Valley. David asks Angie if read the gift that he gave her. Amanda tells David that she knew that he had lied to her about having patients to see at the hospital and instead had gone to Gloucester. Tad reprimands Jake for wanting to go to Gloucester without telling Amanda. Jake gets up to go back to work and sees Amanda and Trevor. Jake asks her how long she had been standing there. Amanda answers, " Long enough." Madison and Angie discuss Madison's mom. Erica finally gives in and agrees to watch the DVD. Opal is thrilled, but Erica insists that she wants to watch it alone. Ryan visits with DVD in hand and suggests that they watch it together. David meets with Dr. Clayton and tells him about Greenlee. Greenlee dreams of her family and friends back in Pine Valley. Erica and Ryan watch the DVD. Liza lets Madison know that her father had gotten jail time, but would be out of jail within a year. Amanda and Jake discuss David and how Jake doesn't believe that he is really sick. Amanda tells Jake that if her persists in accusing David then she doesn't know how much longer they can go on. Greenlee meets with Dr. Clayton about her surgery. Ryan and Erica kiss. Liza and Tad kiss in his apartment.

TVMegaSite Example #1: Model Output

Tad and Jake are at Krystal's. Jake lets Tad know that David is going to Gloucester. Liza walks in and gives Tad a restraining order against him. At the hospital, Angie tells Amanda that she had seen her on Hayley's documentary. David walks up and listens to their conversation. At home, Opal questions Erica if she had watched the documentary on television about Pine Valley. Erica tells Opal that she doesn't want to see the documentary. Ryan gets ready for Emma and Corinna's sleepover. Ryan lets Emma know that he hadn't been able to watch the documentary that Hayley had shown on television. Greenlee dreams that she is back in Pine Valley with her family. Erica awakens from her coma and finds out that Jackson is alive. Jackson tells Greenlee how much he had missed her. Erica lets Opal know that she would like to fall in love again. Opal asks her if she is insecure about Ryan and what is going on with him. Erica gets a visit from a man, who gives her a DVD of the documentary from Hayley. David and Angie argue over the fact that he isn't as sick as she claims to be. Amanda accuses David of lying to her about where he had been the night that she was stabbed. Tad tries to talk Liza out of breaking into David's bar in Gloucester, but she refuses to listen to him. Madison comes into the hospital and tells Angie that she can not go to her father's sentencing. Madison lets Angie know that her father is being sentenced today and she was going to go, but Angie encourages her to go. Jake and Tad try to talk her out of going to the hearing, but Liza insists on going. Jake tries to get Tad to promise that he will not go into Gloucester without Liza's permission. Erica and Opal watch the video of Ryan's confession. Ryan comes to visit Erica and asks her to watch a little TV. David meets with Dr. Clayton about Greenlee's condition. David introduces Greenlee to Clayton. Tad visits Liza at the bar and apologizes to her for putting her in this position. Tad and Liza begin to argue over his interference in her life. David calls Greenlee and tells her that they are going to take her on a tour of the medical facilities in Gloucestershire.

TVMegaSite Example #2: Reference

Erica and Ryan are in her office at Fusion kissing when Greenlee walks up to the door and starts to turn the doorknob. David clasps his hand over her mouth to keep her from screaming. At ConFusion, Liza and Tad kiss before they start to dance. Krystal watches then asks Rob to take her back to his place. Jake and Amanda spend a quiet evening at home when there is an incessant knocking on the door. Jake opens the door and Opal lets them know that she read her tea leaves and knows that someone is headed back into their lives. She fears that it is David. Jake and Amanda don't seem to be too concerned by Opal's anxiety attack over her tea leaves. David reminds Greenlee that Dr. Coleman said she could face another surgery. In talking to David, Greenlee realizes that Ryan is with another woman and comes to the conclusion that it is Kendall. At ConFusion, Tad sees David rushing out to his car. Ryan and Erica come clean to the press that they are involved. Liza visits Amanda and tries to soothe her fears that David is back in town. Tad and Jake visit David at Wildwind. Jake promises David that he will be watching him. Ryan and Erica come home to his penthouse and finds things completely out of order. Erica and Ryan make love in front of the fireplace. Greenlee lets herself into Ryan's place and sees him and Erica making love.

TVMegaSite Example #2: Model Output

At the hospital, Liza kisses Tad. Krystal walks in and sees them kissing. Liza asks Tad if she can steal him. At Wildwind, Jake and Amanda are in bed with the baby when there is a knock on the door. Jake answers it and it is Opal. Opal tells Jake that she knows that David is coming back to town. Jake assures her that he doesn't know where David is. At Fusion, Greenlee questions David as to what he is doing here. Greenlee demands to see Ryan, but David refuses to let her see Ryan. David tries to get Greenlee to calm down and let him examine her, but Greenlee insists on going up on the roof to talk to Ryan. At Ryan's home, Erica tells Ryan that she is not used to things going so smoothly in their relationship. Jake tells Opal that Wildwind is being sold and a real estate agent is showing it to the public. Jake lets Opal know that he hadn't heard from David in a while. Amanda comes downstairs and tells Jake about Opal's tea leaves giving her a strong feeling that something from their past is coming to town and that David could be there already. Jake asks Amanda if she is all right. Amanda lets Jake know that David had disappeared. At the Confusion bar, Tad tells Liza that he thinks that there is something going on between him and Krystal, but Liza denies it. David examines Greenlee and lets her know that Ryan is with another woman. David offers to take Greenlee back to his place, but she insists on knowing who the woman is before she changes her mind. Erica asks Ryan to take her home for a romantic dinner and a fire in the fireplace. Ryan and Erica arrive home to find a picture of the moon on the table. David tells Greenlee that he is taking her back to Gloucester for another surgery. David lets Greenlee know that Zach and Kendall had left town with Spike and had taken Spike with them. Jake and Tad burst into David's hotel room and find him hanging upside down in the attic. Jake orders David to leave town. David insists that he will leave town, but Jake tells him that they will be watching for him. David leaves the hotel room, but when he opens the door to leave, he finds that Greenlee is gone. Jake calls Amanda and tells her that they have to file a lawsuit against David because he is back in town.

ForeverDreaming Example #1: Reference

Sydney races to find a cure for Vaughn, but in order to find the antidote, Sydney must make a deal with Sark that could endanger Sloane's life. Meanwhile, Will continues his research for Vaughn and discovers some disturbing inconsistencies involving 20-year-old standardized IQ tests. Sydney finds out that Vaughn has a girlfriend.

ForeverDreaming Example #1: Model Output

Sydney must find a way to save Vaughn's life while trying to track down Sark's base of operations in order to obtain the antidote to a deadly virus that Sloane has been infected with. Meanwhile, Vaughn is in critical condition after being exposed to Rambaldi's toxin, and Sydney is forced to make a dangerous deal with Sark in exchange for his aid in getting rid of him. Will meets with a professor to find out if any of the CIA's standardized tests were ever used to recruit American children in the 1980's, and discovers that one in ten thousand first graders could pass the test.

ForeverDreaming Example #2: Reference

Half a universe from Earth, the Doctor and Martha answer a distress call from the cargo ship SS Pentallian, which will impact a star in 42 minutes. The ship scooped out part of the star, which is alive, for cheap fuel. The star uses crew members Korwin and Ashton as host bodies, and begins taking out everyone on board. Martha and crew member Riley, while trying to reach the front of the ship, are jettisoned into space in an escape pod by Ashton. The Doctor remagnetises the pod to bring Martha and Riley back. The Doctor begins being taken over by the star, and tells Martha to vent the engines, getting rid of the "sun particles" in the fuel. This causes the engines to start working again, and frees the ship from the star's pull.

ForeverDreaming Example #2: Model Output

The Doctor and Martha are trapped on board a space station in the Torajji system, where the crew are trying to prevent the ship from colliding with the sun. The Doctor uses the sonic screwdriver on Martha's mobile phone to activate Universal Roaming Activation, which allows him to travel anywhere in space and time without interference from the ship's control centre. However, the device malfunctions and the ship begins to fall towards the sun, and the Doctor is forced to use the emergency escape pod to escape. The pod, which contains the Doctor, Martha and two other crewmembers, is destroyed by the impact, but the Doctor manages to return to the control centre to try and stop the ship hitting the sun before it does so.

BookSum Book-Level Example #1: Reference

At the opening of Act I, it is a cloudy autumn day on a Russian country estate. In the garden, the old nurse Marina stands at the samovar and offers Doctor Astrov something to eat, but he refuses. He complains about the difficulty of his job. Telegin, an impoverished local landowner, sits with them. Voynitsky, known as Vanya, comes out of the house and joins them. He is almost fifty and is weary and irritable. He complains about his brother-in-law, Serebryakov, Serebryakov's young second wife, Helen, and about how their visit has turned the place upside down. Serebryakov, Helen, and Serebryakov's daughter, Sonya, join them for a moment. After they depart, Vanya sighs about Helen's beauty and then complains about how he has toiled his whole life on this estate for the professor and it has come to naught. After Vanya's sister's death, he and Sonya worked here so the professor could continue his studies and his writings, but Vanya has come to see that work as foolish and irrelevant. When Astrov suggests that Vanya is jealous, Vanya laughs that he obviously is, especially as the old, gout-and-rheumatism-ridden man seems to attract beautiful women. Helen ventures outside and tells Astrov his services are not needed for her husband. Mrs. Voynitsky, Vanya's mother and Sonya's grandmother, tells them about a new pamphlet written by a friend in Kharkov. When Vanya sneers that all they do is read pamphlets, she becomes distressed and claims he hates her. Vanya merely says he is old, tired, and frustrated. A laborer arrives and tells Astrov he is wanted at the factory; the doctor bitterly departs, but not before they all discuss how he is very interested in forestry work. Sonya speaks up cheerfully about how Astrov is trying to save the old forest from destruction because forests make people happier. Astrov speaks of how Russians have torn down the forests and destroyed the wildlife; they no longer create, but rather destroy. After Sonya walks Astrov out, Vanya tries to seduce Helen, but she pushes him away. She muses about how Sonya clearly seems to love the doctor but he does not love her back. Helen sighs that she is simply bored and life is too much for her. In Act II, Serebryakov complains to Helen of how he is old and no one respects him. His querulous behavior only annoys Helen, who begs him to stop it. Serebryakov ignores her and bemoans how his life of scholarship seems to be nothing now. Sonya joins them and tells them Serebryakov must see Astrov now; she wants her father to stop behaving like a child. The elderly nurse Marina comforts Serebryakov and leads him out. Helen tells Vanya, who entered the room, that her husband wears her. Vanya can only lament that everything is over for him and his life was wasted on trivial things. Helen is annoyed and moves to leave, but he bars her way. She accuses him of being drunk, and he admits to it. After Helen sweeps out of the room, Vanya ruminates on what a fool he was not to fall in love with her when she was younger; he once admired the professor, but now he does not. When Astrov returns, he mocks Vanya for having feelings for Helen, but Vanya will not admit it. Astrov leaves to get a drink; Sonya pulls him aside and makes him promise to stop drinking and stop getting her uncle drunk. He agrees. They continue to talk for a moment. He comments that Helen is beautiful but idle and useless. This country life makes people like that, and he despises it; he has been beaten down and sees no light at the end for himself. The peasants are all the same, and educated people are ridiculous. He only likes forests. Sonya compliments him and tries to cheer him up. As he prepares to leave, she asks how he might feel if he were to out that a friend of hers has feelings for him, and he drolly says he cannot love anyone. After he leaves, Sonya feels a surge of happiness though she is not sure why. In Act III, Sonya confesses to Helen that she loves Astrov, and Helen suggests that she say something to see if the doctor loves Sonya too. Sonya gives her permission for Helen to do this. Astrov and Helen meet to ostensibly look at his forestry maps. He discourses volubly on the patterns of deforestation until he sees that Helen is uninterested. Helen insists she is interested but says they should talk about something else. She point-blank asks if he likes Sonya, and he says no. He then moves in to seduce Helen, but she wants none of it. As he tries to kiss her, Vanya enters the room with flowers. Helen is horrified by the situation and begs Vanya to tell her husband that they must leave today. A moment later, Serebryakov and the others enter and Serebryakov announces that he has an idea to sell the estate because he and Helen need to afford a place in the city. This announcement angers Vanya tremendously, and he begins to complain violently about how Serebryakov is a fraud, is uninspired, is thankless, and how he, Vanya, has labored for Serebryakov his whole life and for no reason. He insists this is Sonya's estate. Serebryakov is startled by Vanya's outburst. He insists he cannot stay here anymore. Sonya implores him to talk to her uncle and he agrees. He departs, and those in the room hear a gunshot, then another. Helen and Vanya struggle over a revolver as Vanya screeches that he missed the professor. Cursing, he sinks into a chair. In Act IV, Telegin and Marina discuss Serebryakov and Helen's planned departure for that day, then exit the room. Vanya and Astrov come in. Astrov mocks Vanya for his behavior and asks him to return what he stole. Vanya maintains that he is innocent of theft. Astrov laments how this parochial existence crushes people: it is stultifying and useless. When Sonya enters Astrov tells her to tell her uncle to return the bottle of morphia he stole. Sonya turns to her uncle and tearfully asks him for the bottle. He complies. She takes him to make up with her father. Helen enters to tell Astrov goodbye. He tries to seduce her again in a rather lackluster fashion; she kisses him and bids him farewell. Everyone bids goodbye to Serebryakov and Helen, who leave the estate. Sonya and Vanya return to work. Marina suggests Astrov stay for dinner; he refuses and says he must be off. Astrov leaves, and even though Sonya knows he did not love her, she is sad. Vanya, though, claims he is extremely depressed. With both in tears, Sonya comforts her uncle. She tells him that life may be difficult for them now, but the afterlife will be full of peace, love, and rest.

BookSum Book-Level Example #1: Model Output

The scene opens in a country house in the Russian countryside. Ivan, a young man, is sitting with his mother, who is knitting him a Christmas stocking. He tells her that he does not want to have any tea, but she insists that he drink it anyway. She asks him how long they have known each other, and he says that it has been ten years since he first met her. He has not had a day of rest since he has known her, and has toiled without repose or a day's freedom ever since. He had a typhoid epidemic in the third week of Lent, and when he returned home, he had to take care of a man who had died of typhoid fever. He then sat down and closed his eyes for a while and wondered if he had killed the man. He wonders if the future generations will forget him, but he is sure that they will not. Ivan tells them that the house is a mess, because the Professor has been up all night writing and doesn't have time to eat or drink. He asks them to wake him up at two in the morning, but when they do not wake him, he thinks that the Professor wants some tea. They all come in from their walk, and as they come in, they talk about how happy they are to be together, and how they are all living in peace and contentment. Ivan is struck by the sight of a beautiful woman, and says that as he looks at her, his heart swells with unbridled happiness. The work of preserving the forest is thrilling, he says, and Dr. Astroff watches over the old woods and sets out new plantations every year. He wants to show them to Helena and Sonia, and Helena asks him if he finds it interesting. Helena is sitting next to him, and tells him to look for Batushka's works in the library the next day. He is worried that he is getting angina from his old age. Helena tries to tell him to make peace with himself, and to stop being so angry with everyone else. But he says he will not listen to her, because he has spent too much time thinking about the past, and now he cannot bear to watch the success of others and to fear death. Helena gets up and walks away from him, sitting down at a distance. She tries to get him to tell her why he doesn't love anyone. He says he is not an idiot, that he can understand her, but that he cannot understand her because she is young and healthy and beautiful and longing for life and he is an old dotard, almost a dead man. She tells him that she can understand him and that he should be able to understand her. Now, she says, she is too old and sick to continue to live in the country, and she has a young daughter and a young wife to care for. She doesn't want to live on the income generated by the estate, so they have to find some way to guarantee that they can live in town on the money generated each year. They decide to sell the woods, because they don't have enough money to do so every year, and they can't afford to buy the woods every year either. They need to find a way to make sure they can afford a certain amount of money to buy a cottage in Finland. They also have to figure out what to do with the rest of the property. The estate is worth ninety-five thousand roubles, and the estate was bought from his uncle, who had a debt of twenty-five. Semyon Lakedemonoff's brother bought the estate from the Lakedemons' uncle. The family ties are what got the estate to be worth so much money. Everyone agrees that the estate is for Sonia's good, and that she should get to keep it. But now that he has gotten old and ill, the time has come for him to dispose of his property in regard to the interests of his VOITSKI, ASTROFF, SEREBRAKOFF, Vanya, and SONIA arrive at the house to say goodbye to Tommo and Marina. They are to move to Kharkov to live with the professor and his wife. They have been frightened by what they have just witnessed, and decide to go to the city to see if they can find a place to live there. They will not be staying in the village any longer. Except for Vanya and Alexander, who stay to say good-bye to his wife and son-in-law. The Professor kisses them all three times, and then goes out to see them off. He gives them one last kiss to each of them before he leaves. They say they will always remember each other with pleasure, that they are interesting and original, and original. They shall rest

Table 13: Summary Samples for BookSum Book-Level

BookSum Book-Level Example #2: Reference

In his London studio, artist Basil Hallward puts the finishing touches on his latest portrait, that of a young man. Although Lord Henry, who is visiting with Basil, asks about the young man's identity, Basil declines to answer, noting his preference for secrecy. Basil never intends to exhibit the painting, because if he did, it would bare the deepest feelings in his soul. However, Basil lets slip that the subject of the portrait is Dorian Gray, who shortly thereafter pays the two men a house call. Lord Henry immediately begins to influence Dorian, suggesting that he should treasure and guard his youth and beauty while he has them, because they will soon fade. Terrified of aging, Dorian wishes he could trade his soul to stay as young as he looks in the portrait; a short while later, he again wishes that he could stay young while the image in the painting aged. The portrait thus begins to take on a life-like existence; in fact, Basil's threat to burn the portrait is likened to "murder" and Basil prefers the company of the portrait to the real Dorian. Dorian falls in love with a young actress, Sibyl Vane, a woman he barely knows. She plays a different woman at each night's performance, earning the label of "genius" from Dorian, who is as smitten with her acting more than with her personality. They become engaged, much to the surprise of Lord Henry and Basil. The sweet, wholesome Sibyl discusses her engagement with her family. Because her mother is indebted to the theatre manager, Mr. Isaacs, for fifty pounds, she is against the marriage unless Dorian is wealthy; they do not know that he is. Sibyl's angry brother, James, is leaving for Australia, but he vows to kill Dorian if he wrongs his sister in any way. James also confronts his mother about gossip he has heard – that his mother and deceased father never married, which Mrs. Vane admits is true. Dorian attends a performance of Sibyl's with Lord Henry and Basil, but the performance is terrible. Sibyl tells Dorian she can no longer act, because he has shown her a beautiful reality. Dorian is disgusted by her poor acting, because her performances were what drew him to her; he dismisses her and returns home. To his surprise, the portrait shows marks of cruelty around the mouth, lines that do not show on Dorian's face. He begins to suspect that his wish is coming true, so he vows to be good so that both he and the portrait can remain young. He, therefore, intends to apologize to Sibyl the next day and makes to marry her after all. However, he is too late: Sibyl commits suicide at the theatre that night. Dorian first feels responsibility for her death, but then views it both as wonderful entertainment and a selfish act on her part. Lord Henry tries to keep Dorian's name out of the scandal. Dorian and Lord Henry spend the evening at the opera. The next morning, Basil arrives and expresses concern for Dorian, given the events of the previous day. Dorian, however, is completely unconcerned about Sibyl or her family; he wants to talk only of happy subjects. The next day, he covers his portrait and moves it to the attic, to which Dorian has the only key. He then settles in to read a yellow book sent by Lord Henry; the book becomes Dorian's blackprint for life. Several years pass, and Dorian lives a hedonistic life according to the guidelines established by Lord Henry and the yellow book. While the face in the portrait has turned ugly, Dorian remains young, beautiful, and innocent. People talk about Dorian's "madness of pleasure" and his dreadful influence on the people around him, but that is of no consequence to him. Finally, when he is thirty-eight years old, Dorian shows the portrait to Basil, who begs Dorian to repent of his sin and ask that the wish be revoked. Instead, Dorian kills Basil and hides his body. Blackmailing his old friend Alan Campbell, Dorian is able to dispose of Basil's body. An hour later, Dorian attends a party, but is bored and distracted. He then heads for an opium den and, out on the street, meets Sibyl's younger brother, who has been waiting for an opportunity to harm Dorian for nearly twenty years. Dorian makes a case for mistaken identity when he claims to have the face of a twenty-year-old and cannot be the man James is looking for. A woman in the street reveals that Dorian "sold himself to the devil for a pretty face," so James again pursues Dorian. At his country estate one week later, Dorian entertains guests but believes James in hunting him. Dorian soon learns, however, that a man accidentally killed in a hunting accident is James, and so he feels safe. The novel concludes six months later. Dorian and Lord Henry dine, and talk turns serious – Dorian talks of Basil, and Lord Henry reflects on a sermon he heard the previous Sunday while walking in the park. Lord Henry also inquires about the secret of Dorian's youth, which Dorian dismisses. Dorian then asks Lord Henry never to give the yellow book to anyone else. That evening, while Dorian examines the portrait, he decides to destroy it with the knife used to murder Basil. Soon after, Dorian's servants and a police officer find an old, ugly man lying dead on the ground in front of a portrait of a young and innocent Dorian.

BookSum Book-Level Example #2: Model Output

Dorian Gray is sitting in the garden of his uncle's house in London, playing the piano. In the center of the room is a portrait of a young man of extraordinary beauty, and in front of it is Basil Hallward's portrait of Dorian Gray. The portrait belongs to Hallward, and he refuses to show it at the Grosvenor Academy, because it contains too much of himself in it. He tells Dorian's uncle, Lord Henry Wotton, that he is in love with Dorian and wants to marry him. Dorian is sitting at the piano and finishes a painting that he has been working on. He looks at the portrait and realizes that it is of him. He realizes that he will never be able to look at it again, but he cannot stop looking at it because he wants to remember the beauty of his own face. He asks his uncle for some information about Dorian, and his uncle tells him that Dorian has a beautiful mother who was married to a poor man who was killed in a duel. She left him a son, who is very good-looking and who has inherited all of her property. Lord Henry tells him to write to her and ask for some advice, and Dorian agrees. One day, Dorian meets Sibyl Vane, a beautiful young woman who works as a governess for a rich family in the East End of London. She is in the employ of Lord Henry's friend, Mr. Erskine of Treadley, and Lord Henry wants to see her. He also wants to get her out of the hands of the Jew who has her bound to him for three years and eight months. He proposes to her, but she refuses him. She says that she does not think he is good enough for her, and she will never love anyone of his rank. He is disappointed, but does not say anything to his mother about it. The next day, he meets the Duchess of Monmouth, who tells him he should find a wife and marry her. She wants him to have a future and not to spend his money frivolously. He agrees, but when he tells her that he does not love her, she laughs at him and refuses to call him by his new name, Prince Charming. He goes to see the play, and is horrified to see that the face on the canvas is that of the portrait of Romeo and Juliet. He cannot believe that he could have done such a terrible thing to Juliet and that she could still be his wife. He leaves the theater and wanders the streets of London until he finds himself in Covent Garden. He finds some women waiting for him, and one of them laughs when he calls her by his nickname, "Prince Charming." She curses him and runs away. He runs into a dark alley and is suddenly grabbed by a man with a gun pointed at his head. It is James Vane. Vane threatens to kill Dorian if he doesn't make peace with God. He gives Dorian one minute to make his peace before he kills him. When Dorian gets to the street, he finds that the man he was trying to kill is not the same man he thought he was. It turns out that Vane is twenty-eight years younger than Dorian. The woman who took his money tells him not to talk to her again. She runs off, and when Dorian looks back, the woman has disappeared. When he wakes up the next morning, he has not had a nightmare. He writes two letters to his assistant, Alan Campbell, telling him that there is a dead man sitting on a table in his house, and that he must destroy the body so that no one will ever know who he is. He then goes to his bedroom and finds a small box of lacquer, which he takes out and puts inside. He puts the box back, gets into a horse-drawn carriage, and gives the driver an address. The driver takes him to the address, and as he is leaving the house, he sees the dead body of a man on the table. When Campbell returns, he tells Alan not to disturb the body, but to come back at seven o'clock in the evening. When the man arrives, he throws the picture over the table, but Dorian does not believe that it has been disturbed. He returns home and finds that Campbell has brought back the chemicals and the irons, and the other things that he needs to do the job. He opens the cabinet where he had hidden Basil's coat and bag, and finds the green paste. At midnight, he gets a hansom and leaves the house with the instructions to meet him at 7 o'clock the next day. He sits in the back of the carriage as the driver drives him through the streets. He wonders if it is possible to cure the soul by means of the senses and the body by way of the soul. He wakes up in the middle of the night to find that the portrait has not changed.

Abstract

Open Information Extraction (OIE) is the task of extracting tuples of the form (subject, predicate, object), without any knowledge of the type and lexical form of the predicate, the subject, or the object. In this work, we focus on improving OIE quality by exploiting domain knowledge about the subject and object. More precisely, knowing that the subjects and objects in sentences are often named entities, we explore how to inject constraints in the extraction through constrained inference and constraint-aware training. Our work leverages the state-of-the-art OpenIE6 platform, which we adapt to our setting. Through a carefully constructed training dataset and constrained training, we obtain a 29.17% F1-score improvement in the CaRB metric and a 24.37% F1-score improvement in the WIRE57 metric. Our technique has important applications – one of them is investigative journalism, where automatically extracting conflict-of-interest between scientists and funding organizations helps understand the type of relations companies engage with the scientists. Our code and data are available at <https://github.com/prajnaupadhyay/openie-with-entities>

1 Introduction

Open Information Extraction (OIE) is the task of extracting triples from unstructured corpora in a domain-independent manner. A triple consists of a subject, a relation, and an object. OIE has important applications, such as question answering (Lu et al., 2019), or automatically creating or extending knowledge bases (Bhutani et al., 2019). OIE is a challenging task, with the performance of state-of-the-art models varying from 88.5% F1 score (Wang

et al., 2021) to 34% (Gashteovski et al., 2021), depending on the difficulty of the benchmark.

When the named entities in a domain are known to be the subject/object of extractions, OIE should also identify relations between these entities. An important use case is automatically creating a knowledge base of relations between scientists and companies, i.e. identifying conflict-of-interest between the scientists and funding bodies, where the named entities are the names of scientists and companies, and the relation describes the conflict of interest between them. Clustering these relation phrases, such as *received a research gift from, received speaker fees or consults for* helps analyze the relationships that companies engage with the scientists. These relations are crucial to understanding scientists’ positions on health issues (Oreskes and Conway, 2010) in investigative journalism. However state-of-the-art OIE models do not always retain named entities in the extractions, for example, given the sentence “*Shahrad Taheri received funding for research through a grant from Cambridge Weight Plan*”, an OIE tool (Kolluru et al., 2020a) returns $\langle \text{Shahrad Taheri, received, funding for research} \rangle$. While this extraction correctly identifies the subject of the triple, the quality of the predicate and object could be improved as follows: the extraction $\langle \text{Shahrad Taheri, received funding for research through a grant from, Cambridge Weight Plan} \rangle$ retains the second important entity (Cambridge Weight Plan) and is precise about the relation. Such sentences are frequent in the declarations of conflict of interest that authors add to articles in PubMed, a dataset of scientific articles on life sciences and biomedical topics.

In this work, we focus on **relation extraction, when the subject and object are named entities**. In particular, we would like to significantly improve the performance of OIE tools, such that triples as $\langle \text{first entity, predicate, second$

The work was done when the first author was at Inria and Institut Polytechnique de Paris.

entity) are not missed or poorly extracted. To achieve this, we leverage deep learning with constraints, i.e. techniques that enforce constraints on the classifier's predictions. Constrained learning is very common in sequence-to-sequence tasks, such as relation or entity extraction, where the output should have a specific form. Constraint learning has also been successfully used in OIE. In our case, we enforce constraints on the subject, object and predicate forms, and we investigate several techniques to achieve the best result, such as constraint-aware training (Nandwani et al., 2019) and constraint inference (Lee et al., 2019). We deployed our technique within OpenIE6 (Kolluru et al., 2020a), a state-of-the-art tool for OIE.

Our salient contributions are: *i*) We extend the OpenIE6 model with entity-centric constraints; *ii*) We implement the constraints as penalties in the loss function, and as hard constraints during inference. *iii*) We show through an extensive evaluation that our method improves over the state-of-the-art; *iv*) We perform a large scale evaluation of the system, on conflict of interest declarations from PubMed bibliographical data.

2 Related Work

In the literature, the extraction of triples of the form $\langle \text{subject}, \text{relation}, \text{object} \rangle$ has been studied in several settings. A relation can be expressed using a surface form, i.e., the tokens present in a sentence, or a canonical form, usually introduced in a knowledge base. In the most general setting, we do not enforce any constraints on the types of the three elements, and the task is referred to as **open information extraction** (OIE). In the most restricted setting, the subject and object are entities, and the relation comes from a predefined set of relations. This task is known as **relation extraction**. Finally, **open relation extraction**, also referred to as **relation discovery**, refers to approaches that use little training (such as distant supervision, few-shot learning, or semi-supervision) or no training (unsupervised) to classify relations between entities. Some inconsistencies arise in the use of the terminology in the literature, e.g., "open relation extraction" has been also used to designate open information extraction, in (Mesquita et al., 2013).

Open Information Extraction. Open information extraction (Kolluru et al., 2020a; Etzioni et al., 2008) extracts triples from unstructured corpora in a domain-independent way. More precisely, the

relations are not known beforehand and the subject and object are not required to be named entities. The state-of-the-art techniques are based on neural networks, which model the problem as a sequence labeling task (Kolluru et al., 2020a; Stanovsky et al., 2018; Cui et al., 2018). OpenIE6 (Kolluru et al., 2020a) is a neural model that achieves state-of-the-art results when compared with several other models (Del Corro and Gemulla, 2013; Gashteovski et al., 2017; Cui et al., 2018; Stanovsky et al., 2018; Roy et al., 2019; Zhan and Zhao, 2020; Kolluru et al., 2020b). Since these tools work without any domain knowledge, they might miss or extract poorly triples containing named entities. We aim to solve this problem, and our technique is trained to improve relation extraction when entities are present in the corpus.

Relation Extraction. In relation extraction (Han et al., 2020), given a sentence containing two entities, the task is to select the relation between the entities from a fixed set of relations. This is achieved via a classifier, and the challenge is in identifying relevant features for classification. Traditionally this has been achieved via hand-crafted features, such as lexical, syntactic, or semantic (Jiang and Zhai, 2007; Nguyen et al., 2007). More recently, neural models such as BERT (Devlin et al., 2018) have been very successful in relation classification (Baldini Soares et al., 2019).

Open Relation Extraction/Relation Discovery. In (Yao et al., 2011), the authors first discover relations between entities using the dependency paths between two tagged entities, and they propose an unsupervised probabilistic generative model for inducing clusters from the surface forms. In (Yu et al., 2017), surface forms of relations are first extracted by taking into account the dependency path between entities, and finally, they are mapped to canonical forms present in a KB. In (Hu et al., 2020), the authors propose a relation encoder based on BERT (Devlin et al., 2018) that computes an embedding representation of the relation based on the sentence where named entities appear, together with an adaptive clustering technique that does not require prior knowledge of the number of clusters. While some approaches (Yao et al., 2011; Yu et al., 2017) extract surface forms of relations when the arguments are entities, similar to our goal in this work, they use for this only dependency path information and do not deal with conjunctive sentences

as OpenIE (Kolluru et al., 2020a). In addition, OpenIE6 has shown better performance than models using dependency parsing such as ClausIE (Kolluru et al., 2020a; Del Corro and Gemulla, 2013).

3 Problem Definition

Our goal is to extract triples from sentences that respect the guidelines detailed by the CaRB metric (Bhardwaj et al., 2019), i.e., they should be *i*) complete: all triples should be extracted from a sentence, *ii*) asserted: the triple should be implied from the sentence *iii*) informative: the triple should contain maximum relevant information from the sentence and *iv*) atomic: extraction cannot be split into multiple extractions.

Given a sentence S containing entities $E = \{e_1, \dots, e_i, \dots, e_n\}$, we denote by $\langle s, r, o \rangle$ a triple that is extracted from S . The CaRB rules can be customized to fit our setting as follows:

- **Complete:** For every e_i , there exists at least a triple $\langle s, r, o \rangle$ where e_i is s or o .
- **Asserted:** Each tuple must be implied by the original sentence.
- **Informative:** The extraction should contain the maximum possible information from S . For instance, from *Joe Biden is the president of the US*, an uninformative extraction is $\langle \text{Joe Biden, is, the president} \rangle$ while the informative extraction is $\langle \text{Joe Biden, is the president of, US} \rangle$.
- **Atomic:** If s or o contains e_i , then it contains only that entity and no additional tokens. If s or o contain e_i and e_j , it is always possible to create two triples $\langle s_1, r, o \rangle$ and $\langle s_2, r, o \rangle$, $s_1 = e_i$ and $s_2 = e_j$, similarly for o .

4 Entity Focused Constraints

OpenIE6 (Kolluru et al., 2020a) receives in input a sentence and outputs a list of extractions of the form $\langle \text{subject, predicate, object} \rangle$. The architecture of the model is a deep neural network that first encodes tokens using BERT (Devlin et al., 2018), and then iteratively identifies at most M extractions, i.e., calls the same architecture for each extraction for M times (Figure 1). The embeddings of the labels generated at the end of the 1st iteration are added to the embeddings of the tokens in the second iteration, and so on. This adds context so

that a new extraction is generated the next time. Each token is assigned a label from $\{S$ (subject), R (relationship), O (object) or N (none) $\}$.

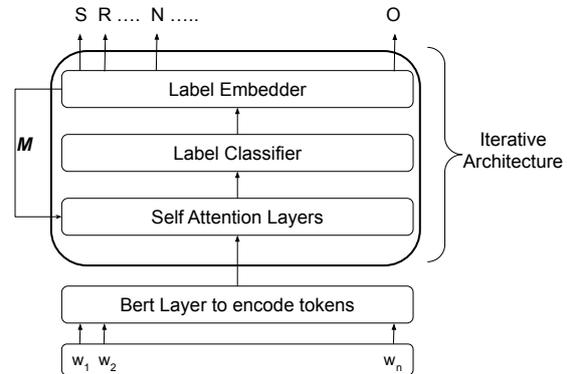

Figure 1: OpenIE6 uses the same architecture to generate embeddings for the words in M extractions, with the output of the previous extraction given as input for the next extraction

OpenIE6 constraint-aware training OpenIE6 uses constraint-aware training to infuse the model with task-related knowledge in the form of constraints. The model learns to satisfy these constraints during training without explicitly enforcing them during the inference, hence these types of constraints are typically referred to in the literature as *soft constraints*. This is achieved by adding additional penalties in the loss function, as follows:

POS Coverage (POSC). Tokens labeled as nouns, verbs, adjectives, or adverbs should be part of at least one extraction.

Head Verb Coverage (HVC). Verbs that are not *light verbs* (e.g., do, give, have, make, etc.), referred to as *head verbs*, should be present in the relation span of *a few but not too many extractions*.

Head Verb Exclusivity (HVE). The relation span of one extraction should contain *at most one head verb*.

Extraction Count (EC). The extractions having head verbs in the relation should be at least equal to the number of head verbs in the sentence.

These are **entity independent constraints**. Their full equations can be found in the OpenIE6 paper (Kolluru et al., 2020a).

Adding entity-specific constraints. We enforce additional constraints to obtain extractions satisfying our problem statement. Let $x_n^{ent} \in \{0, 1\}$ denote whether the n th token w_n belongs to some entity tagged in the sentence, and E be the set of entities. At each extraction level m , the model com-

puts $Y_{mn}(k)$, the probability of assigning to the n th token the label $k \in \{S, R, O, N\}$ (subject, relation, object or none). We introduce the following entity-specific constraints:

1. **Entities as subject or object (ENT-ARG).**

Each entity in the sentence should be present in at least a subject or object of an extraction:

$$J_{ent_so} = \sum_{n=1}^N x_n^{ent} \cdot (1 - \max_{m \in [1, M]} (\max_{k \in \{S, O\}} Y_{mn}(k))) \quad (1)$$

The penalty is 0 when for each token belonging to an entity ($x_n^{ent} = 1$) we have $Y_{mn}(k) = 1$, that is maximum probability of being in the subject or object, for at least one extraction.

2. **Entity exclusivity (ENT-EXCL).** The subject and object should contain at most one entity each. Let $p_e(k)$, with $k \in \{S, R, O, N\}$ be the average token probability of label k in entity e , where e consists of one or more tokens. Then, we express the penalty as follows:

$$J_{ent_exs} = \sum_{m=1}^M \max(0, (\sum_{e \in E} p_e(S) - 1)) \quad (2)$$

$$J_{ent_exo} = \sum_{m=1}^M \max(0, (\sum_{e \in E} p_e(O) - 1)) \quad (3)$$

The penalty is 0 when no entity is labeled as subject/object or when only one entity is labeled as such ($\sum_{e \in E} p_e(O/S)$ is 0 or 1).

3. **Entity in relation penalty (ENT-REL).** A penalty is introduced if an entity appears as a part of a relation of some extraction. This loss is directly proportional to the probability of tokens that are part of some entities and which have been labeled as part of a relation:

$$J_{ent_rel} = \sum_{n=1}^N x_n^{ent} \cdot \sum_{m=1}^M Y_{mn}(R) \quad (4)$$

The penalty is 0 when $Y_{mn}(R)$ is 0 for every token of an entity.

4. **Entity segmentation penalty (ENT-TOG).** A penalty is introduced if tokens describing the same entity are not labeled in the same way, for example, the first token of the entity is part of the predicate, while the rest of the

tokens are part of the object. Let $w(e)$ be the set of tokens in a given entity e . Let $l_p^m(w)$ be the predicted label of a token (the label with the highest probability) at extraction m . As we are concerned with entities described by two or more tokens, the predicted label l_e^m of the entity e is the majority label of its tokens, or the label with the highest total sum of probabilities in case of a tie. For each $w \in w(e)$, we introduce a loss equivalent to $Y_{mw}(l_p)$ if $l_p^m(w) \neq l_e^m$:

$$J_{ent_seg} = \sum_{m=1}^M \sum_{e \in E} \sum_{w \in w(e)} Y_{mw}(l_p) (1 - \delta_{l_p^m(w), l_e^m}) \quad (5)$$

where δ is the Kronecker delta function.

Finally, the total loss can be written as:

$$J_{ent} = J + \lambda_1 J_{ent_so} + \lambda_2 (J_{ent_exs} + J_{ent_exo}) + \lambda_3 J_{ent_rel} + \lambda_4 J_{ent_seg} \quad (6)$$

where λ_* are hyperparameters, while J is the original OpenIE6 loss.

Constraints at inference. We investigate a second type of constrained learning called constraint inference. The constraints applied in this setting are hard constraints, which the model is forced to apply. The constraints are applied in the decoding phase and modify the tokens' labels (S, P, O, N). We propose three constraints inspired by the entity constraints introduced in the constraint-aware training.

1. **Entity exclusivity.** Once we have encountered one entity labeled as a subject or object in the sentence, the following entities are not allowed to receive the same label.
2. **Entity in relation.** We enforce that an entity appearing in the predicate is classified according to its second-best class probability.
3. **Entity segmentation penalty.** We enforce that all the tokens belonging to an entity be labeled with the same label.

We do not transform the constraint *entities as subject or object* in an inference constraint as it cannot be applied at the level of one existing extraction. This constraint can only be a penalty in the loss, such that it rewards sets of extractions in which all the entities are part of the arguments.

5 Experimental Evaluation

5.1 Datasets

We use the OpenIE6 data for training and validation and Pubmed data for testing. The OpenIE6 dataset consists of Wikipedia sentences, while the Pubmed data is a set of conflict of interest statements between authors and various organizations, such as those illustrated in Section 1.

Given that our focus is on improving performance when entities are present in a sentence (Section 3), and in particular, enforcing that entities are the subject or object, we need appropriate training data for the task. We are unaware of a dataset of extractions where arguments are entities, while the extraction also has the surface forms of relation. For example, FewRel (Han et al., 2018) and TA-CRED (Zhang et al., 2017), two standard datasets used in relation extraction, do not contain the surface form of the relation; they only label the entire sentence as containing a particular relation.

Training data. The OpenIE6 training dataset consists of 91K sentences and 190K extractions of the form $\langle \text{subject}, \text{predicate}, \text{object} \rangle$. We tag entities in each sentence using the state-of-the-art named entity recognition tool Flair (Akbi et al., 2019). We focus on extractions of the following form: *i*) The **subject** of the extraction is exactly one entity; and *ii*) The **object** ends with an entity. We discard the extractions that do not match these constraints. In each extraction, we keep only the entity in the object and move the preceding tokens to the relationship part of the extraction. For example, one of the sentences in the original training set is “*Parmenides had a large influence on Plato, who not only named a dialogue, Parmenides, after Parmenides, but always spoke of Parmenides with veneration.*” and one of the extractions is $\langle \text{Parmenides}, \text{had}, \text{a large influence on Plato} \rangle$. The extraction satisfies both the above conditions, hence we transform it to $\langle \text{Parmenides}, \text{had a large influence on}, \text{Plato} \rangle$. If the object contains only an entity, we apply the identify transformation. We refer to a sentence with at least one transformed extraction as a *clean sentence*.

We create 3 training datasets:

ORIGINAL: The original training set containing 91K sentences.

CLEAN: 7K clean sentences with their modified extractions.

MIXED: We add the remaining sentences and their extractions from the original training set to CLEAN.

Gold data. We created a gold standard dataset from Pubmed conflict-of-interest statements to be used as test data. We tagged and counted the entities with NER Flair and selected 282 sentences with a minimum of 2 entities. The maximum number of entities found in a sentence was 14.

We asked the annotators to find all the triples $\langle s, p, o \rangle$ containing those entities as arguments (in *s* or *o*). In addition, the extractions should follow the guidelines explained in Section 3 on completeness, assertion, informativeness, and atomicity. The total number of extractions obtained after annotations were 1113. One annotator annotated each sentence.

Quality of gold data. To evaluate the dataset’s quality, we sampled 50 sentences from our gold sentences, and one of the authors annotated them so that we had two annotations for this set. We found the agreement by considering one annotation as gold and computing WiRE57 F1. The agreement F1 score obtained was 83, which is a high agreement.

Table 1 shows example annotations of triples for the sentence *Menno Huisman reports grants from and personal fees from Boehringer Ingelheim and Bayer Health Care*. For each CaRB property, we show the correct and incorrect extractions. An extraction of the form $\langle \text{Menno Huisman}, \text{reports grants from}, \text{Bayer Health Care}, \text{Germany} \rangle$ violates the assertion property because it adds extra information to the sentence. $\langle \text{Menno Huisman}, \text{reports}, \text{grants} \rangle$ violates the informativeness property even if it is a valid extraction because it lacks the complete second argument, i.e., Boehringer Ingelheim. The extraction $\langle \text{Menno Huisman}, \text{reports grants from}, \text{Boehringer Ingelheim and Bayer Health Care} \rangle$ is not atomic because the two entities in the second argument should be part of 2 extractions. If any of the four correct extractions adhering to the completeness property are missing, this property is violated.

5.2 Models

We experimented with the following models:

OpenIE6. This is the default OpenIE6 model.

OpenIE6 (ECTR). OpenIE6 model with entity constraint training (ECTR), as in Section 4.

	Correct	Incorrect
Completeness	\langle Menno Huisman, reports grants from, Boehringer Ingelheim), \langle Menno Huisman, reports grants from, Bayer Health Care), \langle Menno Huisman, reports personal fees from, Boehringer Ingelheim), \langle Menno Huisman, reports personal fees from, Bayer Health Care)	If any of the extractions is missing
Assertion	\langle Menno Huisman, reports grants from, Bayer Health Care)	\langle Menno Huisman, reports grants from, Bayer Health Care, Germany)
Informativeness	\langle Menno Huisman, reports grants from, Boehringer Ingelheim)	\langle Menno Huisman, reports, grants)
Atomic	\langle Menno Huisman, reports grants from, Boehringer Ingelheim)	\langle Menno Huisman, reports grants from, Boehringer Ingelheim and Bayer Health Care), \langle Menno Huisman, reports grants from and personal fees from, Boehringer Ingelheim)

Table 1: Examples of correct and incorrect annotations for the 4 CaRB properties

`OpenIE6 (ECTR, ECIN)`. To the trained model `OpenIE6 (ECTR)`, we add constraints at inference in the evaluation of the test data.

`OpenIE6 (ECIN)`. To the trained model `OpenIE6`, we add constraints at inference in the evaluation of the test data.

We note that the models use a different coordinate boundary model than the one in the `OpenIE6` paper. We retrained the coordinate boundary model using a newer Huggingface Transformers library version (Wolf et al., 2020) for compatibility with our code. However, we could not reproduce the accuracy, obtaining 83.3 instead of 85.4. A better coordinate boundary model would positively impact performance, both with and without constraints.

Parameters. The model’s training consists of two phases, a warm-up phase, where the training is done without constraints, and a constrained training part. The warm-up training was done for 30 epochs, and the constrained training was done for 15 epochs. During constrained training, all constraints had equal weights. The learning rate was set to $5e-06$. `BERT-base-cased` model was used with two iterative layers. We repeat the experiments with 6 different random seeds for the network initialization, and we average the results. We run our code on a 32GB GPU.

Baselines We implement four baselines.

`ConnectingPhrase`. This simple technique returns the phrase connecting the two entities in a

sentence as the relation between them. It comprises the following steps:

1. We first use the coordinate boundary detection model (available with `OpenIE6` code). Coordinate boundary detection models (Saha and Mausam, 2018; Kolluru et al., 2020a) split a conjunctive sentence into smaller parts. For example, the sentence “*Adrian Brown and Shahrads Taheri received funding for research through a grant from Cambridge Weight Plan.*” is split into:
 - (a) “*Adrian Brown received funding for research through a grant from Cambridge Weight Plan.*”
 - (b) “*Shahrads Taheri received funding for research through a grant from Cambridge Weight Plan.*”

This is crucial to improve the recall.

2. Next, we label the entities in sentences obtained using `Flair` (Akbi et al., 2019).
3. For each consecutive pair of entities e_i, e_{i+1} in the sentence, we return an extraction containing as subject e_i , as predicate the phrase connecting the entities, and as object e_{i+1} .
4. We filter the extractions by removing the ones whose predicates do not contain a token labeled as a verb by a part-of-speech parser. The final set of extractions is obtained at the end of this step.

`DependencyPath`. We follow the same steps as in `ConnectingPhrase`, except that in 3. above, we return as the predicate the tokens on the dependency path between entities e_i and e_{i+1} .

`PostprocessedOpenIE6`. We run the original OpenIE6 tool and post-process its output as follows: we tag entities in `subject` and `object` of the extractions, and then we modify extractions, in the same manner as when we created the CLEAN dataset (Section 5.1), and leave unchanged the ones not satisfying our conditions.

`FilteredOpenIE6`. We remove the extractions from `PostprocessedOpenIE6` that were not modified according to the procedure used for generating the CLEAN dataset.

Evaluation metrics. Several evaluation metrics have been proposed to evaluate the performance of an OpenIE system. **WiRe57** (Lechelle et al., 2019) is a one-to-one matching metric, in which each system extraction is matched to exactly one gold extraction. Given a sentence, a system extraction matches a gold extraction if they share at least one word from each of the relation, subject, and object. Two extractions are compared by computing the token level recall and precision between the gold subject and system subject, respectively, the predicates and objects. Precision is the percentage of system words found in the gold extraction. The recall is the percentage of gold words in the systems’ predictions. The system extractions are matched one-to-one to gold extraction in decreasing order of $F1$ -score. **CaRB** (Bhardwaj et al., 2019) is a many-to-one matching metric in which several gold extractions can be matched to one system extraction when computing the recall. This avoids penalizing a system if one extraction would better correspond to two or more golden extractions, as is the case, for instance, in `<Adrian Brown; has received travel grants from; Cambridge Weight Plan and Oxford University>` (note that there should have been two triples extracted here, each with a different object). Precision is computed by matching system extractions one-to-one to gold extractions, decreasing order of precision score. Hence, we will penalize the extraction above when computing precision, as one gold extraction will not be matched.

We report both metrics, however, WiRe57 is more in line with our task as it respects the atom-

icity constraint in Section 3, given that it does not reward system triples with several entities in one argument.

6 Results and Discussion

Evaluation. In Table 2 we show the results on the test data, measuring both CaRB and WiRe57. We use the different training datasets that we introduced and the different training constraints. When training without any entity constraints, the training dataset can make a significant difference, as we observe `OpenIE6` trained on CLEAN has a more than 26% increase in CaRB F1 than `OpenIE6` trained on the ORIGINAL dataset. In addition, adding entity constraints further improves the results as shown by the models `OpenIE6 (ECTR)` which has the best WiRe57 score for all CLEAN, MIXED and ORIGINAL models. The smallest improvement is for the model trained with the ORIGINAL dataset, as in this case the training data may be in conflict with the constraints, having for example several entities in one argument. `OpenIE6 (ECIN)` improves upon `OpenIE6`, with a significant increase in the precision of the WiRe57 metric, which is expected given the hard constraints are being forced on the triples. However, `OpenIE6 (ECTR)` has a more significant improvement than `OpenIE6 (ECIN)` according to WiRe57 (the metric aligned with our problem statement, as explained in Section 5.2), showing that it is more important to have soft constraints, which are rewarding good extractions during training and hence obtaining a better extraction model. Combining soft and hard constraints gives the best model, `OpenIE6 (ECTR, ECIN)`. Regarding the baselines, `PostprocessedOpenIE6` and `FilteredOpenIE6` have good precision but lower recall than our top-performing models, showing the importance of the constraint learning and adapted training datasets.

Ablation study. We perform an ablation study to evaluate the importance of the entity constraints added during the training. We take our best performing model, `OpenIE6 (ECTR)` trained on the CLEAN dataset, and we train it with 1, 2, or 3 constraints at a time. Table 3 shows the results obtained on our test set. When we add just one constraint, as expected, the constraint ENT-ARG enforces the highest WiRe57 recall, as it has learned to penalize extractions where entities may be missing from the arguments. However, this model has the lowest precision, due to the fact it allows more than one

Table 3: Ablation study with models trained on the CLEAN dataset. We report CaRB, WiRe57, and the percentage of entity constraints violations on the test set.

entity in one argument. Removing the constraint from the set, $EC \setminus ENT-ARG$, gives us the highest precision. A combination of ENT-EXCL and ENT-REL performs the best among the models that were trained with 2 constraints, which is expected since the models trained with ENT-EXCL and ENT-REL were the top-2 performing models when trained individually. Enforcing only ENT-TOG does not bring important improvements, and training with the whole EC is slightly better than when training with $EC \setminus ENT-TOG$. Hence, ENT-TOG could be removed without a significant drop in quality.

For a complete analysis, we also compute the percentage of violations in the extractions (Table 3). For ENT-ARG, we count as a violation every entity that is not found in at least one extraction, and we

divide by the total number of entities in the test set. For ENT-EXCL, we count a violation for each subject or object with more than one entity and normalize by twice the number of extractions. For ENT-REL, a violation is a relation containing an entity, normalized by the number of extractions. Finally, for ENT-TOG, a violation is an entity in extraction with more than one tag (S,O,R,N), normalized by the number of extractions containing an entity. We observe that ENT-ARG is violated the most, followed by ENT-REL. When enforcing ENT-ARG, we obtain the best results for 3 out of 4 constraints. This does not result, however, in the best F1 score, showing the importance of minimizing violations of type ENT-EXCL. ENT-ARG and ENT-EXCL have competing goals: ENT-ARG

enforces the occurrence of entities in arguments, but ENT-EXCL does not allow more than one entity in an argument. So, whenever ENT-ARG is enforced with ENT-EXCL, we see an increase in the number of ENT-ARG or ENT-EXCL violations. Finally, when comparing the model with no entity constraints, `OpenIE6`, with the model enforcing all 4 constraints, `OpenIE6(ECTR)`, we observe a more significant difference in the violations ENT-ARG and ENT-REL, the constraints that are more frequently violated.

Quality of Named Entity Recognition on Pubmed. We sampled and annotated 50 test set sentences, taking care to keep the words together in long named entities, such as “Oregon Health and Science University Center for Embryonic Cell and Gene Therapy”. We obtained 88% F1 score for the NER model Flair (Akbik et al., 2019), in line with the performance of the model on Ontonotes (Weischedel et al., 2017) and CONLL (Tjong Kim Sang and De Meulder, 2003).

Evaluation on the CaRB dataset. `OpenIE6` has been evaluated on the CaRB dataset (Bhardwaj et al., 2019). We evaluate our constrained models to investigate their performance on this standard benchmark, see Table 4. Note that annotating guidelines for CaRB were not the same as for our Pubmed test data: there might be more than one entity in the arguments of a relation. This inherently limits the quality of our results. However, we show that the constrained models trained on the MIXED and ORIGINAL datasets have competitive performance with the original `OpenIE6` model while performing much better on our test data, as shown in Table 2. As expected, the models trained on the CLEAN dataset perform the worst, as they have seen only extractions with entities in the arguments; to achieve the best results, the user should choose a model considering the nature of the dataset. We note that the results for the `OpenIE6` model are slightly lower than those reported in the original paper because of the coordinate boundary model, as mentioned in Section 5. The conjunctive model is a core `OpenIE6` component; gains in its precision would likely improve performance, both with and without constraints.

Conflicts of interest in PubMed. We analyse the extractions by `OpenIE6(ECTR)` and the original `OpenIE6` model on a larger PubMed dataset consisting of 170K sentences. Table 5 shows the

Method	Training data	CaRB	WiRe57
		F1	F1
OpenIE6(ECTR)	CLEAN	24.44	11.59
OpenIE6	CLEAN	27.76	12.42
OpenIE6(ECTR)	MIXED	50.16	38.15
OpenIE6	MIXED	50.27	38.59
OpenIE6(ECTR)	ORIGINAL	50.70	39.28
OpenIE6	ORIGINAL	<u>50.60</u>	<u>39.15</u>

Table 4: Model comparison on the CaRB dataset. Best values are in bold and second best are underlined.

number of extractions (**#ext**), extractions containing one entity in the subject and object (**#ext1**), containing a “Person” entity in subject and “Organization” entity in the object (**#ext2**), and the number of sentences processed by the model per second (**speed**). `OpenIE6(ECTR)` finds more interesting triples where a conflict of interest relation is expressed between a person and an organization entity, compared to the original `OpenIE6`. Also, our model processes more sentences per second compared to the original `OpenIE6`. This is because `OpenIE6` generates more extractions per sentence, however, even with more extractions, the model retrieves fewer conflicts of interest relations between a person and an organization.

speed	87.41	56.14

Table 5: Comparison of extractions from a larger dataset of PubMed conflict of interest statements.

Conclusion. We presented an approach that significantly improves OIE when the input sentence contains entities while being competitive on a standard OIE benchmark. Finally, we showed that our method is much better suited for a real use case, as it extracts high-quality triples from PubMed.

Acknowledgments We thank Rémi Goujot for manually annotating the PubMed dataset used to test our model, during his high school internship. This work was performed using HPC resources from GENCI-IDRIS (Grant 2022-AD011011614R2). The authors were partially funded by the ANR-20-CHIA-0015 project and by the Hi!PARIS Center.

7 Limitations

We identify the following limitations affecting our proposed methods:

- The performance of our models is impacted by the quality of the named entity recognition tool, as well as the performance of the conjunctive model.
- Training OpenIE6 with more constraints requires around 3h/epoch, while the model with the original constraints requires half this time.
- Users trying our tool, but also the original OpenIE model, should have the computational possibility of using the BERT-based model, the main component of OpenIE6. We plan to release trained models based of smaller language models.

School of Informatics, University of Edinburgh

p.papalampidi@sms.ed.ac.uk, mlap@inf.ed.ac.uk

Abstract

In this paper, we focus on video-to-text summarization and investigate how to best utilize multimodal information for summarizing long inputs (e.g., an hour-long TV show) into long outputs (e.g., a multi-sentence summary). We extend SummScreen (Chen et al., 2022), a dialogue summarization dataset consisting of transcripts of TV episodes with reference summaries, and create a multimodal variant by collecting corresponding full-length videos. We incorporate multimodal information into a pre-trained textual summarizer efficiently using adapter modules augmented with a hierarchical structure while tuning only 3.8% of model parameters. Our experiments demonstrate that multimodal adapters outperform more memory-heavy and fully fine-tuned textual summarization methods.

1 Introduction

What happens in the very last episode of “Friends”? Anyone who has seen this episode can summarize its key moments: Ross confesses his love for Rachel, they decide to resume their relationship, while Monica and Chandler adopt twins and move to the suburbs. TV viewers can naturally perform this dialogue summarization task having access to multiple modalities: they not only hear the actors speak but also see their expressions, actions, and whereabouts on screen.

Despite recent advances in summarization (Nalapaty et al., 2016; See et al., 2017; Liu and Lapata, 2019b) and increasing interest in different types of dialogue summarization, e.g., meeting transcripts (Gliwa et al., 2019; Zhong et al., 2021) or screenplays (Chen et al., 2022), the contribution of modalities other than text remains relatively understudied. This is not entirely surprising given the challenges associated with the multimodal summarization task

illustrated above (e.g., produce a written summary of a TV episode). Firstly, the input is long, it cannot fit into standard sequence-to-sequence architectures, and the different modalities have to be somehow combined; secondly, the output is also long, summaries consist of multiple sentences and rich vocabulary; and thirdly, it involves complex inference over long-range dependencies between events and characters and common sense reasoning. At the same time, creating large-scale multimodal datasets with long videos and aligned textual data is challenging and time consuming, limiting the research conducted in this domain.

Previous work on video-to-video summarization identifies highlights from YouTube videos, TV shows, or movies (Song et al., 2015; Gygli et al., 2014; De Avila et al., 2011; Papalampidi et al., 2021b). However, in most cases, either the videos are short or the datasets are small with a few hundred examples. There is also limited work on video-to-text summarization. We are only aware of one large-scale multimodal dataset for this task, namely How2 (Sanabria et al., 2018), which again contains short videos (i.e., 2–3 minutes long) with simple semantics, and short, single-sentence summaries.

In this paper, we focus on video-to-text summarization and investigate how to best utilize multimodal information for condensing long inputs (e.g., an hour-long TV show) into long outputs (e.g., a multi-sentence summary). We create a multimodal variant of SummScreen (Chen et al., 2022), a recently released dataset comprising of transcripts of TV episodes and their summaries. We collect full-length videos for 4,575 episodes and multiple reference summaries. We build our model on top of a pre-trained sequence-to-sequence architecture (i.e., BART; Lewis et al. 2020) fine-tuned on summarization and capable of generating fluent long text. We convert its textual encoder to a multimodal one by adding and tuning adapter layers (Rebuffi et al., 2017; Houlisby et al., 2019),

*Now at DeepMind.

	Modality	Input	Output	Datasets

Table 1: Datasets used for summarization grouped based on the input/output modalities and input/output length. A more detailed comparison and statistics for video-to-text datasets can be found in Appendix A (Table 10).

which only account for 3.8% of model parameters. We also explore strategies for *content selection*, since the input is too long to fit into standard sequence-to-sequence models. Empirical results across evaluation metrics demonstrate that multimodal information yields superior performance over just text, both in terms of content selection and summarization; this is the case even when our adapter model is compared to fully fine-tuned approaches and more memory-heavy architectures (e.g., Longformer; Beltagy et al. 2020) that can process the entire input.

Our contributions can be summarized as follows: (1) we augment SummScreen (Chen et al., 2022) with multimodal information, providing videos aligned with transcripts and summaries; to the best of our knowledge, this constitutes the largest available resource for long video multimodal summarization; (2) we propose a *parameter efficient* approach to augment a pre-trained textual summarizer with multimodal information; and (3) explore different methods for identifying salient moments in a long video and show that multimodal information also improves content selection.

2 Related Work

Video Summarization Much previous work has focused on text-to-text or video-to-video summarization. We provide a comprehensive categorization of existing datasets according to input/output length and modality in Table 1. *Multimodal abstractive summarization* (video-to-text) has attracted less attention, mainly due to the difficulty of collecting large-scale datasets. How2 (Sanabria et al., 2018) is the only publicly available benchmark for this task, it includes short instructional videos with textual transcripts and one-sentence summaries. We generate multiple-sentence sum-

maries from long videos and their transcripts. While previous approaches have focused on various modality fusion methods with small RNN-based models (Palaskar et al., 2019), we take advantage of large pre-trained LMs (Lewis et al., 2020; Raffel et al., 2020; Radford et al., 2019) for generating fluent text summaries.

Recent years have also witnessed increasing interest in multimodal video captioning, a task related to multimodal summarization, which aims to generate one-sentence descriptions for localized events in short videos (Xu et al., 2016; Rohrbach et al., 2017; Zhou et al., 2018; Lei et al., 2020b). Existing methods employ strong language-and-vision encoders with massive pre-training (Li et al., 2020; Luo et al., 2020; Xu et al., 2021; Lei et al., 2020a; Li et al., 2021), while the decoder is typically shallow and under-trained.

Realizing the importance of large LMs for generation, recent work has focused on how to efficiently render pre-trained LMs multimodal. Notably, Tsimpoukelli et al. (2021) convert a pre-trained LM into an image captioning model, by giving images as prompts and training only a vision encoder. Yu et al. (2021) summarize How2 videos by augmenting BART with visual information via a *new cross-attention block* added to every encoder layer. However, their approach adds a very large number of *new parameters* and requires full fine-tuning, which leads to overfitting in our case when the dataset size is small.

Dialogue Summarization In the context of text-to-text generation, dialogue summarization is challenging due to the difficulty of fitting very long input into pre-trained sequence-to-sequence models. Longformer (Beltagy et al., 2020) alleviates this by employing local self-attention in combination

with global tokens for reducing the computational overhead. Despite recent attempts to make self-attention more efficient (Kitaev et al., 2020; Tay et al., 2020; Zaheer et al., 2020), it is still unclear whether it has an advantage over content selection with a full-attention mechanism (Zhang et al., 2021; Shaham et al., 2022) for long dialogue summarization. Zhong et al. (2022) incorporate dialogue-specific objectives for pre-training summarization models, while Zhang et al. (2022) hierarchically summarize the input chunk-by-chunk.

Parameter-efficient Tuning Fine-tuning is a common approach for transferring pre-trained models to different tasks or domains (Howard and Ruder, 2018). It is customary to fine-tune all the parameters of the pretrained model which, however, becomes prohibitive as model size and number of tasks grow. Recent work has proposed parameter-efficient transfer learning methods which fine-tune only a small number of *additional* parameters. Two popular approaches include *adapter tuning*, where bottleneck layers are added and tuned at every layer of the model (Rebuffi et al., 2017; Houlsby et al., 2019) and *prompt tuning*, where (soft) prompts are prepended as part of the input (Brown et al., 2020; Li and Liang, 2021). In this work, we utilize the former method for adapting a textual summarizer to our multimodal setting and dialogue input format.

3 The SummScreen^{3D} Dataset

SummScreen (Chen et al., 2022) is a long dialogue summarization dataset¹ containing transcripts from

¹<https://github.com/mingdachen/SummScreen>

TV episodes and human-written abstractive summaries. We extend this dataset to a multimodal setting by also considering the corresponding full-length videos. SummScreen contains two subsets depending on the series genre: SummScreen-FD and SummScreen-TMS. We use the latter subset which mostly covers soap operas from TVMegaSite², as it is easier to obtain full-length videos and each series has hundreds of episodes.

For each episode in SummScreen-TMS, we automatically search for the title and release date in Youtube. If there is a match with large duration (indicating that this is a full episode rather than a segment), we download the video and closed captions (CC). Overall, we collected videos for 4,575 episodes from five different shows in SummScreen-TMS.³ In addition to TVMegaSite summaries (distributed with SummScreen), we further retrieved summaries from YouTube descriptions, IMDb, and tvdb, again using the episode title and release date as search terms. The statistics of our dataset which we call SummScreen^{3D} (3D for language, video, and audio) are in Table 2 and we provide further details in Appendix A. As can be seen, each episode has (on average) multiple references which vary in length (TVMegaSite summaries are longest).

We split SummScreen^{3D} into training, validation, and test sets with the same distribution over different shows per set. We reserved 296 episodes for validation and the same number for testing, and used the rest for training. Since we have multiple reference summaries for some episodes, we increased the size of the training set by adding m episode-summary pairs, matching the same episode with each of its m references. This resulted in 5,199 unique samples for training.

4 Video-to-Text Summarization

Our approach leverages the generation capabilities of large pre-trained sequence-to-sequence models (Lewis et al., 2020; Raffel et al., 2020). As our backbone model, we employ BART-large (Lewis et al., 2020) which has been fine-tuned on CNN-DailyMail (Nallapati et al., 2016; Zhang et al., 2021) and has thus acquired a summarization inductive bias. As TV show transcripts are very long and cannot fit into BART, we select a subset of utterances (i.e., speaker turns) as input via content

²<http://tvmegasite.net>

³https://github.com/ppapalampidi/long_video_summarization

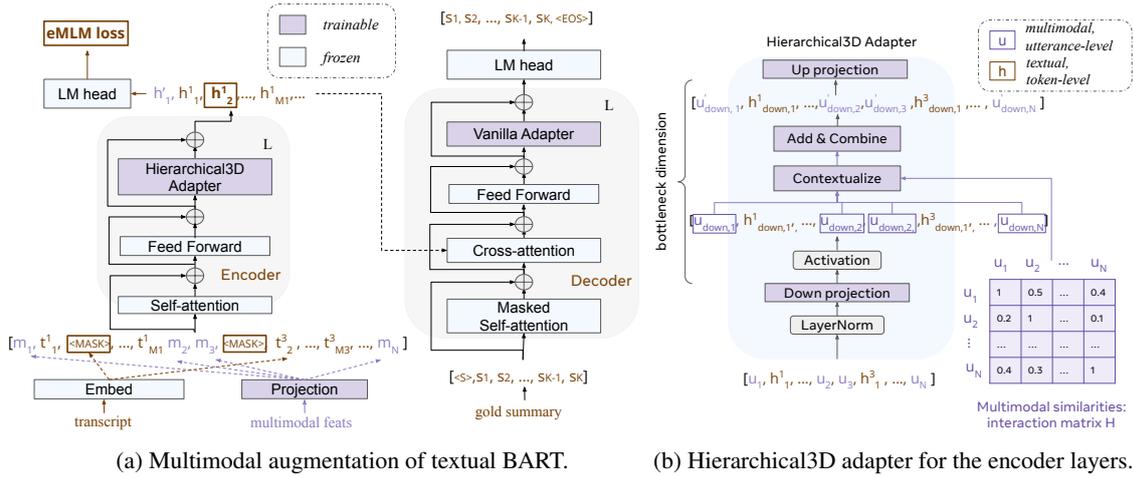

Figure 1: Multimodal augmentation of pre-trained BART. We augment the encoder and decoder layers with adapters which we fine-tune on the target dataset, while the remaining network is frozen. As input, we consider textual tokens and coarse-grained multimodal information which we prepend before each utterance. We also corrupt part of the textual input during training and add an auxiliary MLM loss to the encoder for predicting the corrupted tokens. On the right, we show the hierarchical adapter added to each encoder layer: after down-projecting all representations, we only consider the multimodal ones and further contextualize them via attention. Then, we combine the representations and up-project again to the original model dimension.

selection (see details in Section 5). We transfer this model to our task and domain (i.e., multimodal dialogue summarization), by adding adapter layers (Rebuffi et al., 2017; Houlsby et al., 2019; Sung et al., 2022) in both the encoder and decoder, and tuning them on SummScreen^{3D} while keeping the rest of the network frozen. We briefly discuss below our backbone text-based model and then elaborate on how we incorporate multimodal information.

4.1 Backbone Textual Model

Our summarizer follows a standard sequence-to-sequence Transformer architecture (Vaswani et al., 2017). The encoder maps tokens $[t_1, t_2, \dots, t_N]$ to a sequence of contextualized representations $[h_1, h_2, \dots, h_N]$ which are then fed to the decoder for generating the summary. The encoder consists of L stacked layers, each of which has a self-attention block for contextualizing the token representations, followed by a feed-forward network. The decoder has a similar architecture, it additionally contains a *cross-attention* block for identifying relations between the input and currently generated text and makes use of *masked* self-attention to control access to context for each token. The decoder is followed by a linear layer (i.e., Language Model (LM) head) which projects the output representations onto the vocabulary and a final softmax layer. The model is optimized for predicting the next token s_{t+1} in the summary given $[s_0, s_1, \dots, s_t]$, the context generated so far, and the transcript $[t_1, t_2, \dots, t_N]$.

4.2 Multimodal Augmentation

Our hypothesis is that adding multimodal information to a textual summarizer (i.e., converting the textual encoder to a multimodal one) will increase the quality of its output summaries. We expect that the video/audio will compensate for important non-verbal information typically absent from the transcript (e.g., who is speaking to whom, who is present in the same room, who is crying or yelling). We further expect multimodal information to make up for the loss of context incurred by content selection. We next describe how we compute multimodal representations for an episode and how we augment BART with these representations.

Multimodal Representations We use *utterances* as the unit of representation for multimodal information. We segment episodes into shots (using PySceneDetect⁴) and map these to utterances in the corresponding transcript. Specifically, we align the closed captions in the video which are time-stamped to the utterances in the transcript using Dynamic Time Warping (DTW; Myers and Rabiner 1981; Papalampidi et al. 2021b). We thus create a one-to-many alignment where an utterance corresponds to one or more shots. For each shot, we extract textual, visual, and audio features (see Appendix B.1 for details), and compute an utterance-level representation for each modality by average pooling over all aligned shots.

Given textual x_i , visual v_i , and audio a_i repre-

⁴<https://github.com/Breakthrough/PySceneDetect>

sentations for utterance i , we learn a multimodal representation as part of our network:

$$\begin{aligned} x'_i &= f(W_x x_i) & v'_i &= f(W_v v_i) & a'_i &= f(W_a a_i) \\ m_i &= f(W_m [x'_i; v'_i; a'_i]) \end{aligned} \quad (1)$$

where $f(\cdot)$ is the ReLU activation function, $[\cdot; \cdot; \cdot]$ denotes concatenation, $W_x \in \mathbb{R}^{d_x \times d_i}$, $W_v \in \mathbb{R}^{d_v \times d_i}$, $W_a \in \mathbb{R}^{d_a \times d_i}$, and $W_m \in \mathbb{R}^{3d_i \times d_m}$ are learnable matrices; d_i and d_m are the input and model dimensions with $d_i \ll d_m$, and m_i is the final multimodal representation corresponding to the i^{th} utterance in the transcript.

Multimodal Encoder In order to integrate utterance-level multimodal representations with BART, we consider a “global utterance token” inspired by the Longformer architecture (Beltagy et al., 2020). We preprocess the input into utterances and prepend a global token $\langle \text{EOS} \rangle$ per utterance as a placeholder for multimodal representations. The encoder thus receives as input sequence $[\mathbf{m}_1, t_1^1, t_2^1, \dots, t_{M_1}^1, \dots, \mathbf{m}_N, t_1^N, t_2^N, \dots, t_{M_N}^N]$ where, “global” representations \mathbf{m} constitute a rich multimodal space (i.e., they are not learned solely from text via local self-attention; Figure 1a).

4.3 Self-supervised Auxiliary Guidance

Our primary loss for training the model described above is the negative log likelihood of predicting the next token in the summary given episode \mathcal{E} :

$$L_{LM} = \frac{1}{K} \sum_{t \in [1, K]} -\log p(s_t | s < t; \mathcal{E}) \quad (2)$$

We further wish to encourage the model to attend to multimodal information and learn a meaningful projection (Equation (1)). To do this, we corrupt part of the textual input by masking tokens (see bottom left part of Figure 1a) and adding an auxiliary masked language modeling (MLM) loss for the initial training steps only. So as not to disrupt the bias of the decoder, which is already trained on textual summarization, we apply the MLM loss in the outputs of the encoder while the model is trained on the downstream task. Given token-level encoder outputs $[h_1, h_2, \dots, h_N]$, we copy and re-use the LM head of the decoder in order to project them into the vocabulary (see top left part of Figure 1a). And compute the negative log likelihood only for the set of masked tokens \mathcal{M} :

$$\mathcal{L}_{eMLM} = \frac{1}{|\mathcal{M}|} \sum_{t \in \mathcal{M}} -\log p(t | h_{t_i \notin \mathcal{M}}) \quad (3)$$

We refer to this loss as encoder-based MLM loss (eMLM; Baziotis et al. 2021). It trains the encoder to reconstruct input text representations while attending to multimodal information. After X initial training steps, we drop the auxiliary loss and stop corrupting the textual input in order for the model to be optimized on summarization. We use a mixture of whole utterance corruption (Zhang et al., 2020a; Zhong et al., 2022) and content word corruption, masking out named entities, nouns, and verbs excluding auxiliaries (see Section 6).

4.4 Hierarchical3D Adapters

We specialize BART for our multimodal summarization task by inserting adapter modules (Rebuffi et al., 2017; Houlsby et al., 2019) into each encoder and decoder layer (after the feed-forward block). Each adapter adds only a small number of new parameters, which are randomly initialized and tuned on our end task, while the rest of the network is frozen. A vanilla adapter takes as input hidden representations $[\mathbf{u}_1, h_1^1, h_2^1, \dots, \mathbf{u}_N, \dots, h_{M_N}^N]$, where $h_1^1, h_2^1, \dots, h_{M_N}^N$ are textual token-level hidden representations and $\mathbf{u}_1, \dots, \mathbf{u}_N$ are multimodal utterance-level hidden representations (in accordance to the input format presented in Figure 1a), and performs the following transformations:

$$h_{down,i} = f(\text{LN}(W_d h_i + b_d)) \quad (4)$$

$$h_{up,i} = W_u h_{down,i} + b_u \quad h_i = h_i + h_{up,i} \quad (5)$$

where $W_d \in \mathbb{R}^{d_m \times d_B}$, d_m is the model dimension, d_B is the bottleneck dimension of the adapter, $f(\cdot)$ is a non-linearity, LN a trainable layer normalization, $W_u \in \mathbb{R}^{d_B \times d_m}$, b_d , and b_u are the corresponding bias vectors, and $h_{down,i}$ and $h_{up,i}$ are down and up projections of h_i .

In this work, we augment the vanilla adapters of the *encoder* with a hierarchical structure (illustrated in Figure 1b). After computing (low level) self-attention between all input *textual tokens* in an encoder layer, we add a hierarchical adapter to compute *higher-level interactions* between *utterance-level multimodal* representations. By including this interaction block in the adapter, we can better propagate long-range dependencies between utterances and enforce a more global view of the events in an episode and their associations, while keeping the number of trainable parameters low.

Using the scaled dot product, we compute interaction (aka similarity) matrix H between utter-

ances (see Figure 1b) based on their *multimodal representations* $[m_1, m_2, \dots, m_N]$:

$$e_{ij} = (W_i m_i + b_i)(W_j m_j + b_j) / \sqrt{d_m} \quad (6)$$

where W_i, W_j are learnable projection matrices, d_m is the model dimension, and e_{ij} is the degree of similarity between m_i and m_j .

At each adapter layer of the encoder, after down-projecting all vectors to the bottleneck dimension, we further contextualize utterance-level multimodal representations $u_{down,i}$ with respect to each other given the degree of similarity provided by H ("Contextualize" block in Figure 1b):

$$u'_{down,i} = \sum_{k=1}^N r(H_{ik}/\tau) u_{down,k} + u_{down,i}$$

where N is the number of utterances, $r(\cdot)$ is the softmax function, and τ is a low temperature parameter (< 1) for increasing sparsity. After contextualization, we up-project all vectors to the original dimension d_m , as in vanilla adapters (Equation (5)).

5 Content Selection

As explained earlier, episodes in SummScreen^{3D} are very long ($\sim 5,720$ tokens). BART, which has a maximum token length of 1,024, can approximately encode one fifth of the transcript.⁵ We therefore perform content selection, i.e., identify salient utterances and give these as input to BART. We describe below three approaches inspired by information retrieval, summarization (Gehrmann et al., 2018; Liu and Lapata, 2019a), and computational narrative analysis (Papalampidi et al., 2021b,a).

Retrieval-based Selection We follow previous approaches (Zhang et al., 2021) in determining salient content with BM25 (Robertson and Zaragoza, 2009). BM25 is a widely known retrieval model similar to tf*idf. It assigns each utterance a "relevance" score (by comparing it against the entire transcript). Utterances with high scores are deemed salient and the K best ones are selected.

Learning-based Selection Alternatively, we may also model content selection as a binary classification problem. Given a transcript containing N utterances we predict whether each should be selected as input for the downstream summarization task (label 1) or not (label 0). We create noisy

⁵We can extend positional embeddings to 1,536 by applying bilinear interpolation, however, the memory requirements would still be prohibitive for longer sequences.

labels by matching transcript utterances to (reference) summary sentences. Specifically, we encode sentences and utterances via Sentence-BERT (Reimers and Gurevych, 2019), and assign a positive label to the utterances most similar to the reference sentences. A content selector is then trained on these pseudo-labels to identify salient utterances. We can also incorporate multimodal information in this content selection setting, using the same utterance-level representations fed into BART. We first contextualize them via a shallow transformer encoder, and add a classification head for predicting important utterances. The model is optimized with binary cross-entropy loss. During inference we select the top K predicted utterances.

Turning Point Identification We also perform content selection based on a Turning Point (TP) identification model (Papalampidi et al., 2021b,a) pre-trained on the TRIPOD movie dataset (Papalampidi et al., 2019). TPs are key events in narratives; they are distinguished into five different types depending on their functionality (e.g., Opportunity, Change of Plans, Point of No Return, Major Setback, Climax). The TP identification model considers the same multimodal information as the content selector above and identifies utterances that represent each TP. We consider the top $K/5$ predicted utterances per turning point.

6 Experimental Setup

Implementation Details We provide details of the multimodal feature extraction (i.e., utterance-level visual, audio, and textual features) in Appendix B.1. We corrupt the textual input and use the auxiliary eMLM loss (Section 4.3) only for the first $X = 1,500$ training steps; we train our model for a total of 12,000 steps. During corruption, we mask out all content words (i.e., named entities, verbs, and nouns) and a random 10% of the input utterances. For generating summaries during inference, we use beam search with beam = 5 and 3-gram blocking (Paulus et al., 2018). We provide further implementation details in Appendix B.2.

Training vs. Inference Although we experiment with different content selection methods during inference, we randomly sample input utterances during training. Random sampling acts as data augmentation, since the model sees slightly different input-output pairs during training at different iterations. We experimentally verify in Section 7 this

is preferable to a fixed selection of utterances, especially considering the small size of our dataset. We select $K = 60$ utterances to feed into BART models given the input length limit, and order them according to their original position in the transcript.

Evaluation Metrics We evaluate the generated summaries using ROUGE F1 (Lin, 2004) against reference summaries.⁶ Since ROUGE is not always a good indicator of summary quality and does not discriminate between different error types (e.g., factuality vs. fluency), we consider additional metrics based on Question-Answering (QA).⁷ We obtain questions based on gold summaries and evaluate whether the correct answers exist in the generated summaries. We expect factual summaries to answer a high percentage of questions.

As in previous work (Maynez et al., 2020; Kryscinski et al., 2020; Honovich et al., 2021), we automatically generate QA pairs against reference summaries. We identify named entities and nouns using spaCy (Honnibal and Montani, 2017), and feed them as gold answers alongside the summaries to a question generator. We discriminate between named entities and nouns as answer types for measuring factuality in event-entity associations and other attributes pertaining to nouns. We used T5-base (Raffel et al., 2020) as our question generator and RoBERTa-base (Liu et al., 2019) as the QA system for answering questions given system generated summaries as input passages. Both were fine-tuned on SQuAD2.0 (Rajpurkar et al., 2016).

We measure accuracy as the partial overlap between gold and predicted answers for named entities. For nouns, we resort to textual entailment in order to account for synonyms and paraphrases in the generated summaries. We concatenate the question with gold or generated answer and predict a score for the directional relation between them. If the score is above 0.5, we consider the generated answer correct. We used BART-large (Lewis et al., 2020) fine-tuned on the MultiNLI corpus (Williams et al., 2018) as our entailment model.

We created a test suite of gold QA pairs, by retaining only those that can be answered correctly by the QA model given the reference summaries (Honovich et al., 2021). We overall generated 2,513 questions for named entities and 381 questions for

⁶<https://pypi.org/project/py-rouge/>

⁷We also experimented with BERTScore (Zhang et al., 2020b) but observed no discernible performance differences between any pair of models.

nouns for the 296 episodes in our test set. On average, we have 8.5 questions per episode for named entities and 2.3 questions for nouns.⁸

7 Results

Content Selection Table 3 compares how different approaches to content selection influence summarization performance according to ROUGE F1. We compare some simple baselines like selecting the Lead, Middle, and Last 60 utterances from the transcript as well as at Random. In addition, we compare a text only summarizer against our Hierarchical3D model. Differences amongst content selection methods are generally small. BM25 performs worse than random whilst a multimodal content selector trained on pseudo-labels performs overall best. As an upper bound, we also report results with oracle labels as input demonstrating that there is still room for improvement.

Regardless of how content is selected, we observe that our Hierarchical3D variant significantly improves performance, and interestingly, the performance gap is larger when the selection method is weaker (e.g., random vs. pseudo-oracle). This indicates that to a certain extent multimodal information makes up for suboptimal content selection.

Text vs. Multiple Modalities In Table 4 we compare our multimodal model (with the best performing content selector) against textual summarizers developed for processing long input or specifically for dialogue summarization. These include Longformer (LED; Beltagy et al. 2020) with full fine-tuning¹⁰, a variant of LED pre-trained on

⁸We release our test suite of gold QA pairs together with the SummScreen^{3D} corpus.

⁹Textual summarizers are initialized with the same checkpoint, while some models are further tuned (e.g., DialogLED).

¹⁰Adding (and tuning) adapter layers in LED led to significantly inferior performance, which in turn suggests that adapting such a network is not straightforward.

Models	R-1	R-2	R-L

Table 5: QA evaluation (test set) on named entities (NEs) and nouns (NNs). We denote our Hierarchical3D model with H-3D.

dialogues (DialogLED; Zhong et al. 2022), and Summ^N (Zhang et al., 2022), a two-stage hierarchical approach for long dialogue summarization. We also present text-only BART variants, with full fine-tuning (FT) and adapter-tuning (AT). Finally, we include a SOTA video-to-text model (HERO; Li et al. 2020) with a massively pre-trained encoder, which is tuned on another TV dataset for video captioning of short clips (i.e., TVC; Lei et al. 2020b).

As can be seen in the second block of Table 4, tuning only the adapter layers (BART AT) does not hurt performance compared to full fine-tuning (BART FT), presumably due to the small dataset size. Addition of multimodal information with hierarchical adapters (BART AT + Hierarchical3D) yields substantial ROUGE improvements. Interestingly, our performance is superior to fully fine-tuned, memory-heavy models like LED or DialogLED that process the entire transcript as input. This suggests that representations from multiple modalities are more informative and lead to higher performance compared to efficient self-attention mechanisms. Summ^N performs demonstrably worse than one-stage methods and HERO fails to produce long fluent outputs due to the shallow under-trained decoder and small dataset size.

Modality	R-1	R-2	R-L
Text	34.74	7.11	32.46
Audio	33.95	6.92	31.90

w/o random augmentation	33.45	6.48	31.81

Table 6: The role of multimodal information and hierarchical adapters (validation set).

QA Evaluation The results of our automatic QA evaluation are summarized in Table 5. The second block focuses on model performance with different content selection variants. We only compare text-only and multimodal (+H-3D) BART. Again, we find that augmenting BART with multimodal information regardless of the selection method improves accuracy, especially for named entities. This is true even when content is selected by a pseudo-oracle suggesting that multimodal information provides better associations between events and entities, even when the input contains all salient information. We further observe that supervised content selection and TP identification offer the best performance. The first block reports the performance of state-of-the-art models on dialogue summarization; we find these models perform on par or slightly worse than textual BART (depending on the content selection method) which casts doubts on their ability to efficiently consume longer inputs. Examples of output summaries (and QA pairs) are given in Table 7 and Appendix C.3. We also report additional (entity-specific) results in Appendix C.2.

Ablation Studies In Table 6 we summarize our ablation studies which isolate the contribution of individual modeling components. We observe that individual modalities (Text, Audio, Video) are worse on their own than in combination (Multimodal). The least informative modality is audio, while the most informative is video. In the multimodal case, we substitute hierarchical adapters in the encoder with vanilla adapters and observe a small drop in performance. Removing the auxiliary eMLM loss during training further decreases performance. The auxiliary loss is crucial for rendering the textual encoder multimodal and forcing an already tuned summarizer to consider a different type of input. Finally, data augmentation (via random content selection) during training is also important given the small size of our dataset and BART encoder length restrictions. We report additional ablation

Model	Summary

We show output for a text-only BART model and a multimodal variant with hierarchical adapters (H-3D); in both cases content selection is performed with a model trained on pseudo-labels.

experiments on content selection in Appendix C.1.

8 Conclusions

In this work, we addressed the task of multimodal abstractive summarization and created SummScreen^{3D}, a new dataset which we hope will facilitate future research in this direction. We incorporated multimodal information into a pre-trained textual summarizer in a parameter-efficient manner and have experimentally shown performance gains over text-only models. Our experimental results further underscore the importance of (multimodal) content selection compared to approaches focusing

on self-attention variants for long dialogue summarization. In the future, we plan to explore more *structure-aware* representations for *all* input modalities in order to improve factuality (e.g., entity-event associations) in the generated summaries.

We thank the anonymous reviewers for their feedback. The authors also thank Marcus Rohrbach and Frank Keller for insightful comments on earlier versions of this paper. We gratefully acknowledge the support of the UK Engineering and Physical Sciences Research Council (grant EP/W002876/1).

9 Limitations

Our approach considers only coarse-grained (i.e., utterance-level) multimodal information which we demonstrate is beneficial for summarization. More detailed frame-level visual information e.g., person identification and object recognition in frames, would be useful. However, considering frame-level representations for hour-long videos would bring a considerable increase in memory requirements and additional difficulties in aligning different modalities (e.g., frames vs. tokens vs. audio segments). We leave these challenges to future work and believe that structure-aware methods are necessary for addressing the current limitations.

Following previous work (Maynez et al., 2020; Kryscinski et al., 2020; Honovich et al., 2021), we advocate the use of automatic QA-based methods for evaluating the generated summaries. Although there is supportive analysis (e.g., Tang et al. 2022) that shows better correlation to human judgements for QA-based automatic evaluation in comparison with traditional summarization metrics such as ROUGE, more experimentation is necessary to determine the shortcomings of these metrics.

Finally, conducting human evaluation for SummScreen^{3D} is infeasible, since this would entail asking judges to watch 40-minute long episodes in order to evaluate the content and faithfulness of the summaries. We further cannot assume judges are familiar with the characters, specific details and (complex) storylines of different soap operas contained in our test set in order to be able to make reliable judgments. Therefore, using QA-based metrics for judging specific attributes of summarization quality, such as whether the correct entities are linked to the correct events in an episode (i.e., QA evaluation related to named entities), can provide us with useful insights.

	TMS	SummScreen ^{3D}
TV shows	10	5
Episodes	22,503	4,575
min #episodes per show	168	501
max #episodes per show	3,784	1,356
median #episodes per show	1,973.5	1,113
avg #episodes per show	2,250.0	984.8
Utterances/episode	360.8	322.8
Tokens/episode	6,420.7	5,720.6
Summaries/episode	1	1.53
#tokens/summary	327.0	395.7

Table 9: Comparison between the original SummScreen-TMS (Chen et al., 2022) and SummScreen^{3D} which is a subset of the original dataset.

A Dataset Analysis

As mentioned in Section 3, we create a multimodal version of the SummScreen dataset (Chen et al., 2022) by collecting full-length videos of the episodes contained in the original dataset. Overall, we retrieved videos from YouTube for five different TV shows (i.e., soap operas). We present in Table 8 the names of the TV shows and the number of episodes per show. We made sure to have enough episodes from each TV show and maintain the same distribution when splitting the dataset into train, validation, and test. Moreover, we present an example of the input transcript and output summary from SummScreen (Chen et al., 2022) and how we augment the dataset with additional information from the full-length video in Figures 2 and 3.

Next, we also compare the statistics of SummScreen^{3D}, which is a subset of SummScreen-TMS (Chen et al., 2022), with the original dataset in Table 9. Overall, we include episodes from half the TV shows contained in TMS. The number of episodes per TV show in our dataset is more balanced in comparison with the original (see rows 3–6 in Table 9). SummScreen^{3D} has similar input and output statistics per episode to the original dataset (e.g., number of utterances and tokens per transcript and number of tokens per summary). However, we also collect more summaries per episode when available (see Table 8) for creating an augmented training set and a more robust evaluation set.

Finally, we also compare our dataset against other video-to-text summarization datasets in Table 10. TACoS (Rohrbach et al., 2014) and How2 (Sanabria et al., 2018) are the only available multimodal summarization datasets we are aware of. In comparison, our dataset contains much longer videos (on average 40 minutes long), and fairly elaborate textual summaries (instead of short one-sentence descriptions with simple vocabulary).

B Implementation Details

B.1 Dataset Pre-processing

Given full-length video, we extract features for all modalities at the utterance-level as mentioned in Section 4.2. For text, we extract sentence-level features using Sentence-BERT (Reimers and Gurevych, 2019). Each utterance in the transcript is thus represented by a fixed-size vector. For the frames, we extract two types of features: frame-level features using the CLIP visual encoder (Radford et al., 2021) and motion-level features from video clips using Slowfast (Feichtenhofer et al., 2019). We then aggregate frame- and motion-level features to utterance-level given the automatic alignment by mean pooling. Finally, for audio, we use YAMNet pre-trained on the AudioSet-YouTube corpus (Gemmeke et al., 2017) for classifying audio segments into 521 audio classes (e.g., tools, music, explosion); for each audio segment contained in a shot, we extract features from the penultimate layer, and then aggregate representations again to utterance-level via mean pooling.

B.2 Training Details

We used the Adam algorithm (Kingma and Ba, 2015) for optimizing our networks. We trained all models with a learning rate of $3e-5$ for 12k steps using a linear warm-up of 500 steps, followed by inverted squared decay. All BART-based models were trained with batch size of 1 episode on 4 P100 GPUs with 16GB memory and label smoothing (Szegedy et al., 2016) of 0.1. To fine-tune the LED-based models, we used 4 A100 GPUs with 80GB memory. It took approximately 12 hours to fully train each of these models. Fully fine-tuned models have 406M parameters, which are all fine-tuned on the target dataset, whereas our multimodal adapter-augmented model has 421.6M parameters, from which we only train 15.6M parameters (i.e., multimodal projection layer and adapter layers) on the target dataset. This means that we only tune $\sim 3.8\%$

of the model parameters of the fully fine-tuned models. We report the results of a single run for all models following previous work (Chen et al., 2022; Zhong et al., 2022) due to the computational overhead of running some large comparison models. However, we report in Table 11 the average and standard deviation over three runs for BART AT and BART AT + H-3D in order to demonstrate the performance variation of these models.

C Additional Experimental Results

C.1 Ablation Study on Content Selection

In Table 12, we examine the performance of different content selectors. We report precision (Pre), recall (Re), and F1 score of model variants based on pseudo-oracle labels. We first consider selectors which have not been trained with pseudo-oracle labels, such as Random, Retrieval (i.e., BM25) and TP identification (we refer to these approaches as unsupervised). We observe that unsupervised baselines have significantly lower F1 score in comparison with a supervised approach. Interestingly, although TP identification “agrees less” with the pseudo-oracle labels in comparison with BM25, TPs still present competitive performance against the supervised content selector on abstractive textual summarization (e.g., Table 5). Finally, comparing the multimodal supervised content selector with equivalent unimodal models, we observe that the highest performance is achieved by combining all modalities. With respect to unimodal variants, we find that the textual modality is most informative, while using visual or audio cues alone is not enough to predict salient content.

C.2 Entity-specific Evaluation

Chen et al. (2022) propose a set of entity-specific metrics in order to investigate the role of characters, which are fundamental in TV shows, in the generated summaries. Specifically, they measure several bag of character (BoC) metrics based on character overlap between generated and gold standard summaries. They define precision as the fraction of correctly mentioned characters with respect to all characters that appear in the generated summary (BoC-p) and recall as the fraction of correctly mentioned characters with respect to all characters that appear in the gold summary (BoC-r). Given precision and recall, we also measure F1-score (BoC-f1).

Apart from correctly mentioned characters, Chen

	dataset size	video input	text input	video duration	output tokens
TACoS	147	✓	✗	4.5 minutes	9
How2	79k	✓	✓	90 seconds	20
SummScreen ^{3D}	4.5k	✓	✓	40 minutes	290

Table 10: Comparison between SummScreen^{3D} and other video-to-text summarization datasets (see Table 1).

	R-2	R-L
BART AT	6.71 (0.02)	30.96 (0.23)
BART AT + H-3D	7.58 (0.03)	7.58 (0.03)

Table 11: Results of two models from Table 3 across three different runs. We report the average and standard deviation in parentheses for R-2 and R-L.

Unsupervised	Precision (%)	Recall (%)	F1 (%)
Random	19.55	20.90	20.06
Retrieval	24.63	26.62	25.40
TP identification	20.35	22.10	21.04

Table 12: The role of multimodal information in content selection. We report the Precision, Recall, and F1 for selecting important utterances from an episode. Supervised models are trained on pseudo-oracle labels.

et al. (2022) also compute similar bag of words metrics for relations between characters in the summaries. Specifically, they consider a pair of characters related if they appear in the same sentence in the summary. They do not account for the direction of relations and focus only on co-occurrence. They again consider precision (BoR-p) and recall (BoR-r) of the intersection of pairs of characters similarly to computing the BoC metrics. We also report F1-score (BoR-f1), given the precision and recall for character relations.

We summarize our entity-specific results in Table 13. Overall, especially when considering the F1 scores for characters and relations, we arrive to similar conclusions as with our automatic QA evaluation (Table 5). The multimodal information that is incorporated in our Hierarchical3D approach increases most entity-specific metrics in comparison with text-only variants. Regarding different content selection methods, TP identification and supervised content selection again perform best in comparison with random selection, although differences are not large. Finally, we achieve the best F1 scores in both entity- and relation-specific metrics by using oracle selection, indicating that there is still room

for improvement. Interestingly, we again observe a further increase in performance by adding multimodal information in the pseudo-oracle variant, suggesting that video-based information is important even when we consider the most salient parts of an episode.

We also compare our approach with state-of-the-art, fully fine-tuned textual summarizers for long dialogues. We again notice that Summ^N is weakest according to entity-specific metrics. Next, efficient architectures for modeling the entire input (i.e., LED, DialogLED) have competitive performance against our text-only variants with content selection. However, Hierarchical3D that considers multimodal information outperforms these memory-heavy models while training only a small fraction of model parameters. This further validates our hypothesis that the video can provide additional information which more important for high-quality summaries than processing the entire textual input.

C.3 Examples of Generated Summaries

In this section we provide examples of generated summaries based on different automatic systems. Moreover, we provide examples of questions and answers used for the automatic QA evaluation described in Section 6.

Table 14 shows examples of automatically generated question-answer pairs given gold standard summaries. We provide examples of QA pairs for named entities (first 4 rows of the table) and nouns (remaining 6 rows of the table). We observe that most QA pairs are reasonable and correspond to information given in human-written summaries (first column of the table). However, there are cases where the QA pairs do not provide reasonable questions. Such an example is illustrated in the last row of Table 14, where the question is generated given the summary segment “Jonathan and Lizzie find out their baby has a medical condition, and make a run for it”:

Q: “What do Lizzie and Jonathan do when they learn their baby has a medical condition?”

A: “run”

	BoC-p	BoC-r	BoC-f1	BoR-p	BoR-r	BoR-f1
Random selection	82.55	38.71	52.71	29.82	9.39	14.28
+ Hierarchical3D	81.80	47.37	60.00	31.75	13.77	19.21
TP identification	84.31	38.93	53.26	36.79	10.33	16.13
+ Hierarchical3D	82.20	47.10	59.89	34.82	14.10	20.07
Content Selection	81.60	36.59	50.52	30.54	8.58	13.40
+ Hierarchical3D	81.90	48.48	60.91	33.04	14.37	20.03
Pseudo-oracle	<i>87.42</i>	<i>46.95</i>	<i>61.09</i>	<i>37.92</i>	<i>14.40</i>	<i>20.87</i>
+ Hierarchical3D	85.53	52.37	64.96	36.67	17.51	23.70
LED FT	82.28	33.54	47.65	34.35	10.64	16.25
DialogLED FT	82.93	38.19	52.27	31.71	10.32	15.57
Summ ^N FT	82.74	29.14	43.10	34.73	9.39	14.78

Table 13: Entity-specific metrics (test set). We report bag of character precision (BoC-p), recall (BoC-r), and F1 (BoC-f1). Analogously, we compute bag of relations precision (BoR-p), recall (BoR-r), and F1 (BoR-f1).

Summary	Question	Answer
Sage goes to live with Jack after she learns Carly is planning to marry Craig. Meg agrees to marry Dusty.	Who does Meg agree to marry?	Dusty
	Who does Sage go to live with?	Jack
Joshua is busy preparing for Allison’s arrival, as he unveils Kevin’s latest creation; a portrait of Allison and Joshua in their wedding attire. Lucy goes to church to plead for answers. Ian overhears her plea and swears that he will not let her die. Livvie shows Joshua a picture of Allison appearing to be dead and tells him that he was right her fangs are poisoned.	Who goes to church to plead for answers?	Lucy
	Who swears he will not let Lucy die?	Ian
	What does Lucy do at church? What part of Allison’s body is poisoned?	plea fangs
Lizzie and Jonathan spend some time with their baby. Jonathan gives in to one of Alan s demands. Gus and Harley find a disk with some interesting information on it. Gus still can t figure out what it is that Blake has on him. Dinah and Mallet argue over who will be the next WSPR star. Tammy is heartbroken after a visit to the hospital. Jonathan and Lizzie find out their baby has a medical condition, and make a run for it. Alan realizes that he may have been outwitted by Jonathan. Gus vows to get to the bottom of his supposed secret.	What does Gus vow to find out about Blake?	secret
	What is Lizzie and Jonathan spending time with?	baby
	What do Gus and Harley find?	disk
	What do Lizzie and Jonathan do when they learn their baby has a medical condition?	run

Table 14: Examples of automatically generated QA pairs for the evaluation of generated summaries.

This QA pair does not correspond to a reasonable fact of the episode. This shows that although it is useful to filter the questions, there are still imperfections with the automatic generation of QA pairs, especially when considering nouns.

Next, we give examples of the generated summaries for the TV show "Port Charles" in Tables 15–18. We present the gold or generated summary alongside the QA pairs used for evaluation. First, we compare different content selection methods (i.e., supervised content selection (CS), TP identification (TPs), and pseudo-oracle) for a text-only summarizer based on BART with adapter tuning. We present two examples in Tables 15 and 17 (we also show gold summaries for each episode). In both cases, we observe that the pseudo-oracle selection provides summaries of better quality, with fewer errors in the questions answered (i.e., errors are illustrated with red). Moreover, when compar-

ing content selection (CS) with TP identification (TPs), we find that these two approaches provide similar results, as suggested by our main experimental results (Table 5). Specifically, in Table 15, TP identification seems to provide the most informative summary, whereas in Table 17 supervised content selection is the best option.

Secondly, we compare our approach that considers multimodal information (Hierarchical3D) against text-only BART with equivalent content selection, and LED which considers only text and uses an efficient self-attention mechanism for processing the entire input. We present two examples for the same episodes as above in Tables 16 and 18. We empirically validate that the quality of the generated summaries is improved by adding the multimodal information (both when using supervised content selection and TP identification). Our approach leads to summaries that answer a

larger percentage of automatic questions correctly (i.e., correct answers are illustrated with **green**) outperforming LED, which is fully fine-tuned and memory-heavy. Interestingly, LED summaries cannot answer a large proportion of the given questions, suggesting that such methods may not be suitable for our task and small size dataset.

Victor: To new beginnings and a new way of doing things.

Mary: Aw

Victor: Ladies and gentlemen, I would also like to raise my glass to Joshua. Mr. Joshua Temple. Some of you already know that Mr. Temple is going to be the new owner of our beloved Recovery Room. And he is certainly Port Charles' newest, most distinguished citizen. I haven't known him very long, but I can vouch for the fact that he's a man of drive and vision. Ladies and gentlemen, Joshua Temple.

All: Hear, hear!

Lucy: This is unbelievable.

Joshua: I have many ambitious plans, not just for this place but for all over my new adopted home, the lovely town of Port Charles.

Mary: Aw.

Joshua: I hope you all approve.

[Cheers and applause]

Jamal: Make room, make room, make room. Watch this.

Mary: Ah.

Alison: My God. It's like a vision of hell.

Caleb: It's your city -- the way Joshua intends it to be.

Rafe: We got to find a way to stop him.

Caleb: It looks like the destruction's already begun.

Rafe: This guy worked for you, Caleb. What are his weaknesses?

Caleb: Well, you might want to sit this one out.

Livvie: Or move.

Caleb: Don't worry. With Olivia's help, I won't be mortal for long. And then I'll crush that little worm.

Livvie: It might not be that easy.

Caleb: As long as we have the ring, we -- what happened to the ring?

Livvie: It's gone. I'm sorry, Caleb, but our protection against Joshua is gone.

Caleb is upset when Livvie tells him that Joshua has the ring.

Joshua attempts to sway Ian to the dark side, but Ian vows he will continue to fight Joshua and the other vampires. Rafe tells Caleb the only way he can defeat Joshua now is to remain human and Livvie reluctantly agrees. Lucy pleads with Victor to fight Joshua, however, it's too late, as Victor tells her he enjoys the power Joshua has given him. Karen realizes Frank is a vampire.

gold summary

part of the input transcript

Figure 2: Example of input and output for SummScreen dataset. A long transcript is considered as input for summarization, containing the dialogue parts of a full-length TV episode. Character names are given as part of the dialogue. The goal is to produce a textual summary of most important events in the episode.

Victor: To new beginnings and a new way of doing things.

Mary: Aw

Victor: Ladies and gentlemen, I would also like to raise my glass to Joshua. Mr. Joshua Temple. Some of you already know that Mr. Temple is going to be the new owner of our beloved Recovery Room. part of the input transcript

video

Figure 3: We augment SummScreen (see example of Figure 2) with information from the full-length video, which is aligned to the input transcript. Additional information, such as Joshua touching the ring in a previous scene or Caleb looking concerned when talking to Livvie, can be acquired from the video frames.

Model	Summary	
Gold	Caleb is upset when Livvie tells him that Joshua has the ring. Joshua attempts to sway Ian to the dark side, but Ian vows he will continue to fight Joshua and the other vampires. Rafe tells Caleb the only way he can defeat Joshua now is to remain human and Livvie reluctantly agrees. Lucy pleads with Victor to fight Joshua, however, it's too late, as Victor tells her he enjoys the power Joshua has given him. Karen realizes Frank is a vampire.	
QA pairs	<ul style="list-style-type: none"> • Who tells Lucy that he enjoys the power Joshua has given him? • Who does Karen realize is a vampire? • Who pleads with Victor to fight Joshua? • Who tells Caleb that Joshua has the ring? • Who realizes Frank is a vampire? • What does Livvie tell Caleb Joshua has? • Who does Karen realize Frank is? 	Victor Frank Lucy Livvie Karen the ring vampire
CS (text-only)	Caleb and Rafe discuss how to get close to Joshua and Livvie. Lucy tries to convince Victor that Joshua is an evil vampire who should not be allowed to have his soul. Lucy tells Victor that she can't lose him and wants him to accept her offer to turn him back into a vampire. Joshua tells the people of Port Charles that he will do whatever it takes to breathe new life into this wonderful old place.	
QA pairs	<ul style="list-style-type: none"> • Who tells Lucy that he enjoys the power Joshua has given him? • Who does Karen realize is a vampire? • Who pleads with Victor to fight Joshua? • Who tells Caleb that Joshua has the ring? • Who realizes Frank is a vampire? • What does Livvie tell Caleb Joshua has? • Who does Karen realize Frank is? 	Victor Joshua Lucy Rafe Victor soul vampire
TPs (text-only)	Caleb and Livvie are shocked to find out that the ring has been taken away from them by Joshua. They are unable to get the ring back, but they are determined to find a way to get it back. Lucy tells Victor that Joshua is a liar and that he should not be allowed to have an important position in Port Charles. Victor tells Lucy that he will not give up on her, but she tells him that she will not go to the hospital because she has to be here for Victor. Lucy and Victor agree that they need to stay at the hospital for the sake of Victor, but Lucy is not willing to give up her job as Victor's guardian angel. Rafe tells Alison that if she turns back, she is going to be under Joshua's control, and he doesn't think she will be too happy about taking orders from someone else. He tells her that he would rather slit her own wrists than have Joshua touch her.	
QA pairs	<ul style="list-style-type: none"> • Who tells Lucy that he enjoys the power Joshua has given him? • Who does Karen realize is a vampire? • Who pleads with Victor to fight Joshua? • Who tells Caleb that Joshua has the ring? • Who realizes Frank is a vampire? • What does Livvie tell Caleb Joshua has? • Who does Karen realize Frank is? 	Victor Joshua Lucy Lucy the ring vampire
Pseudo-oracle	Caleb and Livvie find out that the ring that protects them from Joshua is gone, and they have no way of getting it back. Lucy and Ian try to convince Victor to turn Joshua into a vampire, but he tells them that he is not a monster and that he wants to be a good man. Lucy tells Victor that Joshua is evil, but Victor tells her that she is his friend and he will not let her get to him. Victor tells Lucy that he will do whatever it takes to breathe new life into Port Charles. Ricky tells Jamal that he does not want to be his guardian angel anymore, but Jamal tells him to go and hang with the bloodsuckers. Jack tells Jack that the only way he is going to win is to play both sides of the fence. Frank tells Karen that there are benefits to his new role as a vampire and he is willing to do it for the good of the town of Port Charles and his family.	
QA pairs	<ul style="list-style-type: none"> • Who tells Lucy that he enjoys the power Joshua has given him? • Who does Karen realize is a vampire? • Who pleads with Victor to fight Joshua? • Who tells Caleb that Joshua has the ring? • Who realizes Frank is a vampire? • What does Livvie tell Caleb Joshua has? • Who does Karen realize Frank is? 	Victor Frank Lucy Livvie Karen the ring vampire

Abstract

Code comments are critical for maintaining and comprehending software programs, but they are often missing, mismatched, or outdated in practice. Code comment generation task aims to automatically produce descriptive comments for code snippets. Recently, methods based on the neural encoder-decoder architecture have achieved impressive performance. These methods assume that all the information required to generate comments is encoded in the target function itself, yet in most realistic situations, it is hard to understand a function in isolation from the surrounding context. Furthermore, the global context may contain redundant information that should not be introduced. To address the above issues, we present a novel graph-based learning framework to capture various relations among functions in a class file. Our approach is based on a common real-world scenario in which only a few functions in the source file have human-written comments. Guided by intra-class function relations, our model incorporates contextual information extracted from both the source code and available comments to generate missing comments. We conduct experiments on a Java dataset collected from real-world projects. Experimental results show that the proposed method outperforms competitive baseline models on all automatic and human evaluation metrics.

1 Introduction

Code comment generation is the task of automatically producing natural language descriptions for given code snippets. Appropriate and sufficient comments are essential for software maintenance and understanding (Xia et al., 2018). They allow developers to grasp the purpose of source code quickly and accurately. However, in real-life software projects, comments are often missing, incomplete or outdated (Briand, 2003). Existing com-

```

Table 1: Example illustrating the importance of utilizing class-level contextual information.

ments will also need to be adjusted as the associated programs are updated, which could cause large time and labor costs. Hence, there is a significant need for automatic generation technologies that can effectively produce high-quality comments.

Recent works in code comment generation take the neural encoder-decoder architecture as their cornerstone (Hu et al., 2018a; Alon et al., 2019; LeClair et al., 2020; Zhang et al., 2020; Wei et al., 2020). However, these works only utilize the information provided by the target function itself. In object-oriented programming, classes are the building blocks that express algorithmic intentions and they encapsulate the interaction between functions. Therefore, the class-level contextual information should not be ignored when we attempt to generate code comments. There are some existing studies that attempt to fill this gap. Haque et al. (2020) encode all functions in a source file using GRU (Cho et al., 2014) and apply an attention mechanism to learn associations between the encoding results to words in the generated comment. Yu et al. (2020) construct a class graph that connects the

target function to all other functions in the same class to aggregate contextual information. Bansal et al. (2021) present a project-level encoder to augment existing models by introducing contextual information.

Although the above methods have shown promising performance, the way they introduce contextual information is somewhat crude. Since not all surrounding functions are closely related to the target function, indiscriminately utilizing the whole context may introduce noise, which would hurt the model performance. We propose that considering function relations is a better way to leverage the contextual information. For example, Table 1 presents three functions in a Java class. Within this class, we can observe two types of function relations. First, the function `removeTS` calls `firePropertyChange` in its function body. As we can see, the word "*PropertyChangeEvent*" in the human-written comment appears not in the target function, but in the callee function. Second, `removeTS` and `removeAllTS` perform very similar operations, and their comments are almost identical, with the exception of a few noun subjects. This example illustrates that the information required to generate a comment may be located outside the boundary of the target code snippet and within the related functions.

Motivated by the above observation, we define two types of relations between a function pair: extractive relation and inductive relation. The extractive relation captures connections between source code snippets at two levels: call dependencies and semantic similarity, allowing us to derive external knowledge directly from the relevant code snippets. The inductive relation captures common programming patterns within a class. We observe that developers usually create similar comments for functions that conform to a specific programming pattern. Therefore, comments of functions that have inductive relation to the target function can be used as a template to guide the target comment generation.

In this paper, we propose a graph-based encoder-decoder learning framework for code comment generation. Our approach is based on a common scenario where only a few functions in the class file are documented. We construct a heterogeneous graph to model both the extractive relation and inductive relation among functions within a class file. In the encoding stage, we encode all functions and available comments using bi-GRU. Then, we design

an intra-class relational GAT encoder to aggregate information and perform a fusion of both types of relations via a cross-graph mechanism. In the decoding stage, we employ a GRU decoder with a by-pointer mechanism to generate a comment utilizing the encoding results.

To evaluate the performance of our approach, we gather a Java dataset that preserves the class structure. We conduct experiments on this dataset and perform evaluation using automatic and human evaluation metrics. The experimental results show that our model outperforms prior methods by a significant margin, which demonstrates the effectiveness of our proposed framework.

2 Related Works

Early efforts on code comment generation are template-based or information retrieval (IR) based approaches (Sridhara et al., 2010; Haiduc et al., 2010a,b; Eddy et al., 2013; Rodeghero et al., 2014; McBurney and McMillan, 2014). In recent years, the neural encoder-decoder architecture is employed to the code comment generation field, which was designed for neural machine translation (NMT) task originally. CodeNN (Iyer et al., 2016) is an early work that attempts to adopt the encoder-decoder architecture for generating code comments. Followed works develop a variety of models by introducing the Abstract Syntax Tree (AST) to extract structural information of the source code (Hu et al., 2018a; Alon et al., 2019; Allamanis et al., 2018; Liang and Zhu, 2018; LeClair et al., 2019a). More recently, novel code representations are learned via well-designed encoders, such as GNN-based encoders (LeClair et al., 2020; Zhang et al., 2022) and pre-training encoders (Ahmad et al., 2020; Zügner et al., 2021; Guo et al., 2022).

Hybrid methods that integrate the IR-based and neural-based techniques proved to perform well on the code comment generation task. Zhang et al. (2020) retrieve two similar code snippets of the target function at syntax and semantics levels, then utilize their encoding information to generate comments in the decoding stage. Wei et al. (2020) retrieve the most similar code snippet and the corresponding comment to assist the generation process. Liu et al. (2021) retrieve the most similar code-comment pair and add it as auxiliary information to their proposed Hybrid GNN framework.

However, these works rarely utilize contextual information that is external to the target function.

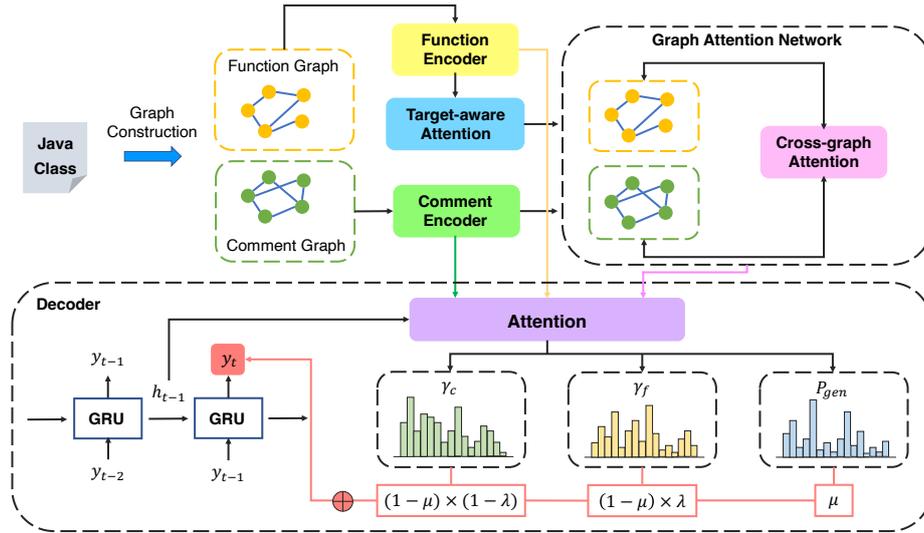

Figure 1: The overall architecture of our approach. Local encoders extract features from code snippets and known comments (Section 3.3). The GAT encoder aggregates class-level information and produces final representations. (Section 3.4). Lastly, these encoding results are fed into the decoder to create the target comment (Section 3.5).

Some of the most recent works make efforts to bridge this gap (Haque et al., 2020; Yu et al., 2020; Bansal et al., 2021). In contrast to these existing approaches, our method explores function relationships within a class and only incorporates related functions. This has the advantage of avoiding noise caused by irrelevant functions and focusing on the valuable contextual information.

3 Approach

This section introduces our proposed framework for code comment generation. Figure 1 illustrates an overview of our approach.

3.1 Relation Extraction

To focus on valuable class-level contextual information, we need to develop extraction rules for function relations. We define the extractive relation as (1) the call dependency; (2) the TF-IDF cosine similarity. Call dependencies can be extracted using the `java-callgraph*` toolkit, and the TF-IDF cosine similarity between functions X^i and X^j is calculated as:

$$s_{ij} = \frac{\overrightarrow{\text{tfidf}}(X^i)^T \overrightarrow{\text{tfidf}}(X^j)}{\|\overrightarrow{\text{tfidf}}(X^i)\| \|\overrightarrow{\text{tfidf}}(X^j)\|} \in [0, 1] \quad (1)$$

If the similarity score $s_{ij} > \alpha$, we consider an extractive relation between X^i and X^j , where α is a pre-defined threshold.

*<https://github.com/gousiosg/java-callgraph/>

Towards the inductive relation, we summarize some common programming patterns and organize them into five heuristic rules based on extensive observations of open-source software projects. Formally, we consider an inductive relation between two functions if:

- (R1) the verbs in function names are antonyms, with the same or no object entities;
- (R2) the verbs in function names are the same, with overlapping object entities;
- (R3) both functions have the same parameters as well as the same verbs in their names;
- (R4) both functions have the same parameters as well as the same return type;
- (R5) the return type of one function corresponds to the parameter type of another.

In (R1)-(R3), we conduct part-of-speech tagging on function names using the toolkit Stanford CoreNLP[†] to identify verbs and noun entities. And we use the NLTK[‡] interface of WordNet[§] to get antonyms of verbs in (R1). Appendix A provides several examples that correspond to the preceding rules.

3.2 Graph Construction

For each class, we build a graph structure that consists of two subgraphs, called function graph and

[†]<https://stanfordnlp.github.io/CoreNLP/>

[‡]<https://www.nltk.org/>

[§]<https://wordnet.princeton.edu/>

comment graph. The node of the function graph represents each function, while the node of the comment graph represents the corresponding comment. Since only a small fraction of comments in the class are known, we use function names to replace unknown comments. According to the previously defined extraction rules, we add edges between the corresponding function nodes if a pair of functions fulfill the extractive relation, and between comment nodes if they satisfy the inductive relation. Formally, we define a graph

$$G = \{ (v_i, r_{fun}, v_j) \cup (u_i, r_{com}, u_j) \},$$

where $v \in \mathcal{V}_f$ is the node of function, $u \in \mathcal{V}_c$ is the node of comment or function name, $\mathcal{V}_f, \mathcal{V}_c$ are the sets of function nodes and comment nodes, and r_{fun}, r_{com} denote edges that represent the extractive relation between functions, and the inductive relation between comments, respectively.

3.3 Local Encoder

Our model contains two local encoders, a function encoder and a comment encoder. They extract features from functions and comments separately. The function encoder employs a bi-GRU (Cho et al., 2014) to convert the source code sequence $\{x_1, \dots, x_n\}$ into numerical vectors $Z = \{z_1, \dots, z_n\}$, where $z_i = [\vec{z}_i || \overleftarrow{z}_i]$ is the concatenation of the hidden states from both directions. We take Z as the representation of the input function. The comment encoder also apply a bi-GRU to the comment sequence $\{w_1, \dots, w_m\}$, and produce hidden states $\{r_1, \dots, r_m\}$. The last hidden state r_m is considered as the comment representation.

3.4 Intra-class Relational GAT

We propose an intra-class relational graph attention network that performs on the previously constructed graph.

Node Initialization For function nodes, we first apply the function encoder to obtain their representations $\{Z_1, \dots, Z_K\}$, where $Z_i = \{z_{i1}, \dots, z_{in_i}\}$ represents the i -th function. Then, we use a target-aware attention mechanism to focus on information in other functions that is beneficial to the target function. We take the last hidden state as the representation of the target function Z_t , which can be denoted as z_t , and use it to compute the attention weight as:

$$\alpha_{t,ij} = \frac{\exp(z_t^T \mathbf{W}_t z_{ij})}{\sum_{k=1}^{n_i} \exp(z_t^T \mathbf{W}_t z_{ik})}, \quad (2)$$

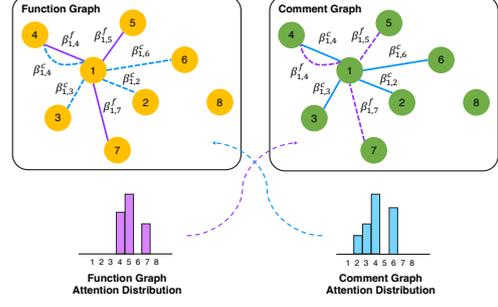

Figure 2: An example of updating node 1 via cross-graph attention mechanism.

where \mathbf{W}_t is a learnable parameter. The attention score $\alpha_{t,ij}$ measures the similarity between the target function and the j -th token in the code sequence of the i -th function. Then, we compute the weighted sum of all elements in Z_i :

$$\mathbf{f}_i^0 = \sum_{j=1}^{n_i} \alpha_{t,ij} z_{ij}, \quad (3)$$

and take it as the initial representation of the function node v_i . Finally, we obtain a set of target-aware initial vectors representing function nodes, which is denoted as $\{\mathbf{f}_i^0 | i : v_i \in \mathcal{V}_f\}$. For comment nodes, the last hidden states are used directly as the initial node representations, and we denote them as $\{\mathbf{c}_i^0 | i : u_i \in \mathcal{V}_c\}$.

Cross-Graph Attention We employ two separate GAT modules, one for the function graph and the other for the comment graph, which have the same structure. In order to interact information between these two graphs, we design a cross-graph attention mechanism that is applied to each layer of the GATs. Fig. 2 illustrates an example of this mechanism. Specifically, the $l + 1$ -th layer of each GAT receives a set of messages $\{\mathbf{f}_i^l | i : v_i \in \mathcal{V}_f\}$ or $\{\mathbf{c}_i^l | i : u_i \in \mathcal{V}_c\}$ from the previous layer. Then, we obtain two output vectors $\mathbf{f}_{g,i}^{l+1}, \mathbf{c}_{g,i}^{l+1}$ and two attention distributions calculated as:

$$e_{ij}^f = \text{LeakyReLU}(\mathbf{a}^T [\mathbf{W}_a \mathbf{f}_i^l || \mathbf{W}_a \mathbf{f}_j^l]),$$

$$\beta_{ij}^f = \text{Softmax}(e_{ij}^f) = \frac{\exp(e_{ij}^f)}{\sum_k \exp(e_{ik}^f)}, \quad (4)$$

$$e_{ij}^c = \text{LeakyReLU}(\mathbf{b}^T [\mathbf{W}_b \mathbf{c}_i^l || \mathbf{W}_b \mathbf{c}_j^l]),$$

$$\beta_{ij}^c = \text{Softmax}(e_{ij}^c) = \frac{\exp(e_{ij}^c)}{\sum_k \exp(e_{ik}^c)}, \quad (5)$$

where $\mathbf{a}, \mathbf{W}_a, \mathbf{b}, \mathbf{W}_b$ are trainable parameters. Next, we exchange the attention weights and com-

pute two cross-graph vectors as:

$$\mathbf{f}_{cross,i}^{l+1} = \sum_{j:u_j \in N_c(u_i)} \beta_{ij}^c \mathbf{W}_d \mathbf{f}_j^l, \quad (6)$$

$$\mathbf{c}_{cross,i}^{l+1} = \sum_{j:v_j \in N_f(v_i)} \beta_{ij}^f \mathbf{W}_e \mathbf{c}_j^l, \quad (7)$$

where u_i is the corresponding comment node of function node v_i , $N_f(v_i)$ is a set of the neighboring function nodes of v_i , $N_c(u_i)$ is a set of the neighboring comment nodes of u_i , and $\mathbf{W}_d, \mathbf{W}_e$ are trainable parameters. Finally, we aggregate the cross-graph vector and the original GAT output vector to obtain an integral context vector that takes into account both extractive and inductive relations:

$$\mathbf{f}_{aggr,i}^{l+1} = \tanh(\mathbf{W}_f[\mathbf{f}_{cross,i}^{l+1} \parallel \mathbf{f}_{g,i}^{l+1}]). \quad (8)$$

$$\mathbf{c}_{aggr,i}^{l+1} = \tanh(\mathbf{W}_c[\mathbf{c}_{cross,i}^{l+1} \parallel \mathbf{c}_{g,i}^{l+1}]). \quad (9)$$

where $\mathbf{W}_f, \mathbf{W}_c$ are trainable weights.

Update Gate Motivated by (Cho et al., 2014), we introduce an update gate to control how much information from the previous representation should be transferred to the current representation:

$$g = \text{Sigmoid}(\mathbf{W}_g[\mathbf{f}_{aggr,i}^{l+1} \parallel \mathbf{f}_i^l]), \quad (10)$$

$$\mathbf{f}_i^{l+1} = g * \mathbf{f}_{aggr,i}^{l+1} + (1 - g) * \mathbf{f}_i^l. \quad (11)$$

We also obtain \mathbf{c}_i^{l+1} by performing the same operation. These two representations are the outputs of the $l + 1$ -th layer. We repeat the above process L times and get the final node representations, denoted as \mathbf{f}_i^L and \mathbf{c}_i^L . Finally, we concatenate the representation of the function node and its corresponding comment node as the output of our GAT encoder, which is denoted as $\mathbf{g}_i = \mathbf{f}_i^L \parallel \mathbf{c}_i^L$.

3.5 Decoder

The decoder employs a GRU to generate comment for the target function Z_t . The initial hidden state is a concatenation of the last hidden state \mathbf{z}_t from the function encoder and the final output \mathbf{g}_t from the GAT encoder.

Attention We consider multiple context vectors: \mathbf{cz}_t toward the output from the function encoder, \mathbf{cr}_t toward the output from the comment encoder, and \mathbf{cg}_t toward the output from the GAT encoder, which can be calculated as follows:

$$\gamma_{tj} = \frac{\exp(\mathbf{h}_t^T \mathbf{W}_s \boldsymbol{\eta}_j)}{\sum_k \exp(\mathbf{h}_t^T \mathbf{W}_s \boldsymbol{\eta}_k)}, \quad (12)$$

$$\mathbf{cv}_t = \sum_j \gamma_{tj} \boldsymbol{\eta}_j, \quad (13)$$

where \mathbf{W}_s is a learnable parameter, \mathbf{h}_t is the current decoder hidden state, and $\boldsymbol{\eta}_j$ represents the function encoder output \mathbf{z}_j , the comment encoder output \mathbf{r}_j , and the GAT encoder output \mathbf{g}_j , respectively.

By-Pointer Since both code snippets and known comments may contain words that are not in the vocabulary, a portion of the predicted tokens could be copied directly from them. Motivated by (See et al., 2017) and (Sun et al., 2018), we design a by-pointer mechanism to solve this problem. In the t -th time step, the decoder takes embedding \mathbf{y}_t as input, and the copy distribution is formulated as:

$$\lambda = \text{Sigmoid}(\mathbf{W}_l[\mathbf{cr}_t \parallel \mathbf{h}_t \parallel \mathbf{y}_t]), \quad (14)$$

$$P_{copy} = \lambda * \gamma_c + (1 - \lambda) * \gamma_f, \quad (15)$$

where \mathbf{W}_l is the trainable parameter. The γ_f is the attention distribution between the current hidden state \mathbf{h}_t and source codes, γ_c is the attention distribution between \mathbf{h}_t and known comments, both calculated by Eq (12). Additionally, the generative distribution over all vocabulary tokens is calculated based on \mathbf{h}_t and three context vectors:

$$P_{gen} = \text{Softmax}(\mathbf{W}_v[\mathbf{h}_t \parallel \mathbf{cz}_t \parallel \mathbf{cr}_t \parallel \mathbf{cg}_t] + \mathbf{b}_v), \quad (16)$$

where $\mathbf{W}_v, \mathbf{b}_v$ are trainable parameters. Finally, we obtain the prediction distribution as follows:

$$\mu = \text{Sigmoid}(\mathbf{W}_m[\mathbf{cz}_t \parallel \mathbf{cr}_t \parallel \mathbf{cg}_t \parallel \mathbf{h}_t \parallel \mathbf{y}_t]), \quad (17)$$

$$P(w) = \mu * P_{gen} + (1 - \mu) * P_{copy} \quad (18)$$

where \mathbf{W}_m is the trainable parameter. This mechanism allows our model to both generate tokens from the vocabulary and copy tokens from two sources during inference.

4 Experimental Setup

4.1 Dataset

Due to most public datasets only consist of independent code snippets, we collect a dataset from Google Code Archive that preserves class-level information. With the help of Sourcerer (Bajracharya et al., 2014), we are able to trace and recover the entire architecture of 1,000 real-world JAVA projects. We assume that only 10% of functions or at least one function have comments in each class. To determine which functions will be treated as commented, we use two different sampling settings. (1)

Random Sampling: we randomly sample 10% of functions in each class as commented based on the assumption that commenting is a stochastic behavior for developers; (2) **Degree Sampling:** since functions that connect to others more frequently often play a key role in programming, we calculate function degrees in the class graph and rank them in descending order. Then we sample the top 10% of functions as commented. After sampling, we split our dataset by projects according to a ratio of 8:1:1. The more detail of our dataset is provided in the Appendix B.

4.2 Baselines

Retrieval-based Models **RandomCopy** randomly copies comments from a known comment set. **MaxCopy** computes the ROUGE-L score between the golden comment and known comments, then copies the comment with the highest score. **NNGen** (Liu et al., 2018) is a IR-based method for generating commit messages that can also be used in the code comment generation task.

Generation-based Models **Seq2Seq** (Sutskever et al., 2014) is a bi-GRU with an attention mechanism. **ASTGNN** (LeClair et al., 2020) applies a GRU encoder for the source code sequence, a GCN (Kipf and Welling, 2017) encoder for the AST and a GRU decoder for generation. **Rencos** (Zhang et al., 2020) retrieves two similar functions from a code retrieval base to enhance the neural generation. **ClassGAT** (Yu et al., 2020) employs a local bi-GRU encoder and a global GNN encoder to obtain two different levels of function representation. The encoder outputs are fed into a GRU decoder with an attention and copy mechanism. **CodeBERT** (Feng et al., 2020) is a pre-trained model that can be adapted to a variety of NL-PL applications. **GypSum** (Wang et al., 2022) learns representations from source codes and ASTs using a pre-trained encoder and a GAT encoder. The encoding results are fused in a Transformer decoder to generate comments.

with Known Comments The baseline models mentioned above only work on the source code itself, whereas our approach incorporates known comments additionally. To explore the influence of known comments, we perform a modification that introduces them into multiple baselines. For Seq2Seq, we produce a comment by combining the target function representation and the weighted

sum of known comment representations. Towards ClassGAT, we take the initial node representation as (i) a concatenation or (ii) a weighted sum of the function representations and their corresponding comment representations, then report the best performance. As for CodeBERT, we set its input as a concatenation of the target function and known comments within the class.

with CodeBERT We also incorporate CodeBERT into our model for verifying whether function relations still provide benefits when employing a strong pre-training model. Specifically, we use the CodeBERT and a transformer decoder to replace the bi-GRU encoder and the GRU decoder, respectively.

4.3 Implementation Details

The value of threshold α is set to 0.7. Word embeddings are randomly initialized, the size of embeddings and hidden states are set to 256. Both the encoder and decoder GRUs have a single layer and the GAT has 3 layers. We use Adam (Kingma and Ba, 2015) optimizer to train our model with the weight decay rate being $1e-6$. We set the learning rate to $1e-4$ and the dropout (Srivastava et al., 2014) rate is 0.3. There is also a scheduler that reduce learning rate when the BLEU on the validation set stops improving for 3 epochs, and the learning rate will not be less than $1e-6$. All our experiments were trained on Nvidia A40 GPUs.

4.4 Evaluation Metrics

We evaluate the quality of generated comments based on BLEU (Papineni et al., 2002) and ROUGE-1, -2, -L (Lin, 2004). We also report 1,2,3,4-gram precisions to determine how many n-grams in the generated text overlap with the reference text. For human evaluation, we invited three experienced raters to score fifty samples randomly selected from the test dataset. For each generated comment, raters assign scores in three aspects: (i) **Fluency**, which measures comment quality in terms of grammaticality and readability; (ii) **Relevance**, which examines whether the generated comment accurately summarizes the functionality of the code snippet; (iii) **Informativeness**, which evaluates whether the comment offers concrete information that is free of redundancy or repetition. These human evaluation metrics have a scale of 0 to 2 (where 2 indicates highly satisfied and 0 means highly unsatisfied).

Model	Degree-Sampling							
	BLEU	p_1	p_2	p_3	p_4	ROUGE-1	ROUGE-2	ROUGE-L
RandomCopy	13.08	30.0	14.4	9.2	7.4	30.72	14.04	29.41
MaxCopy	14.65	32.2	16.2	10.4	8.4	33.60	16.20	32.26

Seq2Seq+KC	16.51	39.4	20.4	12.9	10.6	39.82	20.76	38.37
ClassGAT+KC	18.52	42.8	22.1	14.9	12.6	43.34	22.67	41.05
CodeBERT+KC	19.64	51.9	29.0	18.3	13.6	49.95	27.54	47.87
Ours	21.39	47.3	26.6	18.6	15.9	46.78	25.72	44.87
+ CodeBERT	25.60	51.9	31.8	22.8	18.8	51.87	31.54	49.89

Table 2: Comparison between our model and baselines. "KC" refers to the known comments.

Model	Fluency	Relevance	Informativeness
Seq2Seq	1.19 (± 0.86)	0.72 (± 0.75)	0.93 (± 0.79)
ClassGAT	1.27 (± 0.82)	0.81 (± 0.75)	1.01 (± 0.76)
CodeBERT	1.39 (± 0.78)	1.13 (± 0.77)	1.31 (± 0.75)
Ours	1.54 (± 0.77)	1.21 (± 0.87)	1.36 (± 0.72)

Table 3: Results of human evaluation (standard deviation in parentheses).

5 Results and Analysis

5.1 Automatic Evaluation

The comparative results are summarized in Table 3. Overall, our model outperforms all baselines by a large margin. Retrieval-based models have relatively poor results since they do not adequately exploit the semantic information of the source code. In comparison, generation-based models perform better. ASTGCN surpasses Seq2Seq by incorporating structural information from the AST. Rencos and ClassGAT improve their performance with the assistance of external information. CodeBERT and GypSum exceed other baselines by utilizing their extensive pre-training knowledge. After aggregating related contextual information, our model outperforms all baseline models. This suggests that considering function relations is an effective way to enhance the comprehension of the target function.

We discover that introducing known comments can improve the performance of some baselines. As shown in Table 2, all of the methods achieve an improvement on BLEU and ROUGE. Due to the vast knowledge gained during the pre-training process, CodeBERT significantly improves ROUGE-L from 43.25 to 47.87 (+ 4.62%). This result suggests that known comments from the class context can help with code comment generation. We also ana-

lyze the effect of known comments on our model in the Appendix C.

Although these models present competitive performance with the incorporation of known comments, our model equipped with CodeBERT still manages to make a further improvement and achieves the best BLEU and ROUGE scores among all the involved models. This shows that combining our framework with the pre-trained model can effectively absorb both the contextual information and the pre-training knowledge, which allows our approach to collaborate with more advanced pre-trained models in the future.

5.2 Human Evaluation

We further conduct human evaluation to assess the quality of comments generated by different models, as shown in Table 3. Our model surpasses the baseline models on all metrics. The Seq2Seq model has a much lower score than others, because it only utilizes local information contained in the source code, whereas other models incorporate contextual information or pre-training knowledge as well. Since the by-pointer mechanism enables our model to copy tokens from both the source code and known comments, it significantly improves the fluency of generated comments. Besides, the highest relevance and informativeness score indicates that our model can effectively summarize the behavior of a given function.

5.3 Ablation Study

To examine the contribution of components in our framework, we evaluate the performance after removing each of them, as shown in Table 4. We discover that removing any of the modules has a neg-

Model	BLEU	p_1	p_2	p_3	p_4	ROUGE-1	ROUGE-2	ROUGE-L
Ours	21.39	47.3	26.6	18.6	15.9	46.78	25.72	44.87
w/o function encoder	16.39	42.2	21.4	13.1	10.0	43.45	22.44	41.40
w/o GAT encoder	16.75	44.3	22.0	13.4	10.1	45.09	22.20	42.84
w/o target-aware attention	19.35	46.3	24.7	16.2	12.9	46.41	24.72	44.24
w/o cross-graph attention	18.81	45.0	24.1	15.8	12.6	45.14	23.74	43.06
w/o by-pointer mechanism	20.27	46.9	25.7	17.4	14.7	46.58	25.20	44.53

Table 4: Ablation study results of our approach.

ative impact on the model performance. Without the function encoder or GAT encoder, the performance drops significantly, suggesting that both are critical components in our framework. Removing the target-aware attention or cross-graph attention mechanism also results in a noticeable performance degradation, indicating that both mechanisms contribute to overall performance. Besides, we observe a slight drop in performance without the by-pointer mechanism, confirming that this component can effectively copy tokens from the source code and known comments to improve comment generation.

5.4 Threshold α

The hyper-parameter α determines the lower limit of TF-IDF similarity scores. To explore how model performance varies with α , we run a series of experiments with different values of α , while keeping other hyper-parameters constant. Fig. 3 shows the corresponding results. It illustrates that $\alpha = 0.7$ achieves peak performance in both BLEU and ROUGE-L. When α is equal to 0.5 or 0.9, our model performs poorly in both metrics. This may be because when the α is too small or too large, there are too many or too few functions associated with the target function, and the model is unable to make effective use of contextual information.

5.5 Sampling Settings

To investigate the impact on our approach when programmers select functions to be commented in different ways, we conduct a series of experiments under random and degree sampling settings. The experimental results are reported in Fig. 4. Compared to the competitive baselines, our model presents better performance under both settings. Since our model is able to capture function relations within a class, even randomly commenting functions can help improve the quality of generated comments. Furthermore, it clearly shows that our model performs much better under degree sampling than random sampling, due to the reason that commenting functions with higher degrees can ben-

fully connected	17.73	45.60	23.73	43.42

Table 5: Impact of different types of edges.

efit more functions in the same class. This finding implies that when engineering in the real world, it may be a good idea to start by writing comments for functions with higher degrees.

5.6 Relation Types

To examine the utility of edges constructed by TF-IDF similarity and five types of inductive relations, we remove them from the class graph to observe how it affects model performance, as presented in Table 5. It demonstrates that removing either type of edge leads to a drop in BLEU and ROUGE scores. Specifically, the performance degradation is greatest after dropping edges of type TF-IDFSim and R1, indicating that they are the most influential relation types. While removing R5 edges has the least impact on model performance, this can

	Case 1	Case 2
Target Function	<pre>public boolean isCurrent() { boolean result = false; if (this.getNumber().intValue() == EasyCalendar.getOne().getCurrentYear()) { result = true; } return result; }</pre>	<pre>public Vector parse(final String str, char separator) { if (str == null) { return new Vector(); } return parse(str.toCharArray(), separator); }</pre>
Class Context	<p>Related Function:</p> <pre>public Month getCurrentMonth() { Month month = null; if (isCurrent()) { int currentMonthNumber = EasyCalendar.getOne() .getCurrentMonth(); month = getMonth(currentMonthNumber); } return month; }</pre> <p>Known Comment: gets the current month, but only if this year is the current one</p>	<p>Related Function:</p> <pre>public Vector parse(final char[] chars, int offset, int length, char separator) { if (chars == null) { return new Vector(); } Vector params = new Vector(); return params; }</pre> <p>Known Comment: extracts a list of name value pairs from the given array of characters</p>
Graph		
Golden	checks if this year is the current year	extracts a list of name value pairs from the given string
Seq2Seq	gets the value of the attribute	parses a string from the given
ClassGAT	returns true if the current has the desired result	extracts a character value at the given character
CodeBERT	returns the current year	extracts a vector from the string buffer
Ours	returns true if this year is current one	extracts a list of name value pairs from the given string

Table 6: Examples of the source codes, graph structure and generated comments. "T" refers to the target function and "C" refers to the commented function in the class context.

be attributed to the low occurrence of this relation type in the dataset. Furthermore, we conduct an experiment to investigate the impact of exploiting contextual information in a crude manner. To be more specific, rather than modeling functional relations, we construct a fully connected graph to introduce the entire class context. Our model suffers greatly as a result of this operation, with the BLEU and ROUGE-L dropping 3.66% and 1.45%, respectively. This performance loss verifies the effectiveness of our design for utilizing class-level contextual information.

5.7 Case Study

Table 6 shows two examples of generated code comments. In the first case, there is a commented function in the class that is the caller of the target function. The second half of its comment provides an accurate description of the target function `isCurrent`. Although there is no direct connection between these two functions in the comment graph, our model is still able to extract information from the known comment through the cross-graph attention mechanism and generate a high-quality comment. In contrast, baseline models do not capture the true functionality of the source code and their generation results has a large deviation from the original intention.

In the second case, it is difficult to figure out the purpose of target function solely from the source code. Since there is a defined (R1) pattern between the target function and a commented function from the class context, the constructed edge in the comment graph allows our model to aggregate comment of this related function. Therefore, our model successfully generates "a list of name value pairs", whereas other models fail to capture this key information and produce meaningless comments. Moreover, it is worth noting that our model is unaffected by irrelevant information in the known comment, yielding the true object "string" rather than "array of characters". The final output of our model is exactly same as the human-written comment.

6 Conclusion

In this paper, we propose a graph-based learning framework for code comment generation. Our approach targets a practical scenario where only a few functions in the class file have human-written comments. To identify valuable information from the class context, we model function relations and develop a graph attention network to aggregate class-level contextual information. We conducted experiments on Java programs collected from real-world projects and the results demonstrate that our approach outperforms prior methods.

Limitations

There are four main limitations of our work. First, we only evaluate our model on Java code snippets. Although we expect that our approach could be generalized to other programming languages, further experiments is required to confirm this hypothesis. Second, our model does not utilize syntactic information (e.g. ASTs) of the source code. Thus, our next effort will incorporate this type of information into our framework to advance comment generation. Third, we do not employ Transformers in our approach due to limited resources. This will also be left to our future work. Fourth, in comparison with the widely used datasets TL-CodeSum (Hu et al., 2018b), CodeSearchNet (Husain et al., 2019) and Funcom (LeClair et al., 2019b), the size of our collected dataset is relatively small (Table 7). A large-scale code comment generation dataset that retains class structure information is needed in future studies.

Dataset	Ours	TL-CodeSum	CodeSearchNet	Funcom
Examples	40,328	87,136	496,688	2.1 M

A Examples of the inductive relation

Table 8 shows examples that correspond to the five inductive relation rules defined in Section 3.1.

B Dataset

In order to better suit the scenario of our task, only well-commented JAVA classes are retained, which means classes containing more than three functions and at least 70% of them have manually written comments. The detailed statistics of our dataset are

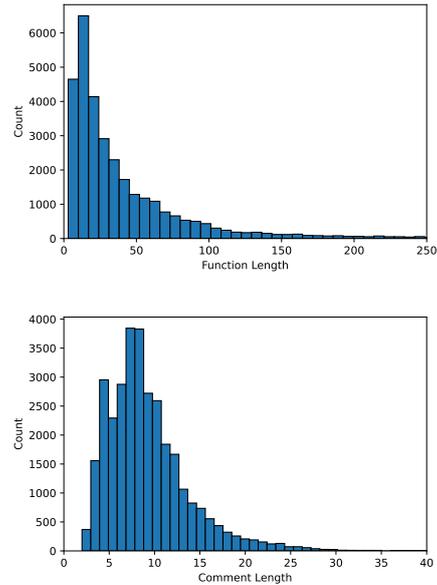

Figure 5: Length distribution of functions and comments in the dataset

shown in Table 9. Figure 5 shows the length distribution of target function and golden comment of our dataset. The length of functions is basically less than 100 and the length of comments are mainly between 3 and 25.

The data is preprocessed in following ways: for each function, (1) we extract the summative content in the Javadoc and take the first sentence as the comment; (2) we remove all the format controlling tokens and only retain comments having at least three words; (3) we serialize the function-comment pairs, remove non-alphabetical characters, and split tokens written in camelCase or underscore style; (4) we truncate the source code sequences to 200 tokens.

C Known Comments

As shown in the section 5.1, incorporating known comments into comment generation can significantly improve baseline model performance. To further demonstrate the effect of known comments, we remove them from our model and evaluate model performance. Specifically, we use function names instead of known comments for comment nodes during the graph construction step while leaving other settings unchanged. The experimental results are shown in Table 10. It illustrates that removing known comments reduces BLEU and ROUGE-L scores by 4% and 3%, respectively, in-

	Function 1	Function 2

Spelling convention sensitivity in neural language models

Elizabeth Nielsen[†] Christo Kirov[°] Brian Roark[°]

[†]School of Informatics, University of Edinburgh, UK [°]Google
e.nielsen@ed.ac.uk {ckirov, roark}@google.com

Abstract

We examine whether large neural language models, trained on very large collections of varied English text, learn the potentially long-distance dependency of British versus American spelling conventions, i.e., whether spelling is consistently one or the other within model-generated strings. In contrast to long-distance dependencies in non-surface underlying structure (e.g., syntax), spelling consistency is easier to measure both in LMs and the text corpora used to train them, which can provide additional insight into certain observed model behaviors. Using a set of probe words unique to either British or American English, we first establish that training corpora exhibit substantial (though not total) consistency. A large T5 language model does appear to internalize this consistency, though only with respect to observed lexical items (not nonce words with British/American spelling patterns). We further experiment with correcting for biases in the training data by fine-tuning T5 on synthetic data that has been debiased, and find that finetuned T5 remains only somewhat sensitive to spelling consistency. Further experiments show GPT2 to be similarly limited.

1 Introduction

The probabilities that neural language models (LMs) assign to strings can be used to assess how effectively they capture linguistic dependencies found in their training data. Much as in psycholinguistic experiments on human language speakers, we can present LMs with strings both with and without agreement in key dependencies and measure the assigned probabilities to determine whether the model has learned these linguistic generalizations or not (see e.g., Futrell et al. 2018). For example, sentences both with and without subject/verb number agreement (but otherwise identical) can be used to assess whether the model accounts for that particular dependency, even over

long distances. Various long-distance dependencies have been investigated in this manner, from purely linguistic phenomena such as syntactic dependencies (e.g., Gulordava et al. 2018) to extralinguistic phenomena such as socio-cultural biases (e.g., Rudinger et al. 2018).

In this paper, we examine dependencies based on orthographic cues to language variety. Many LMs are trained on large corpora scraped from the web, and data from different language varieties are often combined. For example, LMs trained on web-scraped English (e.g., the WebText Corpus of Radford et al. 2019) encounter British English, North American English, and multiple World Englishes. Likewise, Spanish web corpora may include several distinct varieties of Latin American Spanish, as well as Iberian Spanish (e.g., Kilgarriff and Renau 2013). Here we use differences between British and American English spelling conventions to ask whether LMs trained on large and diverse collections of English learn to apply these conventions consistently within the same span of text. For example, if the British spelling of the word *labour* appears in a sentence prefix, will the LM assign higher probabilities to continuations that maintain British spelling conventions (e.g., *organisation*) over those that have American-spelled forms (*organization*)? To the extent that such models are used within response generation systems or for next word prediction in virtual keyboards, maintaining such consistency would be strongly desirable so users receive results appropriate for their locale.

Of course, as with any such dependencies, models can only learn generalizations that are present in the data, so we also look at the degree to which corpora used to train the large LMs (LLMs) that we investigate (as well as a few others) demonstrate spelling convention consistency. Assessing whether syntactic or semantic generalizations are learned by models trained on noisy, errorful and inconsistent data is complicated by the difficulty in

quantifying the actual degree of consistency of the dependency in the data itself. In contrast to structural linguistic generalizations or other implicit information, the explicitness of spelling conventions permits straightforward corpus analysis in addition to model probing, providing another avenue for explaining model performance.

The results of our data analysis are presented in §4. We find that relevant web-scraped English text used to train LLMs unsurprisingly does not provide perfect consistency — and further that it is heavily skewed towards American spelling conventions — but that it provides as much or more consistency than some curated corpora such as the British National Corpus (BNC Consortium, 2007). We then present methods, in §5, to measure the degree to which two neural LLMs – T5 (Raffel et al., 2020) (both with and without additional finetuning) and GPT2 – exhibit spelling variation consistency. We find that T5 without finetuning demonstrates a general preference for consistency, but that this preference is weaker for British than American English and does not extend robustly to nonce words. Finetuning T5 on a synthetically modified portion of the British National Corpus reduces the preference for American English. We then modify our conditional probability calculations to allow demonstration of similar patterns of model behavior for GPT2, a very differently architected and trained LLM (Radford et al., 2019). Lastly, in §6, we take a slightly deeper dive into the kinds of (and reasons for) spelling convention inconsistencies in some corpora analyzed in §4.

Overall, we demonstrate that, while T5 and GPT2 display some sensitivity to spelling convention differences, this cannot be relied on to produce consistent generated output. If reliable spelling consistency is an application requirement, additional post-processing may need to be applied to LLM output.

This paper makes several key contributions. First, we provide methods for straightforwardly assessing the ability of LLMs to capture certain well-attested long-distance dependencies in English, and demonstrate the strengths and shortcomings of two well-known models in doing so. This opens up the possibility of exploratory studies in languages where such conventions are less well documented. In contrast to the most heavily investigated types of long-distance dependencies (e.g., syntactic), the (previously unexplored) dependency of spelling

convention consistency is directly observable in the surface string and hence is relatively easy to assess in both models and data. As a result, it can be seen as a useful task for assessing LM learning in general. We also document the degree to which web-scraped corpora exhibit spelling consistency, making clear that the models have plenty of room for improvement. However, American English is shown to be far more heavily represented in the training corpora than British English, to the point that performance for British English is demonstrably far worse than for American English, something that language generation or word prediction systems must address for equitable performance.

2 Background

2.1 Dependencies and LMs

Much of the work investigating whether large language models capture long-distance linguistic generalizations has focused on non-surface dependencies, such as co-reference. In order to correctly identify that two expressions refer to the same entity, models often need to identify complex syntactic relationships (e.g., c-command), or build a model of entities over an entire discourse (e.g., Clark and Manning 2016). Despite this complexity, LLMs have shown some promise as general-purpose co-reference resolvers (Joshi et al., 2019). This suggests that they can learn to model complex long-distance dependencies.

Other research has shown more directly that LLMs model syntactic dependencies. A common methodology is to compare an LM’s surprisal directly to psycholinguistic data (Futrell et al., 2018). If the LM still performs like a human on examples that require modeling hierarchical relationships between tokens, this suggests that the LM has learned some part of the more complex syntactic structure of the language. Work such as Futrell et al. (2018) has shown that a recurrent neural network language model achieves surprisal rates that mimic human processing, including in these syntactically complex situations. This suggests that an RNN LM can be sensitive to complex syntactic relationships as well. Similar methods have been used to show LMs learning syntactic dependencies in Linzen et al. (2016), Frank et al. (2016), and Brennan et al. (2020).

Another class of methods for assessing whether LMs learn complex syntactic dependencies involves probing the models themselves to evaluate

whether syntax-like relationships between tokens can be discovered. Details of their methods vary widely, but Clark et al. (2019), Hewitt and Manning (2019), and Lin et al. (2019) all suggest that many LMs learn complex syntactic dependencies.

In contrast, the topic of the current paper – spelling convention dependencies – is a relatively surface-level dependency. A model does not need to capture the syntactic or semantic relationship between two words in order to evaluate spelling consistency, rather simply their co-occurrence. Given prior results showing that LMs can and do learn complex semantic and syntactic relationships between words, one might expect that a relatively simple dependency like spelling convention should be easy for an LM to learn.

2.2 Spelling variation

As discussed by Berg and Aronoff (2017), the orthography of English has never been regulated by an official body, but has rather emerged dynamically over time. Dictionaries played a key role in settling spelling conventions, with Samuel Johnson’s (1755) dictionary being the key source of contemporary British spelling conventions and Webster’s (1828) dictionary the key source of contemporary American spelling. The latter included spelling reforms such as using the suffix *-or* instead of *-our* for certain words, e.g., *labor* instead of *labour*. These reforms were adopted in American spelling but not in British spelling conventions.

This history makes English an interesting case study for spelling variation in particular. Languages that have historically had centralized regulatory institutions, such as the French or Royal Spanish Academies, have much less purely orthographic variation. For example, despite many lexical differences, there are few spelling differences between Iberian and Latin American Spanish. On the other hand, there are many language situations that have considerably more spelling variation. For example, speakers of South Asian languages that are traditionally written with Brahmic or Arabic scripts often write using the Latin alphabet in contexts like SMS messages and social media (Roark et al., 2020). This kind of informally romanized text presents many spelling variations due to these languages’ lack of orthography in the Latin script. The well-documented nature of English spelling variation and its close ties to standardized regional varieties make it a good initial case study

for whether LLMs learn systematic variation in the data. If so, such models may be useful in more exploratory studies, such as the above-mentioned scenario where no official orthography exists.

As far as we are aware, the issue of spelling convention consistency in language models has not been investigated. Nguyen and Grieve (2020) looked at whether word embeddings are *robust* to spelling variation, not whether generative language models capture spelling consistency. That paper focused mainly on the kinds of variation that arise in informal social media text, but they also examined British versus American spelling. Unsurprisingly, they found that cosine similarity between British and American spelled variants are high relative to other patterns of informal spelling variability.

2.3 Prompting LMs

In the present work, we construct prompts to measure the probability assigned to various tokens by LLMs. In constructing these prompts, we take into account the findings of recent work on prompting LMs. Our work is different from the sort of prompting described by these papers, which generally includes features such as task-specific prefixes containing instructions (e.g., Raffel et al. 2020), verbalized class labels (e.g., Schick and Schütze 2021), or in-context learning (e.g., Brown et al. 2020), none of which are present in our approach. However, work such as Webson and Pavlick (2022) has shown large effects due to small variations in the wording of prompts, even if the reasons for these effects are not apparent. Therefore, we choose to present the model with several different prompts and average the probabilities over all prompts, in order to account for possible variation.

3 Data and models

To assess the spelling convention consistency of data and models, we use a list of British and American English spelling differences that is part of the open-source American British English Translator.¹ We used the 1706 word pairs in the `data/american_spellings.json` file at that site. This list includes American and British spelling variants for words with common differences such as *-or/-our* (e.g., *vapor/vapour*), *-ize/-ise* (*realize/realise*), consonant doubling (*modeling/modelling*), *-er/-re* (*liter/litre*), along with

¹<https://github.com/hyperreality/American-British-English-Translator>

some number of term-specific spelling differences (aluminum/aluminium). We use this list to create prompts for probing the language models and to establish the consistency of usage within corpora, i.e., whether strings found in this list consistently follow one convention or the other when they co-occur.

For model probing, we examine T5 (Raffel et al., 2020), a general purpose encoder-decoder model. We use the t5-large architecture variant on the T5X codebase,² which has approximately 770M parameters. For English, T5 is (pre-)trained using a span corruption objective on the Colossal Clean Crawled Corpus (C4), an English language collection derived from Common Crawl (Raffel et al., 2020).³

We also examine GPT2, for which we use the open-source HuggingFace implementation (Radford et al., 2019). Unlike T5, GPT2 is a purely autoregressive language model rather than an encoder-decoder sequence-to-sequence model. It is trained to perform next-word prediction rather than fill in corrupted spans of text. GPT2 is built on OpenAI’s WebText corpus (Radford et al., 2019), of which there is an open-source variant available.⁴

We examine C4 and OpenAI’s WebText corpus for spelling convention consistency, along with several other corpora: English Wikipedia (downloaded 06-21-2020); the Billion Word Benchmark (Chelba et al., 2013), which is a collection of newswire text; and the British National Corpus (BNC Consortium, 2007),⁵ which is a balanced corpus of both written and spoken material.⁶

4 Training corpora consistency

To examine spelling consistency in training data, we made use of the list of spelling variants and the five corpora mentioned in Section 3: C4, the OpenWebText Corpus (OWT), English Wikipedia (EngWiki), the Billion Word Benchmark (BWB), and the British National Corpus (BNC). We convert all strings in each corpus to lowercase, and treat all characters outside of the a–z range as whitespace for tokenization. We look for exact matches of list items in the resulting whitespace-delimited tokens.

⁶Code for querying corpora and generating prompts, as well as other relevant data and code, can be found at https://github.com/google-research/google-research/tree/master/spelling_convention_nlm.

Corpus	total # of word pairs	X-matched %		
		US	UK	mis
C4	542,755,756	74.6	14.7	10.8
OWT	42,255,261	79.7	11.5	8.8
EngWiki	1,527,529	58.0	26.5	15.4
BWB	442,733	67.5	23.6	8.9
BNC	74,072	14.5	64.8	20.8

Table 1: Study of word pairs found in the same string from either UK or US spelling list over corpora of different sizes and characteristics, with percent of US-matched, UK-matched and mismatched US/UK pairs.

Let V_{US} be the US spelling variants⁷ of the words in the list and V_{UK} the UK spelling variants. For each corpus C , let $s^k = w_1 \dots w_{|s^k|}$ represent the k th string in the corpus, consisting of $|s^k|$ words. We extract all pairs of words (w_i, w_j) from s^k such that $i < j$ and $w_i, w_j \in V_{US} \cup V_{UK}$. Each extracted pair (w_i, w_j) is placed into one of three classes: the pair is (1) *US-matched* if $w_i, w_j \in V_{US}$; (2) *UK-matched* if $w_i, w_j \in V_{UK}$; and (3) *mismatched* otherwise. We then aggregate the counts for pairs in these three bins across all strings in the corpus.

Table 1 presents the number of pairs extracted from each corpus and the percentage of those within each class. Several things jump out from these results. First, all of the corpora, other than the British National Corpus, have significantly more US-matched pairs than UK-matched pairs, with OWT and C4 being the most skewed towards US-matched pairs. This likely indicates a heavy overall skew towards US spelling variants, leading to a high prior probability of US spelling variants in LLMs. Second, the percentage of extracted pairs that are mismatched are non-negligible, however there is a lot of consistency. For example, in the C4 corpus, if a word from V_{UK} is the first word of a pair, the probability that the next word will also be from V_{UK} is nearly three times the probability that it is from V_{US} .⁸ Finally, both English Wikipedia and the British National Corpus have somewhat elevated levels of mismatch compared to the other corpora, something we look at more closely in Section 6.

Having established that the level of mismatch in the C4 corpus used to train T5 is at the lower end

⁷For convenience, we use US as shorthand for American and UK as shorthand for British.

⁸Mismatched pairs in all corpora are roughly equally split between having V_{US} or V_{UK} words first. Hence, for C4, 5.4% of pairs are V_{UK} followed by V_{US} words (half of the mismatched probability), while 14.7% are V_{UK} followed by V_{UK} .

observed in the data we examined,⁹ we now move on to examine whether the trained models pick up on these dependencies.

5 Language model consistency

From the dictionary presented in Section 3, we kept only the words that can be described by a small number of rules, e.g., the variation between *-ize* and *-ise*, etc, leaving us with 1266 options. For efficiency, we sample $\approx 16k$ prompt-target pairs (16028) from all possible 1266^2 combinations.

To eliminate all sources of variation besides the pair of words being tested, we created several template sentences into which we can insert pairs of words. The full set of templates is presented in Table 9 in Appendix A. Several considerations informed how we formulated the templates so that they work for all the tokens we wanted to test.

First and most obviously, we need to ensure that all tokens in a template are variety-neutral. This ensures that the probability of any of our test words being British or American will not be swayed by any regional bias in the template. While neutrality is difficult to enforce perfectly within a single frame, we hope that by using multiple different templates, we can mitigate unknown sources of bias via averaging.

Second, we need templates that will be syntactically and semantically acceptable, regardless of the inserted tokens. LLMs may assign low probability to tokens that result in grammatically unacceptable or semantically unlikely sentences, and we want to avoid introducing this source of variation. This is challenging, since the tokens we are testing include different parts of speech and come from very different semantic domains, hence there are few contexts where all tokens would be acceptable.

Fortunately, this problem has an analogue in linguistics: linguists interested in detailed phonetic description often elicit tokens in set contexts to eliminate extraneous sources of acoustic variation (Bowerman, 2015). The approach these linguists often take is to use a template that *mentions* the tokens in question rather than *using* them. We follow this approach, and use templates similar to (1), which contain a list of word mentions.

(1) *My preferred words are ..., ..., and tree.*

⁹We note again the benefit of these explicit surface-level dependencies – we can easily assess the prevalence/consistency of the training data, in contrast to structural dependencies.

We then substitute pairs of words from our dictionary into the spaces marked with ellipses, both with consistent and inconsistent spelling conventions. In other words, given the pair of dictionary entries *realize/realise* and *center/centre*, we use the template above to generate the four test sentences:

- (2) a. US/US: *My preferred words are **realize**, **center**, and tree.*
 b. US/UK: *My preferred words are **realize**, **centre**, and tree.*
 c. UK/US: *My preferred words are **realise**, **center**, and tree.*
 d. UK/UK: *My preferred words are **realise**, **centre**, and tree.*

We use T5 to score the probability of generating the second bolded word, as shown in Example (2), given the first.

In the above template, the two words are adjacent in the string. We also include a non-adjacent condition, which augments the templates by adding ten variety-neutral tokens between the bold-face words. For the above sample, the non-adjacent variant would be:

- (3) *My preferred words are ..., flower, interesting, jump, ponderous, sky, skipping, desk, small, ladder, lovely, ..., and tree.*

Since T5 is a seq2seq model trained on a span-corruption objective, we present a prompt that includes a priming word and a blank span token representing the second word:

- (4) My preferred words are **flavour**, <BLANK-SPAN-1>, and tree

The decoder then scores an output string that replaces the blank, but represents the known inputs with span markers instead:

- (5) <INPUT-SPAN-1> **harbour** <INPUT=SPAN-2>

Thus we are effectively computing the probability that the blank span will be filled with a particular word (with a US or UK spelling), given the visible input sentence (which contains a US or UK primer) — $P(\text{“harbour”} \mid \text{“My preferred words are flavour, ..., and tree.”})$.

We report a few different measures to give a picture of how strongly each model prefers spelling consistency: mean conditional probabilities, prediction accuracy and mutual information. We then

Condition	Word 1	T5		T5+FT		C4	
		Word 2		Word 2		Word 2	
		US	UK	US	UK	US	UK
Adjacent	US	0.86	0.14	0.66	0.34	0.91	0.09
	UK	0.39	0.61	0.44	0.56	0.38	0.62
Non-adjacent	US	0.83	0.17	0.69	0.31	0.93	0.07
	UK	0.48	0.52	0.43	0.57	0.27	0.73

Table 2: Conditional probability of Word 2, given a template with Word 1, given by T5 (no finetuning) and T5+FT (finetuned on synthetic balanced BNC data). For each instance, the probability has been normalized over each condition (corresponding to each row for the model). We also present the conditional probabilities from pairs found in the training corpus C4.

examine behavior with nonce words.

5.1 Measure 1: conditional probability tables

The first measure we use to show the preferences of each model is a 2x2 table of the conditional probability of the second probe word, given the first. For ease of interpretation, we normalize the conditional probabilities for each conditioning word as though the two alternative second words (US and UK) are the only possibilities, i.e., the two conditional probabilities are made to sum to 1. That is, $P(UK|US) + P(US|US) = 1$ and $P(US|UK) + P(UK|UK) = 1$ for each example. These conditional probabilities are then averaged over the whole test corpus (16028 word pairs replicated across 29 template sentences¹⁰ for a total of 464812 samples) for both the adjacent and non-adjacent conditions. Table 2 presents these mean conditional probabilities for base T5 and T5 finetuned (TF+FT) on a synthetic balanced corpus derived from the BNC (see §5.2), alongside conditional probabilities calculated from the pairs extracted for the analysis in Table 1 from their training corpus (C4), under the same adjacent and non-adjacent conditions.¹¹

As can be seen from these results, T5 shows a preference for spelling consistency in both the adjacent and non-adjacent conditions — probabilities for both the consistent US and consistent UK conditions are higher than the probabilities for the respective inconsistent conditions. The differences are notably larger in the adjacent conditions than the non-adjacent conditions, indicating that the preference for spelling consistency attenuates somewhat

¹⁰For information on the variance across prompts, see Appendix A.

¹¹The conditional probabilities from C4 are simply the probability that Word 2 is from the UK or US class given the class of Word 1, with extracted pairs split by whether the words were adjacent or not in the string. Adjacent pairs account for roughly 1% of all pairs in the corpus.

over longer strings. The model also shows a preference for US forms overall, assigning a higher probability to a US form after a UK form than to a UK form after a US form. This is likely due to US forms being over-represented in the training data, leading to high prior probability.

Comparing the model and corpus columns in Table 2, the degree of consistency preference displayed by T5 in the adjacent condition is actually very similar to the consistency levels in the C4 training corpus (similarly replicating the bias for US forms). However, C4 is much more consistent in the non-adjacent condition than T5, indicating that the model is failing to capture some long-distance dependencies.

5.2 Finetuning on synthetic data

Finding naturally occurring English text using perfectly consistent spelling conventions of sufficient size to help improve a model’s consistency may be difficult, given the results presented in Table 1. It would be useful, however, to determine if T5 could be finetuned with some resource to exhibit better spelling consistency. To that end, we created a synthetic version of the BNC, which was changed to exhibit perfect consistency of British and American spelling conventions for the words in our lexicon.

This synthetic BNC corpus was produced as follows. Using our list of spelling variants, we identified strings in the corpus that contained an instance of either the American or British spelling. We then produced a synthetic consistent American spelling version of these strings by using the American spelling of all of the words, along with a synthetic consistent British spelling version of these strings by using the British spelling of all of the words. The resulting corpus is thus balanced between American and British spelling for these 1706 words, and every sentence is consistent in using one convention or the other. In total, the syn-

Condition	Word 1 = US		Word 1 = UK	
	T5	T5+FT	T5	T5+FT
Adjacent	92.2	71.1	65.1	63.4
Non-adjacent	88.7	77.7	54.3	63.2

Table 3: Percent of test set examples for which each model prefers consistent over inconsistent spelling.

thetic corpus contains 954238 sentences,¹² equally split between US and UK spelling conventions. A small random subset of 2560 sentences was reserved for validation, and T5 was finetuned on the rest. Finetuning used the same span-filling masked LM task used for pretraining, with dropout set to 0.1, and the loss normalizing factor set to 233472 as suggested in the T5 documentation. Fine-tuning started at the default T5-large checkpoint, which represents 1000700 steps, and proceeded another 99300 steps at a batch size of 128.

As seen in Table 2, finetuning on this synthetic corpus does not appear to improve overall spelling consistency – quite the opposite. However, it does have at least two interesting effects. First, as might be expected, the overwhelming preference for US English shown by base T5 is reduced. Furthermore, the finetuned model is better able to retain long-distance information — there is no dropoff in consistency between the adjacent and non-adjacent conditions as seen for T5 without finetuning.

5.3 Measure 2: prediction accuracy

While the conditional probabilities in Table 2 show the overall preferences of the models over the test set, we also want a measure that captures how often the LLMs assign consistent pairs a higher probability than inconsistent pairs. In Table 3 we show the percentage of the test set examples for which each model predicted consistency over inconsistency. The results show a similar pattern as the conditional probability measures in Table 2. Again, finetuning lowers overall consistency, but results in less drop-off in non-adjacent vs. adjacent conditions.

5.4 Measure 3: mutual information

We also calculated the average mutual information (MI) across all prompt/target pairs in order to measure the strength of association between spelling conventions in both words. For each pair,

¹²In our testing, this was not enough data to reliably train a T5-large LLM from scratch.

Condition	T5	T5+FT
Adjacent	0.0048	0.0017
Non-adjacent	0.0044	0.0015

Table 4: Average mutual information in the adjacent and non-adjacent conditions.

we calculate four joint probabilities — $P(\text{US}, \text{US})$, $P(\text{US}, \text{UK})$, $P(\text{UK}, \text{US})$, $p(\text{UK}, \text{UK})$. We assume these four probabilities make up the entire universe with respect to a particular prompt/target pair, and normalize them so they sum to 1. This also allows us to easily calculate marginal probabilities simply by adding the appropriate joint probabilities – e.g., $P(\text{US prompt}) = P(\text{US}, \text{US}) + P(\text{US}, \text{UK})$. To calculate MI, we use a formula based on the log-likelihood ratio calculation in Moore (2004), but equivalent to the standard formulation for mutual information, where x, y are the two probe words:

$$\sum_{x \in \{\text{UK}, \text{US}\}, y \in \{\text{UK}, \text{US}\}} p(x, y) \log \frac{p(x, y)}{p(x)p(y)}$$

Since T5 is trained on masked token prediction, to measure the joint probability $p(x, y)$ of each pair of probe words x, y we can simply mask both probing tokens and measure the probability of generating both of them. That is, we present T5 with (6-a) and measure the probability of (6-b):

- (6) a. My preferred words are <BLANK-SPAN-1>, <BLANK-SPAN-2>, and tree.
 b. <INPUT-SPAN-1> flavour <INPUT-SPAN-2> harbour <INPUT-SPAN-3>

Table 4 presents these mutual information values. There doesn’t seem to be a significant difference between adjacent and non-adjacent conditions for either T5 variant, though finetuning does seem to cause an overall drop in MI, in line with the overall drop in consistency seen in the measures above.

5.5 Nonce forms

We want to determine if T5 assigns the probabilities reported above on the basis of dependencies between specific lexical items, or if it is learning sub-word generalizations. In other words, does the model learn that specific words like *flavour* and *realise* are more likely to co-occur than *flavour* and *realize*? Or does it learn that words containing *-our* are more likely to co-occur with words containing *-ise*? Since the model is trained using Sentence-

British	American	British	American
glavour	glavor	reptalise	reptalize
mentre	menter	amolirise	amolirize
unulise	unulize	sphectre	sphecter
malvour	malvor	imminise	imminize
larbour	larbor	voitre	voiter

Table 5: Nonce forms created by making one to three changes to words in the American-British dictionary.

		Word 2	
		US	UK
Word 1	US	0.68	0.32
	UK	0.56	0.44

Table 6: Conditional probability table for nonce forms given by T5. The table shows the conditional probability of Word 2 (which is a nonce form), given Word 1. For each instance, the probability has been normalized over each condition (i.e., each row in the table).

Piece tokenization (Kudo and Richardson, 2018), it is possible that it exploits sub-word features.

One way of testing if a model can use sub-word features is to create nonce words that contain British- or American-specific sub-words. If the model treats these as being British or American, this is an indication that the model is able to pick up on sub-word features.

We created a list of ten nonce forms by changing, adding, or removing one to three letters in existing words in our dictionary of American and British forms. These forms are shown in Table 5.

We use the same probing template and method as described above. For each probe, we use a real American or British word for the first probe word, and one of the nonce forms shown in Table 5 for the second. For this experiment we queried the base T5 model in the adjacent condition. The resulting conditional probability table is shown in Table 6.

Table 6 shows that the patterns shown in Section 5.1 above do not generalize very strongly to nonce forms. The probabilities assigned to US forms following UK forms are on average higher than UK forms following UK forms. However, the difference between these alternatives is attenuated compared to when Word 1 is a US form, indicating that (a) there is a heavy skew towards US spelling conditions in the training data; but (b) some sensitivity to the UK context, if not enough to counteract the high US form priors. This suggests that the results in Table 2 are to a large extent driven by lexical

dependencies rather than any lower-level spelling patterns encoded by wordpieces.

5.6 Autoregressive LLMs

Many commonly-used LLMs (including T5) are trained to predict words in the input that have been masked out. Another common class of LLMs, however, are trained to perform next-word prediction instead. To examine how such autoregressive architectures handle spelling consistency, we experiment with OpenAI’s GPT2 (Radford et al., 2019), which has a readily available open-source implementation through HuggingFace.¹³

As GPT2 is purely autoregressive, we cannot compute the probability that a particular probe word will fill a masked sentence span as easily as we could with T5. We can only efficiently compute the probability of a suffix given a prefix. Given this caveat, we have at least two options for assigning conditional probability scores, neither of which should be treated as exactly comparable to the T5 scores above. First, we can count only the logits corresponding to the target word:

$P(\text{“harbour”} \mid \text{“My preferred words are flavour,”})$. This local score ignores any words in the template occurring after the target word. Second, we can compute from the start of the target to the end of the sentence: $P(\text{“harbour, and tree”} \mid \text{“My preferred words are flavour,”})$, which accounts for the post-target suffix of the sentence.

Tables 7 and 8 show results for both of these methods for calculating the conditional probability, compiled in the same way as the T5 results in Tables 2 and 3. Table 7 also includes the conditional probabilities from GPT2’s training corpus, OWT. We see that GPT2 shows a similar preference for consistency as T5, but only very locally. There is a large drop-off in preference for consistency when moving from adjacent to non-adjacent conditions, or when including the completion of the sentence in the calculation. For UK English in particular, any preference for consistency completely disappears beyond the immediate vicinity of the priming word, and the model returns to chance performance on the task.

6 Further analysis of corpora

We now return to a slightly more detailed examination of two of the corpora presented in Table 1,

¹³<https://huggingface.co/gpt2>

Condition	Word 1	GPT2 (tgt only)		GPT2 (to EOS)		OWT	
		Word 2		Word 2		Word 2	
		US	UK	US	UK	US	UK
Adjacent	US	0.87	0.13	0.69	0.31	0.95	0.05
	UK	0.36	0.64	0.51	0.49	0.34	0.66
Non-adjacent	US	0.83	0.17	0.66	0.33	0.95	0.05
	UK	0.49	0.51	0.54	0.46	0.28	0.72

Table 7: Conditional probability of Word 2, given a template with Word 1, given by GPT2 scored until the end of the target word only (tgt only) and scored until the end of the sentence (to EOS). We also present the conditional probabilities from pairs found in the training corpus, OWT.

Condition	Word 1 = US		Word 1 = UK	
	GPT2 target	GPT2 EOS	GPT2 target	GPT2 EOS
Adjacent	94.2	70.1	70.8	49.4
Non-adjacent	92.5	67.5	54.6	45.1

Table 8: Percent of test set examples for which each GPT2 scoring variant prefers consistent over inconsistent spelling.

English Wikipedia and the British National Corpus, both of which had relatively high levels of mismatch compared to the other corpora.

Wikipedia is an interesting case, since the documents are collectively edited by potentially a large number of contributors, which may lead to higher expected mismatch than in other corpora. For example, one version of the article on *air lock* used both US-spelling of the word *vapor* and the UK-spelling (*vapour*). This is explained via three versions of the introductory sentence to the page, shown in Table 11 in Appendix B, where the two spellings are added to the sentence at different times, years apart.

The amount of mismatch in the British National Corpus is perhaps more surprising, given the provenance of the materials and intent of the collection. However the diversity of sources, which include things such as journal articles and edited volumes, likely leads to similar issues to those found in Wikipedia, along with simple human error and/or inconsistency. Table 12 in Appendix B presents a few examples of sentences with words from both spelling conventions, with American *-ize* spellings mixed with British *-ise* or *-our* versions.

7 Conclusion and Future Work

We have presented results showing that T5 does tend towards consistency in spelling, but not to the degree that could be relied upon should such

consistency be desired in generated text. We show that this general preference for consistency reflects the data that the model is trained on, which also is mostly consistent, but with a significant proportion of exceptions. The model’s behavior is also shown to be affected by the relative frequency of language varieties in the training data. We took advantage of the explicit and surface-accessible nature of these dependencies to attribute some model performance to the training data, while also demonstrating that modeling improvements should be possible, since the training data itself is substantially more consistent than the models.

These results suggest several possible avenues for future work. First, methods for addressing bias in training data should yield improvements for British spelling consistency in these models. We also intend to extend these results to languages other than English and investigate how spelling variation in other language situations is learned by LLMs. Some of the methods we used here rely on the fact that English spelling variation is quite thoroughly catalogued. Extending this work to less-documented cases of language variation will require us to either (1) collect data about spelling variation from language informants or data, or (2) develop methods that require less prior knowledge. In the interest of finding methods that are extensible to the greatest number of cases, we intend to pursue path (2), working on methods to mine information about language variation from large corpora and LLMs that have been trained on them.

Acknowledgements

Thanks to Alexander Gutkin, Shankar Kumar, Arya McCarthy and Richard Sproat for useful discussion and comments, and to the anonymous reviewers for helpful suggestions.

Limitations

Our work is focused on just a single case study of spelling variation. As detailed in Section 2, English is a good candidate for a case study for several reasons, but it would be beneficial to extend this work to other language situations.

Another limitation was our choice to focus on already existing pre-trained models, rather than directly controlling the training data that is input to each model. This means some of the conclusions about the connection between training data and outcome are tentative, pending experimental confirmation.

Ethics Statement

This work does not propose a new model or dataset, but rather probes the behavior of existing models. Thus novel ethical considerations about model behavior and dataset contents are not directly raised by this work. While not explicitly focused on ethical considerations, this paper’s methods hopefully contribute to better understanding model behavior, and could be used to understand the ways in which large language models treat underrepresented and marginalized language varieties.

Abstract

Usage-based theories of language acquisition have extensively documented the processes by which children acquire language through communicative interaction. Notably, Tomasello (2003) distinguishes two main cognitive capacities that underlie human language acquisition: intention reading and pattern finding. Intention reading is the process by which children try to continuously reconstruct the intended meaning of their interlocutors. Pattern finding refers to the process that allows them to distil linguistic schemata from multiple communicative interactions. Even though the fields of cognitive science and psycholinguistics have studied these processes in depth, no faithful computational operationalisations of these mechanisms through which children learn language exist to date. The research on which we report in this paper aims to fill part of this void by introducing a computational operationalisation of syntactico-semantic pattern finding. Concretely, we present a methodology for learning grammars based on similarities and differences in the form and meaning of linguistic observations alone. Our methodology is able to learn compositional lexical and item-based constructions of variable extent and degree of abstraction, along with a network of emergent syntactic categories. We evaluate our methodology on the CLEVR benchmark dataset and show that the methodology allows for fast, incremental and effective learning. The constructions and categorial network that result from the learning process are fully transparent and bidirectional, facilitating both language comprehension and production. Theoretically, our model provides computational evidence for the learnability of usage-based constructionist theories of language acquisition. Practically, the techniques that we present facilitate the learning of computationally tractable, usage-based construction grammars, which are applicable for natural language understanding and production tasks.

1 Introduction

Usage-based theories of language acquisition argue that the ability of children to learn language is based on two general cognitive capacities: *intention reading* and *pattern finding* (Tomasello, 2003, 2009). Intention reading refers to the capacity of children to understand the communicative intentions of their interlocutors. Pattern finding refers to the ability to recognise similarities and differences in sensory-motor experiences, and to use this ability for categorisation and schema formation (Tomasello, 2003, p. 3–4). Pattern finding thus provides mechanisms for generalising across different communicative interactions, thereby constructing abstract schemata that represent the linguistic knowledge of a language user. In the context of language acquisition, intention reading and pattern finding are two key cognitive capacities that are highly complementary. Intention reading allows a language learner to reconstruct the meaning of an utterance that they observe during a communicative interaction. Pattern finding then provides the mechanisms to learn a grammar based on the combination of these observed utterances and their reconstructed meanings.

There exists an impressive body of theoretical and empirical evidence for both intention reading (Bruner, 1983; Sperber and Wilson, 1986; Meltzoff, 1995; Nelson, 1998) and pattern finding (Goldberg, 1995; Croft, 2000; Diessel, 2004; Goldberg, 2006). However, no comprehensive mechanistic models that provide a faithful operationalisation of either of these cognitive processes exist to date. In this paper, we aim to fill part of this void by presenting a computational operationalisation of pattern finding mechanisms that can bootstrap a grammar based on a set of semantically annotated utterances alone. As such, we assume that the outcome of the intention reading process is given, hence the availability

of the utterances’ semantic representations, but that neither a segmentation of the utterances nor any pre-existing morpho-syntactic or other grammatical information can be used. For a computational model that operationalises the intention reading process, and that integrates it with the pattern finding mechanisms introduced in this paper, we refer the interested reader to [Nevens et al. \(2022\)](#).

A validation of our methodology on the CLEVR benchmark dataset for visual question answering ([Johnson et al., 2017](#)) shows that it allows for fast, incremental and effective grammar learning. The result of this learning process is a fully-operational, productive construction grammar that can be used for both language comprehension, i.e. mapping from utterances to their meaning representation, and language production, i.e. mapping from a meaning representation to an utterance.

The scientific contribution of this paper is twofold. On the one hand, it provides computational evidence for the cognitive plausibility of usage-based theories of language acquisition by introducing a mechanistic model of the acquisition of construction grammars from scratch. On the other hand, the techniques that we present pave the way for learning computationally tractable, large-scale, usage-based construction grammars that facilitate both language comprehension and production. Apart from their theoretical importance, such grammars are also highly valuable for a large range of application domains, including intelligent conversational agents ([Verheyen et al., 2022](#)) and the semantic analysis of discourse ([Willaert et al., 2020](#); [Beuls et al., 2021](#)).

The remainder of this paper is structured as follows. Section 2 presents the dataset, task and learning problem that we address. Section 3 introduces our novel methodology for learning construction grammars. Section 4 presents the evaluation results. Related work is discussed in Section 5. A concluding discussion is provided in Section 6.

2 Data

There are two main requirements for datasets to be compatible with the methodology that we present in this paper. First of all, they need to consist of utterances that are annotated with a representation of their meaning. Second, they need to be large enough so that they contain enough utterances that are similar to each other, but not equal, in terms of either form or meaning. The availability of ex-

emplars that are sufficiently close to each other is a necessary precondition for any generalisation process and is fully consistent with the prevailing hypotheses of how children acquire language ([Tomasello, 2003](#)). The exact required size of a dataset is as a consequence directly related to the variety and the degree of complexity of the utterances and meaning representations that it contains.

In this paper, we present and validate our methodology using the CLEVR dataset for visual question answering ([Johnson et al., 2017](#)). The utterances in the dataset are semantically annotated and the dataset contains ample examples of utterance-meaning pairs that are similar but not equal to each other. The utterances are English questions about images of scenes depicting different configurations of geometrical figures. Each question is annotated with a semantic representation that captures the logical meaning that underlies it. An example of such a scene, a question and its semantic representation is shown in Figure 1.

The semantic representation in Figure 1 takes the form of a set of predicates that share arguments with each other. In the figure, the predicates are drawn in the form of a network, based on the variables that they share. The meaning representation of a question can naturally be represented as a query, i.e. a series of steps that need to be taken in order to answer the question. Each predicate represents a step in this reasoning process, and intuitively corresponds to an atomic cognitive operation that a human or machine can perform. In the case of the example utterance ‘*How many rubber spheres are there?*’, the reasoning process consists of four main steps. The first predicate, GET-CONTEXT, binds the image to the variable ‘?source’. Then, the FILTER predicate filters the image for instantiations of the concept of SPHERE. The result of this filtering operation, i.e. the set of all spheres that are in the image, is bound to the variable ‘?spheres’. This set of spheres is subsequently filtered by another FILTER predicate for instantiations of the concept of RUBBER. The resulting set of rubber spheres is bound to the variable ‘?rubber-spheres’. Finally, the set of rubber spheres is counted by the COUNT predicate and the result is bound to the variable ‘?nr-of-rubber-spheres’. The meaning of the question ‘*How many rubber spheres are there?*’ corresponds thus informally to filtering an image for spheres, filtering the spheres for rubber objects and counting the result of this

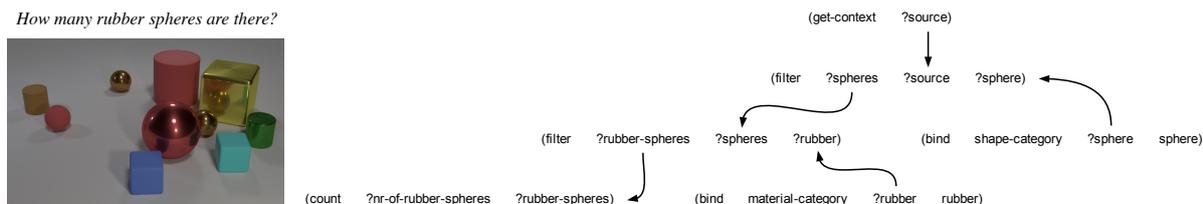

Figure 1: Example scene, question, and procedural semantic representation from the CLEVR dataset.

last operation. Such meaning representations are called *procedural semantic representations* as the representations themselves are at the same time executable procedures (Winograd, 1972; Johnson-Laird, 1977). Our methodology handles procedural semantic representations without problems, but is in no way restricted to it. It can handle any semantic representation, as long as it embraces some notion of compositionality and can be expressed as a set of predicates. Examples of other compatible semantic representations include abstract meaning representation (Banarescu et al., 2013), PropBank frames (Palmer et al., 2005) and the lambda calculus (Church, 1932; Montague, 1974).

The CLEVR dataset consists of three splits: a training split of 70,000 images and 699,989 questions, a validation split of 15,000 images and 149,991 questions, and a test split of 15,000 images and 149,988 questions. The questions in the training and validation splits come with semantic annotations, whereas the test set does not. As we require these annotations in order to evaluate our model, we use the training split of the CLEVR dataset as training set and the validation split as test set. The question-annotation pairs embrace various aspects of reasoning, including attribute identification (*‘There is a large cube; what is its color?’*), counting (*‘How many green spheres are there?’*), comparison (*‘Are there an equal number of large cubes and small things?’*), spatial relationships (*‘What size is the cylinder that is right of the yellow shiny thing that is left of the cube?’*) and logical operations (*‘How many objects are either red cubes or yellow cylinders?’*). For the purposes of this paper, we have selected the subset of CLEVR questions that do not involve comparison, spatial relationships or logical operations. The main reason for this is that these are complex cognitive operations that often correspond to long and complex utterances that are far removed from the linguistic expressions that children (or even other humans) are faced with. Our final training and test sets

consist of 47,134 questions and 10,044 questions respectively.

The learning task that we address consists in operationalising pattern finding mechanisms that facilitate the learning of a bidirectional construction grammar. The grammar should be able to map between the CLEVR utterances and their semantic representation, both in the comprehension (form to meaning representation) and the production (meaning representation to form) direction.

3 Methodology

The input to the learning process consists of utterances that are annotated with a representation of their meaning. The output of the learning process should consist in form-meaning mappings (constructions) that can be used for comprehending and producing utterances. The form-meaning mappings are represented in, and processed using, Fluid Construction Grammar (Steels, 2011; Van Eecke and Beuls, 2017; van Trijp et al., 2022).

3.1 Holophrase Constructions

Let us for a moment take the perspective of the learning algorithm. At the beginning of the learning process, the construction inventory is empty and the first utterance-meaning pair from the corpus comes in. At this point, the only thing that the learning algorithm can do is to store an exact mapping between the observed form and its meaning. Such a holistic mapping corresponds to a holophrase construction and is usable as such, albeit only for comprehending and producing the exact same utterance as the one that was observed. In order to use such a construction in the comprehension direction, it suffices to match the form side of the construction with an utterance and return the meaning side of the construction if the matching process succeeded. In order to use the same construction in the production direction, the meaning side of the construction must be matched with a semantic network and the form side must be returned.

When a next observation comes in, the learning algorithm first checks whether it is already covered by constructions that have been acquired previously. When this is the case, the constructions that are involved in the successful comprehension and production of the observation are reinforced by incrementing their entrenchment score. If the observation is not covered, the algorithm checks whether there are any generalisations that can be made based on the combination of the novel observation and any previously acquired constructions. It is these generalisation mechanisms that embody Tomasello (2003)'s pattern finding capacity and are thereby at the core of the construction learning process. We have identified three classes of mechanisms that facilitate the learning of general constructions by algorithmically reasoning over similarities and differences between existing constructions and novel observations.

3.2 Generalising over Holophrase Constructions

The first class of mechanisms facilitates the generalisation of holophrase constructions with respect to novel observations. These mechanisms can learn item-based constructions that capture the similarities between a novel observation and an existing holophrase construction that was learnt based on a similar, but not equal, observation. These item-based constructions abstract away from the differences between the observation and the holophrase construction.

For example, imagine that a holophrase construction has already been learnt based on the observation of the utterance *'How many rubber spheres are there?'* and the semantic network shown in Figure 1. Now, a novel utterance *'How many rubber cubes are there?'* is observed, along with a very similar meaning network in which the predicate '(bind shape-category ?cube cube)' appears at the place of '(bind shape-category ?sphere sphere)'. The generalisation mechanisms compute the similarities and differences between the construction and the observation in terms of both form and meaning, and make a new item-based construction that maps between the utterance *'How many rubber ?X are there?'* and the semantic network from Figure 1 in which the non-overlapping predicate has been replaced by a variable. At the same time, two new lexical constructions are created, which capture the differences between the observation and the

original holophrase construction. In our example, these will be a construction that maps between the utterance *'cubes'* and the meaning representation '(bind shape-category ?cube cube)' and a construction that maps between the utterance *'spheres'* and the meaning representation '(bind shape-category ?sphere sphere)'. Finally, categorial links are made between the ?X slot in the item-based construction and the new lexical constructions. These categorial links capture that *'cubes'* and *'spheres'* can both appear in the ?X slot of the construction for *'How many rubber ?X are there?'*. A schematic representation of this learning process is shown in Figure 2.

There are three different scenarios in which mechanisms of this class are active. The first scenario concerns utterances which extend holophrases that are already known. An example would be the generalisation of *'Are there any cylinders?'* to *'Are there any red cylinders?'*. In this case, an item-based construction *'Are there any ?X cylinders?'* is learnt, along with a lexical construction for *'red'* and a categorial link between the lexical construction and the open slot in the item-based construction. The second scenario concerns utterances which reduce known holophrases. An example would be the reduction of *'What is the size of the metal block?'* to *'What is the size of the block?'*. In this case, an item-based construction for *'What is the size of the ?X block?'* is learnt, along with a holophrase construction for *'What is the size of the block?'*, a lexical construction for *'metal'*, and a categorial link between the slot in the item-based construction and the lexical construction. The final scenario concerns utterances which are not a mere extension or reduction of each other, but contain different formal and/or semantic material. An example would be the utterances *'How many rubber spheres are there?'* and *'How many rubber cubes are there?'* discussed above, where a holophrase construction for *'How many rubber spheres are there?'* is already in place. An item-based construction for *'How many rubber ?X are there?'* is learnt along with a lexical construction for *'cubes'* and a categorial link between the open slot in the item-based construction and the new lexical construction. Additionally, a second lexical construction for *'spheres'* is learnt, along with a categorial link between the open slot in the item-based construction and the lexical construction for *'spheres'*.

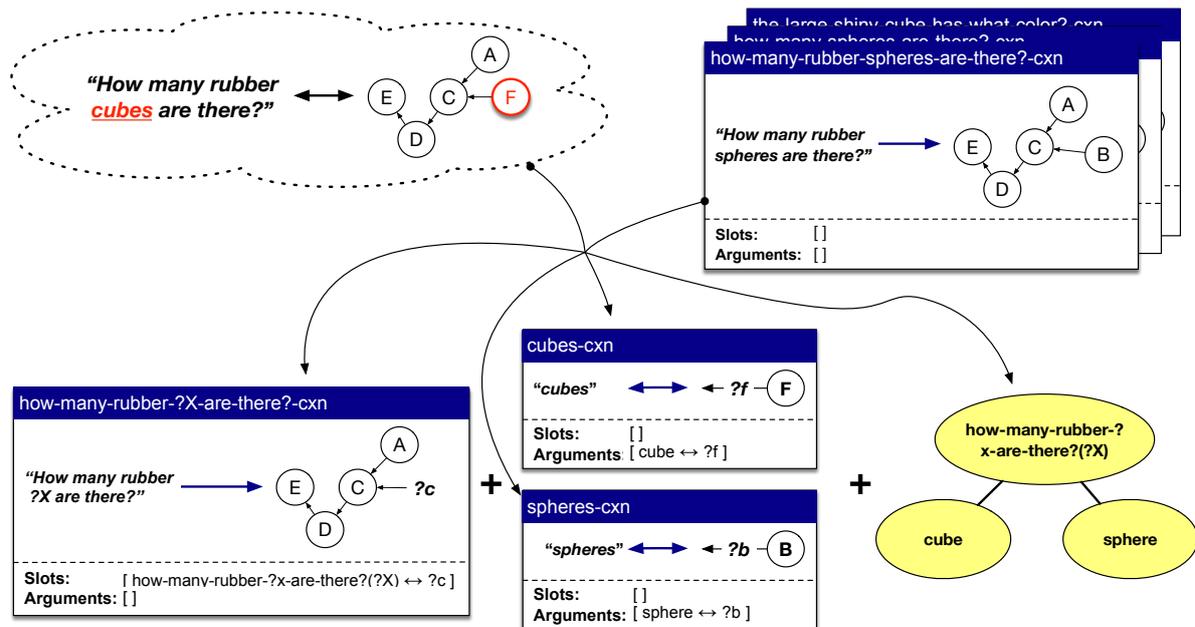

Figure 2: A schematic representation of a generalisation operator learning an item-based construction and two lexical constructions based on an existing holophrase construction and a novel observation.

3.3 Learning Constructions Based on a Partial Analysis

The second class of mechanisms is designed to handle cases where an observation could not completely be processed using the existing constructions of a grammar, but where a partial analysis could be provided. These mechanisms can then create novel constructions that can work together with existing constructions so that the entire observation can be processed successfully. They start thus from the combination of a novel observation on the one hand, and an item-based construction or one or more lexical constructions on the other. The second class of mechanisms is active in two different scenarios.

The first scenario concerns observations to which an item-based construction can apply, but where there remains material that is not covered by any of the existing constructions. An example would be an observation of ‘*What is the size of the green block?*’, where a construction for ‘*What is the size of the ?X block?*’ is already known, while no construction for ‘*green*’ has been learnt yet. The learning algorithm detects that some aspects of the form and the meaning of the observation are not covered by the existing item-based construction and it creates a novel lexical construction that maps between those parts of the form and meaning that were not covered. Additionally, a categorial link is made between the slot in the item-based construc-

tion and the lexical construction. In our example, this means that a lexical construction for ‘*green*’ is learnt, along with a categorial link between this construction and the ?X slot in the construction for ‘*What is the size of the ?X block?*’.

The second scenario concerns observations to which one or more lexical constructions can apply, but where these constructions do not fully cover the input. An example would be an observation of the utterance ‘*There is a big red cube; what is its material?*’, where lexical constructions for ‘*big*’, ‘*red*’, ‘*cube*’ and ‘*material*’ have already been learnt. The learning algorithm will then create a new item-based construction that incorporates all the form and meaning material that remains after the application of these lexical constructions, and that abstracts away from these constructions through the integration of four slots. The result is an item-based construction of the form ‘*There is a ?A ?B ?C; what is its ?D?*’ and four categorial links from the existing lexical constructions to the slots in the new item-based construction.

3.4 Extending the Categorial Network

The third class of mechanisms is designed to handle cases where all necessary constructions are already in place, but where they cannot combine due to the absence of certain links in the categorial network. An example would be the utterance ‘*How many things are there?*’ where an item-based construc-

tion covering ‘How many ?X are there?’ and a lexical construction covering ‘things’ already exist, but where there is no link in the categorial network between the lexical construction for ‘things’ and the ‘?X’ slot in the item-based construction. In such cases, the learning algorithm adds the missing link to the categorial network.

3.5 Entrenchment Scores

The constructions created by the learning operators have scores that reflect their entrenchment. During processing, higher scored constructions are preferred over lower scored ones. Upon creation, the score of a construction is set to 0.5. If used successfully, the score is increased by 0.1 and the score of other constructions of which the application would also have led to a solution is decreased by 0.3. The scores are bounded between 0 and 1. There is no built-in bias towards more general constructions. However, the fact that more general constructions are applicable in a broader range of situations and are therefore more frequently used, will, due to the dynamics of rewarding successful usage and punishing competitors, lead to higher entrenchment scores for more general constructions.

4 Experiments

This section presents a validation of our methodology for acquiring constructions on the CLEVR dataset discussed in Section 2. We first describe the experimental set-up (Section 4.1) and then present the evaluation results (Section 4.2).

4.1 Experimental Set-Up

The primary experiment consists in processing the 47,134 observations from our training set using the learning operators introduced above. For each experimental run, the observations are shuffled, so that any side-effects that might be caused by the order in which the observations are presented are levelled out. The learning operators are only active when an observation cannot be processed successfully by the constructions that have been learnt so far. Entrenchment scores are updated after each communicative interaction. The learning process is evaluated through four quantitative metrics: *communicative success*, *grammar size*, *number of constructions per type* and *active learning operators*. Communicative success is a binary measure computed by comparing the comprehended meaning with the gold standard annotation. In the graphs

below, communicative success and active learning operators are plotted using a sliding window of 50 observations.

For completeness, we also present a secondary experiment in which the grammar learnt on the training set is evaluated on the test set. Communicative success is here averaged over the whole test set, and grammar size and number of constructions per type do not change during evaluation.

The experimental results reported below are based on 10 independent experimental runs. The error bars that are plotted represent percentiles 5 and 95.

4.2 Results

The results obtained through the primary experiment are shown in Figures 3 to 5. Figure 3 displays the communicative success and grammar size metrics respectively on the left and right y-axis as a function of the number of observations (x-axis). We can see that the communicative success starts at 0, as the experiment starts with an empty inventory of constructions. The degree of communicative success rises rapidly, with more than 90% of the observations being successfully processed by the learned grammar after only 500 observations have been encountered. After 2000 observations, communicative success is already achieved in 99.6% of new observations.

The grammar size starts at 0 constructions and grows rapidly in the first phase of the experiment. After 500 observations, the grammar has reached its peak size of around 230 constructions that have some degree of entrenchment. This number then declines as a result of the rewarding and punishing of constructions. At the end of the learning process, the resulting grammar consists of 101.5 constructions on average.

An analysis of the types of constructions that are part of the learned construction inventory is provided in Figure 4. The results show that holophrase constructions flourish in the earliest phase of the experiment. In a second phase, item-based and lexical constructions take over the role of the holophrase constructions, with an abundance of item-based constructions being created. Over the course of the experiment, the linguistic inventory of the learner gradually reaches a stable state consisting of a limited number of entrenched lexical constructions and (more general) item-based constructions. At the end of the experiment, the grammar consists on av-

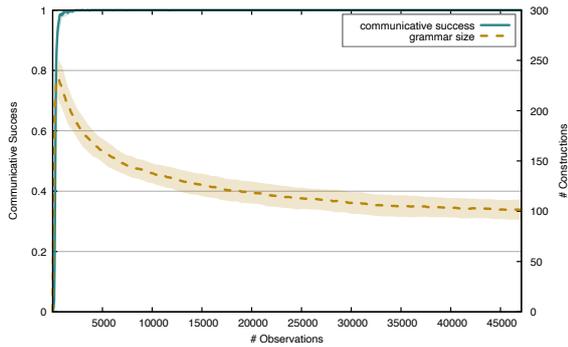

Figure 3: Evolution of communicative success (left y-axis) and grammar size (right y-axis) over time (full dataset).

erage of 10.2 holophrase constructions, 57.1 item-based constructions and 34.2 lexical constructions. These results show that the holophrase constructions have not yet completely disappeared after 47,134 observations and that the theoretical maximum of 35 lexical constructions was attained in 7 out of 10 experimental runs. Note that it is the dynamic evolution of the number of constructions per type over time that is important, rather than the absolute number of constructions at a given moment in time.

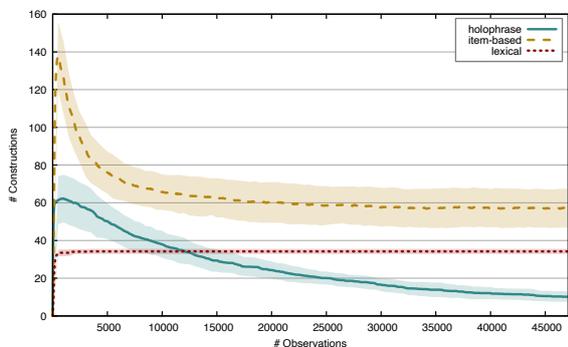

Figure 4: Evolution over time of the number of constructions per type with an entrenchment score > 0 (full dataset).

Figure 5 shows the active learning operators over time, zooming in on the first 1000 observations. In the beginning, only new holophrase constructions can be created. Then, operators of the first class can generalise over these holophrase constructions and create new item-based and lexical constructions. After that, operators of the second class take over and create constructions based on partial analyses. In the final phase of the experiment, mainly operators of the third class, which only create new categorial links, are active.

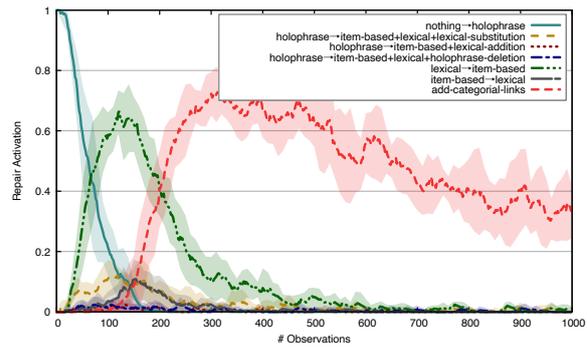

Figure 5: Active learning operators over time (first 1000 observations).

We finally conduct a secondary experiment, which consists in processing all observations from the test set using the grammars resulting from the different experimental runs of the primary experiment. The average communicative success amounts to a perfect 100% in both the comprehension and production direction. The average grammar size amounts to 101.5 constructions, of which 10.2 are holophrase constructions, 57.1 are item-based constructions and 34.2 are lexical constructions.

5 Related Work

Prior mechanistic models that operationalise the learning of constructions can be divided into two groups, based on the learning task that they address. A first class of models learns constructions paired with their meaning representation, either provided in the form of an annotated corpus (Dominey and Boucher, 2005; Chang, 2008; Abend et al., 2017) or obtained through task-oriented communicative interactions in a tutor-learner scenario (Gerasymova and Spranger, 2010; Beuls et al., 2010; Spranger and Steels, 2015). A second class of models, as introduced by Gaspers et al. (2011, 2016), is designed to learn form-meaning pairings under referential uncertainty. As such, the exact meaning representations of the input utterances are not provided to the learning algorithm, but grammars are learnt based on the combination of input utterances and situational context snippets. In these experiments, input utterances always correspond to a single term in the situational context. In general, both classes of models have explored interesting ideas on a rather small scale, either because they were limited to specific linguistic phenomena (Steels, 2004; Gerasymova and Spranger, 2010, 2012; Beuls et al., 2010; Spranger and Steels, 2015; Spranger, 2015, 2017;

Van Eecke and Beuls, 2017, 2018; Van Eecke, 2018), or because of the limited morpho-syntactic and semantic complexity of the input utterances (Dominey, 2005a,b, 2006; Chang, 2008; Gaspers et al., 2011; Gaspers and Cimiano, 2012, 2014; Gaspers et al., 2016; Abend et al., 2017). In all of the aforementioned work, either a segmentation of the input utterances, a lexicon or a set of predefined grammatical categories was provided. With the exception of the studies by Gaspers et al., the corpora that were used to learn and evaluate the models were not made available and were not described in sufficient detail to make reproduction and comparison feasible.

6 Discussion and Conclusion

The scientific contribution of the methodology and experiments presented in this paper is twofold. On the one hand, they provide computational evidence for the cognitive plausibility of constructivist theories of language acquisition. These theories, as most prominently put forward by Tomasello (2003), attribute the ability of children to acquire language to two main cognitive capacities: intention reading and pattern finding. Intention reading deals with reconstructing the intended meaning of observed utterances, while pattern finding implements generalisation processes that distil these reconstructed utterance-meaning pairs into abstract schemata embodying the linguistic knowledge of a language user. These schemata can then be used to fulfil the communicative function of language through the comprehension and production of natural language expressions. The methodology introduced in this paper presents a mechanistic model of the pattern finding capacity. Based on utterances paired with a representation of their meaning, the learning algorithm gradually builds up an inventory of concrete to abstract form-meaning mappings, called constructions, along with a network of emergent grammatical categories that captures how the constructions of the grammar can combine to collaboratively comprehend and produce utterances. The experiments show that a small number of general learning operators, which become active if an utterance cannot be successfully processed by the grammar learnt so far, effectively leads to learning dynamics that are similar to those described in the psycholinguistic literature (Pine and Lieven, 1997; Tomasello, 2003; Ambridge and Lieven, 2015). In the first phase of the learning

process, the learner acquires holistic mappings between utterances and their meaning representation. Soon after that, holophrase constructions are generalised to item-based constructions that integrate a variable slot. At the same time, this generalisation process leads to the emergence of slot-filling constructions, here called lexical constructions. Along with the item-based and lexical constructions, a network of grammatical categories emerges, capturing the distribution of construction slots and their observed fillers. In a third phase, more abstract item-based constructions emerge, with an increasingly large number of variable slots. In the final phase of the learning process, most constructions have already been acquired and most remaining impasses can be solved by adding new links to the categorial network. The learning dynamics are influenced by the degree of entrenchment of constructions. Constructions that are often successfully used become more entrenched, while their competitors are suppressed. As a result of this entrenchment process, the grammar reaches a stable state, while it remains adaptive to any changes in the discourse or environment. Similar dynamics have been observed in earlier experiments in the field of evolutionary linguistics, for instance in experiments on the emergence of compositionality in a population of autonomous agents (De Beule and Bergen, 2006; van Trijp, 2016).

On the other hand, the methodology and experiments presented in this paper pave the way for learning computationally tractable, large-scale, usage-based grammars that facilitate both language comprehension and production. The proposed learning algorithm supports online, interactive, incremental, transparent and data-efficient learning. The learner builds up its human-interpretable inventory of constructions and categories through the application of transparent syntactico-semantic generalisation processes. Already after a single observation, the fragment of linguistic knowledge acquired by the learner can be successfully used for language comprehension and production. As more and more utterance-meaning pairs are observed, the linguistic knowledge of the learner quickly expands and becomes better fit for achieving their communication goals. As a result of the dynamics of rewarding successful construction applications and punishing competing ones, the grammar of the learner remains ever-adaptive to any changes in the task or environment. Due to their online, interactive,

incremental, transparent and data-efficient nature, we strongly believe that the proposed mechanisms for learning computational construction grammars can serve as an excellent basis for implementing the language acquisition ability of truly intelligent agents.

Limitations

This paper has introduced a mechanistic model of the constructivist acquisition of language through syntactico-semantic pattern finding. Even though the results that we presented here proved to be promising and insightful, considerable challenges and limitations remain.

First of all, the learning operators that we present facilitate the learning of holistic, item-based and lexical constructions. At this point, the model does not include operators that give rise to constructions that capture more elaborate hierarchical patterns, including recursive patterns.

Second, the learning operators can adequately handle word order patterns, even non-contiguous ones. However, they provide no mechanisms to learn agreement patterns on an abstract level. As a consequence, different agreement patterns are captured in different constructions. This is a less-than-elegant solution, especially when applied to morphologically rich languages, as it can lead to a multiplication of the number of constructions.

Finally, the CLEVR dataset proved to be an excellent benchmark challenge for an initial validation of this novel methodology, as it consists of utterances with sufficient repetition, variation and overlap. It is however a synthetic dataset that does not reflect the richness of human language use. More research is needed before this methodology can be adequately applied to a broader range of linguistic resources, especially when it comes to finding generalisations over semantic structures.

Acknowledgements

The research reported on in this paper received funding from the imec's Smart Education research programme, with support from the Flemish government, the European Union's Horizon 2020 research and innovation programme under grant agreement no. 951846, and the Research Foundation Flanders (FWO) through a postdoctoral grant awarded to Paul Van Eecke (75929).

Abstract

The COVID-19 pandemic has made a huge global impact and cost millions of lives. As COVID-19 vaccines were rolled out, they were quickly met with widespread hesitancy. To address the concerns of hesitant people, we launched VIRA, a public dialogue system aimed at addressing questions and concerns surrounding the COVID-19 vaccines. Here, we release VIRADialogs, a dataset of over 8k dialogues conducted by actual users with VIRA, providing a unique real-world conversational dataset. In light of rapid changes in users' intents, due to updates in guidelines or in response to new information, we highlight the important task of intent discovery in this use-case. We introduce a novel automatic evaluation framework for intent discovery, leveraging the existing intent classifier of VIRA. We use this framework to report baseline intent-discovery results over VIRADialogs, that highlight the difficulty of this task.

1 Introduction

As COVID-19 vaccines became available in late 2020, they were met with widespread vaccine hesitancy (Goldstein et al., 2015; Sallam, 2021), a phenomena recognized as a top global concern by the World Health Organization (WHO) in 2019. To address such hesitancy, one needs accurate, reliable, and up to date information, constantly available to the general public.

In recent years, task-oriented Dialogue Systems (DSs) have become an integral part of our daily lives, covering domains such as banking, tourism, and government agencies (Androustopoulos et al., 2019).

Correspondingly, we introduced VIRA,¹ the Vaccine Information Resource Assistant – an informational DS that aims to engage with COVID-19 vaccination concerns and questions. VIRA is able

to respond to 181 different concerns, accumulated over the course of the pandemic. VIRA responses were written and vetted by leading medical and public health experts, relying on up-to-date facts and guidelines. An example of a dialog conducted with VIRA is presented in Table 1.

We refer to this list of concerns and questions as *intents*. This is a slightly modified definition of intents, which are usually general tasks or goals which the user tries to accomplish (Jurafsky and Martin, 2009). In VIRA the intents are phrased as complete sentences, e.g., “Is the vaccine safe?”, as opposed to a synthetic class name like “vaccine_safe”, and the goal of the intent classifier is to predict the correct intent, to which VIRA responds to the user with a pre-defined message.

Advancing DSs depends on the availability of conversational datasets on which models can be trained. In domains where fact-based information is a necessity, e.g., healthcare, curating such datasets is often challenging: users in a crowdsourcing setting may not share their authentic concerns, may not represent public opinion, or may even attempt trolling. In addition, creating responses by highly-trained individuals is a very demanding process (Liu et al., 2021). Furthermore, even if one has collected data from a real-world DS, there could be limitations for making such data public.

The availability of VIRA enabled us to collect dialogs with real-world users, following word-of-mouth or social media advertising, presumably conveying genuine interest or concerns related to the vaccines. VIRA was launched in July 2021 and over the course of 10 months it accumulated over 8k conversations. We refer to this collection of conversations as VIRADialogs and release it as part of this work.²

After deploying a DS in a real-world setting, users may introduce new intents, which are not

Side	Text	Intent
System	<i>Hey! Ask me your vaccine questions.</i>	
User	<i>Hi. Should I be concerned about side effects of the vaccine if I'm breastfeeding?</i>	Is breastfeeding safe with the vaccine
System	<i>Perhaps check this out: while trials did not include breastfeeding moms, COVID-19 vaccines are "non-replicating" vaccines. This type of vaccine poses no risk for breastfed infants, so COVID-19 vaccines are also safe when you're breastfeeding!</i>	

Table 1: An example of a dialog in VIRADialogs.

part of the system’s predefined intents (Grudin and Jacques, 2019). VIRA’s use case represents such an extreme example where users’ intents change rapidly due to updates in guidelines and protocols, or as a response to new information (e.g., the outbreak of novel variants). Hence, we needed to frequently update and expand the set of user intents. This makes VIRADialogs a unique resource for *Intent discovery* methods. These methods aim to reveal such new intents from conversational logs, trying to identify the most salient new intents, which can then be reviewed and added to the DS using a human-in-a-loop process.

Existing datasets for intent classification and discovery (e.g., Larson et al. (2019)) were collected, at least in part, by showing crowd annotators queries and asking them to provide rephrases. Thus, for each query, a similar number of rephrases is collected. VIRADialogs, on the other hand, comes from a real-world use-case, and thus presumably better reflects how people communicate; the real intent distribution; and how it evolves over time – an aspect which as far as we know, is not covered by any existing data.

To directly evaluate intent discovery methods, one would need to annotate each user utterance with its gold intent, and compare this intent with the prediction of each method.

While this annotation approach is typically more precise, it is far from trivial in our real-world use-case considering the size of VIRADialogs and the high number of intents involved. Moreover, as we are dealing with rapidly changing user intents in light of new information about the virus and new guidelines, the distribution of user intents over time is not uniform, which means that manual annotation – even for a test set – would require continuous annotation over the whole time period. This makes manual annotation quite challenging.

As a practical alternative, we propose a novel retrospective evaluation paradigm which leverages the existing intent classifier of VIRA. We assume that

this classifier, carefully developed over the entire relevant time period, covers most intents present in the data. Thus, we treat it as an Oracle to evaluate various intent discovery methods, independently in each month.

First, the Oracle is used to induce silver labels over the unlabeled user utterances. Next, to evaluate an intent discovery method, the same Oracle is used to classify intents predicted by this method to silver labels, enabling a fully automatic quantitative evaluation. We use this approach to evaluate various intent discovery methods on top of VIRADialogs and further share the code base to reproduce our experiments.³

To summarize, the contribution of this paper is three fold: i) We release VIRADialogs, a unique dataset of real-world human-machine conversations, reflecting COVID-19 vaccine hesitancy; ii) We propose and implement an automatic retrospective evaluation paradigm for intent discovery, relying on the availability of a high quality intent classifier; iii) We use our evaluation approach to report baseline performance of various intent discovery methods on top of VIRADialogs.

2 Related Work

Benchmark Datasets and COVID-19 DSs. Popular benchmark datasets for intent classification are also used to benchmark the task of intent discovery and were curated (at least in part) by asking crowd annotators to phrase intents suitable to a DS setting (e.g., Liu et al. (2019a); Larson et al. (2019)). Arora et al. (2020) introduce HINT3, a challenging benchmark whose test set comes from real chats in 3 domains. However, the test set contains less than 1,000 queries for each domain collected in a 15-day period, a relatively limited scope for intent discovery.

The pandemic outbreak led to the development of a few other DSs in this domain. Welch et al.

³<https://github.com/IBM/vira-intent-discovery>

(2020) introduce expressive interviewing – an interview style aiming to encourage users to express their thoughts and feelings by asking them questions about how COVID-19 has impacted their lives. Chalaguine and Hunter (2021) built and studied a DS specifically addressing COVID-19 vaccine hesitancy and showed that 20% of study participants changed their stance in favor of the vaccine after conversing with the system. While their motivation is similar to ours, the analyzed data is smaller and is coming from crowd annotators.

Intent Discovery Methods. Recent work by Rabinovich et al. (2022) introduced a fully unsupervised pipeline for detecting intents in unhandled DS logs. Utterances are encoded into vector representations, and a Radius-based Clustering (RBC) algorithm assigns each to an existing cluster, in case it surpasses a predefined similarity threshold; or use it to initiate a new cluster. The algorithm automatically selects the number of clusters, and does not enforce full partitioning of the underlying data, but rather enables outliers — instances that lay in isolation of discovered clusters. The paper suggests a method for selecting cluster representatives aimed at maintaining centrality and diversity.

Key Point Analysis (KPA) (Bar-Haim et al., 2020a,b, 2021a) proposes a framework that provides both textual and quantitative summary of the main points in a given data. KPA extracts the main points discussed in a collection of texts, and matches the input sentences to these key points. It has been shown to perform well on argumentative data, as well as in online surveys and on user reviews. To our knowledge, our work is the first to utilize KPA in the context of DSs.

3 The VIRA System

Users communicate with VIRA using either a web-based User Interface (UI)⁴ or a WhatsApp application. The general flow is that users enter free text expressing their questions and concerns about the vaccine, VIRA detects the intent within a pre-defined intent list, and in turn provides a suitable response, reviewed by medical experts. VIRA supports conversations in English.⁵ Below we describe VIRA’s main components.

⁴The UI is also embedded on the web pages of health departments, vaccine advocacy organizations, and health care facilities.

⁵A later version supported Spanish as well, however those conversations are left out of this work.

Profanity Classifier. We use a dictionary⁶ to identify utterances with suspected offensive language, to which VIRA presents a generic response.

Dialog-Act Classifier. We classify each user input to one of the supported dialog acts. For certain dialog acts, e.g., ‘Hi’, VIRA presents a generic response. Full details can be found in Appendix A.

Intent Classifier. Intents representing distinct vaccine concerns were carefully curated through various means: using a Twitter analysis, reviewing audience questions in Zoom-based public forums hosted by authors’ affiliated academic centers, and synthesizing web pages with frequently asked questions. The intents were defined also by taking into consideration the scientific knowledge towards the vaccine at that point. Over time, new concerns were identified by monitoring incoming queries to VIRA and eventually the list comprised of 181 intents, presented in Appendix G.

The requirement from VIRA was to provide specific answers to specific concerns, and general answers to general concerns – hence, “I am afraid the vaccine will change my DNA” and “I distrust this vaccine” required different answers, and thus were represented as separate intents, although the latter can be entailed from the former.

The intent classifier was trained on data collected from crowd annotators using the Appen platform.⁷ Annotators were presented with an intent and asked to express it in three different ways, as if conversing with a knowledgeable friend (see Section 6.1 for more details). The classifier’s top-ranked intent is selected for providing a response from the Response Database. If no intent passed a pre-defined threshold, a corresponding response is given.

Response Database. This database contains VIRA’s responses to intents. Each entry specifies multiple responses to a specific intent, to increase output diversity. The responses contain varying information and tone from which VIRA selects one randomly. The database was created and is maintained by experts in the field based on up-to-date facts and guidelines. All responses sought to minimize technical language and maintain brevity through a 280-character limit.

Feedback Mechanism. VIRA incorporates a feedback mechanism that enables users to correct the course of conversation. This feedback allows VIRA’s personnel to improve the system over time

(see more details in Appendix B).

All VIRA’s chats, including feedback selections and classifiers output, are recorded for off-line analysis, without storing identifiable information.

4 The VIRADialogs Dataset

VIRADialogs contains the interactions conducted with VIRA by actual users from July 2021 to May 2022. The full dialogues, as well as user feedback, predicted intents, dialog acts, and offensive language predictions are released to the research community. The data has been anonymized by masking locations, names, e-mails, phone numbers, and birth-dates, along with suspected offensive terms, using a range of regular expressions, the Profanity Classifier, and the spaCy Named Entity recognizer.⁸ In addition, we have excluded dialogues between 29-30, July 2021, in which VIRA was confronted with multiple chats containing offensive language, presumably from individuals who attempted to break the system. Stats of VIRADialogs are presented in Table 2.

5 Retrospective Intent Discovery Evaluation

An important contribution of this work is to show how to leverage an existing DS intent *classifier* – like the one described in Section 3, referred to as an *Oracle* – to automatically evaluate intent *discovery* methods over a collection of dialogs. An overview of the proposed approach is depicted in Figure 1. The underlying components are described below, using the following terminology:

ORACLE INTENTS: The intents supported by the Oracle. **SILVER LABELS:** Subset of ORACLE INTENTS, induced over a given data. **PREDICTED INTENTS:** Intents predicted and phrased by an intent discovery method. **PREDICTED ORACLE INTENTS:** Subset of PREDICTED INTENTS mapped by the Oracle to ORACLE INTENTS.

⁸<https://spacy.io/>

5.1 Inducing SILVER LABELS

Given a set of unlabeled user utterances from conversational logs we randomly split it to train and test sets. The train set is used to induce SILVER LABELS, while the test set is used for evaluation. The motivation of the train-test split is three-fold: (i) enabling to evaluate how consistent is the Oracle itself to ensure the emerging SILVER LABELS are representative of the entire data; (ii) preserving an option to evaluate supervised intent discovery methods in future work; (iii) using the Oracle test set results to estimate upper bound test performance.

We apply the Oracle to predict (at most) one intent for each utterance in the train set. Utterances on which the Oracle confidence was below a pre-specified threshold are placed in a *none* cluster. Since each utterance is mapped to one intent, we obtain clusters of utterances around ORACLE INTENTS. Next, we sort all clusters by their size, and define the top K ranked ones and their intent representatives as the SILVER LABELS, where ranking criteria can vary (see Section 6.2 for a concrete example).

5.2 Evaluation Method

5.2.1 Matching PREDICTED INTENTS to SILVER LABELS

PREDICTED INTENTS often cannot be matched directly to SILVER LABELS. E.g., an intent discovery method might output “I don’t want to get a booster shot”, whereas the corresponding intent in the SILVER LABELS would be “Will I need a booster shot?”. Assuming manual mapping is not feasible, we use the Oracle to map each of the PREDICTED INTENTS to – at most – one of the ORACLE INTENTS, resulting in a set of PREDICTED ORACLE INTENTS. Utterances of PREDICTED INTENTS which are not mapped due to low confidence of the Oracle are placed in a *none* cluster. Note, that in principle this set may contain ORACLE INTENTS that were not selected as SILVER LABELS.

5.2.2 Evaluation Measures

We consider two types of measures to evaluate intent discovery methods: (a) the similarity of PREDICTED INTENTS to SILVER LABELS; and (b) the similarity of cluster partitions generated on the test data by the Oracle and the evaluated method.

Intent Discovery Measures

We estimate the quality of PREDICTED INTENTS (PIs) using the PREDICTED ORACLE INTENTS

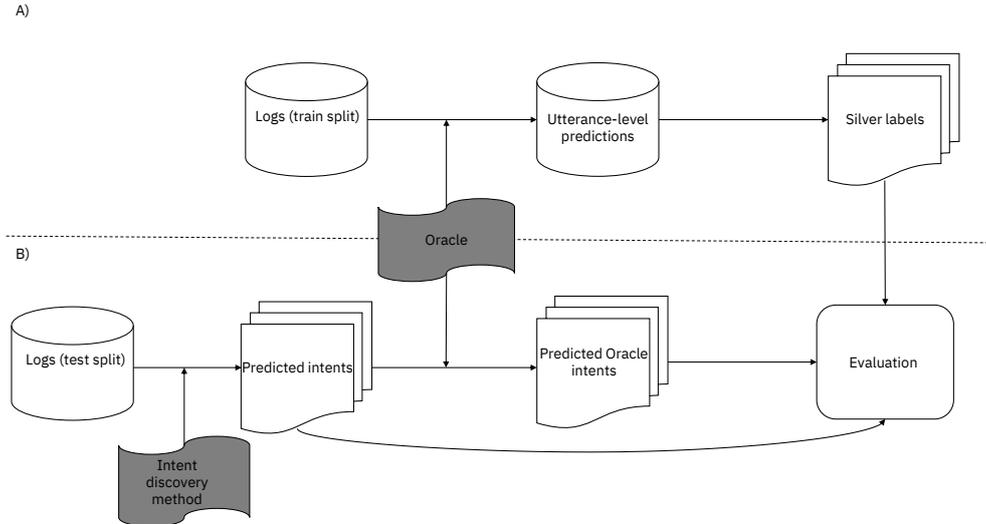

Figure 1: Overview of the evaluation pipeline.

(POIs) and SILVER LABELS (SLs) as follows:

Recall: Coverage of SILVER LABELS by method

$$\frac{|POIs| \cap |SLs|}{|SLs|}$$

Precision: Ratio of PREDICTED INTENTS mapped to SILVER LABELS

$$\frac{|POIs| \cap |SLs|}{|PIs|}$$

JS-distance: We place utterances of PREDICTED ORACLE INTENTS not in the SILVER LABELS in the *none* cluster. We normalize the sizes of the clusters induced by the SILVER LABELS and the PREDICTED ORACLE INTENTS— including the *none* cluster — into two probability distributions, and report their Jensen-Shannon divergence.

Intent Clusters’ Analysis

We compare the partitioning of the test data induced by the PREDICTED INTENTS and the Oracle using the following standard measures: **Adjusted Rand-Index (ARI):** The rand index corrected for chance (Vinh et al., 2010). **Adjusted Mutual-Information (AMI):** The mutual information corrected for chance (Meilă, 2007). **V-Measure:** The harmonic mean between homogeneity and completeness (Rosenberg and Hirschberg, 2007).

6 Experimental Setup

In this section we present a concrete implementation of the framework described in Section 5 using VIRA and VIRADialogs to automatically evaluate various unsupervised intent discovery methods.

6.1 The Oracle

For the Oracle we use VIRA’s intent classifier (Section 3), described below.

Data

For each intent amongst the final 181 intents covered by VIRA, we asked 18 Appen crowd annotators to contribute three different *intent expressions*, i.e., different phrasings of questions or comments by which they could have expressed the intent while chatting with a knowledgeable friend.⁹ Qualified annotators were paid on average 7.5-8\$ an hour.¹⁰ After manual cleaning we ended up with 7,990 expressions, between 20-100 for each intent.¹¹ We release this dataset as part of this work, contributing to the task of single-domain intent classification.¹²

Model and Training

We split the intent expressions associated with each intent to train (65%), dev (8%), and test (27%) sets, with 5,169, 664 and 2,139 examples, respectively, over which we fine-tuned RoBERTa-large (Liu et al., 2019b). Full model implementation de-

⁹Note that we collected data from crows annotators solely for training the intent model. VIRADialogs itself contains real interactions and is not crowd-sourced.

¹⁰For each annotator, we calculate the BLEU score of its expressions w.r.t the intent. Annotators with score < 0.07 are determined as qualified, aiming at promoting diversity.

¹¹The data also contains a small set of 324 intent expressions, extracted manually from VIRADialogs.

Table 3: # utterances in VIRADialogs splits for intent discovery evaluation.

tails and threshold tuning are in Appendix C. Note, when the confidence score of the top prediction was below a pre-specified threshold, the model does not predict any intent.

6.2 Inducing SILVER LABELS

We apply to VIRADialogs filters to reduce noise and irrelevant input.¹³ We split the remaining utterances into monthly intervals, resulting in 10 data folds, and subsequently evenly split the utterances in each fold to train and test (indifferent to which dialogue utterances came from).

To reduce noise in generating SILVER LABELS, we additionally filter from the train set utterances classified with a dialog act (e.g., ‘greeting’) or as offensive, as the ratio of intents related to COVID-19 vaccines in these utterances is much smaller.

We then apply the Oracle on each utterance in the train set, resulting in ORACLE INTENTS and corresponding clusters. We sort them based on their prevalence and define the top K as SILVER LABELS. In practice, we do this by accumulating the clusters until we reach a coverage of 80% (out of all texts on which the Oracle had a confident prediction) or that the number of utterances mapped to an intent is below 3 (removing a long tail of small clusters). The number of utterances and SILVER LABELS for each fold are reported in Table 3.

6.3 Intent Discovery Methods

6.3.1 Clustering Algorithms

We evaluate two clustering algorithms. Since one cannot assume that the number of SILVER LABELS is known *a priori*, we use \sqrt{N} as a simple

¹³We filter user feedback, utterances longer than 250 characters, contain at most one non-masked word, or less than 75% alpha-numeric characters.

heuristic to determine the number of clusters, including the *none* cluster, where N is the number of utterances being clustered. Short utterances, containing less than 5 recognized words, were placed in advance in the *none* cluster. Analysis takes a few minutes on CPU.

K-Means. We use the K-Means algorithm from the SciKit-Learn package (Pedregosa et al., 2011) with the default settings. Each utterance was represented using its Sentence-BERT representation (Reimers and Gurevych, 2019).

sequential Information Bottleneck (sIB). As a bag-of-words baseline, we use the sIB algorithm of Slonim et al. (2002).¹⁴ The algorithm uses as input the Term-Frequency vector representations and is executed with the default settings, after stop-word filtering and stemming.

Intent Extraction

We select a single user utterance per cluster to represent an intent, resulting with the list of PREDICTED INTENTS. The selection is based on a statistical analysis of n-grams in the data. For each cluster, we first find the n-grams that are significantly more common in this cluster compared to other clusters based on hyper-geometric test ($p = 0.05$). Then we select the user utterance in the cluster that includes the maximal number of significant n-grams found in that cluster.

6.3.2 End-to-End Methods

We evaluate two end-to-end methods with mostly default settings. These methods determine the number of clusters internally, and map utterances to a *none* cluster as they see fit. For comparison purposes, we take the top $\sqrt{N} - 1$ prevalent clusters for evaluation. The rest of the clusters are added to the *none* cluster.

Key Point Analysis (KPA). We use KPA as provided by the IBM Debater Academic Early Access Program (Bar-Haim et al., 2021b). The underlying model of KPA matches utterances with key point candidates, identified automatically. Adjustments for this task can be found in Appendix D. The service took about 3.5 hours to complete the analysis.

Radius-based Clustering (RBC). We approached the authors of Rabinovich et al. (2022) to produce the results for this evaluation. Adjustments for this task can be found in Appendix E. RBC took a few minutes to run on CPU.

Recall	Precision	f1	JS-distance
0.79(± 0.08)	0.8(± 0.08)	0.8(± 0.08)	0.16(± 0.04)

Table 4: Evaluation of the Oracle on VIRADialogs test sets (weighted-avg over the monthly intervals.)

7 Results and Discussion

7.1 The Oracle

We first establish the quality of VIRA’s intent classifier used as the Oracle in various ways.

Inference on Intent expressions test set. We evaluate the Oracle on the test set of the collected intent expressions, using the threshold tuned on the dev set (Section 6.1). The Oracle achieves a micro-averaged precision / recall / f1 of 0.85 / 0.74 / 0.79 on dev, and 0.88 / 0.77 / 0.82 on test.

Inducing SILVER LABELS and matching PREDICTED INTENTS. We manually evaluate the Oracle’s accuracy in (i) inducing SILVER LABELS (Section 5.1) and (ii) matching PREDICTED INTENTS to SILVER LABELS (Section 5.2.1).

For (i), we randomly sample 10 SILVER LABELS from the train set of each of the 10 folds. For each silver label we sample 2 utterances mapped to it ($200 < \text{utterance}, \text{SILVER LABELS} >$ pairs overall). For half of the pairs, we randomly replace the silver label with one of the other ORACLE INTENTS (thus, obtaining negative pairs). We asked 3 annotators to annotate whether a given pair of texts has a similar intent or meaning, and took the majority vote as the ground-truth (see more details in Appendix F). The accuracy of the Oracle on this data is 0.85.

For (ii), we randomly select from each fold and for each evaluated method 5 pairs of $< \text{PREDICTED INTENTS}, \text{PREDICTED ORACLE INTENTS} >$ where PREDICTED ORACLE INTENTS are part of the SILVER LABELS (200 pairs overall). We use the same annotation task as in (i). The accuracy of the Oracle on this data is 0.86.¹⁵

Consistency over VIRADialogs test. To recall, we evaluate methods on the *test* set w.r.t SILVER LABELS induced from the *train* set. Here, we would like to examine the consistency of the Oracle’s predictions between the sets which also implies the representativeness of the SILVER LABELS for the entire data. We do that by inferring the Ora-

¹⁵1. We note that on average for 24% of PREDICTED INTENTS the Oracle is not confident (covering 22% of the texts), and for an additional 18% the PREDICTED ORACLE INTENTS are not part of the SILVER LABELS. 2. For one of the methods there were less than 5 pairs, so the overall number of pairs is 199.

cle over the test set of each monthly fold to produce clusters around ORACLE INTENTS. We then rank them by prevalence and accumulate them to define the PREDICTED INTENTS (which are also trivially PREDICTED ORACLE INTENTS), as was done to induce SILVER LABELS on the train set. The results are presented in Table 4. The Oracle achieves a weighted-f1 of 0.795, demonstrating reasonable consistency between the train and test split in each fold. This also can be considered an upper limit of success for other methods.

Overall, the above evaluation has shown that the Oracle performs well in matching utterances and PREDICTED INTENTS to intents, and that SILVER LABELS are relatively representative.

7.2 Intent Discovery Methods

Results for the 4 methods we evaluate are presented in Table 5. RBC has the highest coverage uncovering 45% of the SILVER LABELS, and reaching an f1 of 0.51. These results also indicate the difficulty of this task, as the majority of SILVER LABELS remain undetected. Note that similar precision with worse recall, such as with K-Means compared to KPA, suggests more redundancy in the PREDICTED INTENTS of the former.

KPA is much better at the clustering measures, and is thus useful for finding good examples for each intent. This might be due to KPA’s matching engine, trained to match sentences with key points (similarly to intents in VIRA, key points are concise representations of main points in the data).

It should be noted that for simplicity we used “off-the-shelf” methods with minor adaptations, to resemble a real-world setting where a user would like to get a fast impression of how well such methods perform for a given use-case with minimal effort. In addition, we used a simple heuristic to determine the number of clusters. It is likely that with proper tuning of parameters, domain adaptation of underlying models, tuning of number of clusters, etc., the performance would have been higher.

7.3 Qualitative Analysis of Emerging Intents

The SILVER LABELS and PREDICTED ORACLE INTENTS cover varying issues, and so we sought to analyze some of the more high-profile ones in light of events that occurred in their context.

We selected two intents: i) *How effective is the vaccine against the Omicron variant*, coupled with the rise in Omicron-related cases in December

	Recall	Precision	f1	JS-distance	ARI	AMI	Clustering-f1	V-measure
sIB	0.39(± 0.09)	0.52(± 0.09)	0.44(± 0.09)	0.33(± 0.03)	0.05(± 0.03)	0.24(± 0.05)	0.07(± 0.04)	0.37(± 0.05)
K-Means	0.42(± 0.07)	0.57(± 0.08)	0.49(± 0.06)	0.34(± 0.03)	0.06(± 0.03)	0.32(± 0.06)	0.1(± 0.05)	0.43(± 0.05)
RBC	0.45 (± 0.11)	0.61 (± 0.11)	0.51 (± 0.11)	0.32 (± 0.04)	0.15(± 0.04)	0.28(± 0.05)	0.19(± 0.04)	0.39(± 0.04)
KPA	0.44(± 0.08)	0.57(± 0.09)	0.49(± 0.07)	0.32 (± 0.03)	0.24 (± 0.05)	0.38 (± 0.05)	0.3 (± 0.04)	0.48 (± 0.05)

Table 5: Evaluation of intent discovery methods on VIRADialogs. The numbers are a weighted-average over the monthly intervals. Best method for each metric is highlighted in bold. *Takeaway:* Methods are able to uncover up to 45% of the intents, demonstrating the difficulty of this task. RBC is able to uncover more intents and at better precision. KPA is much better at uncovering correct placements of utterances within clusters.

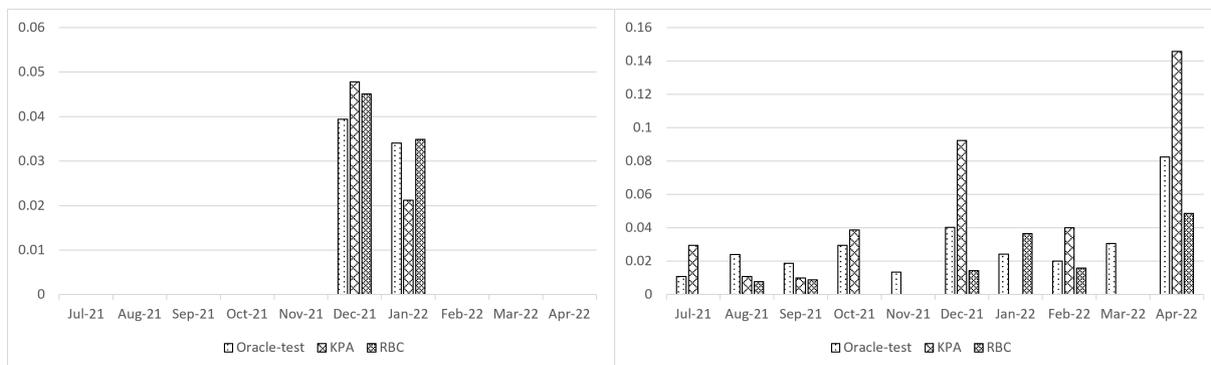

Figure 2: Cluster ratios of *How effective is the vaccine against the Omicron variant* (left); *Will I need a booster shot* (right). *Takeaway:* Predictions of methods on VIRADialogs correlate well with real-world developments.

2021;¹⁶ and ii) *Will I need a booster shot*, coupled with booster recommendations in late November 2021¹⁷ and March 2022.¹⁸ In Figure 2, we plotted the cluster ratio¹⁹ of each intent among all clusters in a given month, as predicted by the Oracle, KPA, and RBC on the test set. Presumably, high ratio indicates a peak of interest for this intent.

For Omicron, methods highlight emerging interest in December and January, correlated with its real-time occurrence. To the right, methods predict interest in boosters peaking in December and April. We also note that differences between systems are sometimes non-negligible (e.g., as evident by the different peaks in the right figure). Overall, this analysis demonstrates how outstanding events in the COVID-19 timeline can be captured by the evaluated intent discovery methods.

8 Conclusions

In this paper we first describe VIRA, an informational DS addressing hesitancy towards COVID-19

¹⁶<https://www.cdc.gov/coronavirus/2019-ncov/science/forecasting/mathematical-modeling-outbreak.html>

¹⁷<https://www.cdc.gov/media/releases/2021/s1129-booster-recommendations.html>

¹⁸<https://www.cdc.gov/media/releases/2022/s0328-covid-19-boosters.html>

¹⁹Cluster ratio is defined as the size of an intent cluster divided by the overall number of utterances for a given month.

vaccines. VIRA provides access to accurate, up-to-date information in English, written by experts. We believe that the associated VIRADialogs data, containing 8k dialogs of VIRA with real-world users, would be a valuable resource to the relevant research community. As an initial example of the potential of this data, we demonstrate how it can be utilized to evaluate intent discovery methods. We propose an automatic evaluation framework that relies on the availability of a corresponding intent classifier, and report the results of 4 diverse methods, concluding that this benchmark represents a significant challenge.

While automatic evaluation is clearly more practical than manual one, developing the required intent classifier involves a non-trivial effort. Still, we envision two potential outcomes of our work. First, additional intent-discovery methods can be easily evaluated over VIRADialogs data using our implementation, and compared to the baseline performance reported here. Second, the same framework can be implemented in other use cases as well for which a reliable intent classifier is available, opening the door for automatic evaluation of intent discovery methods over additional datasets.

Finally, VIRA is constantly maintained and updated, and is now being expanded to additional languages, along with a Whatsapp implementation, to expand its outreach. In future work we intend to

report the lessons learned from developing VIRA, and the implications for developing a DS in the public health domain.

9 Limitations

There are a few limitations to our approach, which stem from assumptions made to establish the evaluation pipeline.

- We implement an evaluation pipeline on a single dataset, which we were part of creating, and did not test its compliance with additional datasets.
- We assume a relatively accurate intent classifier, referred to as an Oracle, is available. Thus, our evaluation is not suited for cold-start scenarios.
- We assume the intents covered by the Oracle indeed cover most intents expressed in the data. It is quite possible that as VIRADialogs is a large dataset it included additional intents, beyond the 181 covered by the Oracle, which probably impacted the accuracy of the evaluation. We note, though, that automatic evaluation, as proposed in this work, is always prone to such issues.
- We evaluated only certain unsupervised methods for intent discovery. Other systems may perform better than the reported baselines.

10 Ethics Statement

This paper describes work around VIRA, a real-world DS addressing COVID-19 vaccine hesitancy. In an attempt to alleviate concerns that users would take action based on information given to them by VIRA which might harm them, the terms of use of the DS state that “This information ... is not intended as a substitute for medical advice”. We were guided with the principle of providing accurate information, thus when building VIRA we incorporated a direct mapping between intents and responses. Future endeavours based on this

dataset, e.g., for building a generative bot for addressing vaccine hesitancy, should be aware of the ramifications of showing to users such content.

In addition, the terms of use stated that queries are stored and may be used for research purposes.

The chats collected might have originally contained offensive language, often as a result of the sensitivity of the domain to some users. We made a dedicated effort to flag these cases and mask problematic terms. However, we did so with automatic measures, so the dataset might still contain such language. Finally, although the data was anonymized by masking various expressions, it is still possible that some sensitive medical concerns remain.

A Dialog-Act Classifier

This classifier is used for categorizing the user input as one of the supported dialog acts: *greeting*, *farewell*, *negative reaction*, *positive reaction*, *concern* and *query*. The classifier was trained on utterances extracted from early chats labeled for their dialog act. VIRA responds to input texts that are classified with one of the first 4 dialog act types with corresponding generic texts. For example, a response to a greeting (e.g., ‘Hi’) is “Hello, what

are your thoughts about the COVID-19 vaccine?”. Utterances classified as either *concern* or *query* are passed to the Intent Classifier.

B Feedback Mechanism

VIRA incorporates a feedback mechanism that gives users the option to correct the course of conversation. When users give a thumbs down for a VIRA’s response, or when the intent classifier is not confident, VIRA shows to the user the top-3 predicted intents in a menu to select from with additional options for indicating that: (a) none of these intents address the concern, or (b) the input does not express a concern at all. This feedback allows VIRA’s developers and persons maintaining the Response Database to improve the system over time. For example, when (b) is selected, it indicates a false positive for the Dialog-Act Classifier.

C Intent Classification Model Details

As a base model for fine-tuning the intent classifier of VIRA, used as the Oracle, we use RoBERTa-large (354M parameters). We use AdamW optimizer with a learning rate of $5e-6$ and a batch size of 16. We fine-tune the model for 15 epochs and select the best performing checkpoint on the dev set according to overall accuracy. Training took 20 minutes on 1 v100 GPU. The confidence threshold of the model was tuned by taking the minimal threshold such that the precision on the dev set > 0.85 , resulting in a threshold of 0.296.

D Key Point Analysis Details

First, utterances for which no match was found above a threshold are placed in a *none* cluster.

Furthermore, preliminary experiments have shown KPA is producing too few intents, so as an adjustment for this task we: (i) set *limit_n_cands = false* to remove the limit on the number of key point candidates; (ii) set *n_top_kps = 1000* to remove the limit on number of clusters in the output, which also implies no minimal cluster size. The hypothesis is that (i)+(ii) will increase the amount and diversity of resulting key points at the expense of run-time.

E Radius-based Clustering Details

As an adjustment, chit-chat utterances which are filtered at the first phase of the algorithm are placed

in a *none* cluster. The minimal similarity threshold is set to 0.55. As with KPA we do not set a minimum size for clusters.

F Labeling User Utterances and PREDICTED INTENTS to SILVER LABELS

We presented annotators with pairs of texts, where one text can be either a user utterance or an intent from the PREDICTED INTENTS, and the other a silver label. We asked, “Do the above two texts convey the same meaning or intent?”. The annotators belong to a group with high success on previous tasks of our team, and the task included a few positive and negative examples to illustrate our objective. In addition, we included test questions of text pairs manually selected from the training data of the Oracle, and annotators with less than 70% accuracy on them were removed from the task.

G Intents Supported by VIRA

Intent
COVID-19 is not as dangerous as they say
Do I need to continue safety measures after getting the vaccine?
How long until I will be protected after taking the vaccine?
How many people already got the vaccine?
I am afraid the vaccine will change my DNA
I am concerned getting the vaccine because I have a pre-existing condition
I am concerned I will be a guinea pig
I’m concerned the vaccine will make me sick.
I am not sure if I can trust the government
I am young and healthy so I don’t think I should vaccinate
I distrust this vaccine
How much will I have to pay for the vaccine
I don’t think the vaccine is necessary
I don’t trust the companies producing the vaccines
I don’t want my children to get the vaccine
I think the vaccine was not tested on my community
I’m not sure the vaccine is effective enough
I’m waiting to see how it affects others
COVID vaccines can be worse than the disease itself
Long term side-effects were not researched enough
Are regular safety measures enough to stay healthy?
Should people that had COVID get the vaccine?
Side effects and adverse reactions worry me
The COVID vaccine is not safe
The vaccine should not be mandatory
Do vaccines work against the mutated strains of COVID-19?
They will put a chip/microchip to manipulate me
What can this chatbot do?
What is in the vaccine?

Intent
Which one of the vaccines should I take?
Will I test positive after getting the vaccine?
Can other vaccines protect me from COVID-19?
Do I qualify for the vaccine?
I don't trust vaccines if they're from China or Russia
Are the side effects worse for the second shot
Can I get a second dose even after a COVID exposure?
Can I get other vaccines at the same time?
Can I get the vaccine if I have allergies?
Can I get the vaccine if I have had allergic reactions to vaccines before?
Can I have the vaccine as a Catholic?
Can I have the vaccine if I'm allergic to penicillin?
Can I still get COVID even after being vaccinated?
Can you mix the vaccines?
COVID-19 vaccines cause brain inflammation
Do the COVID-19 vaccines cause Bell's palsy?
"Do the mRNA vaccines contain preservatives, like thimerosal?"
Do the vaccines work in obese people?
Do you have to be tested for COVID before you vaccinated?
Does the vaccine contain animal products?
Does the vaccine contain live COVID virus?
Does the vaccine impact pregnancy?
Does the vaccine work if I do not experience any side effects?
How can I stay safe until I'm vaccinated?
"How do I know I'm getting a legitimate, authorized vaccine?"
How do I report an adverse reaction or side-effect
How long do I have to wait between doses?
How many doses do I need?
How was the vaccine tested?
I am concerned about getting the vaccine because of my medications.
I don't want the v-safe app monitoring or tracking me
I don't want to share my personal information
Is breastfeeding safe with the vaccine
Is the Johnson & Johnson vaccine less effective than the others?
Is the vaccine halal?
Is the vaccine Kosher?
Is there vaccine safety monitoring?
Other vaccines have caused long-term health problems
Should I get the COVID-19 vaccine if I am immunocompromised
Should I get the vaccine if I've tested positive for antibodies?
The vaccine includes fetal tissue or abortion by-products
The vaccine was rushed
Vaccine side effects are not getting reported
What does vaccine efficacy mean?
What if I still get infected even after receiving the vaccine?
What if I've been treated with convalescent plasma?
What if I've been treated with monoclonal antibodies?
What is mRNA?
What is the difference between mRNA and viral vector vaccines?
When can I go back to normal life?
Why are there different vaccines?

Intent
Why do I need the COVID vaccine if I don't get immunized for flu
Why do we need the vaccine if we can wait for herd immunity?
Why get vaccinated if I can still transmit the virus?
Will 1 dose of vaccine protect me?
Can I take a pain reliever when I get vaccinated?
Will the vaccine benefit me?
Will the vaccine make me sterile or infertile?
Can we change the vaccine quickly if the virus mutates?
Can I get COVID-19 from the vaccine?
I'm still experiencing COVID symptoms even after testing negative - should I still take the vaccine?
Can children get the vaccine?
Can we choose which vaccine we want?
How long does the immunity from the vaccine last?
"The mortality rate of COVID-19 is low, why should I get the vaccine?"
There are many reports of severe side effects or deaths from the vaccine
How can I get the vaccine?
I am worried about blood clots as a result of the vaccine what is covid?
Who developed the vaccine?
Which vaccines are available?
What are the side effect of the vaccine?
Can I meet in groups after I'm vaccinated?
Is it safe to go to the gym indoors if I'm vaccinated?
How do I protect myself indoors?
What are the effects of long COVID?
Do you need a social security number to get a COVID-19 vaccine?
Do you need to be a U.S. citizen to get a COVID-19 vaccine?
Is it okay for me to travel internationally if I'm vaccinated?
Can my kids go back to school without a vaccine?
Will I need a booster shot?
"If I live with an immuno-compromised individual, do I still need to wear a mask outdoors if I'm vaccinated? "
Does the vaccine prevent transmission?
Why is AstraZeneca not approved in the USA?
Do I need to change my masking and social distancing practices depending on which COVID-19 vaccine I got?
Does the Pfizer vaccine cause myocarditis?
Does the Pfizer vaccine cause heart problems?
What can you tell me about COVID-19 vaccines?
Are there medical contraindications to the vaccines?
How many people died from COVID-19?
What about reports of abnormal periods due to the vaccine?
Do I need the vaccine?
Tell me about the vaccine
Is the Pfizer vaccine safe for young men?
Will vaccination lead to more dangerous variants?
Is it safe for my baby to get the vaccine?
Did a volunteer in the Oxford trial die?
Can I get COVID-19 twice?
Are some vaccines safer for younger children than others?
How long am I immune from COVID-19 if I had the virus?

Intent
Are women more likely to get worse side effects than men?
How do I convince my family and friends to get the COVID-19 vaccine?
Why are COVID-19 vaccination rates slowing in the U.S.?
I'm going to get vaccinated
Is getting vaccinated painful?
What do I do if I lose my COVID-19 vaccination card?
Can I get swollen lymph nodes from the vaccine?
Can my newborn become immune to COVID-19 if I'm vaccinated?
"COVID-19 is over, why should I get the vaccine?"
Did one woman die after getting the J&J vaccine?
Do people become magnetic after getting vaccinated?
Does the vaccine contain eggs?
How is the COVID-19 vaccine different than others?
How soon after I've had COVID-19 can I get the vaccination?
Is it safe for my teen to get the vaccine?
Is this Pfizer vaccine equally effective in kids as it is in adults?
Were the COVID-19 vaccines tested on animals?
What are the side effects of the vaccine in children?
What is the delta variant?
What is the J&J vaccine?
What is the Moderna vaccine?
What is the Pfizer vaccine?
Where are we required to wear masks now?
Who can get the Pfizer vaccine?
Who can I talk to about COVID-19 in person?
Why should I trust you?
Will my child need my permission to get vaccinated?
Will the US reach herd immunity?
Will my child miss school when they get vaccinated?
Is the vaccine FDA approved?
Why do vaccinated people need to wear a mask indoors?
Do vaccinated people need to quarantine if exposed to COVID-19?
What is Ivermectin?
Does the Johnson and Johnson vaccine cause Rare Nerve Syndrome?
What is the difference between quarantine and isolation?
Does the COVID-19 vaccine cause autism?
Does the vaccine cause impotence?
Who is required to get vaccinated under the federal vaccine mandate?
Is the Delta variant more dangerous for kids?
Will there be a booster shot for J&J and Moderna?
Is the booster the same as the original vaccine?
What are the side effects of booster shots?
What is the difference between the third shot and a booster shot?
How common are vaccine side effects?
Why do my kids need a vaccine if they're unlikely to get sick with COVID-19?
What happens if there is a COVID-19 case at my child's school?
Are booster shot side effects worse than those from the second shot?
Is the booster shot dangerous?
Can I get the vaccine if I have Multiple Sclerosis?

Intent
Do children receive the same dose of Pfizer as adults?
What is the Omicron variant?
How effective is the vaccine against the Omicron variant?

tigate whether organizing the generative factors in groups may facilitate learning and disentanglement (RQ3). As a result, this work focuses on natural language definitions, which are a textual resource characterised by a principled structure in terms of semantic roles, as demonstrated by previous work which proposed the extraction of structural and semantic patterns in this kind of data (Silva et al., 2016, 2018).

Seeking to address the highlighted issues and answer the research questions, we make the following contributions, also depicted in Figure 1.

1) We design a supervised framework for enhancing disentanglement in language representations by conditioning on the information provided by the semantic role labels (SRL) in natural language definitions. We present two mechanisms for injecting SRL biases into latent variables, firstly, reconstructing both words and corresponding SRL in a VAE, secondly, employing SRL information as input variables for a Conditional VAE (Zhao et al., 2017).

2) We propose a framework for evaluating the disentanglement properties of the encodings on non-synthetic textual datasets. Our evaluation framework employs semantic role label groupings as generative factors, enabling the measurement of several contemporary quantitative metrics. The results show that the proposed bias injection mechanisms are able to increase the degree of disentanglement (separability) of the representations.

3) We demonstrate that models trained with our disentanglement framework are able to outperform contemporary baselines in the downstream task of definition modeling (Noraset et al., 2017).

2 Disentangling framework

In this section we first describe the framework designed for improving disentanglement in natural language definitions with semantic role labels. Secondly, we present three models, shown in Figure 2 based on the Variational Autoencoder (VAE) (Bowman et al., 2016) architecture for achieving disentanglement.

2.1 Disentangling definitions

Definition semantic roles Our framework is based on natural language definitions, which are a particular type of linguistic expression, characterised by high abstraction, and specific phrasal properties. Previous work in NLP for dictionary

definitions (Silva et al., 2018) has shown that there are categories that can be consistently found in most definitions. In fact, Silva et al. (2018) define precise Semantic Role Labels (SRL) for phrases representing definitions, under the name of Definition Semantic Roles (DSR).

The example from (Silva et al., 2018) classifies the semantic roles within "english poets who lived in the lake district" as follows. "poets" as noun category (supertype), "english" as quality of the term (Differentia Quality), "who lived" as event that the subject is involved with (differentia event), and "in the lake district" as the location of the action (Event location). The full DSRs proposed by Silva et al. (2018) are reported in Table 9 in Appendix A.

Disentangling using SRL Our goal is to enhance disentanglement in natural language by injecting categorical structures into latent variables. We find that this goal is well aligned with the findings of Locatello et al. (2019), where it is claimed that a higher degree of disentanglement may benefit from supervision and inductive biases. Our hypothesis is that we may leverage such semantic information for learning representation with higher degree of disentanglement. While in the context of this work we use dictionary definitions as a target empirical setting, we conjecture that these conclusions can be extended to broader definitional sentence-types. The core intuition behind the approach is that the supervision signal should increase the likelihood of point clustering in regions corresponding to, or related to the discrete supervision labels, given the network architecture formulation.

2.2 Definition VAEs

Unsupervised VAE The first training framework that we consider is the traditional variational autoencoder (VAE) for sentences (Bowman et al., 2016), which operates in an unsupervised fashion, as in Figure 2a. The unsupervised VAE employs a multivariate gaussian prior distribution $p(z)$ and generates a sentence x with a decoder network $p_\theta(x|z)$. The joint distribution for the decoder is defined as $p(z)p_\theta(x|z)$, which, for a sequence of tokens x of length T result as $p_\theta(x|z) = \prod_{i=1}^T p_\theta(x_i|x_{<i}, z)$. The VAE objective consists into maximizing the expectation of the log-likelihood which is defined as $\mathbb{E}_{p(x)} \log p_\theta(x)$. Due to the computational intractability of the such expectation value, the variational distribution q_θ is employed to approximate $p_\theta(z|x)$.

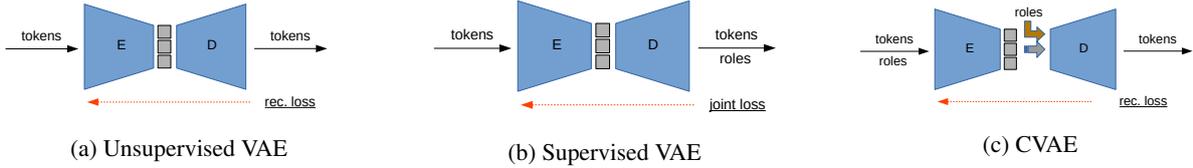

Figure 2: Proposed architectures for learning disentangled representations in definitions.

As a result, an evidence lower bound \mathcal{L}_{VAE} (ELBO) where $\mathbb{E}_{p(x)}[\log p_{\theta}(x)] \geq \mathcal{L}_{\text{VAE}}$, is derived as follows:

$$\mathcal{L}_{\text{Tokens}} = \mathbb{E}_{q_{\phi}(z|x)} \left[\log p_{\theta}(x|z) \right] - \text{KL}q_{\phi}(z|x)||p(z)$$

DSR supervised VAE The aim of this model is to inject the categorical structure of the definition semantic roles (DSR) into the latent variables, by factorizing them into the VAE auto-encoding objective function. In order to achieve this goal, we introduce the variable r for semantic roles, and train the "DSR VAE", where both sentence and semantic roles are auto-encoded. The variable r here operates just as x , with the corresponding label values. As a result, two separate losses are produced and added together for the final loss, as shown in Figure 2b. The ELBO for semantic roles is defined as follows:

$$\mathcal{L}_{\text{Roles}} = \mathbb{E}_{q_{\phi}(z|r)} \left[\log p_{\theta}(r|z) \right] - \text{KL}q_{\phi}(z|r)||p(z)$$

The final loss is given by $\mathcal{L}_{\text{Tokens}} + \mathcal{L}_{\text{Roles}}$.

Conditional VAE with SRL For explicitly leveraging the definition semantic roles, we propose a supervision mechanism based on the Conditional VAE (CVAE) (Zhang et al., 2017), shown in Figure 2c. Similar to the previously described model, we instantiate a VAE framework, where x is the variable for the tokens, and r for the roles. We perform auto-encoding for both roles and tokens, and additionally, we condition the decoder network on the roles. The CVAE is trained to maximize the conditional log likelihood of x given r , which involves an intractable marginalization over the latent variable z .

The ELBO is defined as:

$$\mathcal{L}_{\text{CVAE}} = \mathbb{E}_{q_{\phi}(z|r,x)} \left[\log p_{\theta}(x|z,r) \right] - \text{KL}q_{\phi}(z|x,r)||p(z|r)$$

Training We consider LSTM-based VAE and Transformer-based VAE (Optimus (Li et al., 2020))

as baselines. The training process follows the variational autoencoding methodology (Kingma and Welling, 2014). First, tokenization is performed in the sentences and the roles. The Encoder network involves feeding both first into embedding layers, then into LSTM / Transformer layers. Subsequently, two vectors μ and σ are sampled with two linear layers, and the vector z is computed with the re-parameterization trick. Finally, the decoder network is built with the LSTM / Transformer layers and another embedding layer, which return the same dimension that was given as input.

3 Evaluation framework

We first present the evaluation framework that for measuring disentanglement, then describe and justify the generative factor setup used in the experiments.

3.1 DSR as generative factors

While early approaches for disentanglement in NLP have been proposed in the context of in style transfer applications (John et al., 2019; Cheng et al., 2020) and are assessed purely in terms of style transfer accuracy, evaluating the intrinsic properties of the latent encodings is fundamental for disentanglement, as mentioned in several machine learning approaches (Higgins et al., 2017; Kim and Mnih, 2018). Recently, Zhang et al. (2021) proposed a framework for computing several popular quantitative disentanglement metrics such as (Higgins et al., 2017; Kim and Mnih, 2018) testing it on synthetic datasets. The limitation in (Zhang et al., 2021) is that it works only with synthetic datasets.

In this work, we propose a method where semantic role labels, such as the ones provided in (Silva et al., 2018), are used as generative factors for evaluating the degree of disentanglement in the encodings. The framework, illustrated in Figure 3, considers multiple generative factors, where each factor is composed by a number of semantic roles (for example the factor "location" includes, origin-location, and event-location). In this way, the dataset can be seen as the result of a sampling

of multiple generative factors, which is the same principle used when creating synthetic datasets for disentanglement. Once the generative factors are defined, the framework is enabled to compute a number of quantitative metrics for disentanglement, following the work from Zhang et al. (2021).

Figure 3: Generative factors for definitions.

3.2 Semantics and Syntax groups of DSR

In order to categorize the definition semantic roles (DSR), we consider their structural and semantic dimensions in terms of their contribution to either the meaning (e.g., quality, location) or the structure (e.g., main terms, modifiers) of the definition sentence. We first create two DSR groups with semantic and two based on syntax, to evaluate which one would better facilitate disentanglement. For both syntax and semantic, we then create one group with "supertype" DSR and one without it, in order to understand the impact of the supertype DSR. The importance of "supertype" is due to its contribution to both abstraction groups and its predominant presence on the datasets analyzed ($\geq 97\%$).

Group 1: Semantics with Supertype Sets the factors in terms of their meaning, essentially abstracting categories of the DSRs, including the SUPERTYPE DSR as a single factor. Qualification,

location, modification, declaration (statement) and supplementation (accessory) are semantic roles of a given term to its definition, which are described by the DSRs.

Group 2: Syntax with Supertype Sets the factors in terms of their structural role in the definition sentence, including the SUPERTYPE DSR as a single factor. The ORIGIN-LOCATION DSR is omitted due to its syntactic overlap with EVENT-LOCATION and its low frequency in the datasets.

Group 3: Semantics without Supertype Similar to group 1, but excluding the SUPERTYPE DSR, and repositioning the factor from *modifier* and *accessory* for higher abstraction. Relations of modification and supplementation (present in group 1) are suppressed to focus on lexical semantics, moving label ACCESSORY-DETERMINER to the declaratory group, EVENT-TIME to the event group and all quality related labels to the qualification group.

Group 4: Syntax without Supertype Similar to group 2, but excluding the SUPERTYPE DSR. Further abstractions are not conducted, as the definition roles already offer a stable structure for sentence construction.

4 Related work

Disentangled VAEs in language Early approaches in text disentanglement use VAEs with multiple adversarial losses for style transfer (Hu et al., 2017; John et al., 2019). More recently, Cheng et al. (2020) propose a style transfer method which minimizing the mutual information between the latent and the observed variable, while Colombo et al. (2021) propose an upper bound of mutual information for fair text classification. Disentanglement of syntactic and semantic information on sentences is explored by Chen et al. (2019), using multiple losses for word ordering and paraphrasing, and by Bao et al. (2019) with linearized constituency tree losses. Finally, Dupont (2018) work on discrete factors for image models and the improvements in Mercatali and Freitas (2021) proposed method for NLP lead to this work, where we move from the latter's implicit language features and LSTM-based architecture to explicit automatic annotations and a state-of-the-art Transformer-based architecture. We focus our efforts into the representation of definitions, and propose to promote disentanglement by using biases provided as semantic roles, designing two VAE models to inject structural semantic information into the representation. As an alternative

architecture for generative modeling, Generative Adversarial Network (GAN) was not employed for this problem due to the non-contrastive nature of the input data (trying to leverage informed structural knowledge) and the emphasis on disentanglement as a mechanism to understand separability and control.

Disentanglement Evaluation Vishnubhotla et al. (2021) evaluate disentanglement in synthetic text on various NLP tasks such as classification, retrieval and style transfer. Zhang et al. (2021) evaluate disentanglement of various VAE models on synthetic datasets where generative factors are known. Differently from these methods, we propose a new framework to evaluate non-synthetic natural language, where semantic role labels are used as generative factors. We model linguistic features of natural language definitions, with the goal of exploring the semantic properties that are encapsulated in it.

Definition models Early approaches in definition encoding include (Hill et al., 2016), which propose the first neural embedding model for dictionaries, and (Bahdanau et al., 2017), which present an RNN-based encoder decoder architecture for textual entailment and reading comprehension. More recently, methods based on Autoencoders (Bosc and Vincent, 2018) and transformers (Tsukagoshi et al., 2021) have been proposed. Various approaches for the task of generating a definition from a word (Definition Modeling) have been proposed, including RNN-based methods (Noraset et al., 2017), soft attention mechanisms (Gadetsky et al., 2018), and span-based encoding schemes (Bevilacqua et al., 2020). The semantic aspect of natural language definitions are explored in (Silva et al., 2016, 2018), where the concept of definition semantic roles is proposed.

5 Empirical analysis

In this section, we firstly describe the empirical setup for experiments, secondly, we provide qualitative evaluation and thirdly, we measure various quantitative metrics. Finally, we demonstrate the capacity of the proposed models in the downstream task of definition modeling.

5.1 Experimental setup

Datasets Definition sentences and their respective semantic role structures are sourced from three different datasets by (Silva et al., 2016) with the characteristics described in Table 1. All datasets

Dataset	Num sents.	Avg. length	Version
Wordnet	93,699	9	WordNet 3.0
Wiktionary	464,243	8	Dec, 2016
Wikipedia	1,500,323	12	Dec, 2016

Table 1: Statistics from definition datasets.

are automatically annotated with DSR tags for each token, using the method proposed by (Silva et al., 2016). The datasets differ not only in sentence length and size, but also in textual style: while WordNet and Wiktionary sentences tend to be formatted as dictionary definitions, Wikipedia sentences are lengthier and less adherent to a typical definition structure. For brevity, hyperparameter choices and implementation details are covered in sections C and D of the supplementary material.

5.2 Qualitative Evaluation

We analyse the representations of the trained models in terms of their disentanglement and composition, by applying three different techniques 1) traversals of the latent space, 2) latent space arithmetic, 3) encoding interpolation.

Latent space traversals Traversal evaluation is a standard procedure with image disentanglement (Higgins et al., 2017; Kim and Mnih, 2018). The traversal of a latent factor is obtained as the decoding of the vectors corresponding to the latent variables, where the evaluated factor is changed within a fixed interval, while all others are kept fixed. If the representation is disentangled, when a latent factor is traversed, the decoded sentences should only change with respect to that factor. This means that after training the model we are able to probe the representation for each latent variable. In the experiment, the traversal is set up from a starting point given by a “seed” sentence. As illustrated in Table 2 we observed that the latent variables typically track a single abstract definition role (e.g., supertype, quality, purpose), and change the meaning of the original term according to an abstract interpretation axis (e.g, flying → *movement*, art → *doutrine/teachings*). This means a certain degree of control can be applied to the generation of both the sentence structure and semantics.

Latent space arithmetic In this experiment, the latent vectors for two sentences are added, subtracted or averaged, and then the resulting vectors are traversed. The sentence pairs are

a flying creature a flying animal a flying insect a robot a monster a creature a walking demon a flying creature a moving animal	a martial art developed in Israel an ancient Buddhist dagger used to stab others an ancient martial art practiced in Japan a Roman soldier's movement a military dress worn by monks a knight's ceremonial hat a religious rite in which communion is offered a literary rite in Bible study a medicine school
--	--

Table 2: Traversals showing **changed** and **held** semantic factors in Wiktionary definitions (Optimus-based model).

ADD	a flying machine a flying creature a flying dinosaur a flying robot a flying object	AVG	to make four copies of to make five copies of to make one copy of to make two copies of to make 3 copies of
SUB	a female monarch a monarch the subnormal condition in females originating from... the normal female pregnancy associated with some the female given name in the Japanese game...		

Table 3: Traversals showing **changed** and **held** semantic factors after latent vector arithmetic in Wiktionary definitions (Optimus-based model).

different by a single term, so that we can observe the latent variables affected by the change, and how they are affected. As illustrated in Table 3, these operations tend to produce vectors that, when traversed, generate sentences corresponding to the features manipulated by the operation (e.g., removing the *monarch* supertype, leaving the *female* quality).

Interpolation In this experiment, we analyse the capability of the models built with the proposed approach to provide a smooth transition between latent space representations of sentences (Bowman et al., 2016). In practice, the interpolation mechanism takes two sentences x_1 and x_2 , and uses their posterior mean as the latent features z_1 and z_2 , respectively. It interpolates a path $z_t = z_1 \cdot (1 - t) + z_2 \cdot t$ with t increased from 0 to 1 by a step size of 0.1. This is a deterministic process, and no search is performed. As a result, 9 sentences are generated on each interpolation step. In Table 4 we provide qualitative results with latent space interpolation on Wiktionary. We can observe the transition happening for each concept: *migratory* $\rightarrow \emptyset \rightarrow$ *microscopic*, *aquatic* \rightarrow *aquatic + terrestrial* \rightarrow *terrestrial*, *bird* \rightarrow *mammal* \rightarrow *organism* \rightarrow *invertebrate*. This type of localised semantic control provided by the operations of traversal and interpolation over intensional-level (definitional)

DSR Optimus-based	a migratory aquatic bird found in the temperate regions of the northern hemisphere 1 a migratory bird of the eastern Mediterranean 2 a marine gastropod of the subfamily 3 a terrestrial aquatic mammal of the family 4 a terrestrial aquatic mammal of the suborder 5 a terrestrial invertebrate 6 a microscopic organism or invertebrate a microscopic terrestrial animal or protozoan an automobile 1 a motorcycle a bicycle
-------------------	---

Table 4: Interpolation examples in Wiktionary (Optimus-based model). Only unique sentences are shown.

sentences can potentially support quasi-symbolic operations over the latent space. Such effects could not be observed within the baselines.

Based on those three experiments, the composition of such latent space could be conceptualised as in the projection illustrated in Figure 4.

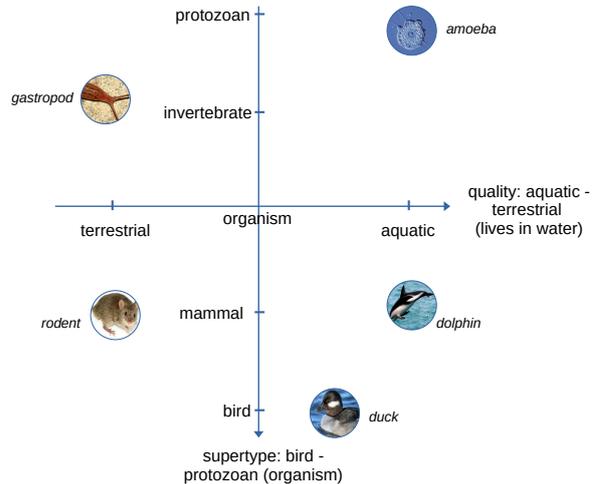

Figure 4: Conceptualisation of a two-dimension cut of the latent space, applied to the first example in Table 4.

UMAP plot UMAP (Uniform Manifold Approximation and Projection) (McInnes et al., 2018) is a popular method for non-linear dimensionality reduction, that allows the visualization of complex high-dimensional feature spaces, such as the representation space produced by a VAE. Figure 5 presents a 2D plot of UMAP transformations for both baselines under three training frameworks, from which the clustering of DSR patterns can be observed. While the supervision with DSR labels promotes clustering of the patterns around the center of the plot, cVAE compacts the cluster on the edges, allowing better separation. In the Optimus-based model, for example, the *SUPER* (green) cluster has a tendency to move

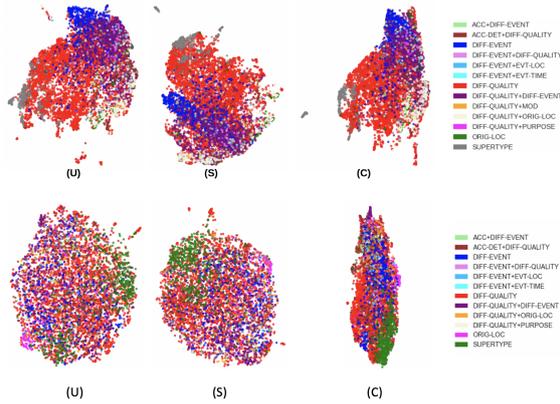

Figure 5: UMAP plot of latent representations from Un-supervised VAE (U), DSR supervision (S) and Conditional VAE (C) (Top: LSTM, Bottom: Optimus-based).

towards the edge of plot from left (U) to right (C). t-SNE transformations are also performed and the plots are presented in the supplemental material (Appendix E).

5.3 Quantitative Evaluation

In this experiment we probe the representation learned by the proposed VAE models using eight popular quantitative metrics for disentanglement, namely: z-diff (Higgins et al., 2017), z-min-var (Kim and Mnih, 2018), Mutual Information Gap (MIG) (Chen et al., 2018), Modularity & Explicitness (Ridgeway and Mozer, 2018), and from (Eastwood and Williams, 2018)(disentanglement, completeness, informativeness). Further details about the metrics are provided in Appendix B. It is relevant to mention that there are considerations regarding inconsistency on classification dependent probes (e.g., z-min-var, modularity), which are not discussed here due to space and scope considerations (we refer to Carbonneau et al. (2022)). Therefore, we decided to include all current metrics that could be applied in this scenario, and the results presented next should be interpreted considering these limitations.

Experimental Setup We evaluate VAE (U), DSR VAE (S) and CVAE (C) on Wordnet (WN), Wiktionary (WT) and Wikipedia (WP) datasets. Evaluation is performed under the framework explained in Section 3. Each combination of VAE architecture, generative factor grouping and representation size was trained and quantitatively tested, by calculating the previously mentioned disentanglement metrics. For computing the metrics we follow the

experiments of Zhang et al. (2021).

Analysis The results presented in Tables 2, 4, and 5 show that, specially when using the Optimus-based model:

LSTM												
D	z-diff			z-min-var ↓			MIG			Modularity		
	U	S	C	U	S	C	U	S	C	U	S	C
WN	.700	.691	.770	.482	.503	.532	.067	.057	.059	.793	.804	.765

Table 5: Quantitative disentanglement metrics (Top: LSTM, Bottom: Optimus-based).

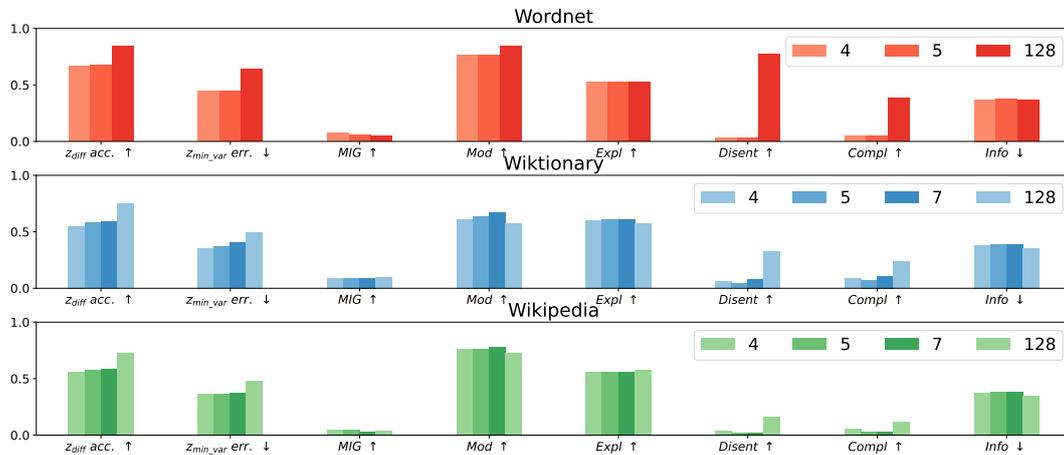

For the Wiktionary and Wikipedia datasets, the application of DSR categories as biases results in a measurable improvement in disentanglement (RQ1). This is evidenced by the proposed model outperforming the unsupervised baseline in six of the eight disentanglement metrics tested, by a margin of at least 2.5%, 81% in average.

The use of DSRs as generative factors produces meaningful disentangled representations (RQ2). The traversal results indicate the tendency of associating certain role abstractions to latent space dimensions, e.g., supertype, statement (purpose, among others). The interpolation results indicate the capture of semantic bridging across definitions, e.g., teaching → loading (process). The UMAP visualisation indicates slightly better factor separation and smoother transitions for the conditional model.

More specifically, in LSTM, z-diff presents the highest and most consistent improvement, specially with the CVAE, indicating higher interpretability when inferring single generative factors from the representations. Explicitness results are also consistent, indicating higher coverage of each factor. Improvements on Modularity, Disentanglement Score, Completeness and Informativeness are less consistent, indicating that the factors share substantial information between them. On the other hand, z-min-var, MIG counter the trend of improvement,

(a) By generative factor

(b) By number of latents

Figure 6: Metrics mean grouped.

Word	Definition Model	Unsupervised LSTM	Supervised LSTM
repuise	the act of making a gun	the act of moving forward	act in a hostile state
colonise	make a new or vital part	the state of being in a particular place	settle or cause to be easily removed
involve	make a specific purpose	make a specific effect	a specific act of making something
mitochondrion	a cell that is used to treat the blood	a substance that is used to treat a body reaction	a cell that is a source of an organic process
heat	a change in the surface of a liquid	a sudden increase in the flow of heat	a sudden increase in the temperature

Table 6: Definition generation examples for the Wordnet dataset.

due to the fact that they are designed to strongly penalize non-alignment of single pairs $\langle \text{factor} \leftrightarrow \text{latent dimension} \rangle$ (e.g., linear combinations). As a result, they penalize the existence of dependency and hierarchy relations which is present in most DSR categories, e.g., DIFFERENTIA-EVENT \rightarrow EVENT-TIME. As for the Optimus-based model, there are similar tendencies on WT and WP corpus. The conditional framework always performs better under 6 of 8 metrics, except z -min-var and

modularity. This result indicates that our conditional framework can improve the disentanglement performance of Optimus.

We also analyse how semantic groupings affect disentanglement in Figure 6b (RQ3). This is done only for the LSTM-based VAE, as the Transformer-based one was set to the optimal configuration in Li et al. (2020). Overall, we notice that syntax based groups have higher scores, indicating that it is easier to disentangle syntactic phrase components. For

Modularity the result is the opposite, indicating that semantic groupings promote higher independence between factors. Following (Zhang et al., 2021), the values in Table 5 for the metrics Completeness and Disentanglement score are multiplied by 10, in order to facilitate the visualization.

Finally, we find that a low number of latent dimensions leads to smaller degree of disentanglement. The experiments with 4,5,7 and 128 latents are reported in Figure 6a.

5.4 Definition Generation

In this experiment, we assess the proposed VAE models in the task of "Definition Modeling" (Noraset et al., 2017), where the goal is to generate a natural language definition given the word to be defined (definiendum).

Experimental setup During training, we adopt the "seed" setup (Noraset et al., 2017), which involves providing the definiendum concatenated with the definition tokens as input for the model. At generation time, the model takes as input only the word which needs to be defined, and leverages a trained model for computing the definition latent encoding. Such encoding is then fed into a softmax function and subsequently a multinomial probability distribution is sampled for decoding the latent variable into the final definition sentence.

To compare with the baseline of definition generation (Gadetsky et al., 2018), we only consider LSTM-based VAEs under the proposed unsupervised and DSR-supervised framework, both using the "seed" setup. The conditional LSTM and optimus-based models are not explored in this experiment in order to have a more fair comparison with the Definition model. We train the baseline and our models with similar setups, following (Gadetsky et al., 2018). We perform language model pretraining on the WikiText-103 dataset (Merity et al., 2016) for 1 epoch, then train on the downstream dataset for 10 epochs. Additionally, all models are initialised using Google Word2Vec pretrained vectors, following (Gadetsky et al., 2018).

Results We report the perplexity and Bleu (Papineni et al., 2002) results in Table 7. We observe that the proposed variational autoencoder models achieve an improvement on both perplexity and Bleu compared to the RNN baseline. The DSR

VAE achieves the best perplexity and Bleu on 2 out of 3 datasets while the unsupervised VAE is the best performing model in the other cases. Success of VAE models can be attributed to their disentangling properties, which promotes learning of latent spaces that are less sparse, a benefit deriving from sampling variable for re-parameterization. Improvements from the DSR VAE are marginal, but can be attributed to the additional information that is injected into its latent variables.

Data	Perplexity ↓			Bleu		
	DM	VAE	DSR	DM	VAE	DSR
WN	88.59	80.36	80.27	9.12	10.27	10.26
WT	42.51	39.09	38.64	6.70	7.53	7.59
WP	13.09	12.39	12.47	11.89	12.32	12.34

Table 7: Quantitative metrics for definition generation.

Some generation examples from the Wordnet dataset are provided in Table 6. Such examples show that the proposed VAE models are able to leverage the structural and semantic information of the learned definition roles to better approximate the defined concept. In particular, we notice some semantically strong linguistic elements in the definitions decoded with DSR supervision, for example DSR is the only model able to link the verb "re-pulse" with the hostile adjective, the verb colonise with the similar verb "settle", and the word "heat" with temperature. We include more generation examples of the Optimus-based model in Appendix E.

The strong performance in this definition generation task indicates that the disentangled representations have provided the VAE models with higher generalization capability, suggesting that disentangling is beneficial for diverse applications.

6 Conclusion

We propose a novel VAE-based framework for learning and evaluating disentangled representations in natural language definitions. We leverage the semantic structure present in dictionaries as inductive biases for improving disentanglement in VAEs, and as generative factors during evaluation. Our evaluation shows, both with qualitative investigations and with quantitative metrics, that the proposed framework is able to produce encodings with a higher degree of disentanglement. Finally, our models outperform existing baselines on a definition modeling application, demonstrating the generalization capabilities of disentangled representations.

Limitations

The type of structural supervision chosen for the approach here proposed is specifically fit to definition (dictionary style) sentences, in order to leverage semantic information from such structures. However, this limits the scope of comparison with other methods applied to general sentences. Additionally, the qualitative improvements we observed in terms of latent space traversals, arithmetic and interpolation do not clearly correlate with the disentanglement metrics, despite overall improvement. This raises some questions regarding the relation between explainability properties and general latent space separability.

A Definition Semantic Roles

The datasets used in our experiments are introduced in (Silva et al., 2018). We report in Table 9 the annotated categories.

Role	Description
Supertype	the immediate or ancestral entity’s superclass
Differentia quality	a quality that distinguishes the entity from the others under the same supertype
Differentia event	an event (action, state or process) in which the entity participates and that is mandatory to distinguish it from the others under the same supertype
Event location	the location of a differentia event
Event time	the time in which a differentia event happens
Origin location	the entity’s location of origin
Quality modifier	degree, frequency or manner modifiers that constrain a differentia quality
Purpose	the main goal of the entity’s existence or occurrence
Associated fact	a fact whose occurrence is/was linked to the entity’s existence or occurrence
Accessory determiner	a determiner expression that doesn’t constrain the supertype / differentia scope
Accessory quality	a quality that is not essential to characterize the entity
Role particle	a particle, such as a phrasal verb complement, non-contiguous to the other role components

Table 8: Semantic Role Labels for dictionary definitions.

B Disentanglement Metrics

1. z_{diff} accuracy (Higgins et al., 2017): The accuracy of a predictor for $p(y|z_{diff}^b)$, where z_{diff}^b is the absolute linear difference between the inferred latent representations for a batch B of latent vectors, written as a percentage value. Higher values imply better disentanglement.
2. z_{min_var} error (Kim and Mnih, 2018): For a chosen factor k , data is generated with this factor fixed but all other factors varying randomly; their representations are obtained, with each dimension normalised by its empirical standard deviation over the full data (or a large enough random subset); the empirical variance is taken for each dimension of these normalised representations. Then the index of the dimension with the lowest variance and the target index k provide one training input/output example for the classifier. Thus, if the representation is perfectly disentangled,

the empirical variance in the dimension corresponding to the fixed factor will be 0. The representations are normalised so that the arg min is invariant to rescaling of the representations in each dimension. Since both inputs and outputs lie in a discrete space, the optimal classifier is the majority-vote classifier, and the metric is the error rate of the classifier. Lower values imply better disentanglement.

3. Mutual Information Gap (*MIG*) (Chen et al., 2018): The difference between the top two latent variables with the highest mutual information. Empirical mutual information between a latent representation z_j and a ground truth factor v_k , is estimated using the joint distribution defined by $q(z_j, v_k) = \sum_{n=1}^N p(v_k)p(n|v_k)q(z_j|n)$. A higher mutual information implies that z_j contains a more information about v_k , and the mutual information is maximal if there exists a deterministic, invertible relationship between z_j and v_k . *MIG* values are in the interval $[0, 1]$, with higher values implying better disentanglement.
4. *Modularity* (Ridgeway and Mozer, 2018): The deviation from an ideally modular case of latent representation. If latent vector dimension i is ideally modular, it will have high mutual information with a single factor and zero mutual information with all other factors. A deviation δ_i of 0 indicates perfect modularity and 1 indicates that this dimension has equal mutual information with every factor. Thus, $1 - \delta_i$ is used as a modularity score for vector dimension i and the mean of $1 - \delta_i$ over i as the modularity score for the overall representation. Higher values imply better disentanglement.
5. *Explicitness* (Ridgeway and Mozer, 2018): Mean of the ROC area-under-the-curve (AUC_{jk}) of a one-versus-rest logistic-regression classifier that takes the latent vectors as input and has factor values as targets, over a factor index j and an index k on values of factor j . Represents the coverage of the representation, in other words, how well each factor is represented. Higher values imply better disentanglement.
6. *Disentanglement Score* (Eastwood and

Williams, 2018): The degree to which a representation factorises or disentangles the underlying factors of variation, with each variable (or dimension) capturing at most one generative factor. It is computed as a weighted average of a disentanglement score $D_i = (1 - H_K(P_{i.}))$ for each latent dimension variable c_i , on the relevance of each c_i , where $H_K(P_{i.})$ denotes the entropy and P_{ij} denotes the 'probability' of c_i being important for predicting z_j . If c_i is important for predicting a single generative factor, the score will be 1. If c_i is equally important for predicting all generative factors, the score will be 0. Higher values imply better disentanglement.

7. *Completeness Score* (Eastwood and Williams, 2018): The degree to which each underlying factor is captured by a single latent dimension variable. For a given z_j it is given by $C_j = (1 - H_D(\tilde{P}.j))$, where $H_D(\tilde{P}.j) = -\sum_{d=0}^{D-1} \tilde{P}_{dj} \log_D \tilde{P}_{dj}$ denotes the entropy of the $\tilde{P}.j$ distribution. If a single latent dimension variable contributes to z_j 's prediction, the score will be 1 (complete). If all code variables contribute equally to z_j 's prediction, the score will be 0 (maximally over-complete). Higher values imply better disentanglement.
8. *Informativeness Score* (Eastwood and Williams, 2018): The amount of information that a representation captures about the underlying factors of variation. Given a latent representation c , It is quantified for each generative factor z_j by the prediction error $E(z_j, \hat{z}_j)$ (averaged over the dataset), where E is an appropriate error function and $\hat{z}_j = f_j(c)$. Lower values imply better disentanglement.

C Hyperparameter choices

Experiments are conducted to cover a set of 3 hyperparameters: First, the VAE architecture used: 1) Unsupervised VAE 2) Supervised with SRL 3) CVAE with SRL. Second, the generative factor grouping, which includes: 1) Semantic w/ supertype 2) Syntactic w/ supertype 3) Semantic w/o supertype 4) Syntactic w/o supertype. Third, the dimensionality of VAE latent representation (z): 4, 5, 7, 128.

The choice of architecture allows evaluation of the impact of DSR label conditioning in two distinct ways: as part of the autoencoding objective function, and as a conditional variable of the decoder, addressing our research questions **RQ1** and **RQ2**. The choice of generative factor grouping can indicate the best ways to organize the factors, addressing **RQ3**.

The dimensionality of the representation is set to match the number of generative factors, in an attempt to force disentanglement by alignment of each dimension to a single factor. The dimension sizes are then defined to be 4 (alignment with groupings 3 and 4), 5 (alignment with grouping 2) or 7 (alignment with grouping 1). However, different levels of disentanglement can be achieved with mismatching dimensions and factors. So all possible combinations of factors and representation sizes are tested and a size of 128 is included to evaluate the impact of a higher number of parameters in each grouping.

D Implementation Details

As for LSTM-based VAE, hyperparameters are chosen with the following values, based on a previous experiment from (Shen et al., 2020). (1) Number of hidden layers: 1, (2) Dimension of the hidden layer: 512, (3) VAE $\lambda_{KL} = 0.1$, (4) Epochs=20, (5) Batch size=32 for Wikipedia, 64 for the rest. Dropout (20%) is done for both encoder and decoder inputs. To provide the inputs and outputs for the VAEs, the definition sentences are tokenized into sub-words with a *Byte Pair Encoding* (BPE) scheme, and converted into token embeddings with the T5 transformer model (Raffel et al., 2020), with an embedding size of 512. With respect to Optimus, we use memory setup to inject latent representation into the decoder. The encoder and decoder are pretrained BERT with bert-base-cased version and GPT2, respectively. Some additional values of hyperparameters are: (1) Epochs=10, (2) Batch size=32. (3) latent size=32. In the supervised framework, a new embedding layer is considered to learn the representations of semantic roles. In the conditional framework, we add semantic roles into the vocabulary of pretrained BERT encoder.

E Further Experimental Results

t-SNE plot Alternative dimensionality reduction method (t-distributed Stochastic Neighbor Embedding) (Van der Maaten and Hinton, 2008), used to

visualise the clustering of DSR patterns, as seen in Figure 7.

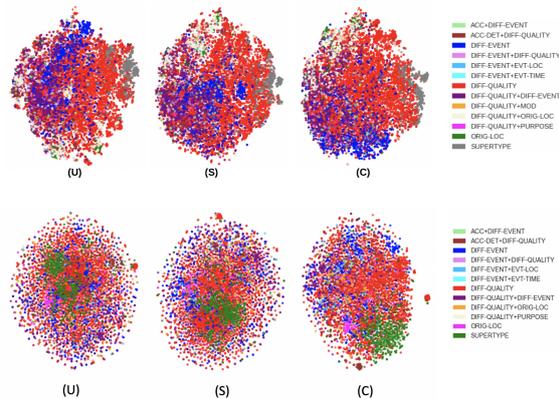

Figure 7: t-SNE plot of latent representation generated from LSTM and Optimus-based models under Unsupervised VAE (U), DSR supervision (S) and Conditional VAE (C) (Top: LSTM, Bottom: Optimus-based).

Optimus-based model definition generation

Table 9 lists the generated definitions from the Unsupervised Optimus-based model on Wordnet. The perplexity is 35.46 that is much lower than 80.27 from LSTM.

Word	Generated Definition
Fox	a member of the Mayflower
Untermeyer	United States writer of short stories
organise	make logical or comprehensible
dishrag	remove the fur from
altocumulus cloud	a clear blue sky
shuffle	move quickly on or move quickly forward
sharpen	make sharp or sharper
semantic error	discrimination that invalidates an earlier characteristic
railway station	station where planes take off and land or take off
Antonio Pignatelli	Italian cardinal and theologian
union	a cooperative level of play in league with other players
love knot	a knot of contrasting color or yarn used for tying a wedding band
commodity brokerage	a place where stockbrokers sell their stock

Table 9: Generation definitions from the Optimus-based model.

Distinguishability Calibration to In-Context Learning

Abstract

Recent years have witnessed increasing interests in prompt-based learning in which models can be trained on only a few annotated instances, making them suitable in low-resource settings. When using prompt-based learning for text classification, the goal is to use a pre-trained language model (PLM) to predict a missing token in a pre-defined template given an input text, which can be mapped to a class label. However, PLMs built on the transformer architecture tend to generate similar output embeddings, making it difficult to discriminate between different class labels. The problem is further exacerbated when dealing with classification tasks involving many fine-grained class labels. In this work, we alleviate this *information diffusion* issue, i.e., different tokens share a large proportion of similar information after going through stacked multiple self-attention layers in a transformer, by proposing a calibration method built on feature transformations through rotation and scaling to map a PLM-encoded embedding into a new metric space to guarantee the distinguishability of the resulting embeddings. Furthermore, we take the advantage of hyperbolic embeddings to capture the hierarchical relations among fine-grained class-associated token embedding by a coarse-to-fine metric learning strategy to enhance the distinguishability of the learned output embeddings. Extensive experiments on the three datasets under various settings demonstrate the effectiveness of our approach. ¹

1 Introduction

Large pre-trained language models (PLMs) (Devlin et al., 2019; Lan et al., 2020; Liu et al., 2019) have been achieved state-of-the-art performance in many Natural Language Processing (NLP) downstream tasks. More recently, the PLMs with prompt learning demonstrate surprising capabilities in numerous

*Equal contribution.

¹Our code can be found at <https://github.com/donttal/TARA>

tasks both in NLP and computer vision, even outperforming their fine-tuned counterparts (Brown et al., 2020; Liu et al., 2021; Lester et al., 2021; Zhou et al., 2022b; Gao et al., 2021a).

Train#1:	Gotta protect'em! It was [MASK].
Train#2:	That's why it's only 20\$. It was [MASK].
Test:	On a boat trip to Denmark. It was [MASK].

Table 1: The prompt templates for emotion classification. The samples are from *GoEmotion* (Demszky et al., 2020) dataset.

In an emotion classification task shown in Table 1, an input sentence X , followed by a prompt, “*It was [MASK]*”, is fed to a PLM to predict the missing token at the position of $[MASK]$. The predicted word can be used to identify the emotion label of the input sentence. Such few-shot learning generates a probability distribution over the $[MASK]$ conditioning on the given prompt/context, which is considered as in-context learning of language models.

However, as in-context learning does not require updating PLM parameters, there arises the problem of distribution mismatch between the data used for LM pre-training and the test samples used in in-context learning, which hinders the full exploitation of the knowledge encoded in PLMs (Xie et al., 2022; Zhao et al., 2021; Ge et al., 2022; Shin et al., 2022). To alleviate the context shift, existing methods rely on prior knowledge to increase the overlapping between the two distributions. For example, *PTR* (Han et al., 2021) appends domain-agnostic tokens to prompts to discriminate the domains, such as “*sports*”, “*politics*”. Another line of studies designs sophisticated handcrafted verbalizers to map the test samples onto the label word space derived from PLMs (Schick and Schütze, 2021; Gao et al., 2021b). Although the gradient-optimized verbalizers (Hu et al., 2022) are proposed to ease the human effort and can be adapted to different downstream tasks via training, it is still consid-

ered inferior to the manual verbalizers, especially in both the few-shot and zero-shot settings where training data are scarce.

In this paper, we first show that PLMs have an inherent *information diffusion* issue in their generated output token embeddings, which share a large proportion of similar information after going through a stack of transformer layers (Gao et al., 2019; Yan et al., 2022). Such token embeddings occupy a narrow cone, leading to largely overlapped output distributions when applied to in-context learning. Next, we elaborate that the overlapped output distributions would violate the distinguishability condition (Xie et al., 2022) under in-context learning. To this end, we propose to flatten the singular value distributions of the output embeddings generated from PLMs to shape the space spanned by the singular values to a desirable manifold. On the one hand, we apply an orthogonal and a scaling constraints to the weight matrix applied to the output embeddings, which can avoid exploding and vanishing values in the feature matrix (Saxe et al., 2014), leading to better discriminative features when trained with limited labelled data. On the other hand, we leverage hyperbolic embeddings to capture the hierarchical relations among fine-grained class labels of training examples to further enhance the distinguishability of output embeddings.

Our proposed framework has been implemented on top of existing prompt-based few-shot learning methods and it demonstrates an average 5.86% performance improvement of F1-measure on three classification tasks under 100-shot learning. We also verify that the improvement stems from a more balanced singular value distribution for the output features and the learnt hierarchical feature space.

In summary, our contributions include:

- We propose a transformation-based constraint to output embeddings by rotation and ratio balancing which is able to guarantee the distinguishability of learned embeddings.
- The proposed hyperbolic embedding-based metric learning strategy not only improves the performance of prompt learning but also measures the relation between different categories.
- The experimental results outperform many strong baselines and the visualisation illustrates that the proposed method is able to project the embedding to a less overlapping

distribution and improve the interpretability and distinguishability of output. Specifically, across three evaluated datasets, our method surpasses the state-of-the-art by 9.60%, 5.11% and 2.87%, respectively, in the 100-shot setting.

2 Related works

Information diffusion in PLMs. In a typical L -layer transformer-based PLM, assuming the prompt is a concatenation of a few training examples and a test input X_{test} , consisting of m tokens in total, the goal of in-context learning is to predict the output distribution over the masked token at the t -th position, $[MASK]$. It is formally defined by the following equation:

$$p(\mathcal{O}_t|X_{\text{test}}) = \mathbb{E}_{h \sim p_{\text{prompt}}(h|X_{\text{test}})} [p(\mathcal{O}_t|X_{\text{test}}, h, \theta)],$$

where h denotes the last-layer hidden state corresponding to the token of X_{test} , θ is the parameters in prompt-based learning.

Although we have limited knowledge of the output distribution $p(\mathcal{O}_t|X_{\text{test}})$ over token $[MASK]$, many existing studies analyzed the geometry properties of the last layer feature h^L , and examined its effects in downstream tasks (Goyal et al., 2020; Zhou and Srikumar, 2022). Due to the softmax bottleneck (Yang et al., 2018) and the likelihood loss in language generation tasks (Gao et al., 2019), the output feature distribution in PLMs tends to be anisotropic and rank-deficient, which limits the expressiveness of the generated representations. Goyal et al. (2020) discussed the information diffusion issue among tokens within a sentence that feeding the tokens in different positions for classification only resulted in a 1.2% variance in classification accuracy. Gao et al. (2019) explored the information diffusion among different sentences via singular value decomposing and they found that the singular value distributions are skewed especially in deeper PLM layers, i.e., larger singular values become more predominant compared to the smaller ones.

Context shift in in-context learning. Many researchers studied the distribution shift (aka. domain shift) between the pretraining corpora and test samples and proposed solutions to decrease the performance variance in prompt-based few-shot learning (Xie et al., 2022; Zhao et al., 2021; Hu et al., 2022; Zhou et al., 2022b; Shin et al., 2022).

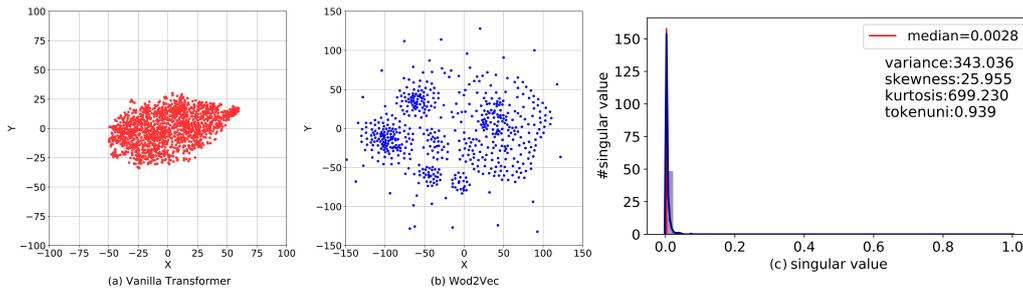

Figure 1: **(a)**: The mapping results of 1,500 *[MASK]* tokens randomly sampled from the *GoEmotions* dataset. Each red dot is the output representations derived from prompt-based learning for the *[MASK]* token of an input example, which will be used to predict the masked token in the corresponding position. **(b)**: Each blue dot is the static word representation of the corresponding predicted token with the largest probability on *[MASK]* for one of the 1,500 samples in (a) from the *GoEmotions* dataset. **(c)**: Singular value distribution (after normalisation) of the output representations of the randomly selected 1,500 *[MASK]*s. It is clear that the representations are dominated by very few singular values.

On the one hand, some in-context learning methods incorporated domain-specific words or learnable tokens in the prompt to discriminate different context. Ben-David et al. (2022) proposed to first generate the name of the domain and then generate domain-related features (DRFs) conditioned on the domain in a supervised manner. Both the generated domain name and DRFs were used as the prompt fed to the model. On the other hand, the sophisticated verbalizers contributed to minimising the distance between the two distributions (Schick et al., 2020; Schick and Schütze, 2021; Gao et al., 2021b; Hu et al., 2022). To broaden the coverage of single-choice verbalizer, *Knowledge Prompt Tuning (KPT)* (Hu et al., 2022) used the knowledge graph to extract more topic-related words as label words and then refine the label word candidates. To incorporate prior knowledge to calibrate the context shift, Xie et al. (2022) simplified a language model as the Hidden Markov Model, where the observed tokens are sampled from a family of concepts and proposed the *distinguishability condition* to measure context shift as the Kullback–Leibler (KL) divergence.

3 Contextual Calibration for Output Distribution

Many existing methods calibrate the probabilities of the generated tokens in a language model in order to improve the generation quality. In prompt-based learning, we want to find out if the output distribution $p(O_t|X_{\text{test}})$ or the output feature $h^{[\text{mask}]}$, which is a part of the hidden representation from the last layer of a PLM, h^ℓ , suffers from the *information diffusion* issue and occupies a narrow

cone. We take RoBERTa-based prompt learning as an example and derive the value of $h^{[\text{mask}]}$ from 1,500 randomly selected test samples from an emotion classification dataset, *GoEmotions* (Demszky et al., 2020), and visualise the results in a 2D plane in Figure 1(a). For comparison, we select the predicted token with the largest probability on each *[MASK]* and map their corresponding vectors from Word2Vec (Mikolov et al., 2013) to a 2D plane in 1(b). It is clear that the word embeddings learned from Word2Vec has a more uniform distribution around the origin. In contrast, the representations derived by RoBERTa degenerate into a narrow cone, which implies limited expressiveness. Inspired by the approach proposed in (Yan et al., 2022), we display the singular value distribution of $h^{[\text{mask}]}$ and calculate the distribution statistics, i.e., the matrix moment and the average cosine similarity between every *[MASK]* pair in Figure 1(c). From the empirical results, we can see that the value of the hidden representation for *[MASK]* in different samples share much similar information with the token uniformity value (Yan et al., 2022) (*tokenuni* in Figure 1(c)) of 0.939. This shows that most $h^{[\text{mask}]}$ concentrates at very few singular values, which implies a severe information diffusion issue.

3.1 Uniform Ratio-based Distinguishability

Although many calibration methods have been proposed, few of them focuses on explicitly addressing the information diffusion issue in the prompt-based learning framework. One main challenge in this task is that the unlabelled data used in language model pre-training is significantly larger than the labelled samples used for prompt tuning. Hence,

the optimised distribution in prompt-based few-shot learning can be very different from the true distribution. To avoid inheriting the *information issue* caused in the pre-training phase, we propose a calibration method to reduce the skewness of the output token distributions, such that the output representations are evenly distributed in the embedding space. The idea is to rotate the original embedding space to an isotropic metric space by an inner product-based operator on a learnable basis. For each dimension of the basis, we use the inner product to measure its relevance with a given input. The dimension-dependent relevance scores are sent to a Multi-layer Perceptron (MLP) decoder to generate the calibrated output embedding for final prediction.

The framework of the proposed calibration method is shown in Figure 2. In practice, due to the small size of training samples in prompt learning, the relevance scores might be dominated by very few dimensions. Therefore, inspired by Zhou et al. (2022a), who proposed a ratio estimator to balance the distribution from different label categories, we design a scaling matrix in our isotropic distribution scenario. That is, for both labelled and unlabelled data, the multi-class ratio between different dimensions should be similar.

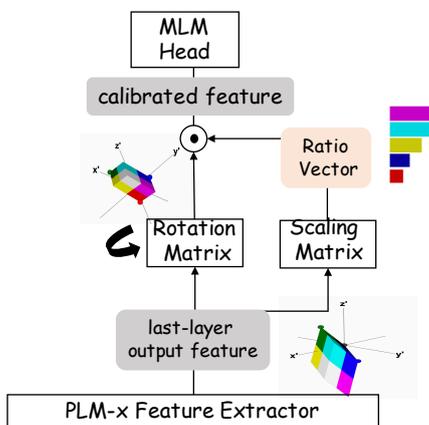

Figure 2: Our proposed calibration method is applied to the output embeddings from the last layer of a PLM. After being transformed with a rotation matrix through a Multi-layer Perceptron (MLP), the resulting output feature is assumed to have a more balanced singular value distribution in different basis directions. Moreover, as the vector norm on each projected direction would change in the new base, we derive a ratio vector to balance the distribution along the rotated directions.

Concretely, assuming we have N labelled data $\{y_j, x_j\}_{j=1}^N$ and M unlabelled data from pre-training $\{x_j\}_{j=N+1}^{N+M}$, where x_j is the input sample,

y_j is the true label, and $M \gg N$. To simplify the notation, in the rest of this paper, we use x_j to represent the feature of the last embedding layer and h_j to represent the output of our calibrated feature. Then, for the representation of a masked token, x_j , we assume there are K isotropic directions in the metric space and the corresponding inner product based relevance score is:

$$\mathcal{H}_k(x_j) = \sigma(\langle x_j, W_k \rangle), \quad (1 \leq k \leq K), \quad (1)$$

where $\sigma(\cdot)$ is the softmax activation function. Here, we can define a **rotation matrix** based on W_k since Eq. (1) projects an input embedding onto a new metric space by rotation. To guarantee the orthogonality of the basis in the new metric space, we use the following regulariser during training:

$$\mathcal{L}_{orth} = \left\| W^\top W - \mathbf{I} \right\|_2^2, \quad (2)$$

where W is the stacking of $\{W_k\}_{k=1}^K$. Correspondingly, for each dimension k , we can define a ratio score which aims to better separate them to avoid the skewed distribution by minimising the following loss:

$$\mathcal{L}_t = \frac{1}{N+M} \sum_{k=1}^K \sum_{j=1}^{N+M} \left\| \mathcal{R}_k(x_j) - \frac{1}{K} \right\|^2, \quad (3)$$

where $\mathcal{R}_k(x_j)$ is an MLP-based estimator with a softmax activation:

$$\mathcal{R}_k(x_j) = \sigma(S_k \cdot x_j + \beta). \quad (4)$$

By minimising \mathcal{L}_t , even if one input sample x_j is similar to a basis vector along a popular dimension k , there will still be a probability to assign it a low ratio score $\mathcal{R}_k(x_j)$ if there are other samples which are more closer to the basis vector in dimension k . In this way, we can balance the distribution after rotation. We define the stacking of S_k as a **scaling matrix** which aims to distribute x_j uniformly into K clusters in the metric space.²

However, it is difficult to optimise the loss defined in Eq. (3) since the size of the unlabelled data for pre-training is much larger than the labelled data and the unlabelled data is usually unseen to the downstream tasks. We instead define an alternative optimisation objective. First, according to Eq. (3), we need to ensure that for any two dimensions k and t , we have $\frac{1}{N+M} e^{S_k \cdot x_j} = \frac{1}{N+M} e^{S_t \cdot x_j}$.

²We measured the impact of different weight initialisations on S_k in Appendix A.2.

By the Jensen’s inequality, we have the following lower bound: $e^{\frac{1}{N+M}S_k \cdot x_j} \leq \frac{1}{N+M}e^{S_k \cdot x_j}$, in which we can achieve the lower bound for any two independent dimensions by taking $\frac{1}{N+M}S_k \cdot x_j = \frac{1}{N+M}S_t \cdot x_j$. It means that for any two dimensions, the sum of their ratio scores should be similar. As such, Eq. (3) can be approximated by:

$$\mathcal{L}_t \sim \sum_{k=1}^K (||S_k||^2 - 1)^2. \quad (5)$$

Accordingly, we can define the distinguishability loss in a more general form by both the relevance score and the ratio score without the need of sampling from unlabelled data:

$$\mathcal{L}_{dis} = \mathcal{L}_{orth} + \mathcal{L}_t. \quad (6)$$

From our findings in Section 3, much information encoded by the output representations generated by the last layer of a PLM only occupies a space spanned by very few singular value directions. This leads to the information diffusion issue. Therefore, our solution here is to re-project the output features into a new hyperplane, in which the information is more evenly distributed in different directions, and at the same time we can derive a ratio vector by aggregating the rotated components.

3.2 Supervised Prompt Learning

By our proposed distinguishability loss-based learning in Section 3.1, an input embedding has been separated into vectors along K independent dimensions. Then, for the labelled data $\{x_j\}_{j=1}^N$, we propose to use k independent decoders to produce the final prediction. The decoding result is based on the relevance score and ratio score on each independent dimension:

$$\mathbf{h}_j = \sum_{i=k}^K \text{Decoder}_k(\mathcal{H}_k(x_j) \cdot \mathcal{R}_k(x_j)), \quad (7)$$

where the Decoder_k is a decoder for the k -th dimension. Then the representation of \mathbf{h}_j can be used in the verbalizer $p_{\text{verbalizer}}(\hat{\mathcal{O}}|\mathbf{h}_j)$, where $\hat{\mathcal{O}}$ is the predicted masked token. Finally, the cross-entropy loss H is defined by the predicted $\hat{\mathcal{O}}$ and the true label y_j :

$$\mathcal{L}_{cls}(x_j) = H(y_j, p_{\text{verbalizer}}(\hat{\mathcal{O}}|\mathbf{h}_j)). \quad (8)$$

By combining the uniform ratio-based distinguishability loss of \mathcal{L}_{dis} and the prompt-based classification loss \mathcal{L}_{cls} , we propose our first model, named as **Transformation based Adaptation for**

Ratio bAlanced (TARA) prompt learning, which aims to minimise $\mathcal{L}_{\text{TARA}} = \mathcal{L}_{cls}(x_j) + \mathcal{L}_{dis}$. Note that $\mathcal{L}_{cls}(x_j)$ is the default loss term in all the baselines and our proposed methods.

3.3 Dimension Rotation by Hyperbolic Embeddings

In Section 3.1, we project the input mask embedding into a K dimensional metric space to avoid skewed distributions. However, we ignore the potential class relations between the dimensions. For example, in emotion classification, both the emotions of ‘gratitude’ and ‘approval’ belong to the *coarse* positive class, but they are associated with different *fine-grained* labels in the GoEmotions dataset (Demszky et al., 2020). Hence, in this section, we only consider those positive pairs under the same coarse category to achieve a better class disambiguation by a proxy based metric learning (Movshovitz-Attias et al., 2017; Yang et al., 2022), which uses an anchor vector to represent a category for metric loss optimisation and capture the hierarchical structure between coarse- and fine-grained labels in the hyperbolic space.

Strategies for Constructing Sample Pairs. Inspired by the hierarchical structure of coarse-to-fine emotion categories, we assume that a fine-grained emotion should be close to the coarse-grained emotion it belongs to. To implement this idea, we construct sample-anchor pairs (\mathbf{h}_j, z_i^+) for training, where \mathbf{h}_j is the representation for prompt prediction and $z_i^+ \in \mathbb{R}^d$ is a learnable anchor representation for each coarse class.

Metric Learning in a Hyperbolic Space. To maximise the similarity in sample-anchor positive pairs, where the sample and the anchor share the same coarse-grained label, while minimising the similarity in negative pairs, we adopt the following metric learning objective:

$$\mathcal{L}_{metric}(\mathbf{h}_j) = -\log \frac{e^{-d(\mathbf{h}_j, z_{p_j}^+)}}{\sum_{i=1}^C e^{-d(\mathbf{h}_j, z_i^+)}} \quad (9)$$

where $\{(\mathbf{h}_j, z_i^+)\}_{i=1}^C$ represents a set of sample-anchor pairs that we constructed for each sample i , C denotes the number of anchors, $z_{p_j}^+$ is the representation of positive pairing anchor of j -th sample, and $d(\cdot)$ is the hyperbolic distance metric defined by the Poincaré ball model of the hyperbolic space (Nickel and Kiela, 2017). In a n -dimensional hyperbolic space, all points will fall into a unit open

interval: $\mathcal{I}^n = \{x \in \mathbf{R}^n \mid \|x\| < 1\}$, where $\|\cdot\|$ denotes the Euclidean norm. The distance $d(\cdot)$ between two points $u, v \in \mathcal{I}^n$ can be formulated as:

$$d(u, v) = \operatorname{arcosh}\left(1 + 2 \frac{\|u - v\|^2}{(1 - \|u\|^2)(1 - \|v\|^2)}\right). \quad (10)$$

The motivation of using $\mathcal{L}_{metric}(\mathbf{h}_j)$ is to push similar categories together in the metric space. Hence, we can obtain our final learning objective by adding the loss of tree-structured metric learning $\mathcal{L}_{metric}(\mathbf{h}_j)$ to **TARA** as:

$$\mathcal{L}_{final} = \mathcal{L}_{cls}(x_j) + \mathcal{L}_{metric}(\mathbf{h}_j) + \mathcal{L}_{dis}. \quad (11)$$

For a comparison, we propose a variant called **TML** by keeping the learning architecture and simply adding $\mathcal{L}_{metric}(\mathbf{h}_j)$ to the classification loss of $\mathcal{L}_{cls}(x_j)$, but without the ratio balancing term of \mathcal{L}_{dis} , that is, $\mathcal{L}_{TML} = \mathcal{L}_{cls}(x_j) + \mathcal{L}_{metric}(\mathbf{h}_j)$.

4 Experiments

Datasets We evaluate our proposed approach on three multi-class text classification datasets, the *Emotion*³ (Saravia et al., 2018) dataset, an academic paper classification dataset, *WOS* (Kowsari et al., 2017), and a fine-grained emotion classification dataset, *GoEmotions*⁴ (Demszky et al., 2020). All of these datasets have hierarchical label structures. The datasets statistics are shown in Table 2.

Name	#Classes	#Train	#Dev	#Test
<i>Emotion</i>	6	16,000	2,000	2,000
<i>WOS</i>	11	5,736	1,147	1,147
<i>GoEmotions</i>	28	23,485	2,956	2,984

Table 2: Dataset statistics.

For all datasets, we remove punctuation, digits, and special characters that do not have specific semantic meanings. For the *Emotion* dataset which consists of tweet, we also remove user mentions.

Baselines We implement our proposed framework on top of the commonly used prompt-based learning methods and compare it with existing approaches including those which can be used for learning more discriminative representations:

- *Prompt-baselines*. Three commonly used prompt-based methods are selected including

Soft Prompts (Brown et al., 2020), *Prompt-Tuning* (Lester et al., 2021) and *PTR* (Han et al., 2021). The best-performing method is used as the default prompt-based training method for the following three comparison models, and denoted as *Prompt-baseline*.⁵

- *KPT* (Hu et al., 2022). It uses a knowledge graph to incorporate topic-related label words to increase the coverage of the verbaliser.
- *Context Calibration* (Zhao et al., 2021). This method calibrates the output representations by one-layer linear transformation, whose weight matrix is optimised to be diagonal.
- *Proxy-NCA* (Movshovitz-Attias et al., 2017). It creates a proxy for each class and uses the Neighbourhood Component Analysis (NCA) loss to pull samples closer to their assigned proxies while pushing negative samples away.

Prompt Settings As the performance of prompt-based methods heavily relies on prompt templates and verbalisers, we use the same template and verbaliser for all models for fair comparison. The prompt templates are shown in Table 3. The original class labels are used as label words in the verbaliser as in (Schick and Schütze, 2021).

Datasets	Prompt template
<i>Emotion</i>	<X>It's [MASK].
<i>WOS</i>	<X>The domain of the text is [MASK].
<i>GoEmotions</i>	<X>The emotional aspect of this text is [MASK].

Table 3: Prompt templates used in three datasets.

4.1 Few-shot Learning on Three Datasets

We randomly select k different training samples for few-shot learning and show the results across the three datasets in Table 4.

For metric-learning, *Proxy-NCA* with contrastive loss leads to performance degradation compared to the *Prompt-baseline*, with more significant performance drops on the *GoEmotions* dataset, which has the largest label categories. By contrast, **TML** gives better results over the *Prompt-baseline* and *Proxy-NCA*, showing its efficiency in encoding hierarchical relations between the coarse- and fine-grained labels. It can be further demonstrated in Figure 3, which shows the similarity matrix

⁵The detailed performance of these three prompt-based training methods is shown in Table A3. We use *PTR* for *GoEmotion*, and use *P-tuning* for the other two datasets.

K -shot	Emotion				WOS				GoEmotions			
	5	10	50	100	5	10	50	100	5	10	50	100
Prompt-baseline	0.336	0.363	0.431	0.625	0.236	0.252	0.359	0.435	0.161	0.173	0.281	0.310
Proxy-NCA	0.333	0.384	0.412	0.637	0.214	0.246	0.295	0.383	0.149	0.166	0.208	0.233
Context Calibration	0.337	0.352	0.531	0.706	0.212	0.361	0.687	0.707	0.164	0.224	0.355	0.420
TML	0.339	0.387	0.466	0.699	0.229	0.277	0.372	0.529	0.158	0.227	0.309	0.355
TARA	0.348	0.401	0.697	0.783	0.245	0.418	0.705	0.728	0.172	0.249	0.364	0.442
Ours full model	0.355	0.441	0.713	0.802	0.278	0.439	0.719	0.757	0.206	0.255	0.384	0.448

Table 4: Weighted F1 scores on three Datasets. The proposed **TML** is better than *Proxy-NCA*. Our full method (**TML+TARA**) achieves the best performance among all the settings.

(28×28) of the 28 fine-grained emotion labels from 3 high-level categories, i.e., “*anger*”, “*joy*” and “*sad*”. The results of *Proxy-NCA* in (c) are similar to the *Prompt-baseline* as shown in (b). Our proposed **TML** in (d) can capture the hierarchical relations among the 28 labels, where the correlations among labels belonging to the same high-level emotion category are similar. By comparison, we replace the hyperbolic distance in **TML** with the Euclidean distance and show the results in (c). It can be observed that the resulting label embeddings fail to exhibit different patterns within and across different high-level emotion categories.

For the calibration methods, *Context Calibration* and **TARA** are overall better than the *Prompt-baseline*. This shows that the simple linear transformation of the output representations can greatly improve the performance of prompt-based learning. The superior performance of **TARA** over *Context Calibration* demonstrates the benefit of using our proposed rotation and scaling transformations. Combining **TML** with **TARA**, our full model achieves the best performance and the improvements are more predominant when K is larger. In the 100-shot setting, our method surpasses the state-of-the-art method, *Context Calibration*, by 9.6% on Emotion, 5.1% on WOS, and 2.9% on GoEmotions, respectively, verifying its superiority in the few-shot text classification task.

4.2 Information Diffusion Alleviation

In addition to the classification results, we also examine the characteristics of the generated output representations to check whether the information diffusion issue has been addressed. Figure 4 shows the PCA projection results of all the [MASK] representations, i.e., $h^{[MASK]}$ in the test samples, which are colour-coded according to their assigned class labels by the model. It is clear that our method can generate more widely distributed [MASK] representations, therefore better reducing the overlaps

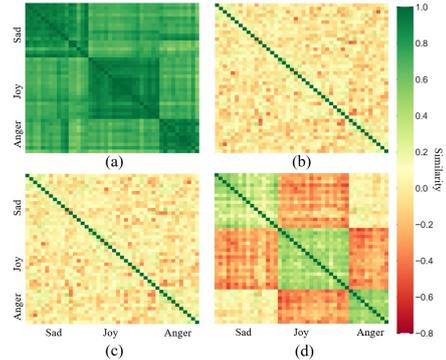

Figure 3: Heatmap for the pair-wise cosine similarity of fine-grained classes on *GoEmotion*. (a) Label representations from PLM without fine-tuning. (b) Fine-tuned label representations by classification module only. (c) Fine-tuned label representations with proposed constraint but based on Euclidean distance, i.e., *Proxy-NCA*. (d) Fine-tuned label representations by **TML**.

of the features from different class labels. For example, in the *Emotion* dataset, the output features from the baseline model mostly reside along the horizontal direction, while ours distribute more evenly across different directions.⁶

We also calculate the summary statistics of the singular value distribution of the output features, as well as the average similarity between every two [MASK] pairs. The results are shown in Table 5. The average cosine similarity (*CosSim*) between every token pair is used as a proxy measure of the degree of information diffusion. We can observe that the *CosSim* value calculated on the output representations generated by our model is significantly lower compared to the other baselines. We also observe an increase in the median and the decrease in variance of the singular value distribution from our model outputs in comparison to the prompt learning baseline. The results show that our model produces the output representations which have a more balanced singular value distribution. The

⁶The T-SNE results and singular value distribution of the output representations in *Emotion* and *GoEmotions* are shown in Figure A1 and Figure A2.

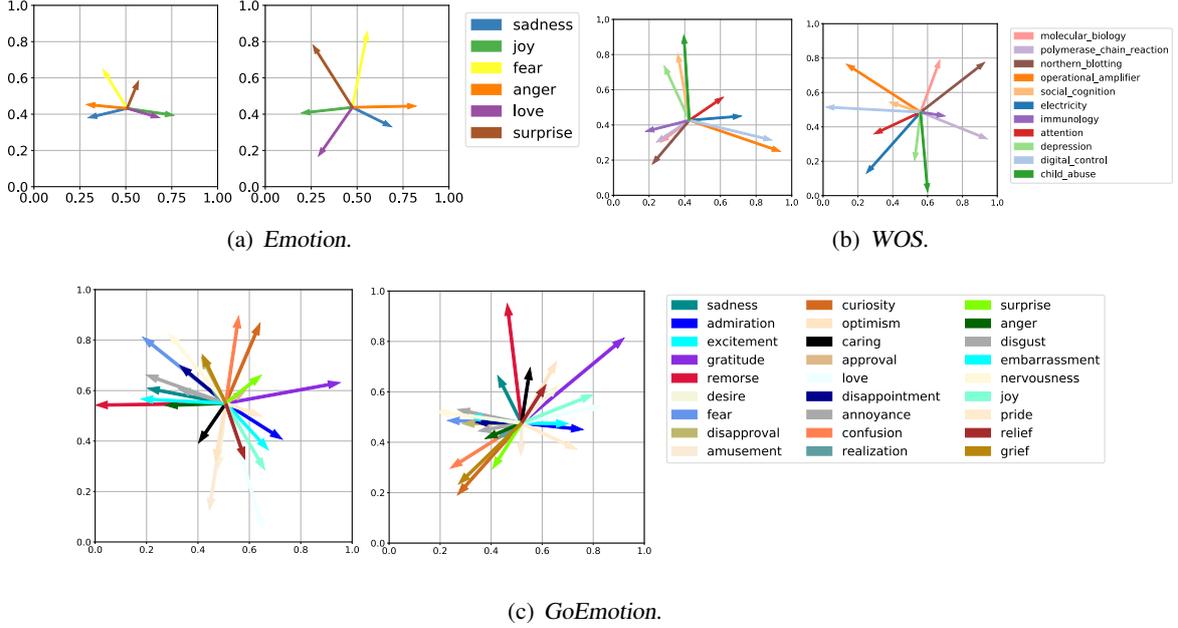

Figure 4: The PCA projection of the output representations belonging to different classes. In each sub-figure, the **left figure is the prompt-baseline**, while the **right figure is our method**. It is clear that our method distributes the output representations more evenly in the embedding space, while the output representations from the baseline appear to be more concentrated.

	Median	Variance	Skewness	CosSim
Emotion-prompt	0.0028	371.9	24.57	0.898
Emotion-Ours	0.0145	5.211	8.960	0.256
WOS-prompt	0.0036	235.8	22.06	0.817
WOS-Ours	0.0117	5.681	9.088	0.191
GoEmotions-prompt	0.0028	822.1	24.64	0.899
GoEmotions-Ours	0.0268	11.20	7.728	0.243

Table 5: The statistics of the singular value distribution of the output features, as well as the average cosine similarity of all $[MASK]$ token pairs.

	Ours	w/o \mathcal{L}_{orth}	w/o \mathcal{L}_t	w/o l_2	w/o all
Emotion	0.802	0.725	0.719	0.723	0.724
WOS	0.757	0.728	0.687	0.741	0.699
GoEmotions	0.448	0.422	0.415	0.427	0.412

Table 6: Ablation study of various loss terms in the learning objective for the distinguishability loss.

smaller skewness value further verifies that our proposed model can generate isotropic representations where the embedding dimensions are uncorrelated.

4.3 Ablation Study

To study the effect of different components of our proposed distinguishability loss, i.e., the constraints applied to the transformation operation for ratio balancing, we remove one of them and compare the performance changes in Table 6. Here, \mathcal{L}_{orth} is applied on W in Eq.2, \mathcal{L}_t is applied on

S_k (from Eq.4 and Eq.5), and l_2 is the weight for the L_2 regularisation term on all the other learnable parameters. The \mathcal{L}_{orth} and L_2 constraints have similar effects on the overall performance, as they both act as axis transformations, while the constraint L_t applied on S_k plays a more important role, whose removal leads to a larger performance drop among all the settings. It partly demonstrates the importance of the balancing ratio vector after the rotation transformation.

5 Conclusion

In this paper, to address the information diffusion issue in prompt-based few-shot learning, we propose a calibration method based on feature transformation which first rotates output embeddings into a new metric space, and then scales the ratio of each dimension to a uniform distribution to guarantee the distinguishability of the transformed embeddings. On the other hand, we utilise hyperbolic embeddings to capture the hierarchical relations between class labels to guide the metric learning strategy to enhance the interpretability of the learned output embeddings. Extensive experiments on the three multi-class classification tasks under various settings demonstrate the effectiveness of our approach with an average 5.9% performance improvement on the F1-measure.

Limitations

In this work, we only focus on the multi-class classification task with hierarchical class labels. Future work could explore extending our idea to other tasks, such as controllable text generation, which has the similar information diffusion issue. Another potential direction in future work is to learn a prior distribution rather than simply using the uniform distribution in ratio balancing. Since the uniform distribution-based ratio balancing is a strong assumption, it might not be suitable for some tasks in real-world applications. One could use VAE or VQ-VAE to learn a distribution which could be subsequently used to regularise the optimisation of feature transformation.

A Appendix

A.1 Model Selection

Following previous research (Gao et al., 2021b; Hambardzumyan et al., 2021; Lester et al., 2021), BERT (Devlin et al., 2019), Roberta and ALBERT (Lan et al., 2020) were used when using the *cloze* prompts. The *cloze* is to fill in the blanks in the prompt template by the model itself.

Model	Zero-shot		
	Accuracy	Macro-f1	Weighted-f1
BERT (fine-tuning)	0.0342	0.0196	0.0329
BERT	0.0716	0.0165	0.0384
RoBERTa	0.1094	0.0465	0.0994
ALBERT	0.0538	0.0217	0.0459

Table A1: Classification results on GoEmotion dataset of different baseline models.

To select the baseline model used as the backbones of our proposed method, we evaluate the baseline models on *GoEmotions* dataset for zero-shot learning, the results are shown in Table A1. We compare the effects of the same model using prompt learning and fine-tuning, respectively (difference in effects between BERT (Devlin et al., 2019) and BERT (fine-tuning)). After comparison, we chose RoBERTa (Liu et al., 2019) as it shows the overall best performance.

Based on the large pretrained language model backbone, we compare different prompt-based training methods and select the best as our *Prompt-Baseline*. The details are shown in Table A3.

A.2 Weight Initialisation

The optimisation of W_k and S_k can be affected by different weight initialisations. As such, we experiment with different initialisation strategies and show the results of 100-shot learning in Table A2 (We use the same initialisation for W_k and S_k). The Gaussian distribution initialisation performs the best overall. Therefore we use the Gaussian distribution initialisation in all the experiments reported in the paper.

B Visualisation results

To better compare the results of Baseline methods and ours, we visualize the output of different labels by mapping them into 2D plane via T-SNE (Figure A1). It is clear that our model separates the data points of different labels ((b) and (d)) rather than

Initialisation	Emotion	WOS	GoEmotions
Gaussian	0.802	0.757	0.448
Xavier	0.817	0.749	0.420
Eye	0.798	0.747	0.387
Orthogonal	0.801	0.757	0.431

Table A2: Initialisation of different distributions on weight matrix.

mixing them up (shown in (a) and (c)). To explore the corresponding effects of singular values distribution, we visualise the normalized singular value distribution of the output embeddings in Figure A2. We observe a more balanced distribution after applying our transformation and metric learning.

K -shot	Emotion			WOS			GoEmotions		
	Soft	P-Tuning	PTR	Soft	P-Tuning	PTR	Soft	P-Tuning	PTR
5	0.295	0.336	0.330	0.165	0.236	0.213	0.072	0.135	0.161
10	0.312	0.363	0.351	0.180	0.252	0.230	0.151	0.151	0.173
50	0.363	0.431	0.409	0.328	0.359	0.319	0.230	0.245	0.281
100	0.423	0.625	0.631	0.412	0.435	0.391	0.331	0.336	0.310

Table A3: Weighted F1 of few-shot for different prompt-based training methods.

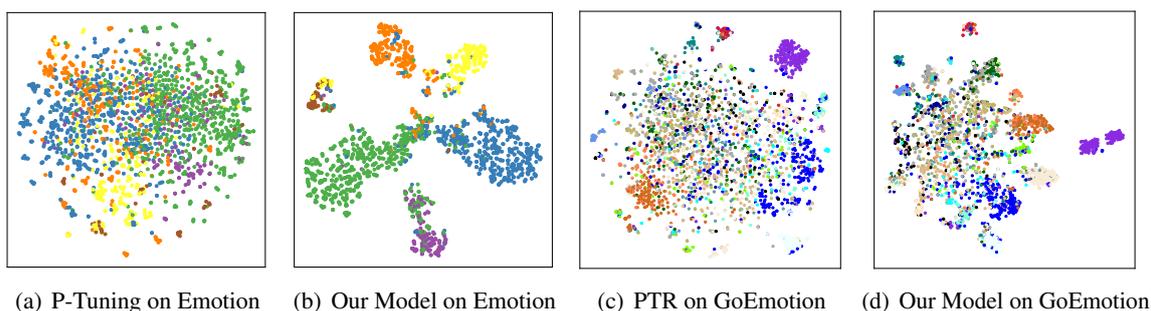

Figure A1: The T-SNE results of test samples in Emotion/GoEmotions Dataset under 100-shot.

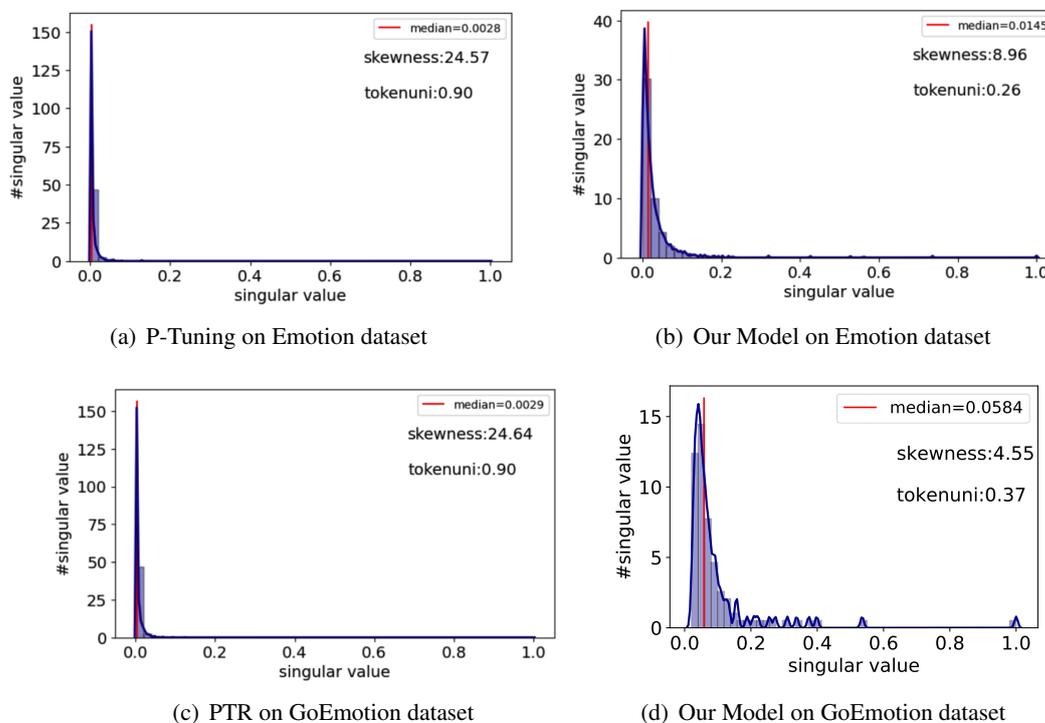

Figure A2: The singular value distribution of test samples under 100-shot. Our methods greatly balance the singular distribution, i.e., decrease the skewness, and alleviate the *information diffusion* issue, i.e., decrease the token similarity (*tokenuni*).

Investigating anatomical bias in clinical machine learning algorithms

Abstract

Clinical machine learning algorithms have shown promising results and could potentially be implemented in clinical practice to provide diagnosis support and improve patient treatment. Barriers for realisation of the algorithms' full potential include bias which is systematic and unfair discrimination against certain individuals in favor of others.

The objective of this work is to measure *anatomical bias* in clinical text algorithms. We define anatomical bias as unfair algorithmic outcomes against patients with medical conditions in specific anatomical locations. We measure the degree of anatomical bias across two machine learning models and two Danish clinical text classification tasks, and find that clinical text algorithms are highly prone to anatomical bias. We argue that datasets for creating clinical text algorithms should be curated carefully to isolate the effect of anatomical location in order to avoid bias against patient subgroups.

1 Introduction

Research in clinical machine learning algorithms have shown promising results for automating clinical tasks. The algorithms could potentially be implemented in clinical practice to provide diagnosis support, improve patient treatment and provide time-savings for medical doctors (Topol, 2019; Matheny et al., 2020).

However, despite appealing research results, there are currently limited examples of algorithms being successfully deployed into clinical practice (Kelly et al., 2019). Barriers for realisation of the algorithms' full potential include bias and general-

sation issues (Char et al., 2018; Hovy and Prabhu-moye, 2021; Carrell et al., 2017).

Algorithmic bias can be defined as systematic and unfair discrimination against certain individuals or groups of individuals in favor of others (Friedman and Nissenbaum, 1996). Previous studies have raised serious concerns of algorithms that contain age, gender and racial bias (Sun et al., 2019; Davidson et al., 2019) — even for algorithms that have been taken into use (Obermeyer et al., 2019). Although machine learning algorithms are trained to be able to generalise to previously unseen data, they tend to overfit to the data they have been trained on. As a consequence of this, bias can unintentionally arise if some subgroups of the target population are not represented in the data used to train the algorithm. Moreover, if the training data itself include biases against some populations, e.g. data reflecting a negative attitude against people with disabilities (Hutchinson et al., 2020), these biases might be encoded and reinforced.

If biased algorithms are adopted, healthcare systems risk doing injustice to certain patient groups and harming patient safety (Obermeyer et al., 2019). Therefore, identifying and mitigating bias is important for successful implementation of novel clinical machine learning algorithms.

This paper investigates *anatomical bias* in clinical machine learning algorithms developed to classify and extract specific medical conditions from the narrative text of electronic health records (EHR). We define anatomical bias as unfair algorithmic outcomes against a subgroup of patients with the same medical condition, where the algorithm performs differently depending on the anatomical location of the condition. If the performance of clinical algorithms varies depending

*Equal contribution

on the anatomical location, it is reflected in some patient subgroups receiving worse treatment than others.

We hypothesised that careful dataset curation is needed to measure and mitigate anatomical bias because the text description of medical conditions in EHRs varies depending on the location, e.g. ‘epistaxis’ is a location-specific word describing nose bleedings.

Specifically, this paper investigates anatomical bias for classification of bleeding and venous thromboembolism (VTE) mentions in the narrative text of Danish EHRs. Automatic extraction of these conditions could be valuable for medical doctors in clinical practice, e.g. to guide diagnostic decision making and treatment options (Decousus et al., 2011). Previous papers (Hinz et al., 2013; Lee et al., 2017; Taggart et al., 2018; Li et al., 2019; Mitra et al., 2020, 2021; Elkin et al., 2021; Pedersen et al., 2021; Shi et al., 2021; Verma et al., 2022) have shown promising results for automatic extraction of these medical conditions but they did not investigate the performance of the algorithms across anatomical subgroups.

Our main contributions are:

- We find that clinical text algorithms are highly prone to anatomical bias.
- The performance of state-of-the-art algorithms developed to extract specific medical conditions varies significantly across anatomical locations with performance drops up to 89.1 percentage points (PP).
- We argue that datasets for creating clinical text algorithms should be curated carefully to isolate the effect of anatomical location in order to avoid bias against patient subgroups.

2 Methods

To investigate if machine learning algorithms are prone to anatomical bias, we performed two experiments. We (1) investigated the performance of a binary classifier on different anatomical subgroups of a medical condition when that subgroup was left out of the training set, and (2) measured how the performance on an anatomical subgroup varied depending on the amount of samples from that subgroup included in the training set.

Table 1: Distribution of the training, validation, and test samples for the balanced bleeding detection dataset.

Label	Location	Train	Validation	Test
Positive for bleeding	Gastrointestinal	750	250	250
	Urogenital	750	250	250
	Internal	750	250	250
	Otorhinolaryngeal	750	250	250
	Dermatological	750	250	250
	Gynecological	750	250	250
	Cerebral	750	250	250
	Ophthalmological	750	250	250
Negative for bleeding		6,000	2,000	2,000
Sum		12,000	4,000	4,000

Table 2: Distribution of the training, validation, and test samples for the balanced VTE detection dataset.

Label	Location	Train	Validation	Test
Positive for VTE	Lower extremity	1,600	200	200
	Lung	1,600	200	200
	Liver	0	0	239
	Cerebral	0	0	218
	Upper extremity	0	0	176
Negative for VTE		3,200	400	1,033
Sum		6,400	800	2,066

2.1 Datasets

We used the binary bleeding classification dataset from Pedersen et al. (2022) and present a new binary VTE classification dataset. The bleeding dataset consists of 20,000 sentences from Danish EHRs labeled as either positive or negative for bleeding mentions. The VTE classification dataset consists of 9,266 sentences from Danish EHRs labeled as either positive or negative for VTE mentions. Both datasets were constructed from Danish EHRs from Odense University Hospital and were labeled with a consensus label from three medical doctors.

In addition to the main labels of each dataset (positive and negative for bleeding or VTE), we created a subgroup label for the positive samples describing the anatomical location of either the bleeding or VTE mention. Samples that did not describe the anatomical location or described multiple locations were omitted.

For the bleeding dataset, we used the following eight anatomical locations: gastrointestinal, urogenital, internal, otorhinolaryngeal, dermatological, gynecological, cerebral, and ophthalmological.

For the VTE dataset, we used the following five anatomical locations: lower extremity, lung, liver, cerebral, and upper extremity.

The locations included for each medical condition were selected by two medical doctors.

For each dataset, we created a balanced training, validation, and test set containing an equal amount

of positive and negative samples. Moreover, for the bleeding dataset, the positive samples of the training, validation, and test sets were distributed equally between anatomical locations. For the VTE dataset, only samples from the lower extremity and lung locations were distributed equally between the train, validation, and test sets. The liver, cerebral, and upper extremity locations were only used for the test set because of a limited number of samples.

All samples were preprocessed by removing special characters, superfluous spaces, and duplicate samples. After preprocessing the samples, the bleeding and VTE datasets had an average token length of 13.3 and 13.6, respectively. The dataset distributions can be seen in [Table 1](#) and [Table 2](#).

2.2 Training set distributions

To measure performance differences for specific anatomical locations, we systematically removed all samples from a specific location, x , from the training set, creating the training set $\mathcal{T}_{\not{x}}$, trained a deep learning model on $\mathcal{T}_{\not{x}}$, and evaluated it on the test set. For example, for the bleeding dataset, we created 8 different training sets, one for each anatomical location being removed, containing 10,500 samples.

For comparison, we created a balanced training set, \mathcal{T} , which included the same amount of samples as $\mathcal{T}_{\not{x}}$, distributed equally between the positive and negative classes, and between anatomical locations.

2.3 Deep learning models

The deep learning models were a transformer-based ELECTRA model ([Clark et al., 2020](#)) and a Long Short-Term Memory (LSTM) model ([Hochreiter and Schmidhuber, 1997](#)).

The ELECTRA model was a Danish clinical ELECTRA (Clin-ELECTRA) ([Pedersen et al., 2022](#)) pretrained on the narrative text from 299,718 EHRs from Odense University Hospital. The model had ~ 13 M parameters and consisted of 12 transformer layers with 4 attention heads. We initialised Clin-ELECTRA from its pretrained checkpoint and followed the HuggingFace ([Wolf et al., 2019](#)) implementations for binary text classification.

The LSTM model had ~ 4 M parameters and consisted of a bidirectional LSTM layer with a hidden layer size of 512. The last hidden state of the LSTM was followed by a dropout layer with probability 0.2, a dense layer of size 256, a ReLU activation

function, a dropout layer of probability 0.2, and a dense classification layer. For word representation, the LSTM model used 300-dimensional FastText ([Bojanowski et al., 2017](#)) word embeddings pretrained on Danish EHRs consisting of 1.4B tokens.

2.4 Model evaluation

For each of the ELECTRA and LSTM deep learning models and training sets \mathcal{T} and $\mathcal{T}_{\not{x}}$, we:

1. Trained the deep learning model with five different learning rates and random initialisations.
2. Computed the test set accuracy of the best performing model based on the loss on the validation set.
3. Repeated step 1 and 2 five times.

We used the five accuracies to perform bootstrapping with 9,999 replicates and calculated mean accuracy, standard error (SE), and 95% confidence interval (CI) for \mathcal{T} and $\mathcal{T}_{\not{x}}$. Moreover, we computed the bootstrapped difference of means between \mathcal{T} and $\mathcal{T}_{\not{x}}$ to evaluate statistically significant differences in performance.

For both deep learning models, we used the Adam optimizer ([Kingma and Ba, 2015](#)) and searched for the best model using learning rates $7e-5$, $8e-5$, $9e-5$, and $1e-4$. Clin-ELECTRA was fine-tuned for a maximum of 10 epochs and the LSTM for a maximum of 30 epochs. One epoch was trained in <1 and ~ 5 seconds for the LSTM and ELECTRA model, respectively, using an NVIDIA v100 GPU.

We measured anatomical bias as the difference in sensitivity on a specific location, x , between two deep learning models trained on \mathcal{T} and $\mathcal{T}_{\not{x}}$.

3 Results

3.1 Bleeding classification

[Table 3](#) shows the binary accuracy of the bleeding classifiers on the test set for each of the training sets \mathcal{T} and $\mathcal{T}_{\not{x}}$. [Appendix A](#) shows additional metrics. With the exception of $\mathcal{T}_{\not{x}Otorhinolaryngeal}$ for the ELECTRA model, all training sets with an anatomical location removed resulted in models with significantly worse performance than when trained on \mathcal{T} .

The decreases in accuracy were caused by a significant drop in sensitivity for the anatomical locations which had been removed from the training

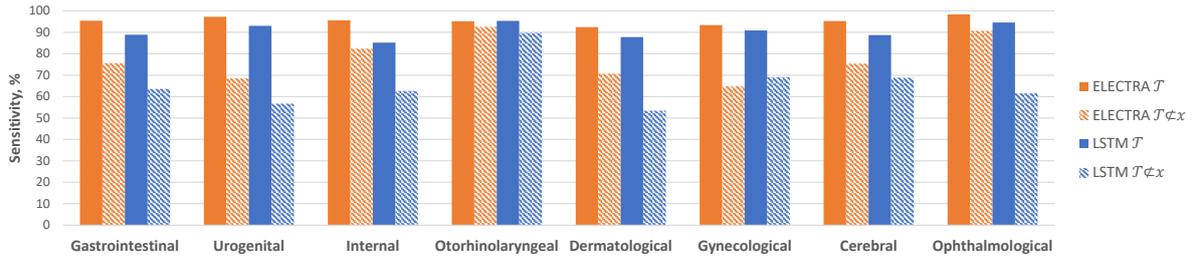

Figure 1: Sensitivity of models trained on $\mathcal{T}_{\setminus x}$ and \mathcal{T} for each anatomical location, x .

Table 3: Accuracy (%), standard error (SE), and 95% confidence interval (CI) for the bleeding classification dataset. $\mathcal{T}_{\setminus x}$ denotes the training set from which an anatomical location, x , has been removed. * denotes a significant difference at the 0.05 level between models trained on \mathcal{T} and $\mathcal{T}_{\setminus x}$.

	ELECTRA		LSTM	
	Accuracy \pm SE	CI	Accuracy \pm SE	CI
\mathcal{T}	95.6 \pm 0.1	95.4 - 95.8	90.6 \pm 0.1	90.4 - 90.7
$\mathcal{T}_{\setminus \text{Gastrointestinal}}$	94.4 \pm 0.2*	94.0 - 94.7	88.8 \pm 0.1*	88.6 - 88.9
$\mathcal{T}_{\setminus \text{Urogenital}}$	93.9 \pm 0.1*	93.7 - 94.2	88.5 \pm 0.1*	88.3 - 88.6
$\mathcal{T}_{\setminus \text{Internal}}$	95.0 \pm 0.1*	94.8 - 95.2	88.8 \pm 0.1*	88.5 - 89.0
$\mathcal{T}_{\setminus \text{Otorhinolaryngeal}}$	95.6 \pm 0.1	95.4 - 95.8	90.0 \pm 0.2*	89.8 - 90.4
$\mathcal{T}_{\setminus \text{Dermatological}}$	94.3 \pm 0.1*	94.0 - 94.5	88.2 \pm 0.1*	88.1 - 88.3
$\mathcal{T}_{\setminus \text{Gynecological}}$	93.8 \pm 0.1*	93.6 - 94.0	89.1 \pm 0.1*	88.9 - 89.4
$\mathcal{T}_{\setminus \text{Cerebral}}$	94.6 \pm 0.2*	94.3 - 94.9	89.0 \pm 0.1*	88.8 - 89.2
$\mathcal{T}_{\setminus \text{Ophthalmological}}$	95.3 \pm 0.1*	95.1 - 95.4	88.2 \pm 0.2*	87.8 - 88.5

data. Figure 1 shows the test set sensitivity for each anatomical location, x , for each training set \mathcal{T} and $\mathcal{T}_{\setminus x}$. The sensitivity for all anatomical locations was significantly worse when not present in the training set with performance drops up to 28.8 PP for ELECTRA and 36.3 PP for the LSTM model. On average, the sensitivity on the anatomies decreased with 17.8 PP (standard deviation \pm 8.8 PP) for ELECTRA and 24.5 PP (standard deviation \pm 9.4 PP) for the LSTM model.

Moreover, it is seen that even though models trained on $\mathcal{T}_{\setminus x}$ achieved high accuracies on the test set overall, the sensitivity on the anatomical location not present in the training set was low. E.g., for ELECTRA, $\mathcal{T}_{\setminus \text{Gynecological}}$ had a 93.8% accuracy on the test set, but the sensitivity for gynecological bleedings was only 64.8%. Appendix A shows the sensitivity, SE, and the differences of means for all anatomical locations and training sets.

Figure 2 shows the sensitivity on each anatomical location by the percentage of total subgroup samples in the training set. It is seen that the accuracy increased as more samples were present in the training set. For the LSTM model, the sensitivity on gastrointestinal, urogenital, cerebral, and ophthalmological bleedings was significantly worse - even when 80% of samples were present in the

Table 4: Accuracy (%), standard error (SE), and 95% confidence interval (CI) for the VTE classification dataset. $\mathcal{T}_{\setminus x}$ denotes the training set from which an anatomical location, x , has been removed. * denotes a significant difference at the 0.05 level between models trained on \mathcal{T} and $\mathcal{T}_{\setminus x}$.

	ELECTRA		LSTM	
	Accuracy \pm SE	CI	Accuracy \pm SE	CI
\mathcal{T}	84.8 \pm 0.3	84.2 - 85.4	75.9 \pm 0.3	75.4 - 76.4
$\mathcal{T}_{\setminus \text{Lower extremity}}$	67.6 \pm 0.6*	66.5 - 68.7	71.6 \pm 0.4*	70.8 - 72.6
$\mathcal{T}_{\setminus \text{Lung}}$	74.0 \pm 1.1*	71.9 - 76.1	69.9 \pm 0.1*	69.7 - 70.2

training set. For ELECTRA, the sensitivity on urogenital and internal bleedings was significantly worse when 80% of samples were present in the training set. Appendix A shows the accuracies and differences of means.

3.2 Venous thromboembolism classification

Table 4 shows the binary accuracy of the VTE classifiers on the test set for each of the training sets \mathcal{T} and $\mathcal{T}_{\setminus x}$. Appendix B shows additional metrics. Models trained on $\mathcal{T}_{\setminus \text{Lower extremity}}$ and $\mathcal{T}_{\setminus \text{Lung}}$ performed significantly worse than those trained on \mathcal{T} .

Similar to the bleeding classifier results, the decrease in the overall accuracy was caused by a significant drop in sensitivity on the anatomical locations which had been removed from the training data. Figure 3 shows the sensitivity for each anatomical location, x , for each training set \mathcal{T} and $\mathcal{T}_{\setminus x}$. The sensitivity on liver, cerebral, and lower extremity VTEs is only reported when not being present in the training set because of limited samples.

The sensitivity on lower extremity and lung VTEs was significantly worse when not present in the training set, e.g. the performance for the ELECTRA classifier decreased by 89.1 PP for lower extremity VTEs and 81.0 PP for lung VTEs. Appendix B shows the sensitivity, SE, and the differences of means for all anatomical locations and

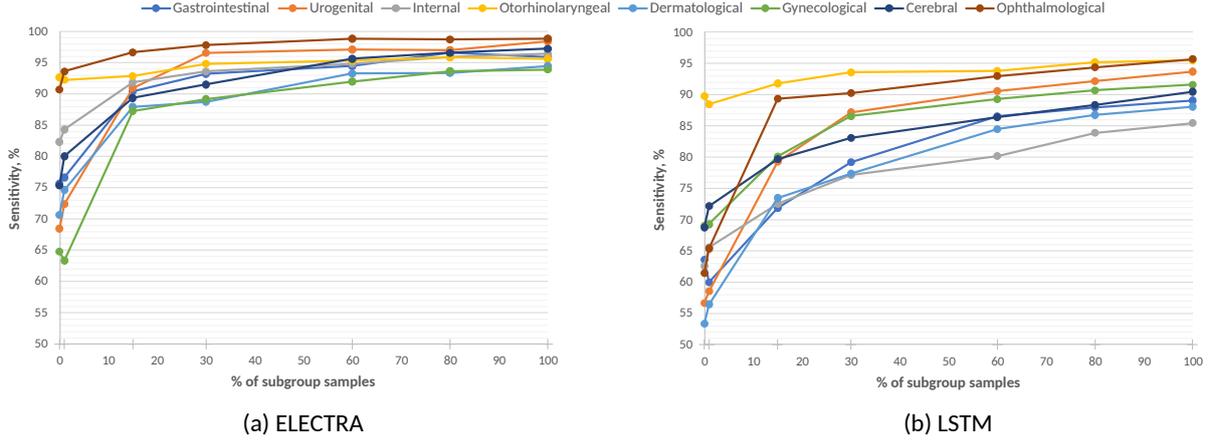

Figure 2: Test set sensitivity on the anatomical locations when removing a fraction of samples from that anatomy from the training set.

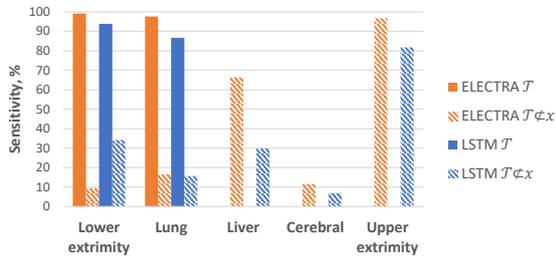

Figure 3: Sensitivity of models trained on $\mathcal{T}_{\mathcal{Q},x}$ and \mathcal{T} for each anatomical location, x . The sensitivity on liver, cerebral, and lower extremity VTEs is only reported when not being present in the training set because of limited samples.

training sets.

Figure 4 shows the sensitivity for lower extremity and lung VTEs by the percentage of total subgroup samples in the training set. Both locations performed significantly worse when 15% and 30% of samples from that location were present in the training set for the ELECTRA and LSTM classifier, respectively. Appendix B shows the accuracies and differences of means.

4 Analysis of word distributions

Medical conditions are often described using different words depending on the anatomical location for which the condition occurs. Table 5 shows the top-3 most frequent words used to describe VTE events for each anatomical location. The column *Location uniqueness* shows the fraction of times a word appears in samples from a specific anatomical

Table 5: Most frequent words used to describe VTE events for each anatomical location of the VTE classification dataset. Words are translated from Danish to English and, therefore, some cells include two words. PE = pulmonary embolism.

Word	Frequency	Location uniqueness
Location: Lower extremity		
dvt	1384	0.92
thrombus	135	0.70
blood clot	108	0.47
Location: Lung		
pulmonary embolism	1058	0.98
le (PE)	483	0.99
pulmonary embolisms	242	0.99
Location: Liver		
porta thrombosis	71	1.00
thrombosis	70	0.36
thrombus	22	0.11
Location: Cerebral		
infarct	93	0.97
sinus thrombosis	32	0.97
blood clot	26	0.11
Location: Upper extremity		
dvt	99	0.07
thrombus	28	0.14
thrombosis	14	0.07

location compared to the complete dataset:

$$Location\ uniqueness = \frac{f_x}{f_D} \quad (1)$$

where f_x is the frequency of the word in samples from anatomical location x and f_D is the total frequency of the word in the dataset, i.e. a value of 1 means that the word is unique for an anatomical location.

The top-3 words for upper extremity had a low uniqueness score (<0.15). This indicates that the vocabulary used to describe VTEs in the upper extremity was also used for other locations — e.g.

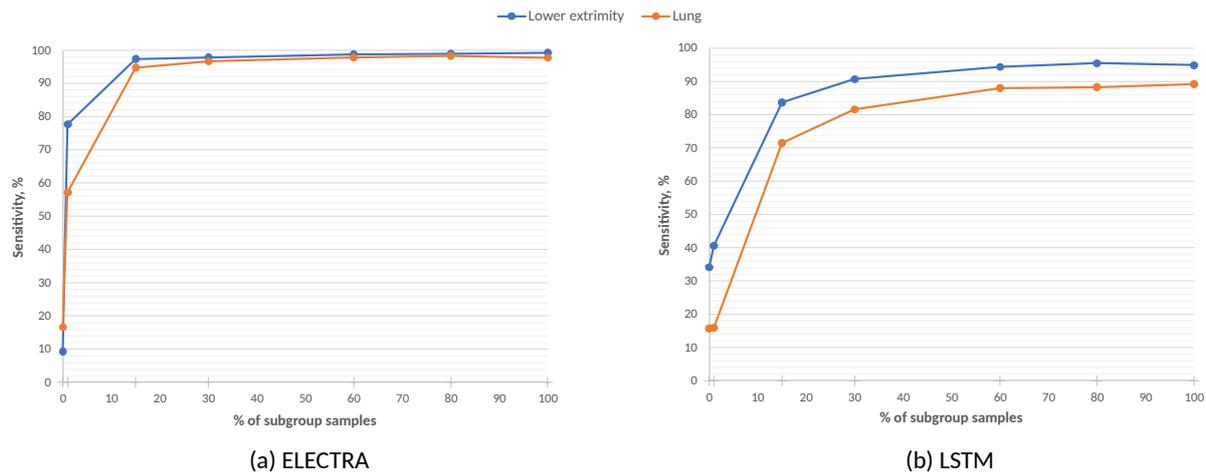

Figure 4: Test set sensitivity on the anatomical locations when removing a fraction of samples from that anatomy from the training set.

‘dvt’ (deep vein thrombosis) was the most frequent word but the uniqueness score was only 0.07. This might explain why the sensitivity for upper extremity was relatively high, as seen in Figure 3, even when samples from that location were not present in the training set. On the contrary, some of the frequent words from the lower extremity, lung, and cerebral locations were close to unique which could explain why the sensitivity of those locations were low. Appendix C shows word frequency and location uniqueness for the bleeding classification dataset which shows similar results.

5 Discussion

This paper has presented evidence that clinical natural language processing (NLP) classification algorithms are prone to anatomical bias, which is unfair algorithmic outcomes against patients with medical conditions in specific anatomical locations. We found that the performance of algorithms for both bleeding and VTE classification can vary significantly depending on the anatomical location with differences up to 36.3 PP and 89.1 PP, respectively.

Moreover, we found that small fluctuations in the training set distribution of anatomical locations can lead to significant performance drops for the under-represented anatomical locations. For the datasets presented in this study, we showed that the words used to describe medical conditions vary depending on the anatomical location. If classifiers do not learn to properly represent the full vocabulary for describing a medical condition, its performance will decrease for some anatomical locations.

We argue that datasets for clinical NLP algo-

gorithms should be created to be able to carefully measure anatomical bias, e.g. by subdividing each sample into an anatomical location. This is essential to avoid implementing clinical algorithms that might discriminate against specific subgroups of patients. For example, one of the developed VTE classifiers in this study performed with sensitivities of >96% for VTEs in the lungs and lower extremity while it performed with a sensitivity of only 11.5% for cerebral VTEs. Applying such a model in clinical practice or research would provide unfair algorithmic outcomes against patients with cerebral VTEs. We also showed that an algorithm not exposed to gynecological bleedings would perform worse on this anatomical location. This would lead to unfair algorithmic outcomes against woman with gynecological bleedings. Similarly, because alcoholics have an increased prevalence of gastrointestinal bleedings (Singal et al., 2018), this group of people would have a higher risk of unfair algorithmic outcomes if the algorithm has not been trained on such bleeding locations.

To the best of our knowledge, anatomical bias has not been investigated in previous research. However, some studies tried to automatically create datasets distributed between different patient groups by extracting data based on International Classification of Diseases 10 (ICD) codes — e.g. Pedersen et al. (2021) extract data based on different bleeding disorders. While this approach could, to some degree, mitigate the problem, studies (Valkhoff et al., 2014; Øie et al., 2018) found that ICD codes have low accuracy and, therefore, this does not ensure an evenly distributed dataset.

Moreover, in order to isolate and measure the performance on different anatomical locations, the dataset should be constructed with a known distribution of these anatomies.

Our work is closely related to the field of domain adaptation. For example, MacAvaney et al. (2017) find that an algorithm trained to extract temporal information from a specific patient population performs worse on another related patient population. Their results highlight that it is a challenging task to develop algorithms that can generalise well across domains. The main difference between our study and theirs is that the algorithms described in this paper are not developed to work on different domains. Rather, the algorithms are specifically developed to work on a specialised domain in the clinical field, e.g. bleeding detection. As our results have shown, the algorithms perform worse on some subpopulations of the population it is supposed to work on, and therefore, we describe this as a bias issue.

6 Conclusion

This paper presented evidence that clinical NLP algorithms are prone to anatomical bias. We found that the performance of clinical classification algorithms for both bleeding and VTE classification can vary significantly depending on the anatomical location of the medical condition. We argue that anatomical bias should be carefully examined when developing clinical text algorithms in order to avoid unfair algorithm performance against patient subgroups.

7 Limitations

Future work should investigate the degree of anatomical bias in other clinical areas and tasks, e.g. named entity recognition, to be able to compare the severity of the bias problem between algorithms and other clinical areas. Moreover, as the datasets used in this study are only from a single institution, the findings of the paper might not be widely representative.

The objective of this work was to stress the need for measuring anatomical bias. We leave it to future work to investigate algorithmic solutions other than dataset balancing for mitigating the problem, e.g. using techniques such as oversampling and data augmentation. Such techniques could also help mitigating anatomical bias in algorithms for which training set balancing is not sufficient.

The classification datasets and machine learning

models presented in this paper cannot be shared publicly due to privacy concerns but we advise interested researchers to contact us for sharing possibilities.

Ethics Statement

Machine learning researchers must be proactive in recognising and counteracting biases such as the one described in this paper. We hope that the findings and focus of this paper will lead other researchers to test and mitigate other kinds of algorithmic biases.

All datasets used in this research were obtained according to each dataset's respective data usage policy. The datasets were stored and processed on a secure platform¹ in compliance with GDPR regulations. According to section 14(2) of the Danish Act on Research Ethics Review of Health Research Projects², studies using retrospective data that do not involve human biological material do not require ethical approval.

Topic Ontologies for Arguments

Abstract

Many computational argumentation tasks, such as stance classification, are topic-dependent: The effectiveness of approaches to these tasks depends largely on whether they are trained with arguments on the same topics as those on which they are tested. The key question is: What are these training topics? To answer this question, we take the first step of mapping the argumentation landscape with The Argument Ontology (TAO). TAO draws on three authoritative sources for argument topics: the World Economic Forum, Wikipedia’s list of controversial topics, and Debatepedia. By comparing the topics in our ontology with those in 59 argument corpora, we perform the first comprehensive assessment of their topic coverage. While TAO already covers most of the corpus topics, the corpus topics barely cover all the topics in TAO. This points to a new goal for corpus construction to achieve a broad topic coverage and thus better generalizability of computational argumentation approaches.

1 Introduction

The term “topic” refers to the subject matter of a text. A text may be about one or more topics and the relationship between topics and texts is called “aboutness” (Yablo, 2014). Topics play a central role in argumentation because they determine argumentation strategies and rhetorical devices by setting the appropriate and expected universe of discourse. This view is supported by pragmatics (van Eemeren, 2015): “The basic aspects of strategic maneuvering [...] are making an expedient selection from the ‘topical potential’ available at a certain discussion.” Although debaters often use commonplace arguments across topics (Bilu et al., 2019), they must be relevant: a black market argument, for example, can be equally well applied to topics such as banning drugs or banning firearms. As recently shown, for example, by Reuver et al. (2021), training computational models to extract, analyze, or generate arguments with a broad topic coverage improves their generalizability.

A set of topics can be organized as a graph, sometimes called a “topic space”. Information theorists and library scientists map hierarchical subject relationships into ontologies in this way (Hjørland, 2001). For this purpose, topics are labeled with a subject heading, a phrase from a controlled vocabulary that describes a topic in a concise and discriminating manner. While library ontologies are not focused on argumentation, others deal specifically with *argumentative* topic spaces. We have identified and tapped three authoritative sources of ontological knowledge covering global issues, controversies, and popular debates: the World Economic Forum’s “Strategic Intelligence” site, Wikipedia’s list of controversial topics, and Debatepedia’s debate classification system (Section 4). They form the basis for The Argument Ontology (TAO).¹

We compile a comprehensive survey of 59 argument corpora (Section 3) and investigate their topic coverage with respect to the three authoritative ontologies (Section 5). The coverage of corpora with topic labels is manually assessed by matching each label with the topics of the ontologies. From this, the ontology topics covered by a corpus and the distribution of corpus arguments in the ontologies are calculated. Our analyses show that the existing corpora focus on only a subset of the known topics. For corpora without topic labels, we categorize their argumentative texts by measuring their semantic relatedness to ontology topics. Given the large number of ontology topics (748 for Wikipedia), this is a challenging classification for which we achieve a remarkable F_1 of 0.59. (Section 6).²

Altogether, we lay the foundation for the study and systematic exploration of controversial topics within computational argumentation analysis. The authoritative sources identified already cover their respective areas quite comprehensively. Future work will need to extend our approach to other subject areas, such as business, domestic, historical, and scientific argument spaces.

2 Related Work

Our review of related work focuses on the role of the variable “topic” in computational argumentation. Moreover, we briefly review topic ontologies and hierarchical topic classification.

2.1 Topics in Computational Argumentation

In computational argumentation, arguments are typically modeled as compositions of argument units, where an argument unit is represented as a span of text. Habernal and Gurevych (2016a) adopts Toulmin (1958)’s (1958) model, which defines six unit types, among which are “claim” and “data”. Wachsmuth et al. (2017) employ a more basic model of two units, which defines an argument as a claim or conclusion supported by one or more premises. These models capture arguments without explicitly identifying the topic they address. Levy et al. (2014) consider claims to be topic-dependent and study their detection in the context of a random selection of 32 topics from idebate.org. This work raises the question why topic-dependence has not been addressed more urgently until now.

Key tasks for computational argumentation include the mining of arguments from natural language (Moens et al., 2007; Al-Khatib et al., 2016), classifying their stances with regard to a thesis (Bar-Haim et al., 2017), and analyzing which arguments are more persuasive (Tan et al., 2016; Habernal and Gurevych, 2016a). Current approaches to these tasks rely on supervised classification. Daxenberger et al. (2017) show that supervised classifiers fail to generalize across domains (\sim topics). More recently, Stab et al. (2018) tweak BiLSTM (Graves and Schmidhuber, 2005) to integrate the topic while jointly detecting (1) whether a sentence is an argument and (2) its stance to the topic. The designed neural network outperforms BiLSTM without topic integration in both tasks; further evidence for the topic-dependence of argument mining and stance classification. Whether model transfer between more closely related topics works better is unknown. As a first step, Reuver et al. (2021) show that cross-topic stance-classification with BERT (Devlin et al., 2018) produces mixed results depending on the topics, but misses the relations between the topics. Gu et al. (2018) show that integrating the topic of an argument helps assessing its persuasiveness.

Topic plays a central role in argument retrieval and generation since it defines what arguments are

relevant. Argument retrieval aims at delivering pro and con arguments on a given topic query. A major challenge in argument retrieval is the grouping of arguments that address common aspects of a topic. As shown by Reimers et al. (2019) and Ajour et al. (2019a), integrating the topic is an important step while clustering arguments. For argument generation, Bilu et al. (2019) introduce an approach that matches an input topic against a list of topics that are paired with sets of topic-adjustable commonplace arguments (e.g., black-market arguments). In a similar vein, Bar-Haim et al. (2019) identify consistent and contrastive topics for a given topic with the goal of expanding the topic in a new direction (e.g., fast food versus obesity). Both approaches show the merit of utilizing argument topic ontologies in argument generation.

Only abstract argumentation may be truly topic-independent, where only the structure and relations among arguments, not their language, are studied.

2.2 Topic Ontologies

In information science, an ontology is defined as “an explicit specification of a conceptualization” (Gruber, 1993). Topic ontologies are a specific type of ontologies which specify topics as nodes of a directed acyclic graph. An edge in the graph then implies an “is part of”-relation between the topics (Xamena et al., 2017). The effort in creating topic ontologies ranges from ad-hoc decisions (e.g., tags for blog posts) to extensive classification schemes for libraries. The oldest classification scheme that is still used today in libraries is the Dewey Decimal Classification. It has been translated into over 30 languages, and it contains several tens of thousands of classes. Most topic ontologies focus on a specific domain, such as the ACM Computing Classification System for computer science, or DMOZ for web pages.³ The only topic ontology directly linked to arguments is that of Debatepedia.

2.3 Hierarchical Text Classification

Hierarchical text classification aims at classifying a document into a class hierarchy. Depending on how the hierarchical structure is exploited, classification can be done top-down (from higher classes downwards), bottom-up, or flat (ignoring hierarchical relations) (Silla and Freitas, 2011). Researchers usually train supervised classifiers for each class in the hierarchy (Sun and Lim, 2001).

Table 1: Survey of argument corpora indicating data source, unit granularity, and size in terms of units and topics (if authors remarked on it). The unit granularity is the one in the corpus’ files, using premises and conclusions as one unit each and the best context-preserving unit for corpora featuring multiple granularities. We presume these topic selection directives from the corpus description: either *manual selection* by the authors, or *source-driven*—i.e., the topics in the selected source(s)—from the units of a specific *time-span* or by random *sampling*. Experiments (Exp.) denotes the count of papers that use the corpus in an experiment among those papers that cite the corpus’ paper.

3 Survey of Argument Corpora

To study arguments and computational argumentation tasks, researchers compile corpora with argumentative texts. To the best of our knowledge, Table 1 compiles all corpora dedicated to argumentation until 2022. We review these corpora and their associated publications with regard to what are the sources of arguments, what is the granularity of the corpus, what is the size of the corpora in terms of their units, and which and how many different topics are covered in them. Reviewing all papers citing a corpus, we also analyzed how many experiments were carried out using them.

The most elaborate discussion of topic selection is given in Habernal and Gurevych (2016a), who chose six topics (homeschooling, public versus private schools, redshirting, prayers in schools, single sex education, mainstreaming) to focus on different education-related aspects. The broadest selection of topics is reported by the researchers of IBM Debater,⁴ who obtain arguments from Wikipedia. However, samples of the topics have been used in their papers without mentioning which ones. The only other work mentioning their source of topics stems from Stab et al. (2018), who randomly select 8 topics from two lists of controversial topics that originate from an online library and the debate portal ProCon.org, respectively. Peldszus and Stede (2015) predefine a set of topics and give writers the freedom to choose which one to write about, but nothing is said about where the set of predefined topics originate from. Conard et al. (2012) and Hasan and Ng (2014) explicitly select one and

four topics, respectively. For all other corpora with topic labels, their authors do not argue on choosing topics, nor selection or sampling criteria. Neither do the authors of corpora without topic labels.

Altogether, it appears that the best practices in argumentation do not as of yet consider topic sampling as a prerequisite task to ensure coverage of a certain domain of interest, diversity, or reproducibility. Based on our review, we presume three basic topic selection directives are in use today: (1) *Manual selection*. Topics are manually defined or selected. Although the process may be random, when aiming for controversial topics, one may often end up with commonplace topics in Western culture (e.g., abortion, death penalty, gay marriage). Still, they are relevant and important today. (2) *Source-driven (greedy within a time-span)*. A source of argument ground truth is either exploited in its entirety, or a maximum subset fulfilling desired properties is used. Since argument-related ground truth is hard to come by, it is understandable that many readily available sources are being exploited. (3) *Source-driven (sampled)*. A source or argument ground truth is exploited and a subset is sampled. Here, it may be infeasible to exploit a source in its entirety. Al-Khatib et al. (2016b) randomly select 300 documents from three websites. Park and Cardie (2018) and Stab and Gurevych (2017) do not mention anything about their sampling process. In general, both source-driven corpus construction approaches inevitably incur the source’s idiosyncracies of topic selection in terms of skew towards certain topics. Scaling up may or may not be a remedy for this problem.

⁴https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml

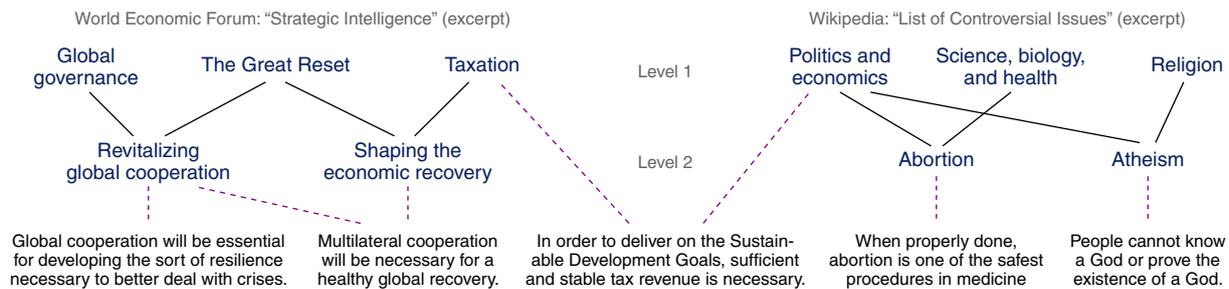

Figure 1: Example for an assignment of arguments (bottom) to topics of a two-leveled ontology. Level 2 topics are subtopics of their linked Level 1 topics. Arguments linked to a Level 2 topic also pertain to its Level 1 ancestors.

We assess how many experiments have been reported on each of the corpora by collecting the publications referring to a corpus as per Google Scholar, focusing on conference and journal papers, but excluding books and web pages. We then check whether the cited corpus is mentioned in its data, experiment, or results section. As can be seen in Table 1, corpora with fewer topics tend to be used more often in experiments than those with larger amounts. In total, 230 experiments were carried out on argument corpora with no clearly defined topic selection directive. The skew towards smaller-scale experiments may affect generalizability.

4 Bootstrapping The Argument Ontology

Topic ontologies provide for a knowledge organization principle, and, especially if widely accepted, also a standard. They are typically modeled as directed acyclic graphs, where nodes correspond to topics and edges indicate “is part of” relations. Topics that are part of other topics are called their subtopics. A topic ontology is often displayed in levels, starting with the topics that are not subtopics of others, continuing recursively with each lower level of subtopics. Figure 1 shows an excerpt of a two-level topic ontology for arguments.

The identification of the topics to be included in The Argument Ontology (TAO), as well as their relations, requires domain expertise. Building an all-encompassing ontology thus requires experts from every top-level domain where argumentation of scientific interest is expected. In the following, we suggest and outline three authoritative sources of expert topic ontologies, which comprise a wide selection of important argumentative topics. We use them to bootstrap a first version of TAO.

World Economic Forum (WEF) The World Economic Forum is a not-for-profit foundation that coordinates organizations from both the public and

the private sector to work on economical and societal issues. As part of their efforts, their “Strategic Intelligence” platform⁵ strives to inform decision makers on domestic and global topics, specifically global issues (e.g., artificial intelligence and climate change), industries (e.g., healthcare delivery and private investors), and economies (e.g., Africa and ASEAN). Domain experts for each topic curate a stream of relevant news articles which they each tag with 4-9 subtopics of their topic (e.g., the continuous monitoring of mental health).

Wikipedia Wikipedia strives for a neutral point of view, but many topics of public interest are discussed controversially. Some editors thus curate a list of controversial Wikipedia articles to highlight where special care is needed, grouped into 14 top-level topics (e.g., environment and philosophy) and 4-176 subtopics (e.g., creationism and pollution).⁶ We omit the “People” topic and articles on countries; their controversiality is not universal.

Debatepedia The Debatepedia portal’s goal is to create an encyclopedia of debates which are organized as “pro” and “con” arguments. A list of 89 topics helps visitors to browse the debates. The debates are contributed by anonymous web users. Topics in Debatepedia tend to address issues of Western culture. For example, the topic “United States” covers 306 debates while “Third World” covers only 12. The site is no longer maintained, but accessible through the Wayback Machine.⁷

The three ontologies are publicly accessible, and two of them are actively maintained and updated. Acquiring the ontologies is straightforward—not straightforward is to make use of them. A key task associated with every topic ontology is to categorize a given document. Having just a short string

Imperative	25	Ban abortions	abortion	Record Debating Dataset 5
Comparison	23	Pro Choice vs. Pro Life	pro choice vs pro life	UKPConvArg1

Table 2: Counts of the topic types in the 39 preprocessed corpora with examples and their normalized form.

label describing a (potentially multifaceted) topic, such as “The Great Reset”, renders this task exceedingly difficult. Fortunately, domain experts have been pre-categorizing documents into the aforementioned ontologies. In particular, regarding the WEF, invited domain experts categorize news articles for every topic, regarding Wikipedia, the text of the associated articles is available, as are the associated debates on Debatepedia.

Articles that are categorized into Level 2 topics are propagated up to their respective Level 1 topics. Table 3 shows the large differences between the ontologies. The WEF ontology contains the most topics, links the most documents, and has the most tokens overall. Wikipedia’s Level 2 topics link to a single article each, yielding less text overall.

5 Topic Coverage

To assess the topic coverage of an argument corpus given the three ontologies, we map their topic labels (if provided) to matching ontology topics.

5.1 Topic Label Normalization

Table 1 lists 39 argument corpora that provide topic labels. Altogether 2,259 different labels have been assigned. They are concise descriptions of the main issues of an argument provided by the corpus authors. The labels possess the text register of the respective corpus: In essays, for instance, topics are usually thesis statements, while Wikipedia-derived corpora use article titles, and the topics of debate corpora include clichés such as “This house should”. Often, topic labels express a stance towards a target issue, e.g., “ban guns”. Five types of topic labels can be distinguished: concept, comparison of concepts, conclusion (includes claim and thesis), question, and imperative. We normalize the topic labels by converting all concepts to singular form, removing clichés, and dropping stance-indicating words such as “legalize”. Our normalization aims at retaining only the central target issue of a topic label and leads to 798 unique topic labels.

5.2 Mapping Topic Labels to Ontology Topics

Using the preprocessed topic labels as queries, we retrieve for each topic label the 50 top-most relevant topics in each level of the three ontologies. To facilitate the retrieval of ontology topics, we employ a BM25-weighted (Robertson et al., 2004) index of the concatenated documents for each topic. This enables us to narrow down the mapping of a topic label to a manageable size. Except for a handful of cases, 50 ontology topics can be retrieved for each topic label. The topic labels were then manually mapped to an ontology topic, if they form synonyms, or if the former is a subtopic of the latter—which thus indicates that all arguments in the corpus with that topic label are about the ontology topic. A topic label can thus be mapped to multiple ontology topics. For example, the topic label “plastic bottles” is mapped to “pollution” and “recycling” in Wikipedia Level 2.

5.3 Analysis of Topic Coverage

Table 3 shows general statistics of this mapping of corpora topic labels to ontology topics. Most of the topic labels (2,141 out of 2,259) are mapped to at least one Debatepedia topic while only 395 labels are mapped to WEF Level 2 topics. For Wikipedia Level 2, only 298 out of the 748 topics are actually covered by argument corpora. This first analysis already suggests that existing argument corpora often only cover a small subset of possible argumentative topics that people are trained to debate. For those topic labels that can be mapped, they belong on average to 2.78 topics in Debatepedia, 1.24 topics in Wikipedia Level 1, and 1.53 topics in WEF Level 1. As discussed in Section 4, topics in Debatepedia focus on the Western culture and are easily accessible, whereas topics in WEF require in-depth domain knowledge and have more global relevance. The broad coverage of Debatepedia’s topics indicates that argument corpora focus on common, widely discussed topics rather than global issues or those that need domain knowledge.

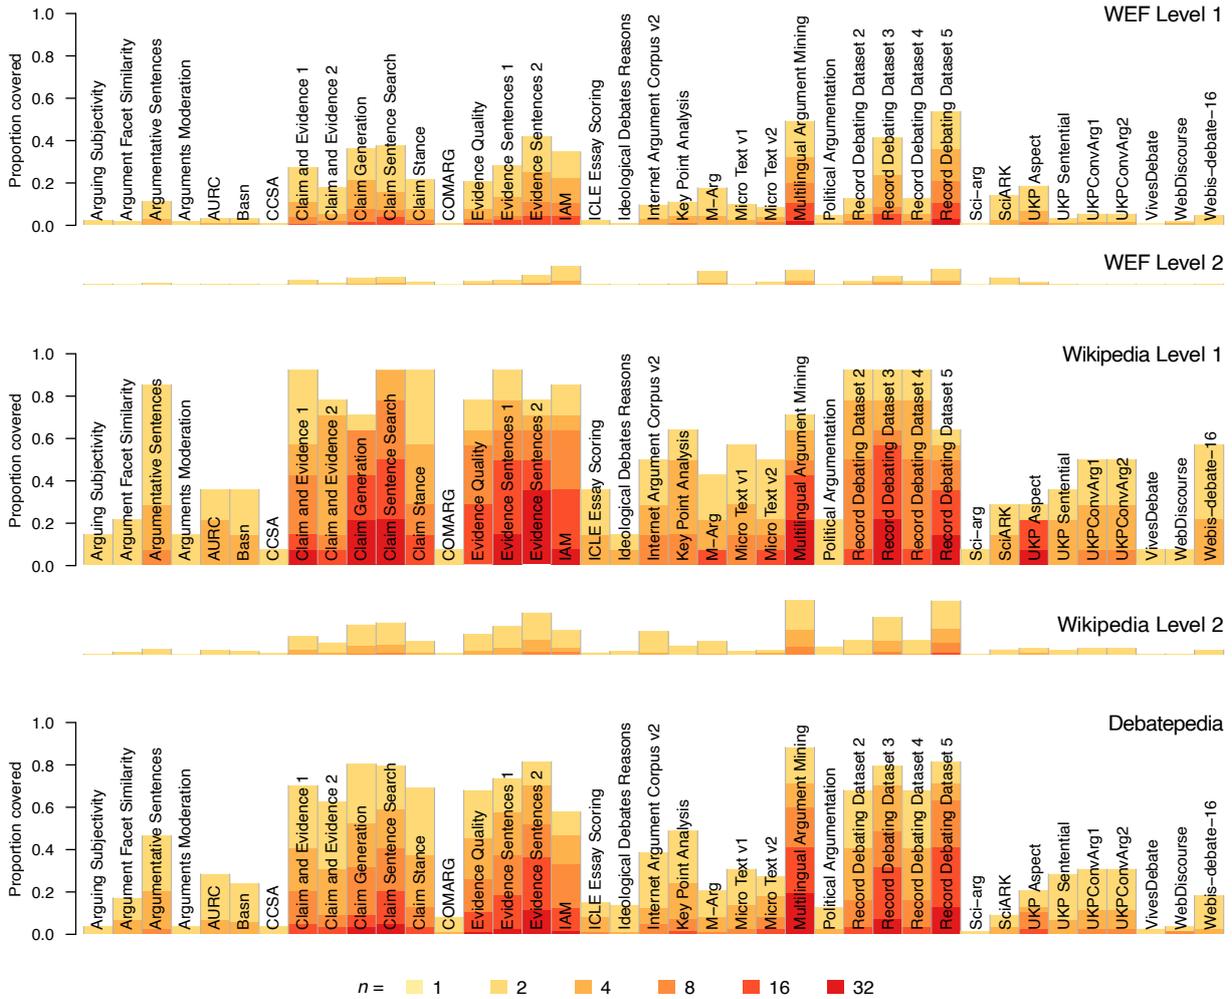

Figure 2: Proportion of ontology topics covered by at least n corpus topics (per ontology level and per corpus).

For a more fine-grained analysis, Figure 2 illustrates the differences regarding the number of ontology topics covered by a corpus: While topics in Wikipedia Level 1 are covered well by some argument corpora, topics in Wikipedia and WEF Level 2 are covered only marginally. Note that topic coverage varies significantly between the corpora: the Claim Sentence Search dataset’s topics cover 93% of the Wikipedia Level 1 topics, while the Ideological Debates Reasons dataset covers only 14%. The colors show the topic granularity of the corpus; especially the Record Debating Dataset 3 dataset is fine-grained: as the highest value, 36 of its topics are mapped to the Wikipedia Level 1 category “Politics and Economics”.

Figure 3 shows how the set of the units of the 39 labeled corpora distribute over the top-matching topics in Debatepedia, Wikipedia Level 1, and WEF Level 1. Distributions over Level 2 are omitted for brevity and can be found in Figure 4 in the Appendix. The distribution is significantly skewed:

while the top ten topics in Debatepedia are matched by 354,811 to 138,407 corpora units, the top ten topics in WEF Level 1 are matched by 344,345 to 28,725 corpora units. This supports our finding that the corpora cover easily accessible topics (e.g., “Media and Entertainment” and “Society”).

6 Unit Categorization

The previous analysis assesses argument corpora which contain topic labels. About a third of the argument corpora do not. As a heuristic step to assessing their topic coverage, we map the ontology topics for a unit (Table 1) in an argument corpus by treating the unit as a (long) query in a standard information retrieval setup, where ontology topics are the retrieval targets. The documents categorized into each topic have been concatenated and used as the topic’s representation. Though the documents associated with a topic are not necessarily argumentative, they cover the salient topic aspects.

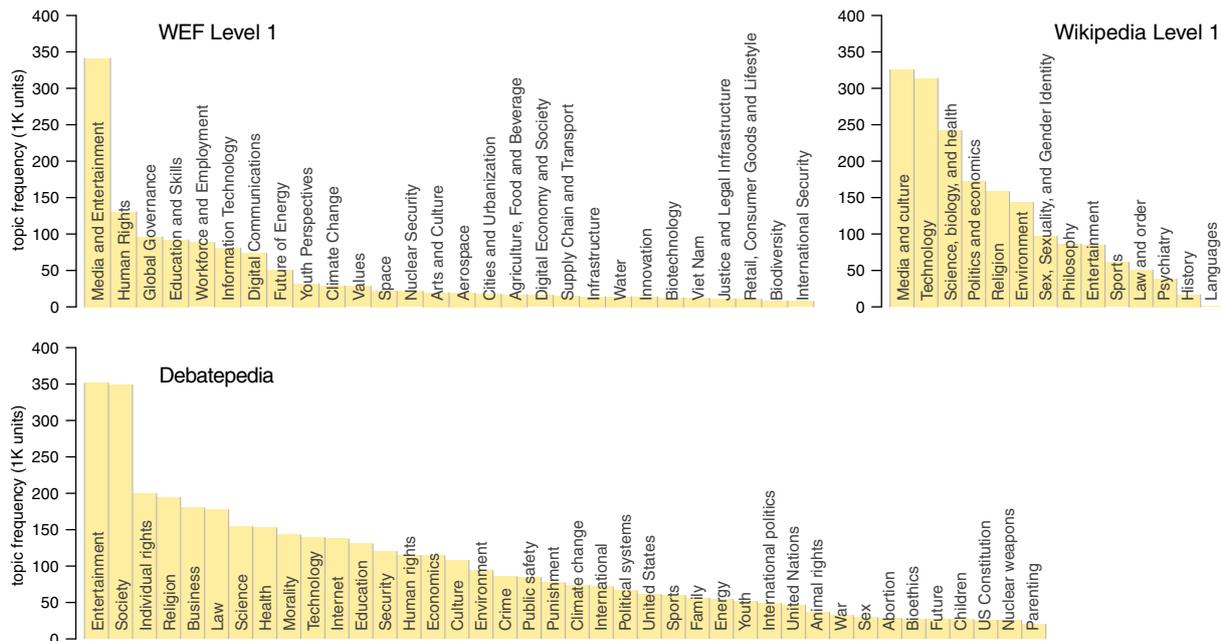

Figure 3: Distribution of corpora units over the top matching topics in an ontology (39 labeled corpora).

Ontology	Acquired ontologies (Section 4)			Topic coverage (Section 5)				Unit categorization (Section 6)												
	Topics	Topic statistics		Mapped topic labels	Covered ontology topics			Direct match			Semantic interpretation			Text2vec-SI						
		Authors	Docs		Tokens	All	Min	Mean	Max	P	R	F	Policy	P	R	F	Policy	P	R	F

Table 3: Statistics for each topic ontology level: for topics and topic documents (Section 4), Count of mapped topic labels of the analyzed corpora for each ontology level, Count of all covered ontology topics by the topic labels and the min, max, and mean count of covered ontology topics per topic label (Section 5), and the effectiveness of the approaches and baseline in unit categorization (in terms of precision, recall, and F_1 -score) (Section 6).

To retrieve topics for a corpus unit, we implement and evaluate the following approaches: Semantic Interpretation (SI) and SI with Text Embeddings (Text2vec-SI). The Semantic interpretation approach computes the semantic similarity of a unit and a topic as follows: it uses the cosine similarity of the TF-IDF vectors for the unit and the concatenated topic’s documents. This corresponds to the semantic interpretation step that is at the core of the well-known ESA model (Gabrilovich and Markovitch, 2007). Text2vec-SI calculates the similarity of topics and corpus units using BERT embeddings (Devlin et al., 2018). Following common practice, we take the dimension-wise average of the word embeddings for all tokens in the text.⁸ We tried other embeddings and approaches that performed similarly. The results of these approaches

⁸For efficiency, we limited the embeddings to 10,000 randomly sampled sentences for the topics that had more sentences associated with them.

can be found in the appendix. As a baseline, we implement a direct match approach, which assigns a unit an ontology topic if the topic’s text appears in the unit text (ignoring case).

For evaluation, we collect 34,638 pooled query relevance judgments (0.53 inter-annotator agreement as per Krippendorff’s α) on 104 randomly selected argument units as queries from 26 corpora. The annotation process is detailed in the Appendix.

Based on the similarity scores of the approaches, we derive Boolean labels that indicate whether a unit is or is not about one of the ontologies’ topics using two policies. The *threshold* policy labels a unit as about a topic if their similarity is above a threshold θ . The *top-k* policy labels a unit as about a topic if the topic is among the top- k topics with the highest similarity to the unit. We report the parameter of the policy that achieved the highest F_1 -score on the pooled judgments for each approach.

Table 3 shows the results of this evaluation. The baseline produces different results across ontologies—it performs poorly for both the abstract topics in Wikipedia Level 1 and the specific topics in WEF Level 2. The semantic interpretation approach clearly outperforms the baseline for all ontologies in terms of the F_1 -score. The Text2vec-SI approach outperforms the baseline and the semantic interpretation on abstract topics (Wikipedia Level 1), but its effectiveness is below that of the semantic interpretation approach on the other ontology levels.

7 Conclusion

The computational argumentation community risks topic bias in its approaches if the representativeness of topics in future corpora is not ensured. Achieving topic coverage is complicated by the fact that the landscape of controversial topics has not yet been well explored, and that there are no widely accepted ontologies for argument topics. In this paper, we venture into this future by mapping the landscape of argument topics and making it accessible for corpus construction and experimental design. We have identified three authoritative sources of ontological knowledge related to argument topics that provide an initial foundation for The Argument Ontology (TAO). For each source ontology, we evaluate the topic coverage of 39 argument corpora labeled with topics by matching the labels with the topics of the ontologies. To evaluate the topic coverage of corpora without topic labels, we develop an approach to identify the ontology topics of an argumentative text and achieve an F_1 of 0.59.

Our analyses show that the topic coverage of existing argument corpora is both limited to a subset of the topics of the ontologies and skewed. Most topics that require expertise, such as mental health, philosophy, or international security, are treated only peripherally in argumentation corpora. Therefore, existing argumentation technologies are more suited to teaching people how to construct arguments in general than to helping them make decisions about such and similarly complex topics. For the development of robust argumentation technologies, corpora need to be carefully drawn from a specific domain to allow for reliable experiments and the development of generalizable classifiers.

Future work for further development of TAO consists mainly of further surveying the argument topic landscape and unifying the various available

ontologies. In addition to “is part of” relationships between topics, other relationship types can also be considered to build an argument topic knowledge base. However, our first version of TAO and our analyses can already help in selecting arguments for future corpus construction and model training.

Limitations

The three topic ontologies we used to evaluate topic coverage of argument corpora are from authoritative sources. Nevertheless, they probably do not cover all possible controversial topics relevant to argumentation (e.g., topics concerning private life). A comprehensive coverage of controversial topics in breadth and depth will likely remain an unattainable goal. Moreover, unifying the three thematic ontologies into a standard ontology is still an open problem given the many possible interpretations and relationships between the topics.

Another limitation is the moderate effectiveness achieved by our approaches for categorizing argument units. This is the case due to the large collection of controversial topics (about 748 for Wikipedia). Future research can be improved by using the structure of the topic ontology and hierarchical classifiers. Furthermore, it is also unclear whether the topic dependence of argumentation approaches decreases with increasing corpus size.

Ethics Statement

Our goal is to investigate whether and to what extent existing argumentation corpora are topic biased. This serves to critically examine the state of the art. However, we by no means want to give the impression that previous corpus authors lack ambition or diligence. Rather, the opposite is the case. The number of corpora that have been created in the last decade shows that the community is aware of the fact that not all areas of the argumentation landscape have been covered yet, and is therefore doing its utmost to explore it further. In a dynamic and rapidly growing research field, standards are usually developed in parallel with contributions, not in advance. Our research may therefore contribute to the further standardization of the corpus linguistics of argumentation.

The manual annotation of arguments and topics was done by expert annotators of our research groups. They were compensated fairly under German law. No personal data was collected.

A Appendix

A.1 Mapping Topic Labels to Level 2 Topics

For completeness, Figure 4 shows the two graphs that are omitted from Figure 3 of the paper as their fine-grained topics are less relevant for the discussion in Section 5.3.

A.2 Annotation Procedure for Unit Categorization

In order to assess the effectiveness of the approaches and baseline outlined in the paper, we employ a pooled evaluation, as it is standard for information retrieval evaluations, where there are too many instances for a complete manual annotation. We randomly sampled four units from 26 corpora, which were all annotated by three expert annotators. The annotators were instructed to label a topic as about the unit if they could imagine a discussion on the topic for which the unit would be relevant. For each unit, we annotated for aboutness only those topics which are among the five topics with the highest similarity to this unit according to at least one of the approaches. The employed assessment interface (see Figure 5) shows the unit (top left), the current topic (top right), as well as all topics in the pool for that unit (bottom; the current topic is marked blue, whereas already annotated topics are marked green (about) and red (not about)). The same interface has been used for the topic label annotations.

To reduce biases, both the units and the topics were shown in a different and random order to each assessor. The annotation took about 40 hours. The annotation process resulted in an inter-annotator agreement of 0.53 in terms of Krippendorff’s α and produced a total of 34,638 annotations of topic-unit pairs, about 2% of what would have been needed for a complete annotation.

A.3 Additional Unit Categorization Approaches

In addition to the approaches listed in Section 6 we used additional approaches and a baseline which we list here. The additional baseline randomly classifies corpora units as per the prior topic probability of each ontology level.

SI with Word Embeddings (W2V-SI) Adapted from Dense-ESA (Song and Roth, 2015), this approach represents each token by its TFIDF-weighted Word2vec embedding vector, and uses the highest cosine similarity between two vectors, one from each text, as the semantic similarity. To limit this quadratic effort, we use only the 100 tokens of each text with the highest TFIDF-score.

Text2vec-SI As a variant for BERT (Devlin et al., 2018), we embedded the ontology documents and corpora units using ELMo (Peters et al., 2018).

Table 5: Performance of semantic interpretation approaches in human evaluation for each topic ontology level in terms of precision (P), recall (R), and F_1 -score (F) for the “aboutness” label. For methods other than the baselines the table shows the values for both the similarity threshold θ and rank k that lead to the highest F_1 -score respectively. The best F_1 -scores for each ontology level are marked bold.

LongtoNotes: OntoNotes with Longer Coreference Chains

Kumar Shridhar[†] Nicholas Monath^{*‡} Raghuveer Thirukovalluru[◇]
Alessandro Stolfo[†] Manzil Zaheer[¶] Andrew McCallum[‡] Mrinmaya Sachan[†]

[†] ETH Zürich [‡] UMass Amherst [◇] Duke University [¶] Google

Abstract

Ontonotes has served as the most important benchmark for coreference resolution. However, for ease of annotation, long documents in Ontonotes were split into smaller parts. In this work, we build a corpus of coreference-annotated documents of significantly longer length than what is currently available. We do so by providing an accurate, manually-curated, merging of annotations from documents that were split into multiple parts in the original Ontonotes annotation process (Pradhan et al., 2013). The resulting corpus, which we call LongtoNotes contains documents in multiple genres of the English language with varying lengths, the longest of which are up to 8x the length of documents in Ontonotes, and 2x those in Litbank. We evaluate state-of-the-art neural coreference systems on this new corpus, analyze the relationships between model architectures/hyperparameters and document length on performance and efficiency of the models, and demonstrate areas of improvement in long-document coreference modelling revealed by our new corpus. Our data and code is available at: <https://github.com/kumar-shridhar/LongtoNotes>.

1 Introduction

Coreference resolution is an important problem in discourse with applications in knowledge-base construction (Luan et al., 2018), question-answering (Reddy et al., 2019) and reading assistants (Azab et al., 2013; Head et al., 2021). In many such settings, the documents of interest, are significantly longer and/or on wider varieties of domains than the currently available corpora with coreference annotation (Pradhan et al., 2013; Bamman et al., 2019; Mohan and Li, 2019; Cohen et al., 2017).

The Ontonotes corpus (Pradhan et al., 2013) is perhaps the most widely used benchmark for coreference (Lee et al., 2013a; Durrett and Klein, 2013;

^{*}Now at Google.

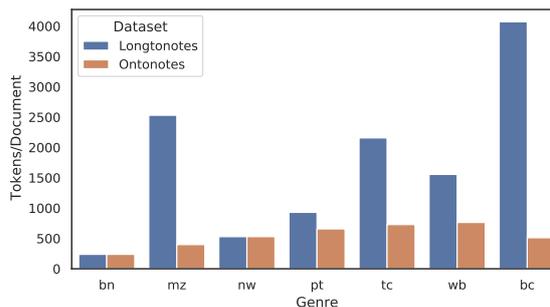

Figure 1: **Comparing Average Document Length.** Long documents in genres such as *broadcast conversations* (*bc*) were split into smaller parts in Ontonotes. Our proposed dataset, LongtoNotes, restores documents to their original form, revealing dramatic increases in length in certain genres.

Sachan et al., 2015; Wiseman et al., 2016; Lee et al., 2017; Joshi et al., 2020; Toshniwal et al., 2020b; Thirukovalluru et al., 2021; Kirstain et al., 2021). The construction process for Ontonotes, however, resulted in documents with an artificially reduced length. For ease of annotation, longer documents were split into smaller parts and each part was annotated separately and treated as an independent document (Pradhan et al., 2013). The result is a corpus in which certain genres, such as *broadcast conversation* (*bc*), have greatly reduced length compared to their original form (Figure 1). As a result, the long, bursty spread of coreference chains in these documents is missing from the evaluation benchmark.

In this work, we present an extension to the Ontonotes corpus, called LongtoNotes. LongtoNotes combines coreference annotations in various parts of the same document, leading to a full document coreference annotation. A carefully trained annotation team merged coreference annotation following the annotation guidelines laid out in the original Ontonotes corpus (§3). The resulting LongtoNotes dataset has an average document length that is over 40% longer than

the standard OntoNotes benchmark. Furthermore, LongtoNotes sees a 25% increase in the average size of coreference chains. While other datasets such as Litbank (Bamman et al., 2019) and CRAFT (Cohen et al., 2017) focus on long documents in specialized domains, LongtoNotes comprises of documents in multiple genres (Table 2).

To illustrate the usefulness of LongtoNotes, we evaluate state-of-the-art coreference resolution models (Kirstain et al., 2021; Toshniwal et al., 2020b; Joshi et al., 2020) on the corpus and analyze the performance in terms of document length (§4.2). We illustrate how model architecture decisions and hyperparameters that support long-range dependencies have the greatest impact on coreference performance and importantly, these differences are only illustrated using LongtoNotes and are not seen in Ontonotes (§4.3). LongtoNotes also presents a challenge in scaling coreference models as prediction time and memory requirement increase substantially on the long documents (§4.4).

2 Our Contribution: LongtoNotes

We present LongtoNotes, a corpus that extends the English coreference annotation in the OntoNotes Release 5.0 corpus¹ (Pradhan et al., 2013) to provide annotations for longer documents. In the original English OntoNotes corpus, the genres such as *broadcast conversations (bc)* and *telephone conversation (tc)* contain long documents that were divided into smaller parts to facilitate easier annotation. LongtoNotes is constructed by collecting annotations to combine within-part coreference chains into coreference chains over the entire long document. The annotation procedure, in which annotators merge coreference chains, is described and analyzed in Section 3.

The divided parts of a long document in Ontonotes are all assigned to the same partition (train/dev/test). This allows LongtoNotes to maintain the same train/dev/test partition, at the document level, as Ontonotes (Table 1). While the content of each partition remains the same, the number of documents changes because the divided parts are merged into a single annotated text in LongtoNotes. We refer to LongtoNotes_s as the subset of LongtoNotes comprising only the merged documents (i.e. documents merged by the annotators).

¹The Arabic and Chinese parts of the Ontonotes dataset are not considered in our study. See Appendix A.3

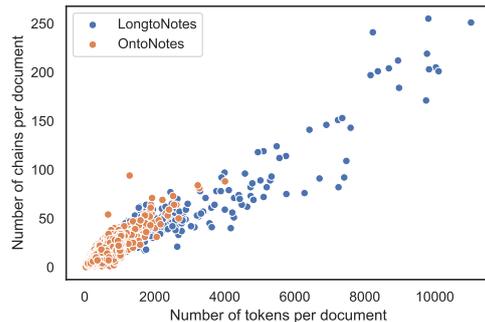

Figure 2: **Document and Coref Chain Length.** The number of coreference chains increases with the increase in token length in LongtoNotes.

Dataset	Train	Dev	Test
OntoNotes	2802	343	348
LongtoNotes	1959	234	222

Table 1: Comparison of the train-test-dev split of documents between OntoNotes and LongtoNotes

2.1 Length of Documents in LongtoNotes

The average number of tokens per document (rounded to the nearest integer) in LongtoNotes is 674, ~44% higher than in Ontonotes (466). Table 2 shows the changes in document length by genre. We observe that the genre with the longest documents is *broadcast conversation* with 4071 tokens per document, which is a dramatic increase from the length of the divided parts in Ontonotes which had 511 tokens per document in the same genre. The number of coreference chains and the number of mentions per chain grows as well. The long documents that were split into multiple parts during the original OntoNotes annotation are not evenly distributed among the genres of text present in the corpus. In particular, text categories *broadcast news (bn)* and *newswire (nw)* consist exclusively of short non-split documents, which were not affected by the LongtoNotes merging process. A list of which documents are merged in LongtoNotes is provided in Table 10 (Appendix).

2.2 Number of Coreference Chains

As a consequence of the increase in document length, LongtoNotes presents a higher number of coreference chains per document (16), compared to OntoNotes (12). Figure 2 shows the length and number of coreference chains for each document in the two corpora. As expected, the number of chains

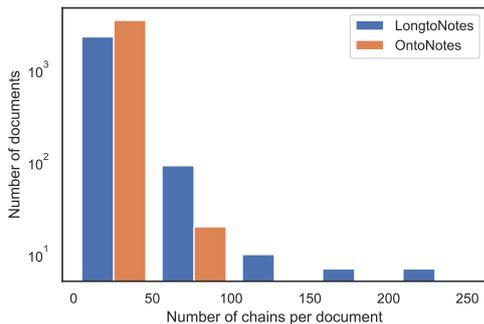

Figure 3: **Number of Chains per Document.** A histogram log plot reveals the long tailed distribution of the number of coreference chains present per document in LongtoNotes. Ontonotes contains more documents with fewer chains.

in a document tends to get larger as the document size increases. For genres with longer average document lengths like *broadcast conversation (bc)*, the increase in the number of chains is as high as 85%, while this increase is only 25% for *pivot (pt)* genre when the document length is comparatively shorter. It is worth noting that the majority of documents had a number of chains in the range of 20 to 50 and only about 20 documents out of 3493 in the OntoNotes dataset had >50 chains per document. For LongtoNotes the number increases to 96 documents. A comparison of the number of chains per document between OntoNotes and LongtoNotes is shown in Figure 3.

2.3 Number of Mentions per Chain

The number of mentions per coreference chain in LongtoNotes is over 30% larger than in OntoNotes. This is primarily because of longer documents and an increase in the number of coreference chains per document. Mentions per chain increase with the increase in document length. For the *broadcast conversation (bc)* genre, the increase in the mentions per chain is highest with 87%, while for the *pivot (pt)* (Old Testament and New Testament text) genre it is only 30% as it has shorter documents.

2.4 Distances to the Antecedents

For each coreference chain, we analyzed the distance between the mentions and their antecedents. The largest distance for a mention to its antecedent grew 3x for LongtoNotes when compared to OntoNotes from 4,885 to 11,473 tokens. Figure 4 shows a detailed breakdown of the mention to

antecedent distance. There are no mentions that are more than 5K tokens distant from its antecedent in OntoNotes. There are 178 such mentions in LongtoNotes.

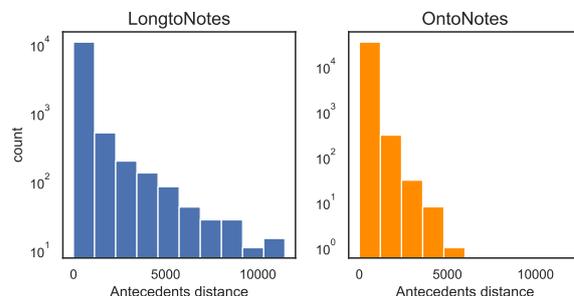

Figure 4: **Distance to Antecedent.** Histogram (log-scale) shows that the largest distance of mention to their antecedents per chain increases in LongtoNotes compared to OntoNotes.

2.5 Comparison with other Datasets

The literature contains multiple works proposing datasets for coreference resolution: Wiki coref (Ghaddar and Langlais, 2016), LitBank (Bamman et al., 2019), PreCo (Chen et al., 2018), Quiz Bowl Questions (Rodriguez et al., 2019; Guha et al., 2015), ACE corpus (Walker et al., 2006), MUC (Chinchor and Sundheim, 1995), MedMentions (Mohan and Li, 2019), inter alia. We compare LongtoNotes to these datasets in terms of number of documents, total number of tokens, and document length (Table 3).

Litbank is a popular long document coreference dataset, presenting a high tokens/document ratio. However, the dataset consists of only 100 documents, rendering model development challenges. Moreover, it focuses only on the literary domain. Other datasets containing long documents (e.g., WikiCoref) are also very small in size. On the other hand, datasets consisting of a larger number of texts tend to contain shorter documents (e.g., PreCo). Thus, by building LongtoNotes, we address the scarcity of a multi-genre corpus with a collection of long documents containing long-range coreference dependencies.

In concurrent work, Gupta et al. (2023) present a generalised annotation platform for coreference with simplified guidelines to users. In the future, such a tool could be used to more easily annotate documents of increased length.

3 Annotation Procedure & Quality

In this section, we describe and assess the annotation procedure used to build LongtoNotes.

3.1 Annotation Task

The annotators merge the coreference annotation in a sequential fashion. That is, they combine annotations from the second split part of an Ontonotes document into the first part, then the third part into the combined first two parts, and so on. Precisely, to build LongtoNotes, annotators successively merge chains in the current part $i + 1$ of the document with one of the chains in the previous parts $1, \dots, i$. We reformulate this annotation process as a question answering task where we ask annotators a series of questions (rather the same coreference determining question for different mentions) using our own annotation tool designed for this task (Figure 5). We display parts $1, \dots, i$ with color-coded mention spans. We then show a highlighted concept (a coreference chain in part $i + 1$) and ask the question: *The highlighted concept below refers to which concept in the above paragraphs?* The anno-

tators select one of the colour-coded chains from parts $1, \dots, i$ from a list of answers or the annotators can specify that the highlighted concept in part $i + 1$ does not refer to any concept in parts $1, \dots, i$, (i.e., a new chain emerging in part $i + 1$). The list of answers here are the merged chains formed in the previous iterations.

The annotation tool proceeds with a question for each coreference chain ordered (sorted by the first token offset of the first mention in the chain). The annotation of all parts of a document comprises an annotation task. That is, a single annotator is tasked with answering the multiple-choice question for each coreference chain in each part of a document. At the end of each part, annotators are shown a summary page that allows them to review, modify, and confirm the decisions made in the considered part. A screenshot of the summary page is provided in the Figure 9 in the Appendix.

From Annotations to Coreference Labels The annotations collected in this way are then converted into coreference labels for the merged parts of a document. The answers to the questions tell us the antecedent link between two coreference chains. These links are used to relabel all mentions in the two chains with the same coreference label, resulting in the LongtoNotes dataset.

Singletons Existing OntoNotes coreference annotation does not include singletons. Considering all parts of a document together might allow mentions that were considered to be singletons in a specific part to be assigned to a coreference chain. To understand the frequency of singletons in a single part of a document that has coreferent mentions in other parts, we manually analysed 500 mentions spread across 10 parts over three randomly selected long documents. We found only 17 instances (~0.03%) where singletons can be merged

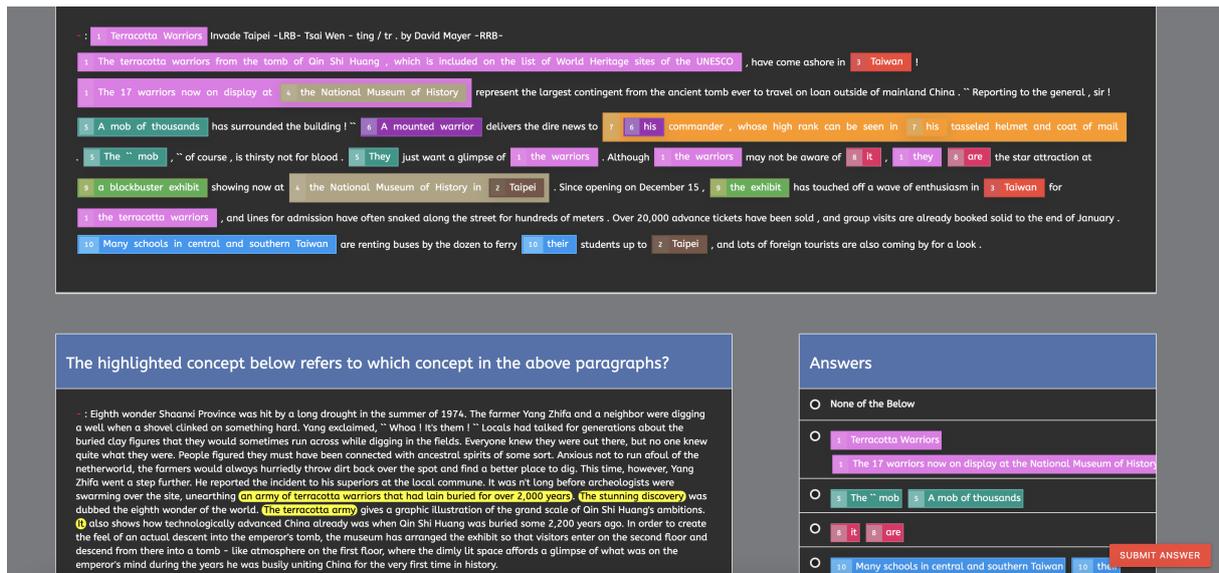

Figure 5: **Annotation Tool Interface.** The upper box represents all the previous paragraphs while the box on the bottom left is the current paragraph. The mentions of the current chain to be merged are shown in yellow. On the right side, the answers are presented which are chains from previous paragraphs and the annotator can select one of them or choose the None of the below option which creates a new chain.

with coreference chains in different parts of the same document. Given that such singletons would constitute only such a small percentage of mentions, we decided it was appropriate to omit them from the annotation process to reduce the complexity of annotation. To merge this small number of singleton mentions, our annotators would have had to label over 50% more mentions per document. We further discuss this in Appendix A.4.

3.2 Annotators and Training

We hired and trained a team of three annotators for the aforementioned task. The annotators were university-level English majors from India and were closely supervised by an expert with experience in similar annotation projects. The annotation team was paid a fair wage of approximately 15 USD per hour for the work. We had several hour-long training sessions outlining the annotation task, setup of the problem, and Ontonotes annotation guidelines. We reviewed example cases of difficult annotation decisions and collaboratively worked through example annotations. We then ran a pilot annotation study with a small number of documents (approx 5% of the total documents). For these documents, we also provided annotations to ensure the training of the annotators and eventual annotation quality. We calculated the inter-annotators' agreement between the annotators and us. After a few rounds of training, we were able to achieve an inter-

annotator agreement score (strict match, defined in the next subsection) of over 95% and we decided to go ahead with the annotation task. This confirmed the annotators' understanding of the task.

After the satisfactory pilot annotation study, the tasks were assigned to the annotators in five batches of 60 documents each. For 10% of the tasks, we had all three annotators provide annotations. For the remaining 90%, a single annotator was used. For the documents with multiple annotators, we used majority voting to settle disagreements. If all annotators disagreed on a specific case, we selected Annotator 1's decision over the others (analysis in the Appendix B).

3.3 Measuring Quality of Annotation

We would like to ensure that LongtoNotes maintains the high-quality standards of OntoNotes. Thus, we compute various metrics of agreement between a pair of annotators. We consider (1) the question-answering agreement (i.e., how similar are the annotations made using the annotation tool), and (2) the coreference label agreement (i.e., at the level of the resulting coreference annotation).

Assume that annotator j receives a set of chains $C_1^{(j)}, C_2^{(j)}, \dots, C_N^{(j)}$. For each chain $C_i^{(j)}$, the annotator links it to a New chain or a chain from their (annotator specific) set of available chains. Let us call $D_i^{(j)}$ the linking decision of the j th annotator, which consists of a pair $(C_i^{(j)}, A_i^{(j)})$, where $A_i^{(j)}$

is the selected antecedent chain. We consider the following question answering metrics:

(i) Strict Decision Matching: When two annotators agreed on merging two chains and there is an exact match between the merged chains. Calculated as $\frac{1}{N} \sum_i \mathbb{I}[D_i^{(1)} = D_i^{(2)}]$.

(ii) Jaccard Decision Match: Jaccard decision calculates the Jaccard similarity between the merged chain: $\frac{1}{N} \sum_i \frac{|A_i^{(1)} \cap A_i^{(2)}|}{|A_i^{(1)} \cup A_i^{(2)}|}$.

(iii) New Chain Agreement: Number of times both annotators select a new chain divided by the number of times at least one selects new chain.

(iv) Not New Chain Agreement: Number of times two annotators agreed on not a *New* chain choice divided by the number of times at least one annotator labels not a *New* chain.

(v) Krippendorff’s alpha: Krippendorff’s alpha (Krippendorff, 2011) is the reliability coefficient measuring inter annotator agreement. We compute Krippendorff’s alpha using a strict decision match as the coding for agreement.

Table 4 presents the results for these metrics. We observed that on average annotators agreed with each other on over 90% of their decisions except when the *No New* chains were considered. Removing *New* chains reduces the total decisions to be made significantly, and hence a lower score on *No New* chains agreement. We found that Annotator 1 agreed most with the experts and hence Annotator 1’s decisions were preferred over the others in case of disagreement between all three annotators.

Where are disagreements found in annotation?

We would like to understand what kinds of mentions lead to the disagreement between annotators. We measure the part of speech of all the disagreed chain assignments between the annotators. We found that the 8% of the mentions within the disagreed chain assignments were pronouns, 8% were verbs, and 9% were common nouns. The number of proper nouns disagreements was lower with just 5%. When considering different genres, it was observed that genres with longer documents like *broadcast conversation (bc)* had more mentions that were pronouns when compared with genres with shorter documents *pivot (pt)*. As expected, the number of disagreements in general increased with the size of the documents. However, we found that the number of disagreements was small even for long document genres such as *broadcast conversation (bc)*. See Appendix B.

Metric	Score
Strict Match	0.90
Jaccard Match	0.95
New Chain	0.88
Not New Chain	0.87
Krippendorff’s alpha	0.90

Table 4: **Annotation Quality Assessment.** We report the average of each metric over all pairs of annotators.

3.4 Time Taken per Annotation

We also recorded the time taken for each annotation. Time taken per annotation increases with the increase in the document length (Appendix Fig. 10). This is expected as more chains create more options to be chosen from and longer document length demands more reading and attention. In total, our annotation process took 400 hours.

3.5 Pitfalls of Automatically Merging Chains

To show the importance of our human-based annotation process, we investigate whether the annotators’ decisions could have been replicated using off-the-shelf automatic tools. We performed two experiments: (i) a simple greedy rule-based string matching system (described in the Appendix A.5) and (ii) Stanford rule-based coreference system to merge chains across various parts. We use the merged chains to calculate the CoNLL F_1 score with the annotations produced by our annotators. We found that our string-matching system achieved a CoNLL F_1 score of only 61%, while the Stanford coreference system reached a score of only 69%. The low scores compared to the annotators’ agreement (which is over 90%) underline the complexity of the task and the need for a human-annotations.

4 Empirical Analysis with LongtoNotes

We hope to show that LongtoNotes can facilitate the empirical analysis of coreference models in ways that were not possible with the original OntoNotes. We are interested in the following empirical questions using the datasets—Ontonotes (Pradhan et al., 2013), and our proposed LongtoNotes and LongtoNotes_s:

- How does the length of documents play a role in the empirical performance of models?

- Does the empirical accuracy of models depend on different hyperparameters in LongtoNotes and Ontonotes?
- Does LongtoNotes reveal properties about the efficiency/scalability of models not present in Ontonotes?

4.1 Models

Much of the recent work on coreference can be organized into three categories: span based representations (Lee et al., 2017; Joshi et al., 2020), token-wise representations (Thirukovalluru et al., 2021; Kirstain et al., 2021) and memory networks / incremental models (Toshniwal et al., 2020b,a). We consider one approach from all three categories.

Span-based representation We used the Joshi et al. (2020) implementation of the higher-order coref resolution model (Lee et al., 2018) with SpanBERT. Here, the documents were divided into a non-overlapping segment length of 384 tokens. We used SpanBERT Base as our model due to memory constraints. The number of training sentences was set to 3. We set the maximum top antecedents, $K = 50$. We used Adam (Kingma and Ba, 2014) as our optimiser with a learning rate of $2e^{-4}$.

Token-wise representation We used the LongFormer Large (Beltagy et al., 2020) version of Kirstain et al. (2021) work, as this approach is less memory demanding and it is possible to fit this model in our memory. The max sequence length was set to 384 or 4096. Adam was used as an optimiser with a learning rate of $1e^{-5}$. A dropout (Srivastava et al., 2014) probability of 0.3 was used.

Memory networks We used SpanBERT Large with a sequence length of 512 tokens. Following Toshniwal et al. (2020b), an endpoint-based mention detector was trained first and then was used for coreference resolution. The number of training sentences was set to 5, 10, and 20. The number of memory cells was selected from 20 or 40. All experiments were performed with AutoMemory models with learned memory type.

4.2 Length of Documents & Performance

Impact of Training Corpus We first investigate whether or not training on the longer documents in LongtoNotes are needed to achieve state-of-the-art results on the dataset. We compare the performance of models trained on Ontonotes to

# Tokens	Training	CoNLL F1
$\leq 2K$	Ontonotes	78.85
	LongtoNotes	78.25
$> 2K$	Ontonotes	65.11
	LongtoNotes	66.20

Table 5: **Performance and Document Length for Span-based Models.** F_1 score across different document length for SpanBERT Base trained model on OntoNotes and LongtoNotes dataset.

those trained on LongtoNotes. We find that by training on LongtoNotes, we can achieve higher CoNLL F1 measures on LongtoNotes than training with Ontonotes for each model architecture (Table 6). This suggests that the longer dependencies formed by merging annotations in various parts of documents in OntoNotes are difficult to model when training on short documents.

We find that to achieve accuracy with hyperparameters such as learning rate/warmup size, we need to maintain a number of steps per epoch consistent with Ontonotes when training with LongtoNotes. A detailed analysis is presented in the Appendix Section C.

Length Analysis - Number of Tokens We break down the performance of the span-based model by the number of tokens in each document. We compare the performance of the model depending on the training set. Figure 2 shows that the majority of the documents in the OntoNotes dataset falls within a token length of 2000 per document. We create two splits of LongtoNotes_s, one having a token length greater than 2000 tokens, the other having a number of tokens smaller than 2000. Table 5 shows that for smaller document length (less than 2000 tokens), the SpanBERT model trained on OntoNotes performed better but the trend reverses for longer documents (more than 2000 tokens), on which the model trained on LongtoNotes outperformed the model trained on OntoNotes by +1%.

Length Analysis - Number of Clusters Table 7 displays the change in F_1 score with the increase in the number of clusters per document. The SpanBERT Base model trained on LongtoNotes outperforms the same model trained on OntoNotes (+0.6%) when the number of clusters is more than 40. Note that, 40 is selected based on the cluster distribution shown in Table 2 with the majority documents in LongtoNotes lying in this range.

	Training	OntoNotes			LongtoNotes _s			LongtoNotes		
		P	R	F ₁	P	R	F ₁	P	R	F ₁
Stanford Coref (Lee et al., 2013b)	-	58.6	58.8	58.6	48.5	58.2	52.7	53.6	57.3	55.2
Span-based (Joshi et al., 2020)	OntoNotes	76.5	77.6	77.4	72.7	69.1	70.8	74.4	73.0	73.7
	LongtoNotes	75.9	77.7	76.8	72.4	70.7	71.5	73.9	74.1	74.0
Token-Level (Kirstain et al., 2021)	Ontonotes	81.2	79.5	80.4	79.6	80.0	79.8	79.7	77.2	78.5
	LongtoNotes	80.0	78.2	79.1	80.3	80.3	80.3	80.2	78.0	79.1
Memory-Model (Toshniwal et al., 2020b)	OntoNotes	73.5	79.3	76.4	63.4	73.8	68.2	67.9	76.6	72.0
	LongtoNotes	73.8	79.4	76.6	66.3	74.6	70.2	69.3	77.0	72.9

Table 6: **Performance Variation by Training Set.** Comparison of F_1 scores on various datasets using different models. All experiments have been performed atleast 2 times and a variance of only ± 0.1 was observed.

# Chains	Training	SpanBERT	Token	Memory
≤ 40	Onto	73.60	79.80	72.80
	Longto	72.86	78.80	71.94
> 40	Onto	68.44	75.60	67.72
	Longto	69.09	76.42	68.60

Table 7: **Performance and Number of Chains for different models.** CoNLL F_1 score across different document length for SpanBERT Base, Token-Level and Memory-Model trained on OntoNotes and LongtoNotes dataset.

4.3 Hyperparameters & Document Length

Each model has a set of hyperparameters that would seemingly lead to variation in performance with respect to document length. We consider the performance of the models on LongtoNotes as a function of these hyperparameters.

Span-based model hyperparameters We consider two hyperparameters: the number of antecedents to use, K and the max number of sentences used in each training example. We found that upon varying K : 10, 25, and 50, there was only a small difference observed in the results for both the models trained on OntoNotes and LongtoNotes (increasing K led to only minor increases). The result is summarized in Table 8. We could not go beyond $K = 50$ due to our GPU memory limitations. However, going beyond 50 might further help for longer documents. Furthermore, we found that the *number of sentences* parameter used to create training batches does not play a significant role in performance either (Figure 8).

Token-wise model hyperparameters Reducing the sequence length when testing from 4096 to 384 leads to a drop in F1 as seen in Figure 6. We observed that longer sequence length (4096) helps

K	OntoNotes	LongtoNotes	LongtoNotes _s
10	77.05	73.44	70.37
25	76.93	73.99	71.61
50	77.60	74.01	71.58

Table 8: **Number of Antecedents vs. Performance** SpanBERT Base model trained on LongtoNotes dataset with varying K value.

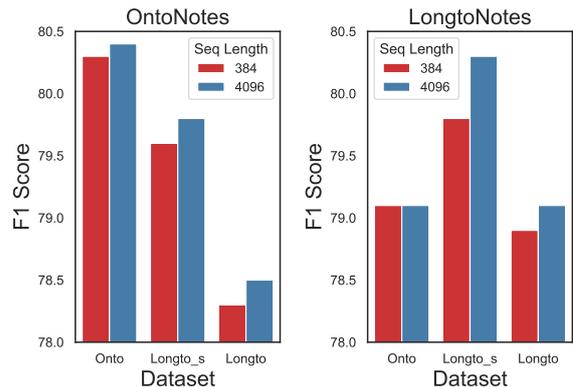

Figure 6: **Sequence Length vs. Performance.** LongFormer is significantly better on LongtoNotes with 4096 sequence length compared to 384. Two sequence lengths perform similarly on Ontonotes.

more for LongtoNotes_s as there are longer sequences than for OntoNotes, which is evident in Figure 6. Furthermore, we analyzed performance on two genres: *magazine (mz)* having 6x longer sequences in LongtoNotes than OntoNotes vs *pivot (pt)* having just 1.4x longer documents. As observed in Figure 7 (and Appendix Table 15), when the document is long as in *magazine (mz)*, there is a significant increase in performance with a longer sequence but the effect is negligible for *pivot (pt)* where the size of the document is almost the same.

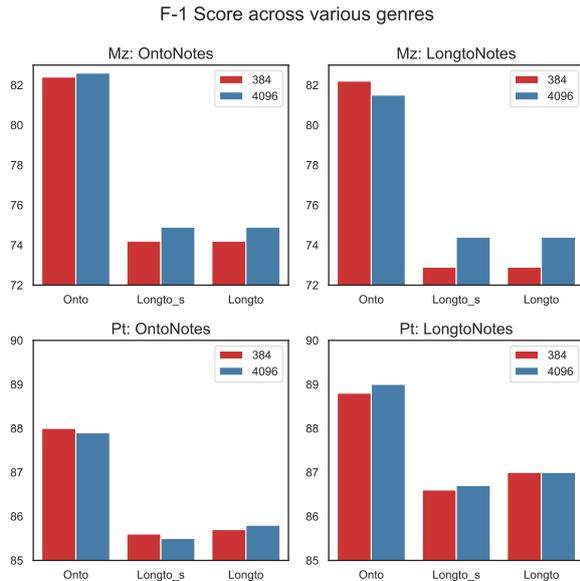

Figure 7: **Sequence Length vs. Performance by Genre** Comparing the effect of sequence length on F1 for two genres: *magazine (mz)*, where LongtoNotes contains 6x longer documents, and *pivot (pt)*, where LongtoNotes has 1.4x longer documents.

Memory model hyperparameters We consider two hyperparameters - the memory size which denotes the maximum active antecedents that can be considered and the max number of sentences used in training. We show that doubling the size of the memory leads to an increase of 0.8 points of CoNLL F_1 for LongtoNotes dataset. (Appendix Table 14). Figure 8 demonstrates that there is no significant improvement in the performance of the model with the increase in the number of training sentences.

4.4 Model Efficiency

We compare the prediction time for the span-based model on the longest length and average length documents in LongtoNotes and Ontonotes in Table 9. We observe that there is a significant jump in running time and memory required to scale the model to long documents on LongtoNotes; this jump is much smaller on Ontonotes. This suggests that our proposed dataset is better suited for assessing the scaling properties of coreference methods.

5 Conclusion

In this paper, we introduced LongtoNotes, a dataset that merges the coreference annotation of documents that in the original OntoNotes dataset were split into multiple independently-annotated

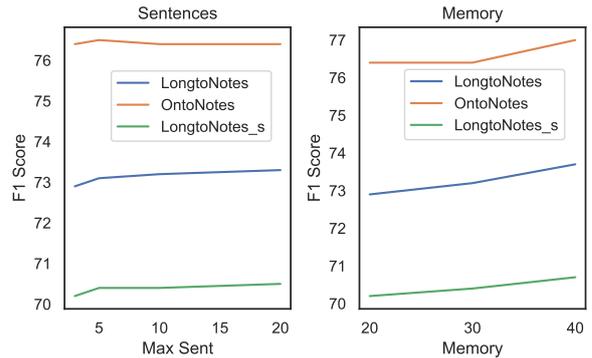

Figure 8: **Max Sentence Length.** Increasing max sentences from 3 to 20 has a small effect on the performance of the SpanBERT large model. On the other hand, the increase is linear with the increase in the memory size alongside the increase in max training sentences.

Dataset	Type	Pred. Time	Pred. Mem
Ontonotes	Average	0.11 sec	1.50 GB
LongtoNotes	Average	0.47 sec	6.50 GB
Ontonotes	Longest	0.37 sec	5.84 GB
LongtoNotes	Longest	2.35 sec	42.68 GB

Table 9: **Model Efficiency of Span-based Models.** We find that LongtoNotes documents have extended length leading to greater variation of prediction time and prediction memory.

parts. LongtoNotes has longer documents and coreference chains than the original OntoNotes dataset. Using LongtoNotes, we demonstrate that scaling current approaches to long documents has significant challenges both in terms of achieving better performance as well as scalability. We demonstrate the merits of using LongtoNotes as an evaluation benchmark for coreference resolution and encourage future work to do so.

Acknowledgements

This material is based upon work supported in part by an ETH Zürich Research grant (ETH-19 21-1), a grant from the Swiss National Science Foundation (project # 201009), the University of Massachusetts Amherst Center for Data Science and the Center for Intelligent Information Retrieval, and in part by the Chan Zuckerberg Initiative under the project “Scientific Knowledge Base Construction”. Alessandro Stolfo is supported by armasuisse Science and Technology through a CYD Doctoral Fellowship. We also thank our annotators from Xsaras.com (a data annotation company) for their sincere efforts in making this project possible.

Limitations

Our dataset is comprised solely of English texts, and our analysis, therefore, applies uniquely to the English language. OntoNotes, however, consists of the Arabic and the Chinese annotations too and those languages were not considered in our study due to the limited expertise of the annotators.

Since our models are not tuned for any specific real-world application, the methods should not be used directly in highly sensitive contexts such as legal or health-care settings, and any work building on our methods must undertake extensive quality-assurance and robustness testing before using them.

Ethical Considerations

The annotation was performed with a data annotation service which ensured that the annotators were paid a fair compensation of 15 USD per hour. The annotation process did not solicit any sensitive information from the annotators.

Replicability We have released the model checkpoints and data at: <https://github.com/kumar-shridhar/LongtoNotes>.

A.2 Comparison with OntoNotes

A detailed genre-wise comparison of the documents from OntoNotes dataset which were merged in LongtoNotes is presented in Table 10. It can be seen that categories like `bn` and `nw` are completely missing in LongtoNotes, while `pt` is partially missing.

Table 10: Comparison of documents from various sub-categories that exists in OntoNotes 5.0 and our proposed dataset LongtoNotes

A.3 Dataset selection decision

Due to budget constraints and the expertise of our team and annotators in English only (and some training of annotators is required to ensure data quality), we only considered the English parts of the OntoNotes dataset in our work. We think that the dataset can be extended to Arabic and Chinese too, but we leave it for future work.

A.4 Annotating singletons

While manually annotating all singletons, we observed that almost all NPs can be thought of as

mentions and all those NPs that are not part of any chain can be thought of as a singleton. Our analysis suggests that there are over 50% mentions that are not annotated by OntoNotes and can qualify for singletons. To annotate all the singletons, the annotator needs to go through all of them, discard the ones that do not abide by the OntoNotes rules and then make a decision whether to merge each singleton to some chain or other singleton. In our analysis, the number of such singletons is very low and all the efforts were not worth it for the small improvement over the current annotations. So we decide to ignore all the singletons in our study.

A.5 Greedy rule-based matching system

We use a greedy string matching system where we take all the mentions in a chain of the current para $i + 1$ and analyse its part of speech provided in the OntoNotes dataset. We take the first Noun (NN or NP) present in each chain and look for the mentions overlap in all other previous paras $1, \dots, i$ chains. We merged two chains if there is a strict overlap with any of the mentions in a given chain. If there are no strict overlaps, we move to the next noun in the given chain and repeat the process. If we find no strict overlap with any mentions in any other para chains, we keep the chain independent (same as assigning *None of the below* in our annotation tool). We repeat the process with all chains in a given document and constantly update the chain after every para.

B Annotation Disagreement Analysis

B.1 Genre wise disagreement analysis

Table 11 presents the genre-wise disagreement analysis for strict decision matching. Genres with longer documents like `bc`, `mz` have more disagreements compared to genres with smaller document lengths like `tc`, `pt`.

The trend is very similar for new chain assignments where genres with larger documents have more disagreements over new chain assignments. The numbers are presented in Table 13.

B.2 Annotators disagreements analysis

Figure 11 shows the cases (in black) when the annotators disagreed for each part of the speech categories (shown in big coloured bubbles). The size of the bubbles is representative of their occurrence in the dataset, suggesting there are more pronominal mentions in the dataset than nouns or proper nouns.

Figure 9: The summary page of our annotation tool that is shown after all the chains decisions in a paragraph is made. The annotators can look and verify all the decisions and confirm answers and proceed to the next para or can change their answers if they want.

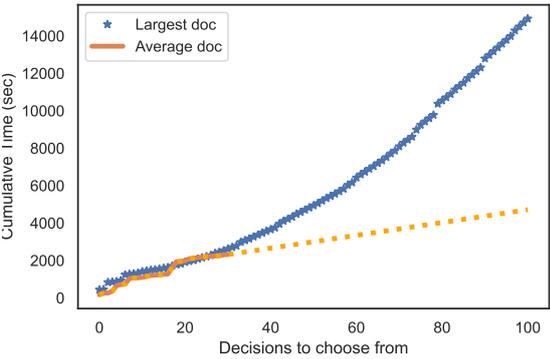

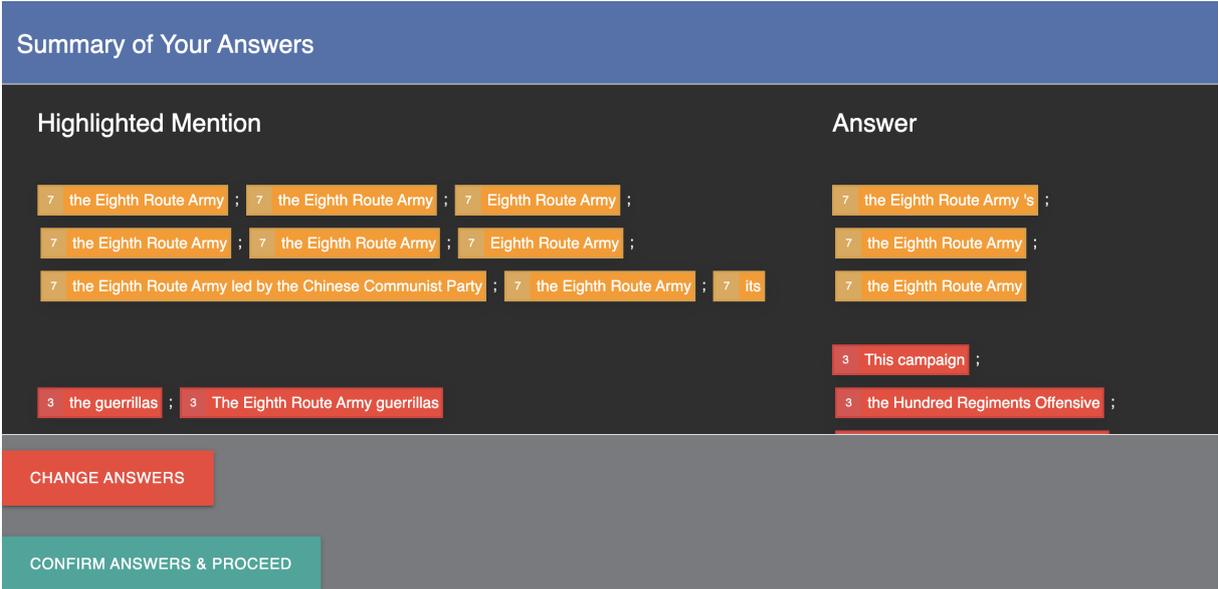

Figure 10: **Annotation Time and Document Length.** Annotation time (cumulative) increases exponentially with the increase in the number of decisions to choose from. A comparison is shown between the longest document in LongtoNotes vs an average document. The dotted lines represent the increase in annotation time if the growth was linear.

B.2.1 Genre wise disagreement analysis

In general, annotators disagree more on pronouns than proper nouns and the trend is consistent for various genres as shown in Table 12.

C Results

C.1 MUC, B^3 and CEAFE scores

Tables 16, 17 and 18 present the MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and

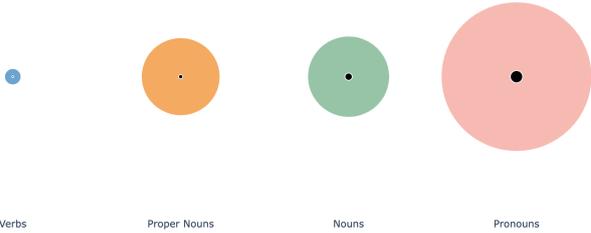

Figure 11: Plot showing the part of speech distribution for the disagreed clusters between annotators.

CEAFE (Luo, 2005) scores for SpanBERT Base (Lee et al., 2017) and LongDocCoref Models (Toshniwal et al., 2020b). On all three metrics, both models trained on LongtoNotes dataset outperforms the models trained on OntoNotes dataset. For SpanBERT base model, we compare three version of the LongtoNotes dataset: LongtoNotes_s and LongtoNotes dataset as mentioned in the paper and LongtoNotes_{eq} where LongtoNotes dataset is reweighted to create the total number of documents equal to the number of documents in OntoNotes dataset. For LongDocCoref model, n represents the maximum number of training sentences, while m refers to the memory used.

C.2 Genre wise F_1 scores vs sequence length

Table 15 shows that LongFormer Large model with larger sequence length (4096) outperforms the one

Abstract

The schema-guided paradigm overcomes scalability issues inherent in building task-oriented dialogue (TOD) agents with static ontologies. Instead of operating on dialogue context alone, agents have access to hierarchical schemas containing task-relevant natural language descriptions. Fine-tuned language models excel at schema-guided dialogue state tracking (DST) but are sensitive to the writing style of the schemas. We explore methods for improving the robustness of DST models. We propose a framework¹ for generating synthetic schemas which uses tree-based ranking to jointly optimise lexical diversity and semantic faithfulness. The generalisation of strong baselines is improved when augmenting their training data with prompts generated by our framework, as demonstrated by marked improvements in average joint goal accuracy (JGA) and schema sensitivity (SS) on the SGD-X benchmark.

1 Introduction

DST is concerned with tracking user goals in task-oriented conversations. The goals are represented as key-value pair sequences, with the keys known as *slots* (e.g. hotel name). Pre-trained language models (PLMs) (Devlin et al., 2019; Raffel et al., 2020) have helped shift focus from systems that can only track slots drawn from a database or *domain ontology* (Henderson et al., 2014) to models that do not require re-training to parse goals in new domains. The Schema-Guided Dialogue (SGD) dataset (Rastogi et al., 2020) facilitates this shift with a large-scale set of conversations grounded in 45 *service APIs* or *schemas* that describe the domains, slots and user intents that annotate the conversations (Appendix A). Test set dialogues are grounded in 6 schemas *seen* during training and 15 *unseen* ones.

Neural models perform impressively on the difficult schema-guided DST task (Rastogi et al., 2020),

¹Code will be released here: <https://bit.ly/3WYB7F1>

but Lee et al. (2022) show that the uniformity of the descriptive language of the schemas facilitates this. They create the SGD-X benchmark to evaluate robust zero-shot generalisation of DST models. This is achieved by grounding the SGD test set conversations in five *schema variants* increasingly dissimilar to the SGD schemata². To perform well, a DST model should correctly track the state of a dialogue when conditioned, in turn, on prompts constructed from the five variants.

We show how to improve DST robustness by introducing controlled variability in the data. We contribute to robust DST research by (1) a flexible framework for generating and ranking diverse outputs of a paraphrase model based on a tree-clustering algorithm designed to control lexical diversity and semantic similarity; (2) combine state-of-the-art paraphrase models and language generation metrics to generate increasingly diverse schemata paraphrases; (3) show that augmenting the training dataset with these schemata improves the robustness and generalisation performance of strong DST baselines.

2 Related Work

Input variety, data scarcity and domain shifts affect the robustness of DST models. Liu et al. (2021) investigate the former. They employ word-level data augmentation (DA) (Wei and Zou, 2019), turn paraphrasing and speech disfluency modeling to approximate their field performance. Turn and dialogue generation are effective in low-resource settings (Campagna et al., 2020; Hou et al., 2018) but are very difficult to scale to new domains and are not effective in the high-resource setting we consider (Campagna et al., 2020; Mohapatra et al., 2021). This also applies to word- and sentence-level meth-

²Variants are ordered according to their lexical similarity to the SGD schemas. The v1 variant is the most similar whereas v5 is the most dissimilar. See Appendix A for details and examples and the schemata here: <https://bit.ly/3Ev0KrV>.

ods (Quan and Xiong, 2019; Louvan and Magnini, 2020). Lee et al. (2022) find word-order changes and deletions to be ineffective in the high-resource, schema-guided setting we consider.

Schema-guided DST tackles both data scarcity and novel domains by using API definitions to prompt PLMs (Zhao et al., 2022). Yet Lee et al. (2022) demonstrate the lack of robustness of schema-guided DST models to prompt styles and vocabulary, creating a new research direction. They show that augmenting the training data with synthetic prompts obtained via backtranslation significantly improves models’ ability to track states under meaning-preserving prompt transformations. Backtranslation is also applied to improve DST robustness to linguistic variation inherent in user communication (Ma et al., 2019; Einolghozati et al., 2019), which is orthogonal to the prompt style and vocabulary robustness setting we consider. Reinforcement learning has also been applied (Yin et al., 2020), but works only in the very constrained single-domain, ontology-driven setting. Other TOD-relevant DA approaches apply to policy learning (Gritta et al., 2021) and response-generation (Gao et al., 2020; Zhang et al., 2020b).

Addressing the dearth of augmentation methods designed to ensure prompt robustness of schema-guided DST models, we propose to generate schemas by ranking large paraphrase candidate lists with learned metrics in a tree ranking scheme.

3 Tree-Based Paraphrase Ranking

Tree construction A large pool of schema candidates is created by generating paraphrases given grids of generation parameters (eg temperature, number of beams). The set is filtered to address generation failures (eg toxic and hallucinated words). We optionally filter candidates with an entailment model to increase semantic faithfulness (Narayan et al., 2022) (see Appendix B.1).

The tree constructor (Algorithm 1) takes as input an object (Node) that stores a metric value, *val*, and the candidate paraphrases which are split at that node, *sents*. A list of metrics to be computed between each candidate and the input is provided by the user. This enables our framework to build arbitrary-depth trees with custom user metrics. Each unique list of metric values describing the distance between the input and a candidate generates a path in the tree (lines 5-13). The *n*-ary tree constructed in this way has the property that level-

order traversal of the first level can yield diverse candidates with respect to the metric it encodes. In practice, the metrics measure lexical and semantic distances between their inputs.

Algorithm 1: Tree building

```

1: def build_tree(root: Node, inp: str,
   cans: list[str], metrics: list[Callable]):
   Data: root, inp input, cans input
           paraphrases, metrics objects to
           eval. dist. between input & cand.
   Result: tree splitting cans according
           to metrics
2:   curr ← root ;
3:   for c in cans:
4:     curr ← root ;
5:     for m in metrics:
6:       m_val = m(inp, c) ;
7:       next ← get_child
           (curr.children, m_val) ;
8:       if next is NULL:
9:         next ← Node (val=m_val,
           sents=[c]) ;
10:      curr.children.add(next)
11:     else:
12:       next.sents.add(c) ;
13:     curr ← next
14:   return root

```

Ranking Our ranker input is the tree and a list of decision functions, with elements corresponding to each level in the tree, *f_{dec}*. Without loss of generality, we assume that the first level encodes a metric with respect to which the user wishes to maximise diversity (eg lexical distance). As shown in Figure 1, our algorithm traverses breadth-first the level for which diversity is to be maximised. Each subtree returned in the traversal is traversed depth-first, guided by the decision functions. For example, in Figure 1 we show that the node $B = 0.77$ is selected by applying the max decision function to the children of $J = 66$, and that applying min to the children of $B = 0.77$ selects the leaf $S = 77$. See Algorithm 3 (Appendix B) for details.

4 Experiments

4.1 Schema generation

Our paraphrase model is PegasusParaphrase³, a fine-tuned Pegasus model (Zhang et al., 2020a).

³Available at <https://bit.ly/3vgY7EZ>.

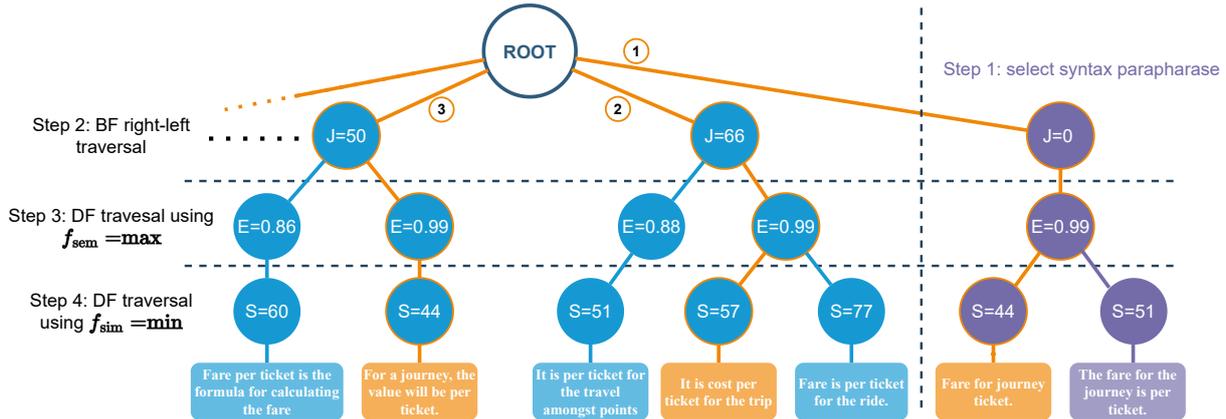

Figure 1: Ranking paraphrases of *Fare per ticket for journey* using a tree. Top level node split is by Jaccard distance (J), middle nodes split by entailment score (E) and leaf nodes store string similarities (S). Here $f_{\text{dec}} = [\text{None}, \text{max}, \text{min}]$. By using J we guarantee that candidates with $J = 0$ are syntactic paraphrases if S is constrained. Orange leaves show top ranked candidates. Numbers on paths show ranking order.

Using 10 settings for the number of beams and temperature, we generate 500 candidates for each input. For efficiency purposes, these are filtered heuristically (Appendix B). We construct a depth $d = 3$ tree which splits the candidates by Jaccard distance J , entailment E , and string similarity S . That is, the input to our tree constructor (Algorithm 2) is $\text{metrics} = [J, E, S]$. Here entailment is computed using BART (Lewis et al., 2020) as described in Appendix B. We prune nodes with $J > 0.75$ to limit hallucination.

We select $k = 5$ lexically-diverse paraphrases that maximise entailment given the constraint that the returned candidates should be lexically diverse. First, we select a syntactic paraphrase by traversing the subtree rooted at $J = 0$ and minimising S . The remainder of the candidates are selected by constraining the breadth-first traversal of the first level, which encodes lexical distance, to return the nodes sorted from high to low. This procedure is depicted schematically in Figure 1. We sort the ranked candidate lists for each description according to the Jaccard distance between them and the SGD descriptions. Hence we obtain $k = 5$ synthetic schema variants, with v_1 being the most similar to the SGD schema and v_5 the most dissimilar. We refer to this scheme as Pegasus + BART.

4.2 State tracking data augmentation

4.2.1 Baseline models

D3ST The Description-Driven Dialogue Modelling (D3ST) model (Zhao et al., 2022) is a state-of-the-art DST model that performs intent tracking, requested slots prediction, and state tracking in a

single pass. See Appendix C for a visual representation of inputs and targets. We process the data and train the model as described in Zhao et al. (2022) and Appendix C, selecting models that maximise the development set JGA.

T5DST We follow Lee et al. (2022) to implement a simplified T5DST (Lee et al., 2021a). It predicts the value of each slot iteratively, requiring a number of decoding passes equal to the number of slots in an API to predict the dialogue state given a dialogue history. Training and inference with this model is very expensive and we train the models with a fixed computational budget of 20,000 gradient steps⁴ for the baseline and 40,000 steps for all augmented data experiments. See Appendix C for prompt structure and implementation details.

4.2.2 Evaluation

On SGD, the JGA (JGA_{orig}) is computed for the 4,201 test set dialogues. 77% of these have a turn span where the agent calls an API unseen in training. Only 6 out of 21 schemata are seen in training.

Evaluation on SGD-X proceeds as follows. First, the SGD descriptions in the prompt are replaced, in turn, with descriptions taken from the five SGD-X variants. The DST model then predicts the state of a given dialogue 5 times, conditioned on prompts that are increasingly dissimilar to the SGD test set. Hence, the JGA_{v_1-5} figures reported are averages over approximately 21,000 conversations. For all experiments except *oracle* (see Section 4.2.3), *none* of the test time prompts are seen during training:

⁴This is the number of steps required for maximising the development set JGA, for all three runs.

the *seen* superscript in the metric names reported in Section 5 identifies conversations where the *SGD test set prompt is seen* during training. Therefore, it quantifies whether the model can robustly identify slots seen in training by interpreting the meaning of the descriptions rather than relying on linguistic patterns in the training schema. Meanwhile *unseen* measures the ability of the model to generalise to new APIs, which may describe new slots and domains, notwithstanding the language used by developers to phrase the descriptions. The JGA coefficient of variation (ie *schema sensitivity*, SS_{JGA}) as the prompt changes measures the sensitivity of a model to the prompt (Lee et al., 2021b).

Metric	Ranking	v1	v2	v3	v4	v5

	SGD-X	-	13.5	11.2	9.9	8.6

Table 1: Automatic synthetic schema evaluation. J is multiplied by 100 for readability.

4.2.3 Experimental setup

We show our approach is effective by augmenting the DST training data with synthetic prompts composed from our generated schemata. To study the effect of controlling prompt diversity augmented datasets are two (2x) to six times (6x) the SGD size. For 2x, augmented data contains prompts constructed from the v1 synthetic schema, whereas for 6x we use all five generated schemas⁵.

Baselines We create three synthetic schema by **backtranslation**. Our pivot languages are Korean, Japanese and Chinese (Lee et al., 2022). The augmented DST training dataset is four times (4x) larger than SGD. Following Huang et al. (2021), we also consider French and Russian as pivot languages to generate two more synthetic schemas and obtain an augmented dataset six times (6x) larger than SGD. We also compare with **easy data augmentation** (EDA) (Wei and Zou, 2019), a word-level DA approach based on synonym replacement

⁵Ordering is from most (v1) to least (v5) similar to SGD.

(SR), random insertion, deletion and substitution. We perform SR with probability 0.25 and the other operations with equal probability of 0.05. Just like for backtranslation, we generate 3 or 5 synthetic schemas with this method via the public API. Augmentation with the **SGD-X** human schemata paraphrases is considered an *oracle* because these models see the SGD-X schemata at training time.

5 Results and Discussion

5.1 Synthetic schema generation

Our ranking method generates increasingly lexically diverse schemata as shown by the increase in Jaccard distance across schema variants (Table 1). This aspect is much more difficult to achieve with EDA without significantly affecting semantics. Furthermore, self-BLEU (Zhu et al., 2018) scores indicate EDA is the least effective in ensuring candidate diversity compared to other approaches. The BLEU difference between the SGD-X variants v1 and v5 is 15.2 but smaller (0.66) for our approach. Hence, the PEGASUS + BART copies n -grams from the input and includes additional information. This information is not always meaning-preserving: *City where the event is happening* is paraphrased as *The bustling city where the event is taking place* (v5) but *End date for the reservation or to find the house* is paraphrased as *End date for hotel reservation to allow time for a replacement both at the struck and in the run up to the event* (v5). The self-BLEU of the SGD-X schemas decreases faster compared to the automatically generated paraphrases, suggesting that Jaccard distance increases partly due to hallucination.

Entailment scores show that backtranslation is effective in preserving semantics. For EDA, the semantic similarity drops significantly as more candidates are generated since more dissimilar schemas are generated with more edit operations which are likely to affect meaning. The entailment scores for the SGD-X paraphrases are also lower since they do not always perfectly semantically overlap with the input by construction (Lee et al., 2022) and because of entailment model errors.

5.2 Dialogue state tracking

D3ST Both the robustness and robust generalisation are improved by augmentation with our synthetic schemas, as demonstrated by maximum JGA_{v1-5}^{seen} (12.35%) and JGA_{v1-5}^{unseen} (5.85%) increases and 23.6% drop in SS_{JGA} (rows 1&4, Ta-

Model	#	Generation method - Dataset size	JGA _{orig} ↑	JGA _{v1-5}	JGA _{v1-5} ^{seen}	JGA _{v1-5} ^{unseen}	SS _{JGA} ↓
D3ST	1	None - 1x	69.8	56.5	73.6	50.8	70.1

Table 2: SGD and SGD-X dialogue state tracking performance when training with augmented data. Best performance (excluding the oracle setup) is in **bold**. Dataset size is the number of times the augmented dataset is larger than SGD.

ble 2). The most benefit is obtained by training with syntactically diverse prompts (Pegasus + BART 2x). Adding more diverse data (rows 3&4) improves DST performance. Part of this improvement may arise because paraphrasing leaves out domain-dependent information: *Average review rating of the doctor* is paraphrased as *The rating is average, so it's not perfect*, so the model can learn to identify ratings more generally⁶. Moreover, inputs are noisy due to hallucination, so the models trained with our augmentation are less likely to overfit to the linguistic patterns of the training schemas. BLEU scores indicate high lexical overlap between EDA-generated and SGD schemas (Table 1). This limits the magnitude of EDA improvement (row 5) and we perform better with less data (rows 3&6, 2&5).

Backtranslation is comparable with our method given the same data quantity (rows 3&7). When we also backtranslate via French and Russian (Huang et al., 2021) the data diversity does not significantly increase (Table 5, Appendix D.1). This negatively impacts the DST performance, while our method improves it (rows 4&8). We can control the schema generation process to match SGD backtranslation performance (Appendix E).

T5DST⁷ We outperform EDA (rows 12&13) but not backtranslation (row 14). This may be due to (1) the larger computational budget needed to maximise T5DST performance⁸ and (2) T5DST's sensitivity to noisy descriptions owing to its prompt format (Appendix C). We control hallucination by pruning candidates with $J > 0.5$ and entailment

smaller than 0.58 and maximise J while minimising S to produce an augmented dataset 4x larger than SGD (Pegasus B + BART 4x). Limiting lexical diversity improves entailment compared to Pegasus + BART 6x (Table 6, Appendix D.1), and the scheme improves DST robustness compared to the backtranslation baseline (rows 11&14).

The best augmentation schemes fail to improve robustness and generalisation relative to the human baseline (rows 9&15). This is due to the intrinsic challenge of generating diverse yet semantically faithful paraphrases but also due to the fact that humans use common sense and schema information when paraphrasing, so the SGD-X paraphrases are not strictly semantically equivalent. However, the proposed automatic process of paraphrase generation enhances DST, yielding non-trivial improvements in model robustness, while being less costly and more scalable compared to gathering human-written schemata paraphrases.

6 Conclusion and Future Work

We presented a simple tree-based ranking algorithm for optimising lexical diversity and semantic faithfulness during schema generation. The synthetic schemas improve both the DST models' robustness to schemata writing style and their generalisation. Our framework will allow researchers working on paraphrase generation and semantic faithfulness to measure the generalisation of their models in a way that may be difficult to capture by existing benchmarks: it can generate schemata paraphrases and train SOTA dialogue state trackers which were shown to benefit from augmentation with high quality, crowdsourced paraphrases.

⁶It appears in 4 unseen services in the test set.

⁷Lee et al. (2021b) report 72.6% JGA on SGD and 64.0% SGD-X but we could reproduce only 69.98% and 50.42%.

⁸Each training example is seen only once.

Limitations

The optimality of our ranking method depends on the ability of the underlying paraphrase model to generate a search space that contains paraphrases which are lexically and syntactically diverse and preserve the meaning of the input description. This is sometimes challenging with schema inputs which tend to be short (e.g. *name of event*) and contain little information. Our future work will focus on addressing this by contextualising these inputs to enable the paraphrase model to produce a richer space of candidates. Secondly, our method requires that the semantic faithfulness metrics capture semantic similarity well even as the vocabulary of the candidates and their syntax are very diverse. Previous work on abstractive summarisation (Narayan et al., 2022; Maynez et al., 2020; Kryscinski et al., 2019) finds entailment scores to be best correlated with human judgment of faithfulness. However, the correlations are not perfect so the output of the ranking algorithm is still expected to contain noisy candidates. For slot description paraphrases, this is challenging because different inputs are very closely semantically related and the entailment model may not identify paraphrase model errors that map a slot description (e.g. departure time) to one with related semantics (e.g. arrival time). We intend to address this in future work by developing finetuning schemes for semantic faithfulness metrics.

Ethics Statement

Our work is concerned with the use of language generation models to augment training datasets for schema-guided dialogue datasets. The generation phase is unconstrained, so the model may generate candidates that exhibit biases inherited from the C4 (Raffel et al., 2020) and HugeNews (Zhang et al., 2020a) pre-training datasets. In our experiments, we did not observe toxic or harmful outputs, but on one occasion the model did generate the word *apartheid* as part of an incoherent sentence. For this reason, our filtering stack rejects any candidates containing sensitive words. The list of words that parameterize the sensitive words filter is defined by the user.

A The SGD and SGD-X datasets

SGD As mentioned in Section 1, the conversations in the SGD dataset are grounded in schemata, which describe a set of service APIs. The most important schema *elements* are⁹:

- a *service name* (e.g. *Messaging_1*) followed by a *service description* (e.g. *Connect and share locations with your contacts*)
- one or more API functions to be invoked as users solve tasks, referred to as (*user*) *intents*; each intent has a *name* (e.g. *ShareLocation*) and an *intent description* (e.g. *Send your location to a contact*)
- optional and required arguments for each API function, or *slots*; each slot has a *name* (e.g. *location*) and a *slot description* (e.g. *Location to share with the contact*)

SGD-X Lee et al. (2022) observe that 71% of intent names and 65% of slot names from unseen APIs exactly match the train set. Furthermore, descriptions are stylistically uniform across the train and test sets. For example, all boolean slots begin with the phrase *Boolean flag ...* or *Whether...*. Therefore, they create the SGD-X dataset as follows:

- crowdsource schema element paraphrasing to more than 400 authors via Amazon Mechanical Turk. Each crowdworker either paraphrases all names or all descriptions for a given schema

⁹Examples below are taken from the SGD test set.

- manually vet responses for quality and correctness.

The slot names collected are sorted in increasing order of their Levenshtein distance to the SGD slot names whereas the descriptions are sorted according to the Jaccard distance between their lemmatized forms (excluding stop words). An example of SGD-X description paraphrases is shown in Table 3.

Variant	Description
SGD	Category to which the attraction belongs
v1	The category that describes what kind of attraction it is
v2	Category of place of interest
v3	Type of tourist attraction
v4	Choose the kind of tourist landmark
v5	The kind of tourist hotspot

Table 3: Example of descriptions paraphrases from the SGD-X test schemas. The more similar v1 description contains overlapping vocabulary with the SGD test set description, whereas v4 and v5 variants are dissimilar both stylistically and lexically

While the examples above are paraphrases of the SGD input, in general, the semantic content of the schema element paraphrases is not perfectly overlapping with the input as the crowdworkers use information from the wider service context when creating new elements.

B Ranking Framework

B.1 Candidate generation

Algorithm 2 summarises the candidate generation procedure, which takes any paraphrase model, a list of model-specific generation parameters and, optionally, a list of filters as an input (line 1). These parameters are temperature and number of beams for Pegasus, or a grid of lexical, semantic and syntactic distances for the Quality Controlled Paraphrase Generation (QCPG) (Bandel et al., 2022) model presented in Appendix E. The model generates one or more paraphrases, which are filtered before returning (lines 3-8). We describe the filtering process next.

Heuristic filtering Our main motivation for implementing heuristic filters is to filter the majority of poor quality candidates, without making use of the large GPU cards required to run the entailment model. We also address the fact that the model is free to generate a very large number of candidates and therefore is expected to hallucinate significantly. These filters are general purpose and are

implemented in few lines of code using the spaCy and nltk libraries. Table 4 lists active filters along with typical examples filtered.

Entailment filtering We implement our entailment filter using BART (Lewis et al., 2020)¹⁰. This model is pre-trained on the MNLI dataset (Williams et al., 2018). To measure entailment this model consumes a premise and hypothesis in the format premise <SEP> hypothesis. In our implementation we replace premise with the description to be paraphrased. By default, the hypothesis is a template of the form This example is {}, where {} is a placeholder for the user hypothesis, in our case the paraphrased description. We find that considering alternative templates improves the reliability of the model, so we consider {}, This example has the same meaning as {}, This text is about {}, and This example implies that {}, averaging the entailment scores across templates to calculate the entailment score. The same procedure is followed when computing the entailment of candidates during ranking.

Algorithm 2: Candidate generation

```

1: def generate_candidates(model: Any,
   inp: str, params: dict, filters:
   Optional[list[Callable]]):
   Data: model text generation model, inp
           input sentence, params model
           specific parameters, filters a
           list of boolean functions
   Result: cand_s list of inp paraphrases
2: cand_s ← [] ;
3: for p in params:
4:   c ← model.forward(inp, **p) ;
5:   c ← [p for p in c if not any(f(p,
   inp) for f in filters)]
6:   cand_s.extend(c)
7: return cand_s

```

B.2 Ranking

Ranking Algorithm 3 summarises the tree-ranking procedure. This procedure takes as an input the tree constructed as described in Algorithm 1, along with a list of decision functions f_{dec} . Our algorithm starts by selecting a paraphrase via depth first traversal of the subtree rooted at $J = 0$ (line 2). The remainder of the candidates are selected by

¹⁰Available at <https://huggingface.co/facebook/bart-large-mnli>.

Filter name	Filtered example
contains advice	An appointment is necessary for your hair .
describes action	They commemorate the number of flights to the airport.
has named entities	Enter the doctor’s Leningrad address.
has low frequency words	The address is ofadvisory .
discard multiple sentences	The address is the dentist’s box. Guidelines for hiring a dentist.
has repeated ngrams	The dentist is Address of the dentist .
has repeated similar bigrams	The type of event is stated in the title of the event .
has consecutive repeated words	Average review rating for a hotel hotel.
is past tense sentence	It was the dentist’s address.
is passive voice sentence	The address was given by abrasives from the dentist.
is question	Is there a balance of the account?
has alphanumeric words	400 baths in an apartment.

Table 4: Filters implemented along with sample examples they discard

Algorithm 3: Tree ranking

```

1: def tree_rank(root: Node, n: int, f_dec:
    list[Callable]):
    Data: root, n number of candidates, f_dec
        decision functions
    Result: list of n ranked candidates
2: ranked ← syntax_select (root);
3: n ← n - len(ranked);
4: while len(ranked) ≠ n:
5:     for next in level_order (root):
6:         for f in f_dec:
7:             cand ← select (next.sents);
8:             ranked.add(cand);
9:             prune (next, cand);
10: return ranked

```

traversing the first level in a breadth-first manner (line 5) and depth-first traversal of each subtree returned during the level-order traversal (lines 6-8). Here the semantics of $f(\text{next.children})$ is that the decision function f takes all the children of next as input and returns a single node which is next in the traversal. A candidate is selected from the leaf¹¹ (line 8) and subsequently removed from the candidates list (line 10). This is to avoid selecting the same candidate multiple times in situations where the paraphrase model generates few distinct candidates.

C State Tracking Baselines

D3ST We process the data as described by Zhao et al. (2022) with the following differences:

- The indices are separated by the = symbol in both the inputs and the targets, to avoid a

¹¹There can be multiple, possibly repeated candidates in a leaf because the generative model may generate the same output given different parameter settings. We select the most common one if there are repeated candidates and randomly otherwise.

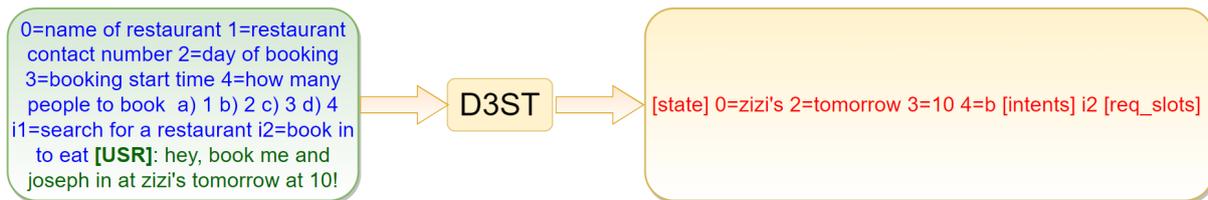

parsing ambiguity which occurs for time slots if : is used as a separator for targets

- For categorical slots which take the dontcare special value, our output contains slot_index: dontcare substring and we do not include the dontcare value in the prefix together with the other options
- We lowercase the inputs and the targets¹².

We obtain 175,780 examples from the original SGD dataset, which are truncated to the last 1,024 tokens on the input side. See Figure 2a for a visual representation of the model inputs and outputs. We optimise the model using the Adafactor optimizer and effective batch size 32, starting from the initial weights google/t5-v1_1-base published by huggingface (Wolf et al., 2019). We interpolate the learning rate linearly between 0 and 10^{-4} over the first 1000 steps and keep it constant thereafter. We select the model by evaluating the development set JGA every 5000 gradient updates, stopping the training if said metric fails to improve after 3 consecutive evaluations. All numbers in Table 2 are averages of 3 runs, except the SGD-X experiment for T5DST which is a single run.

T5DST Given a dialogue in the SGD training set we consider all partial dialogue histories $\{u_1, s_1, \dots, s_{t-1}, u_t\}$ with $t \in \overline{0, T}$ where T is maximum index of the user turn in a dialogue. The turns in each dialogue history are lowercased and separated [usr] and [sys] tokens, *not treated* as special tokens. For each dialogue history we create a training example for each slot in the ground truth schema, which contains the concatenated turns suffixed with the string

¹²This appears in illustrations but is not explicitly stated by (Zhao et al., 2022).

(a) Visual representation of D3ST inputs and targets. Blue font `blue`, preceding the `[USR]` special token represents the prompt, consisting of slot descriptions extracted from the schema. Each slot is assigned an index, which is used to recover the slot value pairs during post-processing. Note that slot 4 is categorical, and so the string `a) 1 b) 2 c) 3 d) 4` is appended to the description to indicate the model that it should output one of the choices. The dialogue history follows the `[USR]` token. The **model outputs** only active slots, in this case omitting slot 1 because it has not been mentioned. The entire dialogue state (as opposed to turn state) is generated at every turn.

```
input: " [user] can you find me something economical to eat in pleasanton. [slot] name of the restaurant"
output: none
```

```
input: " [user] can you find me something economical to eat in pleasanton. [slot] price range for the
restaurant a) expensive b) moderate c) inexpensive d) very expensive"
```

```
output: b
```

```
input: " [user] can you find me something economical to eat in pleasanton. [slot] city in which the restaurant
is located"
```

```
output: pleasanton
```

...

(b) Visual representation of T5DST inputs and targets. The string `[slot]` separates the dialogue history from the slot description. In the first example the model outputs the special value `none` to indicate that the slot was not mentioned by the user. For categorical slots (second row from the top), the slot description is concatenated with options containing all possible slot values and the model predicts the correct option. For non-categorical slots (third row), the exact value is predicted. The ellipsis indicates that `none` is predicted for all other slots in the `Restaurant_1` schema that are not mentioned in the dialogue history

Figure 2: Prompt formats for a) D3ST b) T5DST

`[slot] [slot_description]` where the placeholder `[slot_description]` is replaced by the lowercase descriptions extracted from the SGD schemata. This yields 1,601,356 examples for the SGD training dataset. See Figure 2b for a representation of the model inputs and outputs.

We optimise the model using the Adafactor optimizer and effective batch size 256, starting from the initial weights `google/t5-v1_1-base` published by huggingface. We interpolate the learning rate linearly between 0 and 10^{-4} over the first 1000 steps and keep it constant thereafter. We perform 20,000 optimisation steps¹³, limiting the number of training steps to 40,000 steps¹⁴ for all augmented data experiments. All numbers in Table 2 are averages of 3 runs, except the Oracle experiment on T5DST which is a single run.

¹³For a single run, this is approximately 6 hours of computation on 8 nvidia A100-80GB cards. Moreover, decoding a single run on SGD and SGD-X takes 6 hours.

¹⁴This is sufficient so that the model sees every example once when working with an augmented training set six times the size of SGD.

D Additional Results

D.1 Increasing backtranslation dataset size

We include Table 5 to substantiate our intuition that the training with the Backtranslation 6x scheme does not yield further improvement compared to the Backtranslation 4x scheme as the additional data does not significantly increase the prompt diversity. Most clearly, this is indicated by the fact that the `v5` variant has similar BLEU to variant `v3` in Backtranslation 4x, indicating that a large proportion of additional data has some overlaps more with the SGD distribution than the data backtranslated to Chinese, Korean and Japanese. This is also indicated by how self-BLEU decays as more data is added, comparatively, between Backtranslation 4x and Backtranslation 6x.

D.2 Controlling schema generation diversity

Table 6 shows that the alternative schema scheme generates schemas with lower average Jaccard distance and higher entailment with respect to the SGD schemata. We find this effectively controls the noise in the data, leading to improved performance

Metric	Ranking	v1	v2	v3	v4	v5
Jaccard Dist	Backtr. 4x	18.2	29.9	43.9	-	-
	Backtr. 6x	12.9	22.7	27.8	35.6	46.7
Entailment	Backtr. 4x	97.5	96.5	95.9	-	-
	Backtr. 6x	98.0	97.5	95.2	94.8	95.5
BLEU	Backtr. 4x	36.4	26.01	18.9	-	-
	Backtr. 6x	51.3	37.2	29.5	23.4	18.2
self-BLEU	Backtr. 4x	-	49.3	41.7	-	-
	Backtr. 6x	-	55.3	49.7	44.6	39.6

Table 5: Effect of using French and Russian as additional pivot languages on automatic metrics

Metric	Ranking	v1	v2	v3	v4	v5
Jaccard Dist	Pegasus + BART	13.0	61.2	68.8	71.2	76.2
	Pegasus B + BART	10.2	38.3	46.9	55.1	54.5
	SGD-X	55.6	65.6	71.2	78.1	85.7
Entailment	Pegasus + BART	99.1	96.3	94.6	94.2	94.2
	Pegasus B + BART	98.8	98.2	96.4	96.2	96.7
	SGD-X	89.7	88.0	88.4	86.8	87.5

Table 6: Comparison of diversity and semantic faithfulness metrics for slot description paraphrases

Index	Augmentation	JGA _{orig}	JGA _{v1-5}	JGA _{v1-5} ^{seen}	JGA _{v1-5} ^{unseen}	SS _{JGA}
1	Pegasus+BART 6x	71.2	<u>63.9</u>	<u>85.9</u>	56.6	46.5
2	Pegasus+BLEURT 6x	<u>72.4</u>	64.0	86.6	<u>56.4</u>	<u>46.6</u>
3	QCPG+BLEURT 6x	72.7	63.2	85.2	55.9	47.3
4	Backtranslation 4x (Lee et al., 2021b)	72.1	62.2	84.0	54.9	53.1

Table 7: Ranking with a more accurate semantic faithfulness metric (row 2) or generating candidates with a controllable paraphrase model (row 4) can be used to boost SGD performance over our Pegasus+BART approach (row 1). Bold font marks column maximum, underlined second largest number.

for T5DST and similar performance to PEGASUS + BART for D3ST.

E Schema Generation with BLEURT and QCPG

BLEURT (Sellam et al., 2020) is a BERT-based natural metric commonly used in translation, so it is expected to be highly sensitive to semantic differences. In Table 7 we show that simply re-ranking the Pegasus output space with BLEURT improves SGD performance comparably with backtranslation (rows 2&4) and the robustness and generalisation improvements are maintained.

Bandel et al. (2022) exploit high quality examples in paraphrase corpora by conditioning the model with a string *quality parameters string* outlining target semantic, syntactic and lexical distances of the generated paraphrase during finetuning. At inference one must specify these parameters to obtain diverse yet high quality paraphrases. We could not apply the quality parameter selection method proposed by QCPG authors at inference time as the code had not been fully released at the time of writing. Instead, we generated a large number of paraphrases with different quality targets and greedy decoding, and re-ranked the candidates using our framework. This demonstrates the versatility of our framework. In Table 7 we show that this model can equally achieve improved performance on SGD. The improvement on SGD-X is slightly less than achieved by PEGASUS+BART 6x, as expected since greedy decoding and better semantic faithfulness optimisation generate schemata closer

to the SGD distribution so less out-of-distribution improvement is achieved.

This experiments in this section and Appendix D.2 demonstrate the versatility of our framework and its usefulness as a tool for generating synthetic schema prompts.

Language Model Decoding as Likelihood–Utility Alignment

Abstract

A critical component of a successful language generation pipeline is the *decoding algorithm*. However, the general principles that should guide the choice of a decoding algorithm remain unclear. Previous works only compare decoding algorithms in narrow scenarios, and their findings do not generalize across tasks. We argue that the misalignment between the model’s *likelihood* and the task-specific notion of *utility* is the key factor to understanding the effectiveness of decoding algorithms. To structure the discussion, we introduce a taxonomy of misalignment mitigation strategies (MMSs), providing a unifying view of decoding as a tool for alignment. The MMS taxonomy groups decoding algorithms based on their implicit assumptions about likelihood–utility misalignment, yielding general statements about their applicability across tasks. Specifically, by analyzing the correlation between the likelihood and the utility of predictions across a diverse set of tasks, we provide empirical evidence supporting the proposed taxonomy and a set of principles to structure reasoning when choosing a decoding algorithm. Crucially, our analysis is the first to relate likelihood-based decoding algorithms with algorithms that rely on external information, such as value-guided methods and prompting, and covers the most diverse set of tasks to date. Code, data, and models are available at <https://github.com/epfl-dlab/understanding-decoding>.

1 Introduction

Large transformer-based *language models* (LMs) have been pushing the boundaries on tasks ranging from natural language generation (Radford et al., 2018) to information extraction (Josifoski et al., 2022), theorem proving (Polu and Sutskever, 2020), code generation (Zügner et al., 2021), and even protein generation (Ferruz et al., 2022). At inference time, these models rely on a decoding algorithm to generate an output. The goal of decoding algorithms is to select an output of high utility from

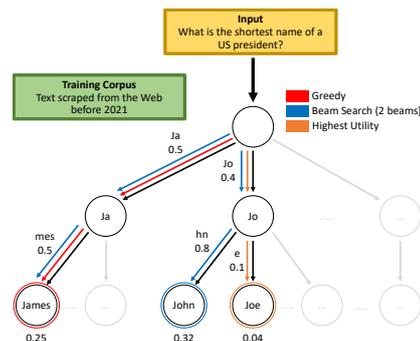

Figure 1: **Example of likelihood–utility misalignment.** Imagine a fictional LM trained before Joe Biden became the US president. The input asks for the shortest name of a US president. After Joe Biden’s inauguration, this is ‘Joe’, but before, it was ‘John’. Greedy search returns ‘James’ since its first token ‘Ja’ has the highest likelihood. Beam search manages to find the highest likelihood sequence ‘John’. Both fail to find the correct answer ‘Joe’ with the highest utility since ‘Joe’ has a very low likelihood.

the exponentially large output space. In contrast to the generic language modeling training objective, which is based on the data likelihood, the notion of utility is task-specific. The potential gap between the two can create a *misalignment* between *model likelihood* and *task utility*; see Fig. 1 for an illustration of this concept.

Indeed, across different tasks, researchers noticed that high likelihood is often not associated with desired properties of the output (Stahlberg and Byrne, 2019; Zhang et al., 2021; Klein et al., 2017). Naturally, this has led to the development of decoding strategies aimed at mitigating this problem. In the context of natural language generation (NLG), Nucleus Sampling (i.e., top- p) (Holtzman et al., 2020) has been proposed to avoid dull or degenerate text. Similarly, in the context of machine translation (MT), solutions ranging from simple ad-hoc tweaks like enforcing a minimal sequence length (Stahlberg and Byrne, 2019) to leveraging a value model to directly optimize for utility in de-

coding (Leblond et al., 2021) have been developed. These methods for alignment are task-specific and have been tested only in narrow domains, making it difficult for practitioners to compare them.

Recently, Meister et al. (2022) and Wiher et al. (2022) explored the likelihood–utility misalignment across tasks. However, these studies still largely focus on a group of similar tasks — NLG tasks — and, more crucially, do not include decoding strategies that make use of external sources of information at inference time. Therefore, a general framework to structure our thinking about decoding algorithms is still missing.

Our work makes the first step towards filling this gap. We propose a unified perspective of decoding as a tool for mitigating the likelihood–utility misalignment without modifications to the model. Looking at decoding through this functional lens, in Sec. 3, we provide a taxonomy of misalignment mitigation strategies (MMSs). The taxonomy groups decoding algorithms based on the implicit assumptions about likelihood–utility misalignment that need to hold for them to be effective.

Equipped with this taxonomy, we conduct a comprehensive empirical analysis in which we choose a representative set of decoding algorithms and a representative set of tasks to cover the relevant types of misalignment. We identify three main sources of misalignment: *training imperfections* (finite dataset, differentiable surrogate loss), *distribution shift*, and changes in the model’s intended usage, which we call *utility drift*. Then, we measure the likelihood–utility misalignment across tasks (RQ1) by estimating: the correlation between likelihood and utility for the generated outputs after decoding (RQ1-a) and the correlation between likelihood and utility among candidate outputs explored by the decoding algorithm (RQ1-b). We proceed by investigating the benefits of decoding algorithms that leverage external information at inference (RQ2). Finally, we experiment with large generalist LMs (LLMs) and show that prompting can be seen as means for improving the alignment at inference time (RQ3).

Our experiments reveal that: (i) When no distribution shift or utility drift happens, decoding based solely on the likelihood is enough to provide high utility, i.e., likelihood is a strong predictor of utility. (ii) In such cases, there is no significant difference between different kinds of decoding algorithms, and we would recommend keeping beam search.

(iii) In the presence of distribution shift or utility drift, value-guided beam search is both an effective and efficient decoding algorithm that leverages a value model at inference time to fix misalignment. Finally, (iv) for LLMs, prompting is a mechanism that sets the model in a state where the likelihood is well-aligned with the utility. This perspective provides a tentative explanation for the empirical success of prompting LLMs.

This work studies the fundamental problem in decoding, which involves a complex interaction between models, tasks, and data. Our unifying conceptual framework (the MMS taxonomy), accommodating all known decoding algorithms, enables the systematic study of decoding in a considerably broader scope than previously. By sharing the taxonomy and open-sourcing our implementations, we hope to pave the way for a more structured discussion in the future.

2 Background

High Utility Is the Goal. For a task t and input x , the utility function assigns a score $u_t(y|x)$ to each element y in the output space \mathcal{Y} . This score quantifies the goodness, or quality, of the output y with respect to a specific input x . For instance, in translation, the utility quantifies the extent to which the output conveys the same message as the input. For question answering, the utility simply quantifies the correctness of the answer. These task-specific notions of utility are operationalized in the evaluation metrics. The development of evaluation metrics that correlate with the human-defined notion of utility is a very active research area (Sai et al., 2022) and beyond the scope of this work. In our analysis, we use the canonical evaluation metric of each task as the utility function. For partially-decoded sequences, the utility can be approximated using a *value function* (see Sec. 3.3).

Given some input x , an *ideal model* would generate the element from the output space corresponding to the highest utility score: $\operatorname{argmax}_{y \in \mathcal{Y}} u_t(y|x)$.

Unfortunately, most of the practically relevant utility functions are not amenable to optimization, forcing us to work with proxy functions, such as the canonical likelihood.

Language Models. A language model corresponds to a probability distribution p over $y \in \mathcal{Y}$, where \mathcal{Y} is the set of all sequences that can be constructed using a vocabulary \mathcal{V} . In this work, we focus on conditional LMs $p(\cdot|x)$. Usually, these

conditional distributions are modeled autoregressively (parametrized by θ): $p_\theta(y|x) = \prod_{i=1}^{|y|} p_\theta(y_i | y_{<i}, x)$. The model is trained to maximize the target sequence’s conditional log-likelihood with teacher forcing, using the cross-entropy loss $\mathcal{L}(\theta) = -\sum_{(x,y) \in \mathcal{D}} \log p_\theta(y|x)$, where \mathcal{D} is the training corpus (Sutskever et al., 2011, 2014).

Once an LM is trained, it provides a next-token probability distribution across the output vocabulary. Decoding algorithms define how tokens are chosen during generation.

3 Proposed MMS Taxonomy

In this section, we propose a taxonomy of misalignment mitigation strategies (MMSs). This work focuses on decoding-based MMSs that mitigate the misalignment without modifying the model. As a primary signal, they rely on the model’s likelihood. However, additional components (e.g., value model, knowledge base, etc.) can be leveraged. Decoding algorithms, which we define as procedures that take in an input — and potentially some context (e.g., a prompt with a task description or examples) — and return a sequence from the output space, can be seen as specific implementations of an MMS. Apart from fixing the misalignment problem at inference time, it is also possible to retrain or finetune the model with newly collected data that better reflect the intended utility and target testing distribution. We leave the detailed treatment of this part of the taxonomy for future work. See the Limitations section at the end of the writing for further discussion of these alternatives.

3.1 Greedy Likelihood-Based Strategy

Given the LM’s probabilistic formulation, one could strive to select the most likely sequence under the model: $\operatorname{argmax}_{y \in \mathcal{Y}} p_\theta(y|x)$. However, due to the exponentially large state space, this optimization problem is intractable.

The class of algorithms following the greedy likelihood-based MMS approximate the intractable argmax by following the greedy heuristic of making *locally* optimal choices at each decoding step w.r.t. the *likelihood* under the language model. However, reaching a globally optimal solution may require locally sub-optimal steps. When this happens, we say that the likelihood landscape is *greedy adversarial* (Meister et al., 2020). For a likelihood model that is not greedy adversarial, greedy heuristics will retrieve the highest-likelihood solution.

Therefore, the algorithms’ effectiveness depends on the likelihood–utility alignment.

Contrarily, greedy decoding algorithms may fall arbitrarily short of the global maximum for likelihood models that are greedy adversarial. Indeed, greedy decoding algorithms implicitly optimize a different objective function — a *tampered* version of the *likelihood* objective in which a term that encourages locally optimal solutions is added (Meister et al., 2020). Therefore, the ability of greedy decoding algorithms to retrieve high-utility sequences even from a likelihood model that is perfectly aligned with the utility is inversely proportional to how greedy adversarial the likelihood landscape is. In some cases, the particular bias induced by the greedy heuristic *mitigates* the likelihood–utility *misalignment*, and makes the tampered likelihood objective better aligned with the utility than the original (Meister et al., 2020, 2023; Su et al., 2022).

The decoding algorithms in this category can be further divided into two subgroups: (i) deterministic ones, such as greedy search (GS) and beam search (BS); and (ii) stochastic ones, such as top- k sampling (Fan et al., 2018), top- p sampling (Holtzman et al., 2020), and stochastic beams (SB) (Kool et al., 2019). For more details, see Appendix A.1.

3.2 Greedy Likelihood-Based Strategy with Pruning

An understated fact in the literature is that even for tasks for which the canonical decoding algorithms (e.g., BS) perform well, a non-negligible portion of the performance relies on some bespoke, ad-hoc tweaks on the likelihood scores (Stahlberg and Byrne, 2019). These tweaks are usually based on either: (i) post-hoc observations that likelihood-based decoded sequences often contain specific undesirable patterns (e.g., empty or short sequences, repetitive patterns, etc.); or (ii) problem-specific knowledge about the utility landscape suggests that high-utility sequences have a specific property, which can be explicitly enforced by the decoding strategy (e.g., sequences should correspond to triplets of elements from a predefined set). Conceptually, all these tweaks employ mechanisms that *discourage* the generation of *high-likelihood* patterns that are known (or expected) to be associated with *low utility*.

This category includes: (i) decoding algorithms with ad-hoc heuristics such as the n -gram repetition

penalty (Klein et al., 2017); (ii) constrained beam search (CBS) (Scholak et al., 2021; De Cao et al., 2022; Josifoski et al., 2022); (iii) NeuroLogic (Lu et al., 2022). For more details, see Appendix A.2.

3.3 Greedy Likelihood- and Value-Based Strategy

Heuristics such as the ones used in the previous category can capture some properties associated with high utility but are limited to properties that can be easily expressed explicitly. While the utility function is generally defined for complete sequences only, to guide decoding algorithms, one can rely on the general concept of a value model. A value model approximates, for partially decoded sequences, the expected utility of the final sequence if the decoding keeps following the same policy. The most prominent algorithm in this category is value-guided beam search (VGBS) (He et al., 2017; Ren et al., 2017; Krishna et al., 2022). It uses a greedy strategy similar to BS but selects the next token using a linear combination of the LM’s likelihood and the value model’s scores. See Appendix A.3 for details.

3.4 Simulation-Based Strategy

Even though VGBS considers both likelihood and value, it remains greedy by only looking one step ahead. Simulation-based decoding algorithms explore further into the future before making the next decision. When the value landscape is complex and constructing a good value model is hard, such strategies with a look-ahead may become particularly effective. By turning the knob controlling the number of simulations, one can trade off computational efficiency for obtaining better value estimates. Monte-Carlo Tree Search (MCTS) is the canonical example of simulation-based tree exploration informed by a value model. For details, see Appendix A.4.

3.5 Prompting-Based Strategy

The decoding algorithms described in the last two sections address the likelihood–utility misalignment post-hoc. An alternative is to change the conditioning of the model’s probability distribution such that the misalignment never happens. The effort now goes into choosing a context that aligns the likelihood landscape with the task-specific utility. The strength of this class of decoding algorithms lies in the fact that they can readily be applied to a new task without requiring any modifications to

the model or increasing the computation cost of inference (beyond the processing of the prompts’ tokens). However, they only work for large generalist LMs (Chowdhery et al., 2022). The most prominent members are the few-shot (FS) and the chain-of-thought (CoT) prompting methods, described in Appendix A.5.

4 Experimental Setup

4.1 Research Questions

In contrast to previous works that have studied the misalignment problem in constrained settings, we propose quantifying it in a unified and large-scale analysis across tasks (RQ1). We investigate the benefits of a diverse set of previously proposed solutions to the misalignment problem. Our study includes value-guided approaches (RQ2) and prompting (RQ3), covering each class of the MMS taxonomy with at least one representative. Specifically, we ask the following research questions.

RQ1: How correlated are the utility and the likelihood across tasks? As argued in Sec. 3, greedy likelihood-based strategies only require the likelihood to be a strong predictor of utility. We investigate whether this holds across tasks. Specifically, we measure two important aspects of the likelihood–utility alignment: (a) **Post-decoding alignment.** For each data point, the decoding algorithm chooses one output; we measure the likelihood and utility of the prediction and analyze their relation. Is high likelihood associated with high utility in the same way across tasks? (b) **During-decoding alignment.** Decoding algorithms typically explore a set of high-scoring candidates (e.g., BS returns one candidate per beam). We measure the correlation between likelihood and utility among these candidate outputs to analyze the likelihood landscape of the model.

RQ2: How effective are value-guided MMSs? In particular, we investigate the benefit of value-guided decoding algorithms as a function of the value model’s quality.

RQ3: Is prompting an MMS? We investigate the efficacy of prompting as a likelihood–utility alignment tool for generalist LMs (LLMs).

4.2 Tasks and Datasets

To organize the discussion, we propose a simple classification of the sources of misalignment: (a) **Training imperfections (TI)**, when the model is trained on a different objective than the true util-

Tasks	Utilities	Misalignment Types	Model	Dataset
Closed Information Extraction (cIE)	F1 score [M]	TI	GenIE (BART)	REBEL
Machine Translation (MT)	BLEU [M]	TI, DS	mBART50	WMT14
Non-Toxic Text Generation (NTTG)	Non-Toxicity [T]	TI, DS, UD	GPT2	RTP
Non-Soluble Protein Generation (NSPG)	Non-Solubility [T]	TI, DS, UD	ProtoGPT2	SwissProt
Sports Understanding	Solve Rate [M]	TI, DS, UD	MT-NLG 530B	Sports

Table 1: **Overview of the tasks.** Utility functions are categorized into: (a) [M]: Metric-based and (b) [T]: Trained model-based. The three misalignment types are TI: Training imperfection, DS: Distribution shift, UD: Utility drift.

ity, because of the finite size of the dataset and the approximation error in training (e.g., via stochastic gradient descent); (b) **Distribution shift (DS)**, when the training and testing data distributions differ; (c) **Utility drift (UD)**, when the utility used in development differs from the utility at test time.

While we can expect TI to affect all machine learning tasks (due to the finiteness of datasets and approximations resulting from gradient-based training), DS and UD are task-specific. DS typically occurs when the distribution of the data changes between the training and testing scenarios. UD occurs when the notion of utility changes, i.e., the labels for the same data points are changing.

We carefully selected a variety of generation tasks covering (a) different *notions of utility*, and (b) different expected types of *(mis)alignment between utility and likelihood*. Table 1 gives a high-level overview of these tasks, their utility functions, and associated datasets.¹ In closed information extraction, the training and testing data come from the same distribution, and we expect only TI-type of misalignment. In machine translation, the mBART model is pretrained on a different dataset, inducing some DS as the texts used for training may come from different domains. For non-toxic text and non-soluble protein generation, the task definition changed from generating low perplexity sequences to generating non-toxic sequences. Therefore, UD is expected to be the main driver of misalignment. Similarly, for the sports understanding task, since MT-NLG was not trained for this specific task, we also expect UD to be the main source of misalignment, but here VGBS and MCTS are too expensive due to the size of the LM. Instead, we use this setting to investigate prompting-based MMSs.

4.3 Decoding Algorithms

To cover the full space of MMSs, we experiment with at least one representative from each class from the taxonomy defined in Sec. 3. From

¹For more details about the models, data, and utility functions, see Appendix B.1.

the Greedy Likelihood-based category, we include the canonical GS and BS, as well as the sampling-based SB. From the Greedy Likelihood-based Strategies with pruning, we use CBS. VGBS and MCTS are representatives of the Greedy Likelihood- and Value-based, and Simulation-based decoding classes, respectively. For prompting, we consider the FS and CoT methods. The hyper-parameters for each algorithm are given in Appendix B.2. Appendix B.3, provides a complexity analysis in terms of LM and value model calls.

4.4 Value Models

The quality of a value model reflects its ability to approximate the expected utility. To determine the relationship between the value model’s quality and the benefit of leveraging it in decoding, we craft models that allow us to instantiate versions with varying levels of quality, ranging from a random predictor to an oracle.

Non-Toxic Text Generation. The state-of-the-art method for detecting toxicity is via classification (Hanu and Unitary team, 2020). Such a classifier can readily be used as a value model in decoding. We reproduce the training procedure from Hanu and Unitary team (2020) and save checkpoints at regular intervals until the training is complete. Due to the gradually decreasing under-fitting, these checkpoints give us a sequence of classifiers that systematically improve in terms of quality.

Machine Translation. To achieve a similar effect for MT, we start by assigning to each data point in the dataset another randomly chosen data point which will serve as a false target. This assignment is fixed across all runs. During inference, the value model calculates the BLEU score for both correct and incorrect targets and returns a linear combination between the points. By gradually increasing the weight assigned to the false target from zero to one, the perfect value model (oracle) slowly degrades to a random predictor.

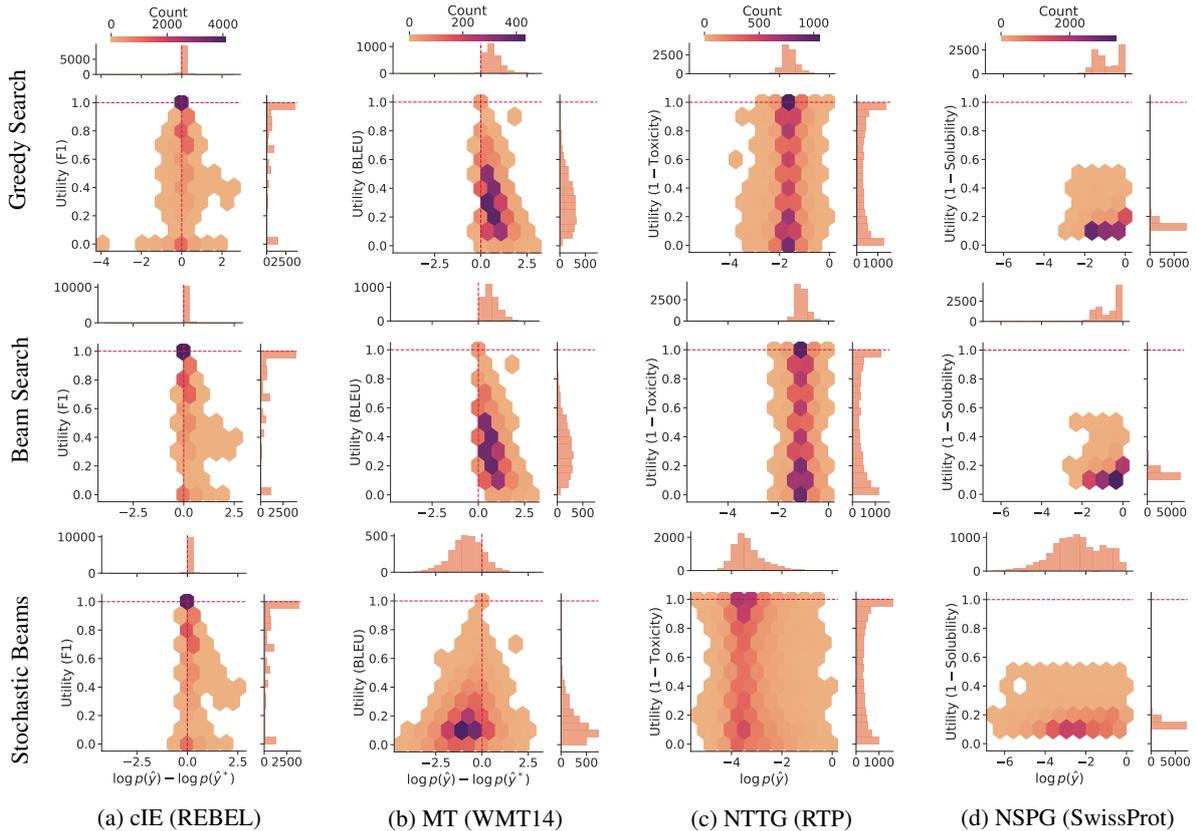

Figure 2: **RQ1 (post-decoding alignment)**: Each decoding algorithm is applied to each dataset-model pair. For each subplot, the x -axis represents the outputs’ log-likelihood under the model, and the y -axis the output’s task-specific utility score. The plots are frequency heatmaps counting the number of decoded outputs pertaining to a given hexagon. For MT and cIE, the x -axis is normalized such that 0 is the log-likelihood of the target answers². These plots show where the outputs are located in the likelihood-utility landscape across tasks and decoding algorithms.

5 Experiments and Results

5.1 RQ1: The Likelihood–Utility Relationship

We present two analyses, one measuring the likelihood–utility misalignment after decoding and one measuring it during decoding.

Post-decoding alignment. In this experiment, we first run each likelihood-based decoding algorithm (GS, BS, and SB) for each dataset–model pair. Then, for each output, we compute both the model likelihood and the task-specific utility.³ We report the results in Fig. 2.

For cIE (first column), most outputs have a likelihood close to the targets’ likelihood. The majority of the outputs have perfect utility — the decoded output is exactly the target, and the model is well-calibrated. This confirms the intuition that when the UD and DS are small, greedy likelihood-based MMS are very effective and can cope with the TI.

²See Fig. 6 for a plot without the target normalization.

³We also ran experiments with top- p and top- k but did not observe a behavior different from BS.

However, in tasks with larger DS and UD, the story is different. In MT (second column), the combined effect of TI and DS gives rise to a negative global correlation ($-.56$ for BS and $-.52$ for GS in terms of Pearson’s correlation; $p < 10^{-3}$) between the predictions’ utility and likelihood after decoding. This is an instance of *Goodhart’s law*, where a surrogate metric (likelihood), when being optimized heavily, becomes a poor approximation of the original property it is supposed to track (utility).

In tasks with large UD, NTTG (third column), and NSPG (fourth column), decoding according to likelihood does not guarantee utility. For example, in NTTG, the likelihood–utility correlation is $-.10$ for GS, $.10$ for SB, and $.03$ for GS in terms of Pearson’s correlation; $p < 10^{-3}$. These scenarios require external information that can guide the decoding towards high-utility outputs.

During-decoding alignment. Now, we investigate the likelihood–utility alignment where it matters: for outputs close to being extracted by the decoding

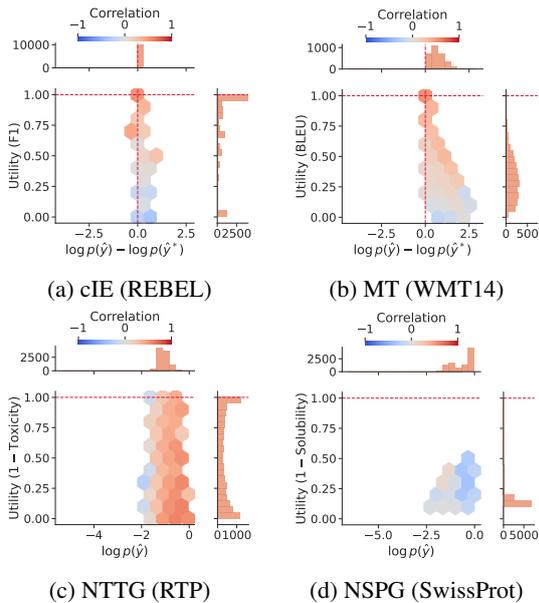

Figure 3: **RQ1 (during-decoding alignment)**: For each dataset-model pair, we run BS and analyze the correlation between likelihood and utility of the top-5 candidate hypotheses. The y-axis represents the task-specific utility score, and the x-axis the log-likelihood under the model. The plots are generated as follows: (i) take the BS outputs from Fig. 2 with their log-likelihood and utility scores, which indicate the x and y coordinate of each data point; (ii) for each data point measure the Kendall’s τ correlation between likelihood and utility of the top-5 candidate hypotheses; and (iii) average the correlation across the points belonging to the same hexagon.

algorithms. BS maintains k candidate hypotheses, one per beam, before returning the top-scoring one as the final output. In this experiment, we analyze the correlation between the likelihood and utility of the top-5 candidates. The results are reported in Fig. 3. There are three dimensions to this problem: (i) the likelihood (x-axis); (ii) the utility (y-axis); (iii) the correlation (color). Ideally, we would like to see red everywhere, indicating that failure to retrieve a high-utility output is due to the decoding algorithm, but the likelihood of the model is still a good predictor of utility. However, this is not what we observe.

For MT and cIE, we see a clear picture, red color (high likelihood–utility correlation) occurs at the top of the plot (high-utility): high likelihood-utility correlation among candidate outputs is enough to yield close to perfect-utility outputs.

For the NTTG (Fig. 3c), the correlation between utility and likelihood among the beams increases as the likelihood increases. When the model generates high-likelihood outputs, there is a positive correlation between being more likely and being less

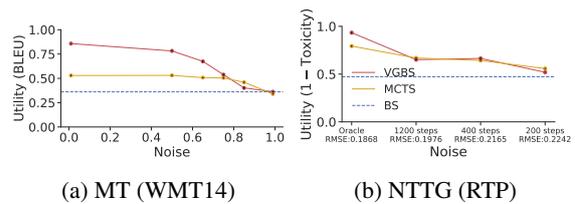

Figure 4: **RQ2**: For MT and NTTG, we ran VGBS and MCTS with value models displaying various levels of noise. We report the average utility of outputs on the y-axis (with 95% confidence interval). The noisy value models are described in Sec. 4.4.

toxic. However, the likelihood mass is assigned to low-utility regions of the output space, which cannot be resolved with decoding based only on the likelihood. For NSPG (Fig. 3d), the correlation across all bins is negative, indicating that high likelihood is a very bad predictor of high utility.

Takeaways. When TI is the only cause of misalignment, the likelihood is a strong predictor of utility; then, likelihood-based decoding algorithms are expected to retrieve high-utility outputs. When UD and/or DS are present, the correlation between likelihood and utility post-decoding plummets, indicating that likelihood-based decoding algorithms are ill-suited. When UD is present (bottom row of Fig. 4), good correlation among the beams does not necessarily mean good utility. However, without UD (top row of Fig. 4), higher correlation among the beams is associated with high utility.

5.2 RQ2: The Benefits of Value Models

We now analyze the benefits of value-guided decoding algorithms (VGBS and MCTS) as a function of the value model’s quality (see Sec. 4.4). Due to the high computational cost of running the experiments with both VGBS and MCTS, we focus on two tasks: MT and NTTG. For each version of the value model, we first perform a hyperparameter search on a small subset of the data and use the best hyperparameters on the test set. The results are reported in Fig. 4. VGBS and MCTS are always at least as good as BS, even with random value models, as the small-scale hyperparameter search selects parameters that ignore the values when they are not useful. However, when there is some signal in the value model, both VGBS and MCTS effectively leverage it and quickly start outperforming BS. When the value model is accurate, very high-utility outputs are discovered. Interestingly, VGBS mostly outperforms MCTS, and can extract almost

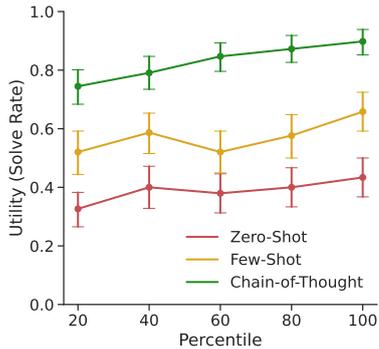

Figure 5: **RQ3:** ZS, FS, and CoT prompting, on the Sports understanding dataset. We report the utility (y-axis) of outputs binned according to the empirical percentiles of their likelihood (x-axis). The lineplot is the average utility per bin with 95% confidence intervals.

perfect outputs, whereas MCTS plateaus. This is significant because VGBS has a substantially lower complexity than MCTS (see Appendix B.3).

Takeaways. Value-guided decoding algorithms can overcome the likelihood–utility misalignment and significantly outperform likelihood-based decoding algorithms even with noisy value models, as long as a small-scale hyperparameter search is done. VGBS offers a better trade-off between performance and computation cost than MCTS.

5.3 RQ3: Prompting as an MMS

Recently, Wei et al. (2022) showed how the simple and broadly applicable idea of including in the prompt a few examples where the targets contain a sequence of steps that lead to the answer can greatly enhance the reasoning capabilities of LMs. We mimic the Sports Understanding task in their work by taking the same in-context examples and evaluating the same two prompting methods: CoT and standard FS prompting. Additionally, we evaluate the model in the standard zero-shot (ZS) setting, without any examples in the context, as a baseline. This results in unstructured answers that need to be labeled manually, see Appendix C.2.

To test our hypothesis that prompting is a means of addressing misalignment, we measure the utility and the likelihood under the model for all the testing data points. The results, summarized in Fig. 5, provide three insights. First, similarly to Wei et al. (2022), CoT outperforms FS and ZS with an accuracy of 83%, versus 57.3% and 38.9% for FS and ZS, respectively. Second, (and complementary to the information visualized on the plot) the average log-likelihood of the outputs generated

by CoT is significantly higher than the FS and ZS generated outputs, -0.067 as opposed to -0.17 and -2.472 . Third, the correlation between the likelihood and the utility when decoding with CoT is higher: 0.11 Pearson’s correlation compared to 0.07 and 0.09 for FS and ZS, respectively.⁴ Referring back to the observation made in RQ1b on Fig. 3, the value-guided MMSs studied in Sec. 5.2 address the misalignment post-hoc. However, the hidden representations building up to that misalignment are not modified, and the undesired information will still be attended to in predicting the next token probability distribution. In contrast, an effective prompting strategy addresses the misalignment before it affects the hidden representations, thereby (i) forcing the model to assign high likelihood to high-utility regions of the output space and (ii) improving the likelihood–utility alignment, making it easier to find high-utility outputs with greedy likelihood-based decoding algorithms.

Takeaways. Effective prompting methods put the model in a state where the generated outputs’ likelihood is well-aligned with the desired utility.

6 Discussion

RQ1 reveals that decoding based solely on the likelihood gives poor expected utility whenever DS or UD occurs. DS and UD make the likelihood a poor predictor of utility. When only TI is present, these decoding algorithms perform well because the likelihood is a strong predictor of utility.

Then, in RQ2 and RQ3, we saw that methods bringing in external information at decoding time manage to effectively solve the likelihood–utility misalignment problem. While finetuning (or re-training) would be an obvious and apparently ideal MMS, this is often neither possible nor necessary. Indeed, our experiments show that if a value model can be crafted and we can afford the extra compute for the value model calls, then VGBS becomes a strong decoding algorithm capable of fixing misalignment problems at inference time. It is more efficient than MCTS and performs better than BS, even if the value model is only a poor approximator of the utility. When crafting a useful value model is difficult (e.g., protein function depends on the 3D structure, which cannot be easily approximated from partial amino-acid sequences), MCTS with a large number of simulations with roll-outs can be

⁴The differences are statistically significant ($p < 10^{-3}$).

used to “estimate” one. However, the price to pay is a higher computational cost at inference time. Finally, for large, generalist LMs, decoding algorithms such as MCTS or VGBS are prohibitively expensive due to the high computational cost of each call to the LM. Prompting methods combined with greedy or top- p decoding can be considered as a way to leverage external information in the form of few-shots prompts to set the model in a state where the likelihood is better aligned with the utility. Our experiments support this explanation of the success of prompting large LMs. For a similar perspective, comparing prompting methods with training-based MMSs see [He et al. \(2021\)](#).

Limitations

Non-exhaustive empirical analysis. This work studies a fundamental problem that involves a complex interaction between tasks, models, and data; and sequence-to-sequence models have been applied to a very broad set of tasks. Covering all possible combinations is impossible, and for our empirical analysis, we chose a subset to evaluate. Our choice is guided by the classification of misalignment sources proposed in Sec. 4.2 and aims to cover different areas of the misalignment space. A seemingly small difference between two choices (e.g., a difference in the loss function used in training the model) can give rise to a considerably different misalignment and, consequently, performance. This is why the goal of the proposed conceptual framework is to make a step toward enabling a more systematic study of decoding. To further help the community investigate the broader space of tasks, models, and datasets through this lens, we open-source the implementation of our analysis.

Alternative ways of fixing misalignment. Apart from value-based decoding, other techniques could be considered to fix the misalignment problem: (a) Retrain or finetune the model with data that better reflects the task’s utility. For instance, to generate non-toxic text, one could retrain or finetune GPT2 on curated datasets that contain toxic prompts and non-toxic sentence continuations. (b) Optimize more directly the utility function instead of surrogate differentiable objectives. This could be done via reinforcement learning (see [Wang et al. \(2018\)](#); [Wu et al. \(2018\)](#) for BLEU).

In this work, we focused on decoding algorithms and ways of fixing the likelihood–utility misalignment problem at inference time. Future research

could further investigate the trade-offs involved in finetuning and retraining. Is it better to invest resources in acquiring new data that fits the task for finetuning? Or is it better to fix DS and UD at inference time with VGBS, MCTS or prompt engineering? Where do the inflection points lie?

A Proposed MMS Taxonomy

This section describes some of the most prominent members in each class of the proposed taxonomy.

A.1 Greedy Likelihood-Based Strategy

Deterministic

Greedy Search (GS). The simplest among the decoding algorithms, at each step t , GS selects the token with the highest likelihood under the model.

Beam Search (BS). An extension of GS, BS, maintains not one, but $k \in \mathbb{N}^+$ partially-decoded sequences, called beams, in parallel. At each step t , BS: (i) pre-selects the most likely k tokens for each beam; (ii) from the resulting $k \times k$ nodes, the algorithm selects the k with the highest likelihood and drops the rest.

Stochastic

An alternative that increases the diversity of output sequences is to sample the tokens at each step from the likelihood distribution $\hat{y}_t \sim p(y_t | \hat{y}_{<t}, x)$. Instead of sampling from the full distribution, these decoding algorithms typically focus greedily on the tokens corresponding to the high-probability regions.

Top- k Sampling. Top- k samples the next tokens from a truncated distribution where only the k most probable tokens are considered (Fan et al., 2018).

Top- p Sampling. Top- p samples the next tokens from a truncated distribution where only the smallest set of tokens with a probability mass bigger than (or equal to) p is considered (Holtzman et al., 2020).

Stochastic Beams (SB). SB samples completed outputs without replacements according to the LM’s likelihood. The implementation relies on applying BS on likelihood scores perturbed with Gumbel noise (Kool et al., 2019).

A.2 Greedy Likelihood-Based Strategy with Pruning

Ad-Hoc Heuristics. Currently, most tasks utilize some ad-hoc heuristics. For instance, in MT, it is often necessary to discourage empty (or short) sequences by enforcing a minimal sequence length (Stahlberg and Byrne, 2019). Similarly, state-of-the-art language generation models often get stuck in repetitive loops. Therefore, an n -gram repetition penalty is now part of the standard toolkit (Klein et al., 2017).

Constrained Beam Search (CBS). The idea of constraining the likelihood during decoding can be extended to include task-specific knowledge. For example, in information extraction tasks, the BS decoding strategy has been constrained to only extract outputs satisfying the predefined schema (Scholak et al., 2021; De Cao et al., 2022; Josifoski et al., 2022). Then, BS only searches high-scoring outputs among the smaller subset of valid ones.

NeuroLogic. The NeuroLogic strategy enforces the satisfaction of given lexical constraints by controlling the decoding stage of sequence generation (Lu et al., 2022). While BS aims to maximize the likelihood of the generated sequence, NeuroLogic searches for optimal output sequences among the strings that also satisfy the given constraints. Hard logic constraints are converted into a soft penalty term in the decoding objective, and beam-based search is used to find approximately optimal solutions.

A.3 Greedy Likelihood- and Value-Based Strategy

Value-Guided Beam Search (VGBS). It is the most intuitive example of a greedy decoding algorithm that leverages a value model (He et al., 2017; Ren et al., 2017). It uses a greedy strategy similar to BS but selects the next token using a linear combination of the LM’s likelihood and the scores from the value model.

More specifically, instead of expanding each beam by the m highest-scored tokens according to the likelihood, the algorithm chooses the top m tokens according to the following scoring function:

$$s_{y_{<i},x}(y_i) = \frac{\alpha}{i} \log(p(y_{<i}y_i|x)) + (1 - \alpha)v(y_{<i}y_i,x),$$

where the factor α weights the contribution of the the value model, $y_{<i}$ denotes the partially decoded sequence, and y_i corresponds to the next token under consideration.

A.4 Simulation-Based Strategy

Monte-Carlo Tree Search (MCTS). MCTS is the canonical example of simulation-based tree exploration informed by value. In our setup, it differs from all other decoding algorithms because, at step i , it may explore sequences of length greater than i . It is not tied to committing to local decisions without exploring the tree. In each step, MCTS

has a fixed computational budget that it uses to explore multiple paths before choosing the next token. For more details, we refer to Chaffin et al. (2022), whose implementation we adapt for this work.

A.5 Prompting-Based Strategy

Few-Shot (FS). At inference time, instead of only passing the input x , a context comprised of k examples $(x_i, y_i)_{i=1}^k$ is added as a prefix. The main idea is that the model will build on its semantic understanding of the relation between x_i and y_i and make the “guided” likelihood better aligned with the utility (Brown et al., 2020).

Chain-of-Thought (CoT). The CoT decoding method (Wei et al., 2022) is a conceptual extension of FS which presents the examples’ targets as a sequence of steps that lead to the solution. This format is particularly helpful for tasks that require multi-step reasoning, with which transformers generally struggle.

B Experimental Setup

This section provides additional details about the experimental setup.

B.1 Details about Data, Models, and Utility Functions

In Table 1, we present a summary of the tasks, utility functions, misalignment types, model, and dataset. We now give a brief description of each task:

Closed Information Extraction (cIE) with the REBEL dataset (Huguet Cabot and Navigli, 2021) and GenIE model (Josifoski et al., 2022) (an instance of BART finetuned to extract the exhaustive set of triples in a sentence following the Wikidata schema). The utility is the F1 score between the generated and the target set of triples.

Machine Translation (MT) with the WMT14 dataset (Bojar et al., 2014) and a pretrained mBART50 model (Tang et al., 2021) to translate *English to French*. The notion of utility is the match between the generated and the target translation, as measured by BLEU-4.

Non-Toxic Text Generation based on the Real Toxicity Prompt (RTP) dataset (Gehman et al., 2020) for prompting a GPT2 model. The notion of utility is whether the generated output contains toxic language or not. The utility function is an ALBERT model (Hanu and Unitary team, 2020)

	LM calls	Value calls
Greedy Search	N	–
Beam Search	$N \times B$	–
Stochastic Beams	$N \times B$	–
VGBS	$N \times B$	$N \times B \times K$
MCTS	$N \times S$	$N \times S$

Table 2: Coarse complexity analysis of the decoding algorithms used, in terms of LM calls and Value calls. N is the number of tokens to be generated, B the number of beams, K the number of next tokens considered by the value model per beam in VGBS, S the number of simulations per generated token in MCTS. In all our experiments, B=5, K=20, S=50.

trained on the Jigsaw dataset with an unintended bias to measure the toxicity of a text.

Non-Soluble Protein Generation: We use the SwissProt-EF dataset (Bairoch and Apweiler, 2000) for prompting a ProtoGPT2 model (Ferruz et al., 2022), which is pretrained on sequences of amino acids from protein prompts. The notion of utility is whether the generated protein is *soluble* or not. To measure non-solubility, we use ProtBERT (Elnaggar et al., 2021), which is a BERT-based model trained on a large corpus of protein sequences in a self-supervised fashion. Finally,

Sports Understanding with the Sports Understanding (SU) task, part of the BIG-bench effort (BIG-bench collaboration, 2021), with a 530B parameter pre-trained language model: MT-NLG (Smith et al., 2022). The primary purpose of this task is to test the general understanding of sports by asking the model to discriminate between plausible and implausible statements relating to sports.

B.2 Hyperparameters of Decoding Algorithms

The number of beams for BS, SB, VGBS is fixed to 5 for all tasks, except for cIE where it is 10 — the model’s default; and the number of simulations in MCTS is fixed to 50. Due to the high computational cost, to decide the optimal value for MCTS’s c_{puct} and VGBS’s α in RQ3, we run a hyperparameter search for each level of noise over a small sample of 80 data points (see Appendix C.3 for the ranges of the search). For both of the prompting-based strategies, we use greedy decoding during inference.

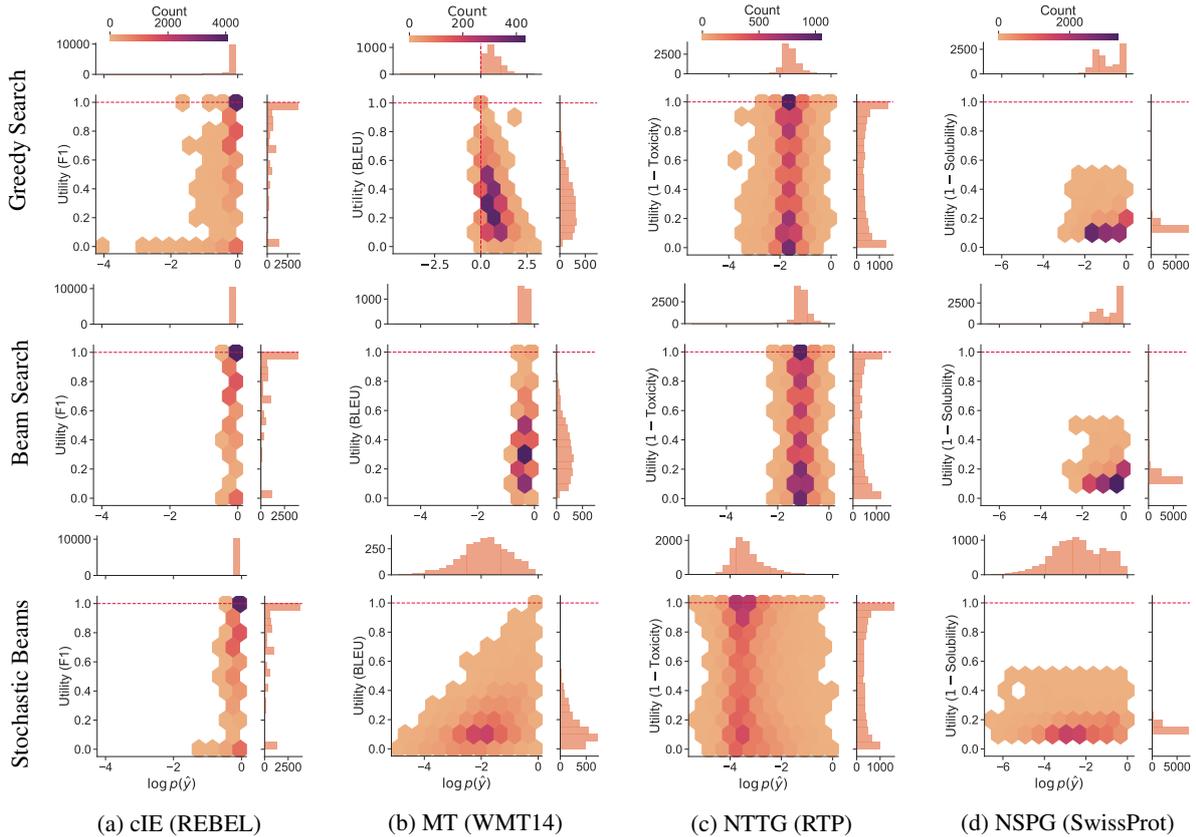

Figure 6: **RQ1 (post-decoding alignment) – without target normalization**: A version of Fig. 2 without the target answer log-likelihood normalization.

ID	Input	Prediction
1	Is the following sentence plausible? Leon Draisaitl grounded out to second base in the National League Championship Series. A:	i'm pretty sure that's not really a grammatical sentence, although one might...
2	Is the following sentence plausible? John Collins threw a touchdown in the NFC divisional round. A:	the nor gates give you (not(a)) and (not(b))
3	Is the following sentence plausible? Jack Eichel dunked the ball. A:	hmm? well, i'm not really sure. let me look it up in

Table 3: Examples of outputs that are not providing an answer. The first and the second row provide an example where the model produces unrelated text, while the third row is an example of an indefinite answer.

B.3 Complexity Analysis of Decoding Algorithms

Most of the compute during decoding is allocated on querying the LM or the value model. Therefore, to show how decoding strategies compare in terms of the computation cost, in Table 2 we provide a coarse complexity analysis in terms of the LM and value model calls.

C Experiments and Results

C.1 RQ1: The Likelihood–Utility Relationship

Fig. 6 is an alternative version Fig. 2 where the x-axis (for cIE and MT) is not normalized using the log-likelihood of the target answers.

C.2 RQ3: Prompting as an MMS

Extracting Labels from Zero-Shot Predictions

The outputs produced with zero-shot prompting do not follow a particular structure that can be used to extract the answer and therefore need to be processed manually. In some cases, it was not possible for an answer to be extracted. The two most common reasons for this were unrelated text as an answer or an indefinite answer. We provide examples of such predictions in Table 3. Overall, 24.9% of the answers could not be parsed. In such cases, we favored putting an indefinite label instead of "yes" or "no", and counting the answer as wrong irrespective of the ground truth label. If the answer and explanation were unrelated, but an answer was given, we did consider the answer.

	Number of Beams	Time (in GPU hours)
cIE + Greedy	1	1.5
cIE + BS	10	10.5
cIE + SB	10	10.5
MT + Greedy	1	0.5
MT + BS	5	1.0
MT + SB	5	1.5
NTTG + Greedy	1	2.0
NTTG + BS	5	3.5
NTTG + SB	5	4.5
NSPG + Greedy	1	3.5
NSPG + BS	5	5.5
NSPG + SB	5	7.0

Table 4: **Parameters for the greedy likelihood-based decoding algorithms.** The default parameters for each model were used, and no hyperparameter search was conducted.

C.3 Computational Infrastructure and Runtime

The evaluation for RQ1 as well as the hyperparameter search for RQ2 were conducted on a single machine with 24 Intel(R) Xeon(R) CPU E5-2690 v4 @ 2.60GHz processor cores and 441 GB of RAM, equipped with 4 NVIDIA V100-PCIE-16GB GPUs. Table 4 provides the details for RQ1.

For VGBS, we performed a small hyperparameter search over different values for $\alpha = 0.01, 0.25, 0.5, 0.75, 0.99$ on 80 datapoints for each noise value of the value model. The same procedure was conducted for MCTS, over $c_{puct} = 0.25, 1.25, 3$. Each of these runs took 20 to 30 minutes of wall time, that is, slightly over 1 to 2 hours of GPU time. Table 5 and Table 6 provide the final parameters for VGBS and MCTS respectively.

The evaluation for RQ2 and RQ3, as well as the hyperparameter search for RQ2, were conducted on a single machine with 96 processor cores and 840 GB of RAM, equipped with 8 NVIDIA A100-SXM4-80GB GPUs. Table 5 and Table 6 provide the details for RQ2.

The evaluation for RQ3 was performed following the Sports Understanding setup in Wei et al. (2022), by taking the same in-context examples. We used greedy decoding for all of the prompting methods. The running time for all prompting experiments (ZS, FS, and CoT) was 6 GPU hours.

	α	Time (in GPU hours)
MT ($\lambda = 0.99$)	0.01	4
MT ($\lambda = 0.5$)	0.01	4
MT ($\lambda = 0.35$)	0.25	4
MT ($\lambda = 0.25$)	0.25	4
MT ($\lambda = 0.15$)	0.25	4
MT ($\lambda = 0.01$)	0.75	4
NTTG (oracle)	0.25	32
NTTG (1200 steps)	0.25	30
NTTG (400 steps)	0.25	30
NTTG (200 steps)	0.25	29

Table 5: **Parameters for VGBS.** For all the experiments, the value models consider the top-10 tokens according to the likelihood. The BLEU to the true target is weighted by λ (i.e., high λ translates to high-quality value model).

	c_{puct}	Time (in GPU hours)
MT ($\lambda = 0.99$)	1.25	41
MT ($\lambda = 0.5$)	0.5	41
MT ($\lambda = 0.35$)	0.5	40.5
MT ($\lambda = 0.25$)	0.25	40
MT ($\lambda = 0.15$)	0.25	40
MT ($\lambda = 0.01$)	1.25	40
NTTG (oracle)	1	125
NTTG (1200 steps)	1	96
NTTG (400 steps)	1	100
NTTG (200 steps)	1	98

Table 6: **Parameters for MCTS.** For all the experiments, at each node, we consider the top-20 tokens according to the likelihood and perform 50 simulations. The BLEU to the true target is weighted by λ (i.e., high λ translates to high-quality value model).

Lightweight Spatial Modeling for Combinatorial Information Extraction From Documents

Abstract

Documents that consist of diverse templates and exhibit complex spatial structures pose a challenge for document entity classification. We propose *KNN-Former*, which incorporates a new kind of spatial bias in attention calculation based on the K-nearest-neighbor (*KNN*) graph of document entities. We limit entities' attention only to their local radius defined by the *KNN* graph. We also use combinatorial matching to address the one-to-one mapping property that exists in many documents, where one field has only one corresponding entity. Moreover, our method is highly parameter-efficient compared to existing approaches in terms of the number of trainable parameters. Despite this, experiments across various datasets show our method outperforms baselines in most entity types. Many real-world documents exhibit combinatorial properties which can be leveraged as inductive biases to improve extraction accuracy, but existing datasets do not cover these documents. To facilitate future research into these types of documents, we release a new ID document dataset that covers diverse templates and languages. We also release enhanced annotations for an existing dataset.¹

1 Introduction

Structured document information extraction (IE) attracts increasing research interest due to the surging demand for automatic document processing, with practical applications in receipt digitization, workflow automation, and identity verification etc.

Recent state-of-the-art methods for processing documents with complex layouts extensively exploit layout information, such as position, relative distance, and angle, with transformer-based models. Spatial modelling is a key contributing factor to the success of these methods (Xu et al. 2020, Appalaraju et al. 2021, Xu et al. 2021, Hwang et al. 2021). However, absolute coordinates, pair-wise

relative Euclidean distance, and angle are insufficient to capture the spatial relationship in complex layouts. Two document entity pairs could carry different importance despite having the same position and distance, due to the presence or absence of other entities positioned between the pairs. We believe that spatial information can be better exploited for document entity classification.

We propose *KNN-Former*, a parameter-efficient transformer-based model that extracts information from structured documents with combinatorial properties. In addition to relative Euclidean distance and angle embeddings as inductive biases (Hwang et al., 2021), we introduce a new form of spatial inductive bias based on the K-Nearest Neighbour (*KNN*) graph which is constructed from the document entities and integrate it directly into the attention mechanism. Specifically, we first construct a *KNN* graph based on the relative Euclidean distance of document entities. Then we incorporate hop distance between entities, which is defined as the shortest path between two entities on the *KNN* graph, in training their pair-wise attention weight. For entity pairs with the same Euclidean distance but different hop distance, the difference in hop distance would still contribute to different attention weights. We limit an entity's attention calculation only to its local radius of neighborhood defined by the *KNN* graph. This also strengthens the inductive bias as reflected by our experiment results.

Furthermore, many real-world document information extraction tasks come with combinatorial properties, such as one-to-one mapping between field categories and values. Such combinatorial properties can be leveraged as inductive biases to improve the extraction accuracy, but are under-explored because existing datasets do not cover such documents. Current methods that do not address the combinatorial constraints suffer suboptimal performance on these types of documents. We further leverage this inductive bias by treating the

¹<https://github.com/miafei/knn-former>

entity classification task as a set prediction problem and using combinatorial matching to post-process model predictions (Kuhn, 1955; Carion et al., 2020; Stewart et al., 2016).

In addition, *KNN-Former* is parameter-efficient. Recent baseline models are initialized with parameters of pre-trained language models (Xu et al., 2020, 2021; Hwang et al., 2021; Hong et al., 2022), making their model size larger or at least comparable to the language models. *KNN-Former* does not utilize initialized parameters of existing language models, therefore free from the parameter size floor restriction. It is designed to be 100x smaller in trainable parameters compared to prevailing baselines. *KNN-Former*'s parameter efficiency makes it energy-efficient, contributes to faster training, fine-tuning and inference speed and makes mobile deployment feasible.

To encourage the progress of IE research in complex structured documents with combinatorial mapping properties, we release an ID document dataset (named POI). While the existing ID document dataset has only 10 templates (Bulatov et al., 2021), POI exhibits better template and lingual diversity. It also has a special mapping constraint where one field category has only one corresponding entity. In compliance with privacy regulations, the documents in the POI dataset are specimens and do not contain information about real persons.

We conduct extensive experiments to evaluate the effectiveness of our proposed method. *KNN-Former* outperforms baselines on most field categories across various datasets, despite having a significantly smaller model size. Extensive ablation studies show the importance of the *KNN*-based inductive bias and combinatorial matching.

To summarize, our contributions include (1) a highly parameter-efficient transformer-based model that (2) incorporates *KNN*-based graph information in sparsified local attention; (3) combinatorial matching to address the one-to-one mapping constraint; (4) a new ID document dataset with good template diversity, complex layout, and a combinatorial mapping constraint.

2 Related Work

Researchers have tried multiple approaches for document information extraction (Jaume et al., 2019; Mathew et al., 2021; Stanisławek et al., 2021). However, these works do not have spatial cues, such as the position of the information in the origi-

nal document. To address this shortcoming, a number of works introduce the modality of layout information as additional input features. Majumder et al. (2020) adopts positional information as inputs to their method to extract information from receipt documents. LayoutLM (Xu et al., 2020) adds 1-D and 2-D absolute position encodings to text embeddings before passing them to the transformer. Hong et al. (2021) proposes to train a language model from unlabeled documents with area masking, encoding relative positions of texts. StructuralLM (Li et al., 2021) assigns the bounding box cell position as the position coordinates for each word contained in it. DocFormer (Appalaraju et al., 2021) encodes 2D spatial coordinates of bounding boxes for visual and language features. LayoutLMv2 (Xu et al., 2021) uses learnable pair-wise relative positional embeddings as attention bias.

A few works propose to use graphs to represent spatial entity relationships in documents. SPADE (Hwang et al., 2021) uses a three steps graph decoder and formulates the information extraction task as a dependency parsing problem. FormNet (Lee et al., 2022) constructs a k-nearest neighbor graph and applies a 12-layer graph convolutional network (GCN) to get the entity embeddings before feeding them into a transformer network. However, there are some limitations in using GCN to obtain embeddings. It is well established that the message passing-based GCN are limited in their expressive power (Xu et al., 2018; Arvind et al., 2020; Morris et al., 2019; Chen et al., 2020; Loukas, 2019; Dehmamy et al., 2019). In addition, FormNet does not use the hop distance between nodes, which could serve as a strong inductive bias to capture the spatial relationships between document entities.

Datasets with positional information such as Funsd (Jaume et al., 2019), Cord (Park et al., 2019), Sroie (Huang et al., 2019) are released to facilitate research in document understanding. However, they do not contain documents with combinatorial properties which are common in real-world applications. MIDV500 (Arlazarov et al., 2018) and MIDV2020 (Bulatov et al., 2021) are two synthetic ID datasets with combinatorial properties, but are unsuitable for document information extraction tasks due to incomplete annotations. They also lack template diversity.

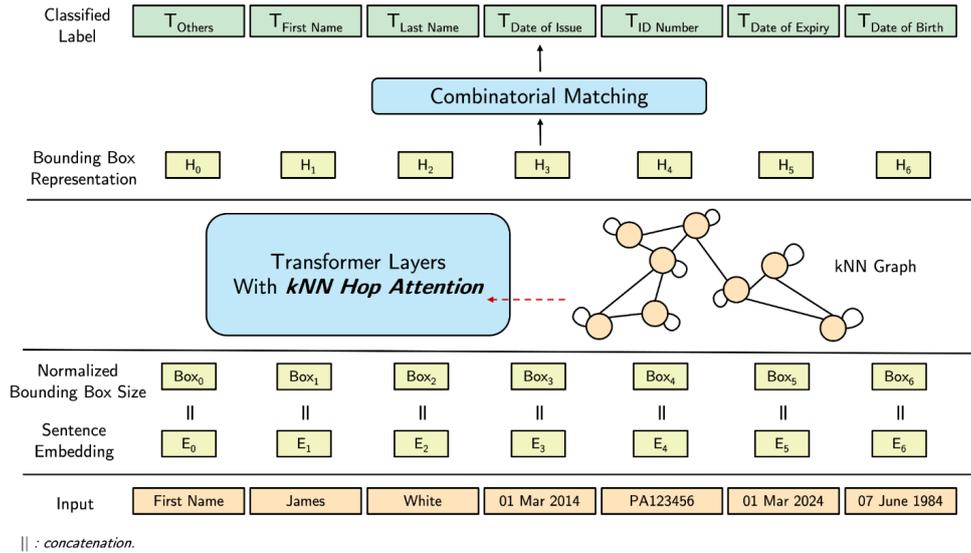

Figure 1: An illustration of *KNN-Former*. Bounding box texts are embedded using sentence transformer, which are concatenated with embeddings of bounding box size to form input embeddings. The concatenated embeddings are then passed to the transformer layers with *kNN Hop Attention*, which incorporates pair-wise relative hop distance between entities on *kNN* graph in attention calculation. The output entity representations of the transformer layers are passed to combinatorial matching for set prediction.

3 Methodology

In this section, we discuss the methodology for our model. We formulate the problem in Sec.3.1 and explain our overall model architecture and the details of each component in Sec.3.2.

3.1 Problem Formulation

Given a document D which consists of multiple entities $\{e_i, \dots, e_j\}$, and the bounding box coordinates and texts $\{x_i, \dots, x_j\}$ detected by Optical Character Recognition (OCR) tool. We measure the relative distance and angle between two entities e_i and e_j as $\sigma_{(i,j)}$ based on the coordinates of bounding boxes. Our task is to map each entity e_i in document D to its field category y_i , which is one of the predefined labels. For each field category y_i , there is only one corresponding entity e_i .

3.2 Model Architecture

We propose *KNN-Former*, a transformer-based model for document entity classification. The architecture of *KNN-Former* is shown in Fig. 1. *KNN-Former* uses K-Nearest Neighbours Hop Attention, which incorporates a new inductive bias into attention computation. *KNN-Former* also treats document entity classification as a set prediction problem and uses combinatorial assignment to address the one-to-one correspondence between entities and fields. *KNN-Former* is highly parameter-

efficient compared to baselines. Details of model size can be found in Tab 4.

3.2.1 K-Nearest Neighbors Hop Attention

One key contribution of *KNN-Former* is the proposed attention mechanism. Following (Lee et al., 2022), we first construct a *kNN* graph based on the Euclidean distance between each pair of entities. We represent entities as nodes and then connect edges between each entity and its K nearest neighboring entities. We also add a self-loop to each entity to improve performance (Kipf and Welling, 2016). While previous works focus on leveraging pair-wise relative Euclidean distance (Xu et al., 2021; Hwang et al., 2021), we propose to incorporate pair-wise relative **hop distance**, which is defined as the shortest path between two entities on the *kNN* graph. Two entities could be in proximity in terms of Euclidean distance but not so in terms of hop distance. For example, in documents with complex layouts, it is common to have two entities that are close to each other in the Euclidean space, but there is a third entity positioned in between. This type of entity pair should be treated differently from pairs that are close to each other in both Euclidean and hop distances. In this case, the spatial attention mechanism based solely on the relative Euclidean distances between entity pairs is insufficient since it neglects this structural information. We argue that the *kNN* graph structure is an

effective way of capturing the structural information and propose to incorporate it as an inductive bias into the attention computation.

Intuitively, different hop distances should carry different weights in calculating pairwise attention. We use $\phi_{(i,j)}$ to represent the hop distance between entity i and j and H to represent a learnable embedding lookup table based on the hop distance $\phi_{(i,j)}$. Inspired by DeBERTa (He et al., 2020) and Transformer-XL (Dai et al., 2019), we integrate the hop distance bias into attention as described in the following equations

$$e_{ij} = [x_i W^Q (x_j W^K + H_{\phi_{(i,j)}}^Q + R_{\sigma_{(i,j)}}^Q) + (H_{\phi_{(i,j)}}^K + R_{\sigma_{(i,j)}}^K) x_i W^K] / \sqrt{d}, \quad (1)$$

$$z_i = \sum_j a_{ij} (x_j W^V + H_{\phi_{(i,j)}}^V + R_{\sigma_{(i,j)}}^V), \quad (2)$$

where $\sigma_{(i,j)}$ is a concatenation of the relative Euclidean distance and angle between entity i and j , and R is a learnable matrix. H could be a learnable matrix or a lookup table that maps $\sigma_{(i,j)}$ to learnable embeddings. e_{ij} is the attention weight between entity i and j . a_{ij} is calculated as the weight of $\exp(e_{ij})$ in the exponential sum of all e_{ik} , as described in Eqn.3.

$$a_{ij} = \frac{\exp(e_{ij})}{\sum_k \exp(e_{ik})}. \quad (3)$$

Similar to how pair-wise relative Euclidean distance is added to attention, we add pair-wise hop distance as three learnable weight matrices, two of which multiply with query and key vectors respectively while the remaining one is added to the value vector. We further limit an entity’s attention only to its local radius of neighborhood defined by the KNN graph. Specifically, we do not calculate e_{ij} if the hop distance between entity i and j exceeds a certain threshold. This also strengthens the inductive bias as supported by our experiment results.

3.2.2 Combinatorial Matching

We hypothesize that combinatorial properties between field categories and entities can be leveraged as inductive biases to improve extraction performance. Different from existing methods that treat the classification of each entity independently (Xu et al., 2021; Hwang et al., 2021; Lee et al., 2022),

we propose to treat the entity classification task as a set prediction problem to exploit the one-to-one mapping constraint, where one field has one and only one corresponding entity. The combinatorial assignment is described in Eqn.4.

$$\tau_{opt} = \underset{\tau}{\operatorname{argmin}} \sum_i^N L_{match}(y_i^{label}, y_{\tau(i)}^{pred}), \quad (4)$$

where τ is an assignment, and L_{match} is the matching cost. N is the number of entities in a document. In practice, N is often much larger than the number of entities of interest. Therefore, we pad the number of ground truths to N in order to perform a one-to-one combinatorial assignment. This can be done with the Hungarian algorithm in polynomial time (Kuhn, 1955; Carion et al., 2020; Stewart et al., 2016).

4 Datasets

Many real-world documents exhibit combinatorial properties, such as a one-to-one mapping between its fields and entities. However, existing public datasets do not cover documents with such properties (Jaume et al., 2019; Park et al., 2019; Huang et al., 2019). To fill the gap, we release a new ID document dataset POI, and enhanced annotations of MIDV2020. We also verify our method on a private dataset PRV. All 3 datasets exhibit combinatorial properties.

In addition, we design the POI dataset to be template-rich with diverse languages. We also design the enhanced MIDV2020 with a difficult split such that templates in testing are unseen during training. BERT alone without spatial information can achieve above 90% F1 on some existing datasets (Hong et al., 2022; Park et al., 2019; Huang et al., 2019), indicating relative sufficiency of leveraging text information alone. Yet in many real-world use cases, using text alone is insufficient. This motivates us to work on more challenging datasets where the exploitation of spatial information is important. Dataset statistics are summarized in 1 and Tab. 2. More details are as follows.

	#Train Doc.	#Test Doc.
POI	421	109
MIDV2020	500	200
PRV	3480	807

Table 1: Number of documents in training and testing.

Dataset	Avg # of Ent. per Doc.	Total # of Ent.	Total # of Doc.
POI	31.79	16850	530
MIDV2020	32.85	23000	700
PRV	24.31	104245	4287

Table 2: Statistics of entity distribution in documents. Ent. stands for entities and Doc. stands for documents.

POI We collect and annotate 530 Proof-of-Identity documents from online sources. We will release this POI dataset which consists of 10 document types, 265 distinct templates, and 131 countries of origin. The template and language diversity of POI create a challenging task for document understanding. All images are specimens with dummy values. The document type distribution is shown in Tab.3.

There are 8 field categories in total: last name, first name, date of birth, date of issue, date of expiry, ID number, key, and others. Key represents entities that indicate the field names for the important entities (e.g. Last Name) that we are interested to extract. The first 6 field categories appear in each document image once and only once, creating a special mapping constraint unseen in other datasets. The last 2 field categories (key and others) are not subject to the constraint. In real-world applications, it is common to extract a set of entities from documents that have combinatorial properties between its field and entities. ID document information extraction is one such use case, where we only expect to extract one entity for each field category of interest. This one-to-one correspondence can be leveraged to improve classification performance. Despite being a common task setting, we notice the lack of method exploration and innovation in this direction, due to the unavailability of such property among existing popular document datasets. More details about the dataset can be found in the Appendix.

Document Type	# Document
Passport	238
Driving License	119
Travel Document	109
ID	30
Resident Permit	21
Seafarer ID	10
Others	3

Table 3: Distribution of document types in POI dataset

MIDV2020 We utilize the 1000 synthesized ID documents from the initial MIDV2020 dataset (Bulatov et al., 2021). These documents are generated from 10 templates, with 100 documents for each template. Each document image is annotated with a list of bounding box coordinates and field values. We find that only artificially generated entities, such as the values of names and ID numbers, are annotated, while entities that belong to the original templates, such as document title and field names are not. We proceed to annotate the remaining entities. The newly annotated ground truths of MIDV2020 will be released alongside POI. These enhanced annotations enable us to perform information extraction task in a setting that is closer to real-world application, where all texts recognized by the OCR engine are used. The train/test split we introduce for MIDV2020 is a split by countries, this ensures that the document templates in the training dataset are unseen in the testing dataset. The country split simulates real-world scenarios where the model extension to new countries or new versions of documents is needed. More details can be found in the Appendix.

PRV Since POI and MIDV2020 only contain specimens or artificially generated images, we run our model on a private dataset (named PRV) that mostly consists of US driver licenses. The documents are protected by strict privacy requirements and massive human annotations are not available as raw images are inaccessible. Therefore, we build automatic fuzzy labeling to annotate the ground truth.

Comparison on Datasets POI exhibits better template and language diversity. POI contains 265 templates from 131 countries, while MIDV2020 has 10 templates from 10 countries. The number of templates in PRV is unknown due to privacy-related limitations. In addition, POI consists of templates in a multitude of languages, whereas MIDV2020 and PRV dataset lack such diversity. Texts in POI and MIDV2020 are made up largely by artificial text which is more readable and clearer, while PRV contains real texts. POI and PRV samples are split randomly. Since MIDV2020 has only 10 templates, we split the samples by country to make the task more challenging. PRV is the easiest dataset among the three due to its lingual monotony and random split.

Dataset	Method	F1 Score						Input Modality	#Parameters	
		L.Name	F.Name	DoB	DoI	DoE	ID No.		Trainable	Total

Table 4: Entity-level F1 score of *KNN-Former* compared to baselines. Column L.Name, F.Name, DoB, DoI, DoE and ID No. correspond to results of Last Name, First Name, Date of Birth, Date of Issue, Date of Expiry, and ID Numbers. GCN and *KNN-Former* have additional 22.7 M fixed parameters since we employed a light-weighted 6-layer sentence transformer (Reimers and Gurevych, 2019) to get the text embeddings.

5 Experiments

In this section, we conduct extensive experiments to evaluate our proposed *KNN-Former* on aforementioned datasets. We first compare our results with several baselines in Sec. 5.1. Then in Sec. 5.2, we evaluate the generalization ability of our method on unseen templates. We then conduct ablation studies in Sec.5.3 and Sec.5.4 to assess the effects of each component in *KNN-Former* and the impact of different K in the *KNN* graph.

5.1 Comparison with Baselines on Multiple Datasets

We first evaluate the performance of *KNN-Former* against multiple competitive methods. We choose base models for most of the baselines, because these are closest to *KNN-Former* in terms of the number of parameters. Brief description of baseline models as well as the implementation details of all the models can be found in Sec. A.1. We do not have results for StructuralLM on POI dataset because of an OOV error.

Tab.4 shows the entity-level classification performance. The results show that our method outperforms the baselines on most entity types across

various datasets. In particular, *KNN-Former* outperforms LayoutLMv2_{BASE}, a state-of-the-art model that uses additional image features. We also observe that BERT performs poorly on these datasets, indicating the importance of exploiting spatial information.

Secondly, as shown in Trainable Param column in Tab.4, *KNN-Former* is highly parameter-efficient. All baselines except GCN have more than 100 million trainable parameters, while *KNN-Former* has only 0.5 million and is magnitudes smaller than competing methods. Even after adding the sentence transformer, *KNN-Former* has only 23.2 million parameters, still 5x smaller than baselines. The parameter efficiency has 4 benefits. First, it contributes to learning and inference time efficiency, with details illustrated in 5.5. Second, it allows for faster fine-tuning on new datasets and domains, especially in real-world use cases when training datasets are big and re-training requirements are frequent. Third, smaller model size and faster inference time make mobile deployment more feasible. Fourth, training, fine-tuning and inferring smaller models reduces power consumption and carbon footprint. Despite the smaller model size, *KNN-*

Former achieves comparable or better performance across datasets.

Thirdly, we observe that *KNN-Former* underperforms both $\text{LayoutLM}_{\text{BASE}}$ and $\text{LayoutLMv2}_{\text{BASE}}$ for name related entities in both POI and PRV datasets. The robustness of the two baselines in predicting names could be attributed to their extensive pre-training. The two baselines learn common names in pre-training, enabling them to predict names correctly regardless of context. However, despite no extensive pre-training, *KNN-Former* still outperforms BROS and StructuralLM which are also pre-trained on 11 million documents.

Fourthly, we observe all methods suffer performance degradation on MIDV2020, compared to the other two datasets. This is because in MIDV2020, training and testing documents are split by countries, templates in testing are not seen during training. In addition, MIDV2020 has only 6 templates in training data, which easily leads to overfitting. Detailed discussion on the generalization ability can be found in Sec. 5.2. we find that BERT outperforms several baselines with spatial modelling on names, this may be due to overfitting to limited number of training templates. We notice that our method do not perform well on id number entity. We conducted manual inspection on several error cases, and find that in many documents there exist two different types of id numbers(see Fig. 3(b)), but only one of them is labeled as id number according to the provided annotations. Our model sometimes predicts the other one as id number. This also explains the poor performance on id number for some other baselines.

Lastly, we notice that on the PRV dataset, *KNN-Former* performs poorly on DoB field, underperforming even GCN. *KNN-Former*'s performance on DoB drops after combinatorial matching, despite an overall increase macro average F1. This could be due to the presence of noise in groundtruth, since this dataset is annotated by automatic fuzzy labeling logic. Manual examination of a few documents confirms our hypothesis.

5.2 Evaluation of generalization ability on unseen templates

To assess the generalization capability of our model, we test and compare our model with other competitive baselines on MIDV2020 dataset using two train/test settings: random split and split by country. The country split is a more difficult set-

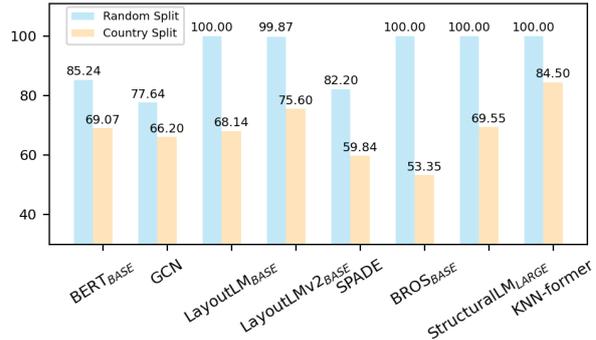

Figure 2: Macro average F1 scores of *KNN-Former* and various baseline models under random split and country split on MIDV2020 dataset.

ting as the templates in testing are unseen during training. Intuitively, we would expect a decline in performance as compared to the random split setting. Fig. 2 shows the Macro average F1 scores comparison of *KNN-Former* and multiple baselines under both the random split and the country split. We observe across-the-board performance degradation for all methods after switching from random split to country split. However, the drop is least significant on *KNN-Former*, enabling it to achieve 10% higher F1 than the best baseline. These experiments indicate that our method is more robust and generalizes better to unseen templates as compared to existing baseline models. This is helpful in real-world applications where models frequently encounter new types of documents.

5.3 Effects of each component in *KNN-Former*

Model	F1
<i>KNN-Former</i>	90.76
(-) <i>KNN</i> hop attention	88.33 (-2.43)
(-) Local attention based on <i>KNN</i> hop & (-) <i>KNN</i> hop attention	85.67 (-5.09)
(-) Relative Euclidean distance & angle attention	87.17 (-3.59)
(-) Relative Euclidean distance & angle attention & (-) <i>KNN</i> hop attention	86.67 (-4.09)
(-) Combinatorial Matching	88.16 (-2.60)
(+) Absolute positional encoding	86.33 (-4.43)

Table 5: Ablation results on POI dataset. (-) indicates the component is absent compared to *KNN-Former*, (+) indicates the component is additional.

To better understand how *KNN-Former* works, we ablatively study the effects of each component and report the results in Tab. 5. Entity-level detailed results can be found in the Appendix.

Firstly, we observe a 2.43% drop in performance with the removal of *KNN* hop attention and an even bigger 5.09% drop when local attention is removed

together with *KNN* hop attention. This demonstrates that the *KNN* graph-based inductive bias is effective in capturing the structural information between document entities. It also shows that local attention, the practice of masking out attention weights when the hop distance between two entities exceeds a pre-defined threshold, further strengthens the inductive bias.

Secondly, we observe that the commonly used spatial inductive bias based on the pairwise relative Euclidean distance and angle also plays an important role. When both relative Euclidean distance attention and *KNN* hop attention are absent, there is a 4.09% drop in performance, an additional decrease of 1.66% compared to when only *KNN* hop attention is ablated(2.43%). The overlap of performance drop suggests some information are captured by both Euclidean distance and hop distance, as some pairs are similarly close/far from each other as measured in both distances. However, each distance also complements the other by capturing additional information. For example, two pairs could carry different importance despite having the same Euclidean distance, due to the presence or absence of other entities positioned between the pairs, signifying the importance of hop distance.

Thirdly, we notice that the F1 score drops drastically by 4.76% when combinatorial matching is ablated. This demonstrates the important contribution of combinatorial matching, as the datasets we experiment on are all subject to a special one-to-one mapping constraint between fields and entities. Combinatorial matching enables our method to treat entity classification as a set prediction problem, instead of predicting each entity’s class independently, which enhances our model robustness.

Lastly, we observe that there is a 4.43% drop in performance when absolute positional encoding is added. Previous works (Hwang et al., 2021) have similar findings that adding absolute positional encoding is not helpful, especially when the test set contains a diverse set of unseen templates. In our experiments, adding absolute positional encoding improves performance in training but generalizes poorly in testing.

5.4 Impact of different *K* in the *KNN* graph

To further study the effect of how the hyper-parameter of the *KNN* graph affects the performance, we conduct experiments with different values of *K* on the POI dataset. As shown in Tab. 6, the

#K	(+) H (-) R	(-) H (+) R	(+) H (+) R
2	90.67	89.33	89.50
5	88.74	90.23	89.51

Table 6: Impact of number of *K* in *KNN-Former* on POI dataset. (+) indicates presence, (-) indicates absence. H refers to the *KNN* hop attention. R refers to relative Euclidean distance and angle attention.

2-NN graph achieves the best performance when *KNN*-based hop distance is used and relative Euclidean distance is removed. This is because when only 2 nearest entities are counted as an entity’s first-hop neighbors, the correlation between hop distance and entity pair’s importance is pronounced. However, a 5-NN graph achieves the best performance when *KNN*-based hop distance is ablated and only relative Euclidean distance is used. This is because the information of who is an entity’s 5 nearest neighbors is less useful in documents with an average of 31.79 annotated bounding boxes per file. Models with 2-NN and 5-NN graphs underperform the 4-NN graph in the POI dataset, underscoring the importance of choosing the correct *KNN* graph hyper-parameter for different datasets.

5.5 Runtime Comparison

In addition to performance evaluation, we also evaluate the runtime of our model against competitive baselines. For fair comparison, we report the total runtime of sentence transformer plus *KNN-Former*, since *KNN-Former* uses sentence transformer for text embeddings. In fact, the sentence transformer takes up half of the time in our pipeline.

Model	Single	Batch
LayoutLM _{BASE}	19.61	237.90
LayoutLMv2 _{BASE}	56.64	2941.32
SPADE	39.47	6091.52
BROS _{BASE}	23.45	646.65
<i>KNN-Former</i>	22.60	77.57

Table 7: Runtime comparison with baselines. Time taken is reported in milliseconds.

We first measure the runtime to process a single document for each method. As shown in Tab. 7, time taken for sentence encoder plus *KNN-former* is comparable to LayoutLM and BROS, and is faster than SPADE, LayoutLMv2. We run StructuralLM(written in tensorflow1.14) on CPU due to cuda version mismatch, hence there is no speed measurement.

Moreover, our method allows for significantly larger batch sizes because of the smaller model size. Therefore, runtime for documents in batch is significantly faster than the baselines. Running with maximum possible batch size for each model using a 16GB V100 GPU, *KNN-Former* is significantly faster than the rest, as shown in Tab. 7. This experiment demonstrates that our model is advantageous when faster execution time is desirable, and this could be attributed to the lightweight property of our model.

6 Conclusion

We propose *KNN-Former*, a parameter-efficient transformer-based model for document entity classification. *KNN-Former* uses *KNN* Hop Attention, a new attention mechanism that leverages *KNN* graph-based inductive bias to capture structural information between document entities. *KNN-Former* utilizes combinatorial matching to perform set prediction. We also release POI, a template-rich ID document dataset subject to combinatorial constraints. Experiments show that *KNN-Former* outperforms baselines in entity classification across various datasets.

Limitations

We identify the following limitations in this work. First, the robust performance of baseline methods that leverage image features (Appalaraju et al., 2021) testifies to the importance of visual cues. The inclusion of image features to *KNN-Former* might contribute to better performance. Second, unlike models that perform extensive pre-training (Xu et al., 2020, 2021), *KNN-Former* might lack generic domain knowledge. Third, *KNN-Former* uses a vanilla sentence transformer to get the text embedding inputs. The sentence transformer model is pre-trained and not fine-tuned on the new datasets. An end-to-end training pipeline that jointly trains the text encoding model and *KNN-Former* could lead to better results. Fourth, there are many design choices we did not explore, such as applying attention directly at the token level and pooling representations at the end. Lastly, *KNN-Former*, along with all baselines used in this work, are subject to OCR failure. All models consume OCR outputs such as bounding box coordinates and texts. In the case of OCR failure, where one bounding box is detected as two or two boxes are merged as one, models that consume OCR results are less likely to

make correct predictions.

Ethics Statement

This work has obtained clearance from author’s institutional review board. The annotators for POI and MIDV2020 are all paid full-time interns and researchers hired by our institute, whose compensation are determined based on the the salary guidelines of our institute. Among the datasets and annotations released, POI only contains specimens with dummy values, while MIDV is a synthetic dataset. External data are accessed and used in compliance with fair use clauses. We conduct experiments on the private dataset PRV in a secure data zone with strict access control, using auto-labeling scripts for annotations.

A Appendix

A.1 Implementation details

We briefly describe the baseline models as well as detailed implementation details of all models in this section.

- **BERT_{BASE}** (Devlin et al., 2019): We use the pre-trained BERT base model for token classification.
- **GCN** (Kipf and Welling, 2016): We use sentence transformer (Reimers and Gurevych, 2019) to get the embeddings of text inputs and use them as the node features for the constructed *KNN* graph. Then we train a 2-layer graph convolutional network to classify the nodes/entities.

- **LayoutLM_{BASE}** (Xu et al., 2020): LayoutLM is a transformer-based model for document image understanding. It is pre-trained on IIT-CDIP Test Collection with 11 million scanned images.

- **LayoutLMv2_{BASE}** (Xu et al., 2021): In addition to LayoutLM, the LayoutLMv2 adds a new multi-modal task during pre-training to take in the visual cues and incorporates a novel spatial-aware self-attention mechanism.

- **StructuralLM_{LARGE}** (Li et al., 2021): On top of LayoutLM, Structural LM uses cell position for each word, and introduces a new pre-training task that predicts the cell position. It is also pre-trained on the IIT-CDIP dataset.

- **SPADE** (Hwang et al., 2021): SPADE builds a directed graph of document entities and extracts and parses the spatial dependency using both linguistic and spatial information.

- **BROS** (Hong et al., 2022): Similar to LayoutLM, BROS is also pre-trained on the IIT-CDIP dataset, but with a different area masking pre-training task, and a different method to encode the 2D positions of bounding boxes.

- **DocFormer** (Appalaraju et al., 2021): DocFormer is a multi-modal transformer that takes in both text and visual cues. It proposes a multi-modal attention mechanism and is pre-trained with several tasks involving both text and image input.

All models are trained on 16G V100 GPUs and implemented with Pytorch, except for StructuralLM_{LARGE}, for which we use their official repository ² that is implemented in Tensorflow1.14 and we train it on cpu because of cuda version mismatch. We use APIs open-sourced by Huggingface ³ for Bert, LayoutLM_{BASE} and LayoutLMv2_{BASE}. SPADE is implemented using the official implementation released by ClovaAI⁴. BROS is implemented using their released official repository ⁵. Only text inputs are passed to BERT_{BASE} for classification while bounding box coordinates are neglected. Results are obtained after training for 100 epochs. We trained the SPADE

²<https://github.com/alibaba/AliceMind/StructuralLM>

³<https://huggingface.co>

⁴<https://github.com/clovaai/spade>

⁵<https://github.com/clovaai/bros>

model for 10 to 20 hours up to 1000 epochs depending on the datasets. All settings of $\text{LayoutLM}_{\text{BASE}}$ and $\text{LayoutLMv2}_{\text{BASE}}$ are from the authors. For BROS, we use the same tokenizer as LayoutLM , same learning rate in their paper and fine-tuned BROS on each dataset for at least 100 epochs, and made sure it converged. We report results for epoch 80. For $\text{StructuralLM}_{\text{LARGE}}$, we were only partially successful to reproduce it due to OOV error when running on POI dataset. In addition, this is the only baseline that we use the large version because there was an error with the base version. We train the model with 25 epochs with all other hyperparameters following their paper. We reproduced DocFormer from an unofficial repository⁶ since there is no official repository available. There is no released pretraining weights for DocFormer, but DocFormer uses plain ResNet50 (He et al., 2016) as the first step for image feature extraction, and the language embedding weights are initialized with $\text{LayoutLMv1}_{\text{BASE}}$ pre-trained weights. We trained DocFormer for at least 100 epochs and used hyperparameters for fine-tuning setting mentioned in the paper. We report results for epoch 100.

For *KNN-Former*, we use 8 layers, 8 heads, and 80 hidden dimensions for the architecture. Results are obtained after training for 400 epochs. We use a 6-layer sentence transformer to extract text features in for both *KNN-Former* and GCN baseline model implementation. We use Adam optimizer with learning rate of $5e-3$. We perform a grid search in choosing hyper-parameters, with learning rate in [$5e-3$, $1e-3$, $5e-4$], the number of layers in [4, 8], local attention threshold in [1,2,3], and the number of attention heads in [4,8]. To incorporate relative Euclidean distance and angle, we tried both real and quantized angles in our initial exploration and did not find a significant difference. We use real angle values throughout the experiments. In the implementation of combinatorial matching, we choose class probabilities as matching cost following (Carion et al., 2020). Despite no theoretical justification, they observe better performance than log probabilities. We conduct experiments comparing class and log probabilities but do not observe significant differences in POI dataset ($<0.005\%$). Reported results are the average performance of 3 runs. The sentence transformer we used is paraphrase-MiniLM-L6-v2 from hugging face.

A.2 Experimental Results on MIDV2020 random split

Tab 8 shows the additional experimental results on MIDV2020 random split. Column L.Name, F.Name, DoB, DoI, DoE and ID No. correspond to results of Last Name, First Name, Date of Birth, Date of Issue, Date of Expiry, and ID Numbers. GCN and *KNN-Former* have additional 22.7 M fixed parameters since we employed a light-weighted 6-layer sentence transformer (Reimers and Gurevych, 2019) to get the text embeddings. MIDV dataset has 10 templates, and each template has 100 images. As a result, this random split is an easy setting where performance results are generally good. $\text{BERT}_{\text{BASE}}$ still produces relatively poor performance, which reiterates the point that spatial information is important.

A.3 Experimental Results on DocFormer

Tab 9 shows the experimental results of DocFormer on various datasets. On POI, PRV dataset and MIDV2020 dataset random split, DocFormer performs reasonably well. On POI dataset, it only falls behind $\text{LayoutLMv2}_{\text{BASE}}$ and *KNN-Former*; on PRV dataset, it outperforms $\text{BERT}_{\text{BASE}}$, GCN and SPADE; on MIDV2020 dataset random split, it achieves 100% F1 score for every field like *KNN-Former*, $\text{StructuralLM}_{\text{LARGE}}$, $\text{LayoutLM}_{\text{BASE}}$ and $\text{BROS}_{\text{BASE}}$. However, on MIDV2020 dataset country split, we cannot get reasonable performance for DocFormer although we made sure our training was converged.

We also measured the runtime of DocFormer, results shown in Tab. 10.

A.4 POI Dataset Details

All images are publicly available specimen ID documents and do not contain information about real persons. Despite that, due to the sensitivity of the subject and increasing societal concerns about the role artificial intelligence should play in protecting people’s privacy, we will only release the annotated JSON file instead of the actual images to comply with fair use of specimens.

We store a list of objects in the annotated file; each object contains annotations for an image. The annotations include bounding box coordinates, text, and category.

The released dataset is subject to fair use clause and should only be used for academic purposes.

We implement quality control during the annota-

tion process by having annotators cross-check each other’s results to affirm the correctness of labels.

A.5 Sample documents of POI and MIDV2020

In Fig. 3, we show samples documents with bounding boxes and annotations.

A.6 PRV Dataset Details

Since POI and MIDV2020 only contain specimens or artificially generated images, we run our model on a private (PRV) dataset that consists of actual ID documents. The documents are protected by strict privacy requirements and massive human annotations are not available as raw images are inaccessible. Therefore, we build automatic labeling to annotate the ground truth. Specifically, we map personal information in the existing database to OCR-ed text outputs. The matched bounding box is classified as the corresponding entity if a match is found. All bounding boxes that are not matched are classified as ‘others’.

On the Generalization Ability of Retrieval-Enhanced Transformers

Tobias Norlund^{1,4*} Ehsan Doostmohammadi² Richard Johansson^{1,3} Marco Kuhlmann²

¹ Chalmers University of Technology ² Linköping University

³ University of Gothenburg ⁴ Recorded Future

Abstract

Recent work on the Retrieval-Enhanced Transformer (RETRO) model has shown that off-loading memory from trainable weights to a retrieval database can significantly improve language modeling and match the performance of non-retrieval models that are an order of magnitude larger in size. It has been suggested that at least some of this performance gain is due to non-trivial generalization based on both model weights and retrieval. In this paper, we try to better understand the relative contributions of these two components. We find that the performance gains from retrieval largely originate from overlapping tokens between the database and the test data, suggesting less non-trivial generalization than previously assumed. More generally, our results point to the challenges of evaluating the generalization of retrieval-augmented language models such as RETRO, as even limited token overlap may significantly decrease test-time loss. We release our code and model at <https://github.com/TobiasNorlund/retro>

1 Introduction

Large-scale generative language models have shown promising results toward creating a general-purpose foundation for many natural language applications. While sheer scale-up has resulted in better language modeling performance, the immense costs are an inhibiting factor towards further improvements (Sharir et al., 2020).

Recent work on retrieval-augmented language models, such as the Retrieval-Enhanced Transformer (RETRO; Borgeaud et al., 2022), suggests that *memory* can be effectively off-loaded from the model parameters to an external database. In RETRO, the information retrieved from the database is used to augment the context from which the model predicts new tokens, reducing the need to memorize this information in the model parameters. This opens up for smaller language models with retained performance. Specifically, Borgeaud et al. (2022) report that, with a large enough retrieval

database, RETRO can achieve a performance comparable to GPT-3 (Brown et al., 2020) and Jurassic-1 (Lieber et al., 2021) on the Pile (Gao et al., 2020), at only 4% of the parameters. Similarly, RETRO achieves significantly lower bits-per-byte performance compared to a baseline of the same size without retrieval.

Borgeaud et al. (2022) conclude that RETRO has the capacity for non-trivial generalization based on both the model parameters and the retrieval database, even though they find that part of the performance gains can be attributed to lexical overlap between retrieval and test data. In this work, we want to better understand the nature and magnitude of this effect. Our findings indicate that performance gains¹ originate *almost exclusively* from RETRO’s ability to copy tokens verbatim from retrieved data, effectively exploiting any (small or large) overlap between training and test data. This suggests that the ability of RETRO to fuse retrieved and in-parameter information may be more limited than previously assumed.

2 Method

To investigate gains from retrieval, we re-implement the RETRO model described by Borgeaud et al. (2022) (with a few deviations; see below). We present the model here in brevity.

2.1 The RETRO Model

RETRO is an autoregressive language model trained with the next-token prediction objective, where the prediction probability is conditioned on additional context retrieved from a database.

Retrieval Retrieval occurs at the granularity of contiguous token chunks with a fixed size m . More specifically, assume that RETRO has already generated a sequence of tokens $x_{1:t}$. Each token x_i

¹Results on RETRO were originally reported in bits-per-byte, while we report results in loss.

*Corresponding author, tobiasno@chalmers.se

belongs to a chunk $C_{c(i)}$, where $c(i) = \lceil i/m \rceil$. The probability of the next token x_{t+1} depends on the previously generated tokens and the context retrieved from the previously seen chunks:

$$P(x_{t+1} | x_{1:t}, \text{RET}(C_1), \dots, \text{RET}(C_{c(t+1)-1}); \theta)$$

Database RETRO’s database takes the form of a key–value storage $R(N) \mapsto [N, F]$, where N is a chunk from one of the indexed documents, F is the immediately following chunk, and the key $R(N) \in \mathbb{R}^d$ is the embedding of N according to some embedding model R . This database is used to retrieve the k nearest neighbors of a chunk C , based on the embedding $R(C)$:

$$\text{RET}(C) = ([N^1, F^1], \dots, [N^k, F^k])$$

Architecture RETRO is based on the original Transformer architecture (Vaswani et al., 2017). Chunk neighbors are encoded by the encoder and attended to by the decoder. Due to the quadratic complexity in self-attention, each neighbor is encoded separately; all representations are then concatenated and made available to the decoder (Izacard and Grave, 2021). The original decoder is modified such that for the prediction of token x_{t+1} , cross-attention (CA) can only attend to the neighbor representations retrieved based on the previous chunk $C_{c(t+1)-1}$. This is called *chunked cross-attention* (CCA). Furthermore, the encoder is modified to include a restricted form of cross-attention to the decoder. Specifically, the encoder CA attends to the decoder hidden states immediately before the first CCA. We refer to Borgeaud et al. (2022) for more details.

Implementation Details For tokenizing documents, we use the pre-trained T5 tokenizer. The retrieval was performed using approximate nearest neighbor search with the high-performant faiss library (Johnson et al., 2019). We implement RETRO in PyTorch (Paszke et al., 2019) and use PyTorch Lightning for distributing the training and validation data across GPUs and compute nodes. Our implementation deviates from that of Borgeaud et al. (2022) only in that we

- use learnable relative positional biases as in T5 (Raffel et al., 2020), with a bucket for each unique relative position; and
- instantiate the chunk embedding model R by a pre-trained Sentence-BERT (SB) model (Reimers and

Gurevych, 2019) instead of BERT. We deemed SB to be preferable over BERT as it is smaller (i.e. cheaper to compute) and produces embeddings of lower dimensionality (i.e. saves disk space).

2.2 Dataset

Borgeaud et al. (2022) used a multi-lingual version of *MassiveText* (Rae et al., 2021) for both training and retrieval data. To replicate the English portion of this data, we sought open-source alternatives. *MassiveText* comprises text from the categories web text, news, code, books, and Wikipedia. By pooling matching categories from Pile (Gao et al., 2020) and adding the RealNews dataset (Zellers et al., 2019), we obtain a large dataset composed of all five categories, consisting of 36M documents and 52B tokens. We keep the training/validation splits from the Pile categories. For RealNews, we use the provided training set and a subsample of 16,400 documents from the validation set. The full description of our dataset is shown in Table 1.

2.3 Model Training

For our experiments, we train a RETRO model that resembles the 425M model² in Borgeaud et al. (2022), as shown in Table 2. We train and test on our open-source version of *MassiveText* as described in Section 2.2. During training, we retrieve neighbors from the training set, while at validation time, we retrieve from the union of training and validation sets. We filter out neighbors that originate from the same source document as the query chunk. Each model is trained on sequences of no more than 1,024 tokens; longer sequences are truncated. We use a chunk size of 64 and retrieve two neighbors during both training and validation. We train the model for 140k training steps with a batch size of 16. This means that only 6% of the training documents are actually used during training, excluding retrieved neighbors. We use the Adam optimizer with a fixed learning rate of $1e-4$.

3 Experiments

Borgeaud et al. (2022) observed that retrieval increases language modeling performance. To validate this observation, we compare two configurations of our model: RETRO[ON], where we enable retrieval, and RETRO[OFF], where we remove the CCA layers, thereby reducing RETRO to a standard decoder-only language model. As we can see in

²The 425M parameters exclude embeddings.

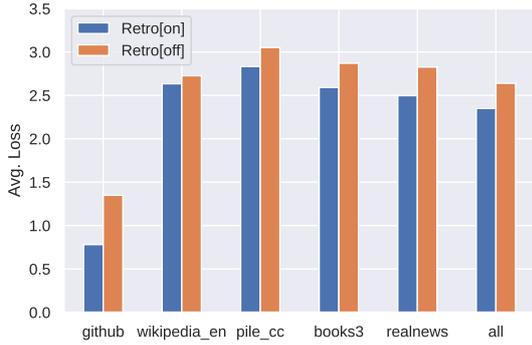

Figure 1: Comparing loss on validation set categories, when using retrieval vs. no retrieval.

Figure 1, retrieval reduces the loss across all data categories, and with 11% across the full validation set. GitHub data has the lowest validation loss among all categories and is also where we see the largest reduction in loss, at 42%. Wikipedia sees the smallest reduction in loss, at only 3%. A closer comparison to the results from Borgeaud et al. (2022) is available in Appendix D.

3.1 Loss per Degree of Overlap

As Borgeaud et al. (2022) note, retrieval-based models such as RETRO may more easily exploit evaluation dataset leakage. To quantify how much of the positive effect of retrieval on language modeling performance can be attributed to such leakage, the authors computed bits-per-byte (bpb) for evaluation chunks with different amounts of consecutive token overlap relative to their retrieved neighbors. This analysis showed that, while the positive effect of retrieval decreased with smaller overlaps, it was still significant at overlap levels of at most 8 contiguous tokens, which the authors considered small enough to conclude that while RETRO actually learns to *generalize* from retrieval data, not merely copy-and-paste it. Here we investigate the hypothesis that the bpb reductions observed by Borgeaud et al. (2022) are localized exclusively in the overlapping tokens. If this was true, it would challenge the conclusion that RETRO learns non-trivial generalizations based on retrieval data.

To test our hypothesis, we sort the validation set tokens into buckets based on their leftward overlap. Specifically, we put a token x_i into a bucket $\Phi(n)$, where n is the largest number such that x_i and the $n - 1$ tokens preceding it consecutively overlap with some neighboring chunk in $\text{RET}(C_{c(i)-1})$. For example, the bucket $\Phi(1)$ contains all tokens x_i for

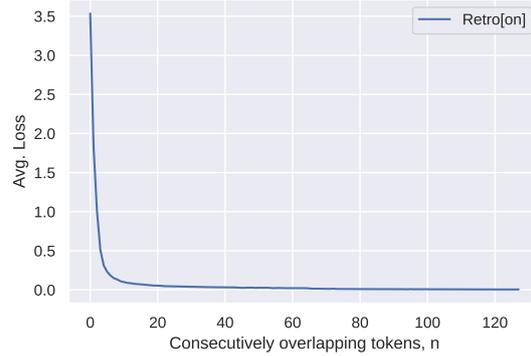

Figure 2: Average loss from RETRO[ON] over tokens in $\Phi(n)$. Note the drastic decrease with increasing overlap.

which the unigram x_i appears in some neighbor, but not the bigram $x_{i-1}x_i$; the bucket $\Phi(2)$ contains all x_i for which $x_{i-1}x_i$ overlaps but not $x_{i-2}x_{i-1}x_i$, and so on. As a special case, the bucket $\Phi(0)$ contains all tokens that do not overlap with any of its neighbors. This includes all tokens that occur in a first chunk C_1 , which lacks neighbors.

In Figure 2 we plot the average loss per bucket,

$$\frac{1}{|\Phi(n)|} \sum_{x_i \in \Phi(n)} \mathcal{L}_{x_i}^{\text{RETRO[ON]}}, \quad (1)$$

as a function of n . Here, $\mathcal{L}_{x_i}^{\text{RETRO[ON]}}$ is the loss when predicting token x_i using RETRO[ON]³. We see that the loss drastically decreases as the consecutive overlap increases. For example, at an overlap of $n = 5$ tokens, the loss is only 6% of the loss for non-overlapping tokens. This suggests that RETRO enters “copy mode” when the previous tokens overlap with those from a neighbor.

3.2 Loss Reductions per Degree of Overlap

For a more detailed analysis of the effect of overlap on predictive performance, we look at the token-specific loss differences between the two configurations RETRO[OFF] and RETRO[ON]:

$$\Delta \mathcal{L}_{x_i} = \mathcal{L}_{x_i}^{\text{RETRO[OFF]}} - \mathcal{L}_{x_i}^{\text{RETRO[ON]}}$$

Note that a loss difference $\Delta \mathcal{L}_{x_i}$ is positive if the access to the retrieved context reduces the token-specific loss for x_i . The overall reduction in loss visible in Figure 1 is the average of the loss differences across all tokens in the validation data. By aggregating loss differences per bucket $\Phi(n)$, we get a fine-grained picture of how the reductions

³The sizes of each bucket (accumulated over the validation data) are shown in the appendix, Figure 4.

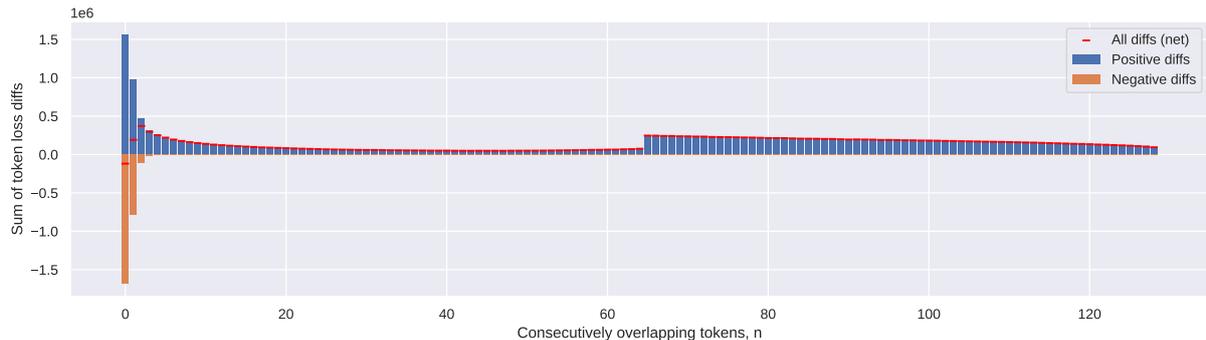

Figure 3: Token-specific loss differences, as distributed over different degrees of overlap. *Positive diffs* shows the sum of all positive loss differences, $\sum_{x_i \in \Phi(n)} \max(0, \Delta \mathcal{L}_{x_i})$, and *Negative diffs* shows the sum of negative loss differences, $\sum_{x_i \in \Phi(n)} \min(0, \Delta \mathcal{L}_{x_i})$. *All diffs* shows the total sum. We see that the vast majority of loss reductions comes from overlapping tokens, e.g. $n > 0$.

are distributed with respect to different degrees of consecutive overlap. This is illustrated in Figure 3.

For non-overlapping tokens ($n = 0$), we can see that there are both positive and negative differences, with a small negative net. For all overlapping tokens ($n > 0$), the net differences are positive, and for buckets with 3 or more overlapping tokens, there are almost no negative differences at all.⁴ This shows that the largest share of all loss reductions originates from tokens that are consecutively overlapping in neighbors. Interestingly, the net differences are positive even for very small degrees of overlap. Borgeaud et al. (2022) considered reductions in bits-per-byte from chunks with up to 8 consecutively overlapping tokens as evidence of a non-trivial generalization capacity. However, our results suggest that even a small number of overlapping tokens may cause a large reduction in loss, which we take as an argument against this conclusion.

4 Related Work

Equipping language models with a retrievable external memory has been extensively studied (Guu et al., 2020; Karpukhin et al., 2020; Lewis et al., 2020; Izacard and Grave, 2021; Li et al., 2022). Explicitly leveraging the training data through retrieval to reduce perplexity is proposed in kNN-LM (Khandelwal et al., 2020). kNN-LM matches the leftward context with the leftward context of all training data tokens, and explicitly interpolates between generating and copying the next token. A recent study analyzes kNN-LM to better understand

⁴We note a sudden increase in accumulated loss difference for $n > 64$ which is expected considering the way in which we construct the buckets; see Appendix C for more details.

the causes of performance gains (Xu et al., 2023). Similar to our findings in RETRO, lexical overlap has also been found to play a significant role in explaining retrieval performance gains in kNN-LM as well (Drozdo et al., 2022). The idea of kNN-LM is extended in SPALM (Yogatama et al., 2021) to instead learn a gating function that facilitates more dynamic interpolation.

In both kNN-LM and SPALM, retrieval is incorporated at the top of the network. This might induce a bias towards surface-level rather than semantic augmentation. In contrast, retrieval in RETRO is incorporated in lower layers of the network, which opens up for more sophisticated integration of the retrieved information. Our results suggest, however, that retrieval in RETRO also contributes at the surface rather than at the semantic level, similar to the previous works.

5 Conclusions and Future Work

The capacity of language models for generalization is often measured intrinsically using perplexity, loss or bits-per-byte on held-out validation data. Low perplexity language models perform well as few-shot learners on many downstream tasks due to their capacity to both memorize and non-trivially combine textual information from many sources (Brown et al., 2020; Rae et al., 2021; Lieber et al., 2021; Chowdhery et al., 2022). The hope is that we can externalize memory to reduce the footprints of language models without reducing generalization and downstream task performance.

Our results show that the low loss in RETRO almost exclusively originates from tokens overlapping between retrieval and validation data, rather than from more sophisticated generalization. To better

understand this effect, it would be interesting to modify the retrieval component and deliver semantically similar but lexically different context during training. If the retrieved context is uninformative, the model will learn to ignore it, but if the context is too specific (e.g. literal overlap) the model will learn to copy. By better balancing between these two modes, models may become better at utilizing retrieved information at a deeper and more generalizable level.

Limitations

We have made our best effort in trying to reproduce the model and results of [Borgeaud et al. \(2022\)](#). Nonetheless, our experiments were performed on one of the smaller model sizes and with a dataset that is only $\sim 2.5\%$ of their size (52 billion vs. 2 trillion tokens). This was due to computational constraints and lack of larger open datasets. However, as was also shown by [Borgeaud et al. \(2022\)](#), the performance gain of retrieval is constant with respect to model size. We speculate that larger RETRO models mostly improve with respect to loss on tokens that are not overlapping, which would not change our conclusions here.

One noteworthy limitation of our work is the fact that we compare to a non-retrieval baseline (RETRO[OFF]) that was trained with access to retrieved context. We were not able to train a separate non-retrieval baseline due to computational constraints, but note that the bits-per-byte results of RETRO[OFF] and the baseline in [Borgeaud et al. \(2022\)](#) were close to identical.

	CA layers	[2]
Decoder	Num layers	12
	Num heads	12
	Hidden size	1536
	FFN	6144
	CCA layers	[6,9,12]

Table 2: Hyperparameters of our trained Retro model.

C Consecutively overlapping tokens

As explained in Section 3.1, we sort validation set tokens into buckets denoted $\Phi(n)$ depending on the longest overlapping leftward context.

In Figure 4 we show the number of tokens in each bucket. We note a big “jump” from $n = 64$ to $n = 65$, which can be explained by the following rationale. A neighbor $[N, F]$ to a chunk C_i is retrieved based on the similarity between C_i and N . In the case where both $C_i = N$ and $C_{i+1} = F$, tokens in C_{i+1} will be put into $\Phi(n)$ with $n = 65, \dots, 128$. The jump in Figure 4 indicates such duplicates are common in our data.

D Model validation

As we aim to reproduce the 425M model trained in Borgeaud et al. (2022), it is important to validate that the implementations are equivalent and that their evaluation results are comparable. However, evaluations of the 425M model in Borgeaud et al. (2022) on the Pile are not available, making it hard to make direct comparisons. Borgeaud et al.

(2022) report evaluation results on the C4 (Raffel et al., 2022) dataset, with various sizes of retrieval datasets. For their setup with 36B retrieval tokens, which is the most similar to our own retrieval size, they report that bits-per-byte is reduced by $\sim 2\%$ (from 0.92 to 0.90) when using retrieval. That could be compared to our results on Pile-CC, as both datasets originate from Common Crawl. In our experiments, loss is reduced by 7% (from 3.05 to 2.83) on Pile-CC.

Evaluations on the Pile in Borgeaud et al. (2022) are only reported for their largest model (7B params) and largest retrieval set (2T tokens). For example, on Pile-GitHub their reduction is $\sim 53\%$ whereas our reduction is 42%.

While these numbers are not directly comparable, we believe they indicate that our reimplementation of the RETRO model is working as expected.

Assessing Monotonicity Reasoning in Dutch through Natural Language Inference

Gijs Wijnholds

Institute for Language Sciences

Utrecht University

g.j.wijnholds@uu.nl

Abstract

In this paper we investigate monotonicity reasoning in Dutch, through a novel Natural Language Inference dataset. Monotonicity reasoning shows to be highly challenging for Transformer-based language models in English and here, we corroborate those findings using a parallel Dutch dataset, obtained by translating the Monotonicity Entailment Dataset of Yanaka et al. (2019). After fine-tuning two Dutch language models BERTje and RobBERT on the Dutch NLI dataset SICK-NL, we find that performance severely drops on the monotonicity reasoning dataset, indicating poor generalization capacity of the models. We provide a detailed analysis of the test results by means of the linguistic annotations in the dataset. We find that models struggle with downward entailing contexts, and argue that this is due to a poor understanding of negation. Additionally, we find that the choice of monotonicity context affects model performance on conjunction and disjunction. We hope that this new resource paves the way for further research in generalization of neural reasoning models in Dutch, and contributes to the development of better language technology for Natural Language Inference, specifically for Dutch.

1 Introduction

Natural Language Inference (NLI) is one of the standard benchmark tasks for current-day NLP architectures. In this task a model takes two sentences as input, and has to classify the relationship between the former (premise) sentence and the latter (hypothesis) sentence, typically between Entailment, Contradiction, and Neutral. NLI makes for an interesting task as drawing the correct inference may require subtle aspects of syntax, lexical semantics, and even pragmatics. While many NLI datasets exist like SICK (Marelli et al., 2014), SNLI (Bowman et al., 2015) and its extensions (MNLI Williams et al. (2018), XNLI Conneau et al. (2018),

e-SNLI Camburu et al. (2018)), much is still unknown about how and why neural language models (LMs) like BERT (Devlin et al., 2019) perform on the task. Evidence shows that fine-tuned LMs don't generalize well across NLI benchmarks (Talman and Chatzikyriakidis, 2019), and other investigation shows that LMs may be exploiting dataset heuristics to solve the task (Naik et al., 2018; McCoy et al., 2019). More generally, LMs do seem to encode a certain amount of syntactic structure (Rogers et al., 2020), but the relation to NLI remains unclear.

In order to shed light on the performance of large-scale LMs, specific datasets have been developed to understand what models do and don't understand. Specifically in the context of NLI, Yanaka et al. (2019) introduce the Monotonicity Entailment Dataset (MED), which targets models' capacity for understanding *monotonicity reasoning* (Icard III and Moss, 2014). Monotonicity reasoning is a staple test of human reasoning which requires lexical knowledge, as well as syntactic knowledge, making it suitable for an NLI benchmark.

In cases of monotonicity reasoning, a particular lexical item in the sentence licenses inferences by means of substituting specific syntactic constituents by either more general (upward context) or more specific (downward context).

- (a) *Every* [*man* ↓] [*sung and danced* ↑].
- (b) *Every bald man sung and danced.* ✓
- (c) *Every man danced.* ✓
- (d) *Every human sung and danced.* ✗

Figure 1: Example cases of monotonicity reasoning as natural language inference.

In Figure 1, the quantifier *Every* is downward entailing in its first argument, and upward entailing in its second arguments, meaning that either *man* may be replaced by a more specific instance to obtain an inference pair – as in 1(b) – while *sung and*

danced ought to be substituted for a more general constituent to preserve inference, as in 1(c). Violating the entailment context leads to a hypothesis for which there is no entailment (but not necessarily a contradiction), as in 1(d).

While the field of research into NLI is lively, it is largely focused on English. In this article, we work with Dutch, a language that has a relatively high digital prevalence, while at the same time being underrepresented in terms of typical sentence-level NLP benchmarks.

For Dutch there is the Lassy corpus, which contains a smaller gold standard, and a larger silver standard syntactically annotated corpus of written (van Noord et al., 2013), and the SONAR corpus of written Dutch (Oostdijk et al., 2013). Given the availability of these corpora combined with a rich Wikipedia dump, two transformer-based language models have been developed for Dutch, based on the BERT architecture (BERTje, de Vries et al. (2019)) and the RoBERTa architecture (RobBERT, Delobelle et al. (2020)), both available through HuggingFace’s transformers library.¹ In terms of investigations into these Dutch language models, de Vries et al. (2020) argues that BERTje encodes a typical ‘NLP pipeline’, which had been argued for BERT before (Tenney et al., 2019), whereas Kogkalidis and Wijnholds (2022) show through probing that long-distance dependencies are hard to recognize for both Dutch language models.

In order to extend the research done on NLI and on Dutch NLP, we add a benchmark for monotonicity reasoning in Dutch by translating the MED dataset of Yanaka et al. (2019). We perform an evaluation of large-scale language models for Dutch on this novel benchmark, that we dub MED-NL. We corroborate the findings of Yanaka et al. (2019), observing that the Dutch LMs similarly have difficulty with inferences coming from downward entailing contexts. Further inspection suggests that the main problem comes from inference pairs containing negation. In what follows, we first detail the creation of the dataset and the experimental setup for the evaluation, after which we report results and inspect the model predictions.

2 Dataset Creation & Evaluation

The dataset is obtained by translation from the English MED dataset of (Yanaka et al., 2019). First,

¹There is also a distilled version of RobBERT (Delobelle et al., 2021) which we did not include in our experiments.

all 5241 unique sentences are collected and lexicographically sorted to ensure consistency among sentence translations. These sentences are given to a native Dutch speaker for translation who could ensure quality and naturality of the translated examples. Using the translated sentences, we populate the original dataset with its Dutch incarnation. Since the original Entailment/Neutral labels derive from monotonicity properties, the entailment labels are preserved in Dutch. It is important to note that the labelling is binary, since MED only considers entailment and non-entailment (or neutral).

	MED	MED-NL
No. of tokens	81209	83809
No. of unique tokens	3614	3883
Avg. sentence length	7.54	7.79
Avg. word overlap	74.60%	73.25%

Table 1: Basic statistics of MED vs MED-NL.

Table 1 shows that in the translation, there is a 3% blowup in the number of words used in Dutch, with the corresponding increase in average sentence length. However, the number of unique tokens in the Dutch dataset increased, owing to a plurality of interpretation of English source words that may get disambiguated in the translation process.

To evaluate, we then performed a standard language model fine-tuning routine. We use two state of the art Dutch neural language models; BERTje (de Vries et al., 2019), a BERT-based model pre-trained for Dutch, and RobBERT (Delobelle et al., 2020), a RoBERTa-based model for Dutch. For multilingual comparison, we furthermore train multilingual BERT (Devlin et al., 2019). Each model was trained on the SICK-NL dataset (Wijnholds and Moortgat, 2021), which is the only existing NLI benchmark for Dutch. We binarize the labels in SICK-NL by conflating all Neutral and Contradiction labels into one class, as to make the training data compatible with the binary format of MED-NL. Training proceeds for 20 epochs, and the model is saved for the epoch for which highest development accuracy is obtained.² We test on the SICK-NL for validation purposes, after which testing is performed on MED-NL. To reduce any potential influences of performance perturbation due

²For BERTje, highest development accuracy was achieved at epochs 3, 5, and 5, whereas RobBERT achieve peak development set performance at epochs 5, 11, and 13.

to model seed initialization, we train each model thrice and report seed-averaged accuracy.

3 Results & Analysis

Table 2 displays the average development and test accuracy on SICK-NL, and test performance on MED-NL.

	SICK-NL _d	SICK-NL _t	MED-NL
BERTje	86.89	87.40	47.56
RobBERT	86.43	85.79	46.07
mBERT	71.20	71.38	49.74

Table 2: Seed-averaged (over 3 runs) accuracy results for two Dutch BERT models and multilingual BERT, trained on SICK-NL, evaluated on both SICK-NL and the new MED-NL dataset.

Performance on the development and test set of SICK-NL are slightly higher than reported in related work (Wijnholds and Moortgat, 2021; Delobelle et al., 2021), which may be due to the fact that the classification labels have been binarized. The high drop in accuracy on MED-NL is however on par with reported results on its English counterpart (Yanaka et al., 2019), despite the models and training dataset being different. In terms of difference between the models, overall accuracy barely distinguishes BERTje and RobBERT in terms of pure performance. Interestingly, multilingual BERT has a performance decline of ca 15% compared to RobBERT, yet reached highest performance on MED-NL. The multilingual model has more trouble with the Dutch training data, although all three runs reached peak validation accuracy after one epoch of training.

Monotonicity Contexts A breakdown of accuracy results by the type of monotonicity context is given in Table 3, which shows that non-upward entailing contexts typically represent a challenge to the language models’ predictions.

	Total	Up	Down	Non
(Support)	(5382)	(1818)	(3272)	(292)
BERTje	47.56	64.76	38.72	39.50
RobBERT	46.07	61.13	39.22	28.30
mBERT	49.74	65.57	36.67	97.60

Table 3: Seed-averaged (over 3 runs) accuracy results on the MED-NL dataset, by monotonicity category.

Specifically, these results contrast the performance of the monolingual Dutch LMs with multilingual BERT, the latter doing the worst on downward entailing contexts while trumping the former models on non-monotone contexts.

Linguistic Features In order to delve deeper in the results, we make use of the annotations in the dataset that indicate specific linguistic features for premise/hypothesis pairs. Table 4 displays detailed scores for linguistic features that have a significant overall occurrence in the MED-NL dataset, where we display the number of occurrences next to the name of the feature.

Phenomenon		BERTje	RobBERT	mBERT
<i>Lexical</i>	743	62.72	58.73	77.39
<i>Conjunction</i>	177	65.16	61.77	58.76
<i>Disjunction</i>	96	24.31	29.86	53.12
↑ <i>Conditionals</i>	24	48.61	44.44	70.83
<i>NPI</i>	64	33.33	36.98	64.06
<i>Reverse</i>	235	52.91	51.63	50.21
<i>Other</i>	698	74.79	69.91	58.74
<i>Lexical</i>	477	33.47	34.45	29.98
<i>Conjunction</i>	106	34.91	32.08	23.58
<i>Disjunction</i>	138	49.76	49.52	40.58
↓ <i>Conditionals</i>	125	45.60	43.47	18.40
<i>NPI</i>	266	36.59	39.10	32.71
<i>Reverse</i>	9	29.63	33.33	33.33
<i>Other</i>	2249	39.6	40.15	39.88
<i>Lexical</i>	182	37.73	31.32	98.35
= <i>Disjunction</i>	20	56.67	31.67	100.0
<i>NPI</i>	8	66.67	37.50	100.0
<i>Other</i>	90	39.26	23.70	95.56

Table 4: Seed-averaged (over 3 runs) accuracy results on the MED-NL dataset, by monotonicity category and phenomenon.

These results start to highlight an interesting pattern: with an overall performance on upward entailing contexts of 64.76 (BERTje), we see that cases of disjunction, conditionals, negative polarity items and reverse (e.g. double negation) are most challenging in this context. The surprising result here is that such cases are much more on par with the rest in a downward entailing context. Most strikingly, cases of disjunction become easier to deal with than conjunction in a downward entailing context, even though the situation was converse in the case of upward entailing contexts.

Model Comparison Although the results in Table 4 give some insight into the difference between models – e.g. RobBERT appears to perform higher at cases with negative polarity items, whereas BERTje performs better at cases of conjunction –, the models seem to be relatively equal in their overall accuracy. To better distinguish the models we analyse the overlap between model predictions.

Phenomenon	\cap	Shared	BERTje	RobBERT
Lexical	75%	47.61	55.26	44.74

Table 5: Seed-averaged overlap accuracy results on the MED-NL dataset, between BERTje and RobBERT, by monotonicity category and phenomenon.

Table 5 displays the average overlap between the two monolingual models by feature, together with their shared and individual accuracy, to shed light on where the models differ, color-coded for clarification purposes.

We first observe that the overlap between model predictions overall (the \forall rows) is relatively high with a minimum of 75% and a maximum of 94%. Generally speaking, given that the overlap between model predictions is high, the shared ac-

curacy shows whether models make the same correct/incorrect decisions. This is particularly pronounced in the low accuracy on disjunctions in upward entailing contexts, where models make a lot of shared mistakes, but in their diverging decisions RobBERT has a significantly higher accuracy. The converse is true for conjunction in a downward entailing context where BERT is individually stronger than RobBERT. For the sake of completeness, in Tables 8 and 9 we report overlap results between the Dutch models and multilingual BERT.

The Role of Negation One explanation for the fact that the models perform significantly worse on downward entailing contexts may be that such cases are often constructed through the use of negation words. Table 6 displays the percentages of sentence pairs containing at least one negation word, with specification for conjunction and disjunction.

	Total	Up	Down	Non
	(5382)	(1818)	(3272)	(292)
% Negation	58.86	22.5	84.2	1.37
	\uparrow Conj.	\uparrow Disj.	\downarrow Conj.	\downarrow Disj.
	(177)	(96)	(106)	(138)
% Negation	22.60	18.75	92.45	73.19

Table 6: Percentage of premise/hypothesis pairs in MED-NL containing negation words (*geen, niet, zonder, nooit, niemand*).

Indeed, negation is highly represented in downward monotone contexts, indicating that part of the reason why the models perform so poorly in such context is that they are not sensitive (enough) to negation. Inspection of the distribution of negation in SICK-NL (train set) and MED-NL, displayed in Table 7, shows that models may have learnt to incorrectly classify cases involving negation.

% Negation	SICK-NL	MED-NL
Entailment	1.26	69.80
Non-entailment	31.94	47.81

Table 7: Distribution of negation in cases of entailment and non-entailment in SICK-NL and MED-NL.

However, this explanation can’t be replicated in the case of conjunction and disjunction, leaving a further inspection into these cases to future work.

4 Conclusion

In this paper we provided MED-NL, a novel NLI dataset for Dutch, which specifically targets monotonicity reasoning. The evaluation of two Dutch language models on this test set shows that the models specifically struggle with cases in downward entailing contexts, which had earlier been established for English as well (Yanaka et al., 2019). However, we indicate specifically that the role of negation words may play a large role in the poor model performance on such cases, giving way for future research into language models and negation.

On the other hand, the evaluation also shows that disjunction is much easier to handle by the models than conjunction, for which no explanation was found. In future investigations, we hope to provide more analysis of these language models, specifically regarding negation.

<i>Other</i>	21%	94.71	4.25	95.75

Table 9: Seed-averaged overlap accuracy results on the MED-NL dataset, between RobBERT and multilingual BERT, by monotonicity category and phenomenon.

5 Limitations

This study was performed with monolingual Dutch models and with multilingual BERT, yet comparison with multilingual BERT on the original MED dataset could be insightful. Given that the distribution of cases of negation is skewed between the dataset used for training and the introduced evaluation dataset, another experiment could have been included in which models are trained to deal with cases of negation in a uniformly distributed way.

Noisy Parallel Data Alignment

Ruoyu Xie, Antonios Anastasopoulos

Department of Computer Science, George Mason University

{rxie, antonis}@gmu.edu

Abstract

An ongoing challenge in current natural language processing is how its major advancements tend to disproportionately favor resource-rich languages, leaving a significant number of under-resourced languages behind. Due to the lack of resources required to train and evaluate models, most modern language technologies are either nonexistent or unreliable to process endangered, local, and non-standardized languages. Optical character recognition (OCR) is often used to convert endangered language documents into machine-readable data. However, such OCR output is typically noisy, and most word alignment models are not built to work under such noisy conditions. In this work, we study the existing word-level alignment models under noisy settings and aim to make them more robust to noisy data. Our noise simulation and structural biasing method, tested on multiple language pairs, manages to reduce the alignment error rate on a state-of-the-art neural-based alignment model up to 59.6%.¹

1 Introduction

Modern optical character recognition (OCR) software achieves good performance on documents in high-resource standardized languages, producing machine-readable text which can be used for many downstream natural language processing (NLP) tasks and various applications (Ignat et al., 2022; Van Strien et al., 2020; Amrhein and Clematide, 2018). However, attaining the same level of quality for texts in less-resourced local and non-standardized languages remains an open problem (Rijhwani et al., 2020).

The promise of OCR is particularly appealing for endangered languages, for which material might exist in non-machine-readable formats, such as physical books or educational materials. Digitizing such

¹Data and code are available online: https://github.com/ruoyuxie/noisy_parallel_data_alignment

Figure 1: Synthetic data example in Griko with character differences highlighted. Our synthetic data manage to mimic the real OCR noise.

material could lead to the creation of NLP technologies for such otherwise severely under-served communities (Bustamante et al., 2020).

Beyond the primary goal of digitizing printed material in endangered languages, the need for robust alignment tools is wider. The majority of the world’s languages are being traditionally oral (Bird, 2020), which implies that to obtain textual data at scale one would need to rely on automatic speech recognition (ASR), which in turn would produce invariably noisy outputs. It is worth noting that the availability of translations can significantly improve systems beyond machine translation (MT), such as OCR (Rijhwani et al., 2020) or ASR (Anastasopoulos and Chiang, 2018). This creates a chicken-and-egg situation: on one hand, OCR and ASR can be used to obtain noisy parallel data; on the other hand, having good quality aligned data can improve OCR or ASR.

In this vein, We focus on the scenario of digitizing texts in a less-resourced language along with their translations (usually high-resource and/or widely spoken) similar to Rijhwani et al. (2020). Digitizing parallel documents can also be beneficial for educational purposes, as one could then create dictionaries through word- and phrase-level alignments, or ground language learning on another language (a learner’s either L1 or L2). Also, as Ig-

nat et al. (2022) showed in recent work, such parallel corpora can be meaningfully used to create MT systems. However, the process that transforms digitized books or dictionaries into parallel sentences for training MT systems requires painstaking manual intervention.

In theory, the process could be semi-automated using sentence alignment methods, but in practice, the situation is very different: OCR systems tend to generate very noisy text for endangered languages (Alpert-Abrams, 2016, *inter alia*), which in turn leads to poor alignments between two parallel sides. As we show, alignment tools are particularly brittle in the presence of noise.

In this work, we take the first step towards solving the above issue. We investigate the relationship between OCR noise and alignment results and build a probabilistic model to simulate OCR errors and create realistic OCR-like synthetic data. We also manually annotate a total of 4,101 gold alignments for an endangered language pair, Griko-Italian, in order to evaluate our methods in a real-world setting. We leverage structural knowledge and augmented data, greatly reducing the alignment error rate (AER) for all four high- and low-resource language pairs up to 59.6%.

2 Problem Setting

Our work is a straightforward extension of previous word-level alignment work. Given a sequence of words $\mathbf{x} = (x_1, \dots, x_n)$ in a source language and $\mathbf{y} = (y_1, \dots, y_m)$ in a target language, the alignment model produces alignment pairs:²

$$\mathcal{A} = \{(x_i, y_j) : x_i \in \mathbf{x}, y_j \in \mathbf{y}\}$$

The difference with previous work is that the starting data will be the output of an OCR pipeline, hence producing noisy parallel data ($\mathbf{x}^*, \mathbf{y}^*$) instead of “clean” (\mathbf{x}, \mathbf{y}) ones. The level of noise may vary between the two sides.

Hence, our goal is to produce an alignment

$$\mathcal{A}^* = \{(x_i, y_j) : x_i \in \mathbf{x}^*, y_j \in \mathbf{y}^*\}$$

that will be as close to the alignment \mathcal{A} that we would have obtained without the presence of noise. We measure model performance using the alignment error rate (AER; Och and Ney, 2003) against the gold alignments.³

²Sometimes denoted with a latent variable, but we use an equivalent notation for simplicity.

³Lower AER means a better alignment. More details on the metric in Appendix A.

3 Method

We create synthetic data that mimic OCR-like noise, that can be used to train/finetune alignment models. Our *simple yet effective* method mainly consists of (i) building probabilistic models based on edit distance measures and capturing real OCR errors; (ii) creating synthetic (noisy) OCR-like data by applying our error-introducing model on clean parallel data; (iii) training or finetuning alignment models on synthetic data.

3.1 OCR Error Modeling

Error types For OCRed text, different types of texts, languages, and corpora will lead to different error distributions. At the character level, there are generally three types of OCR errors: insertions, deletions, and substitutions. In most cases, deletions and substitutions are more common, with spurious insertions being rarer.

Noise model By comparing the OCRed text with its post-corrected version, we use Levenshtein distance to compute the edit distances and the probability distributions of edits/errors over the corpus with a straightforward count-based approach.

We treat deletion error as part of substitution error. Given a sequence of characters x_i, \dots, x_j from a clean corpus \mathbf{x} and a sequence of characters y_i, \dots, y_j from its OCRed noisy version \mathbf{y} , we simply count the number of times a correct character x_i is recognized as character y_i (or recognized as the empty character ϵ if it is erroneously deleted). We can then compute the probability of an erroneous substitution or deletion as follows:

$$P_{sub}(x_i \rightarrow y_i) = \frac{\text{count}(x_i \rightarrow y_i)}{\text{count}(x_i)}$$

and the overall substitution error distribution is conditioned on the correct character x_i :

$$\mathcal{D}_{sub}(x_i) \sim P_{sub}(x_i \rightarrow y_i).$$

For insertion errors, we consider that insertion occurs when ϵ becomes another character y_i and count the number of times that insertion occurs after its previous character. A special token `<begin>` is used when insertion occurs at the beginning of the sentence. In general, we calculate the insertion error probability with:

$$P_{ins}(x_{i-1}\epsilon \rightarrow x_{i-1}y_i) = \frac{\text{count}(x_{i-1}\epsilon \rightarrow x_{i-1}y_i)}{\text{count}(x_{i-1}\epsilon)}$$

and the insertion error distribution for x_{i-1} :

$$\mathcal{D}_{ins}(x_{i-1}\epsilon) \sim P_{ins}(x_{i-1}\epsilon \rightarrow x_{i-1}y_i).$$

3.2 Data Augmentation

Synthetically noised data can be created by leveraging the calculated probability distributions from the previous section and traversing through the clean corpus for every character.

For each character c , we obtain its probability to be erroneous in the OCR output by sampling from the distribution of the substitution and insertion probabilities $\mathcal{D}_{ins}(c), \mathcal{D}_{sub}(c)$.⁴ We randomly decide whether to add an error here based on its error distribution.

If an error will be introduced on c , we then randomly choose its corresponding error based on $P_{sub}(c)$ or $P_{ins}(c)$ depending on either substitution or insertion operation receptively.

Our method attempts to mimic the real OCR errors in given languages and corpus, resulting in very similar noise distributions. Figure 1 shows a side-by-side comparison of three versions of the same sentence, to showcase how realistic our synthetic text is.

3.3 Model Improvement

Given our synthetically noised parallel data, and potentially along with the original clean parallel data, we can now train or finetune a word alignment model to improve the model performance.

In the case of unsupervised models like the IBM translation models (Brown et al., 1993), fast-align (Dyer et al., 2013), or Giza++ (Och, 2003), we simply train on the concatenation of all available data.

We also work with the state-of-the-art neural alignment model of Dou and Neubig (2021), which is based on Multilingual BERT (mBERT) (Devlin et al., 2019).⁵ For this model, we distinguish two cases: supervised and unsupervised finetuning.⁶ Under a supervised setting, we first obtain silver alignments from the clean dataset and use them as targets for the synthetic noisy data. The unsupervised setting is conceptually similar to training models like Giza++: we feed synthetically-noised sentence pairs into the alignment model, without

⁴Including a third option for not inserting an error

⁵See Section 5.1 for more details.

⁶We use provided default parameters for both cases, which can be found on <https://github.com/neulab/awesome-align>

Language	Total CER	Sub. %	Ins. %
English	7.4	79	21
German	4.9	87	13
French	4.8	85.7	14.3
Griko	3.3	96.8	3.2
Ainu	1.4	91.9	8.1

Table 1: Total character error rate (CER) and percentage of substitution and insertion errors. Generally, substitution is the most common error in OCR output.

using the target alignment as supervision. In low-resource scenarios, we leverage a diagonal bias to further improve the model’s performance.

4 Languages and Datasets

We study four language pairs with varying amounts of data availability: English-French, English-German, Griko-Italian, and Ainu-Japanese.⁷

4.1 Dataset for Error Extraction

The ICDAR 2019 Competition on Post-OCR Text Correction (Rigaud et al., 2019) dataset provides both clean and OCRed text for English-French and English-German, which we use our noisy model to learn and mimic OCR errors for English, French, and German.

For Griko-Italian and Ainu-Japanese, Rijhwani et al. (2020) provide around 800 OCRed noisy and clean (post-corrected) sentences for both Griko and Ainu, from which we extract error distributions; for Italian and Japanese, only OCRed text is provided.⁸

To understand the characteristics of our datasets, we report the observed CER in Table 1. Generally, substitutions are the most common errors. Notice that Griko and Ainu have seemingly lower scores than any high-resource languages; that’s because both use the Latin alphabet, the data that were digitized are typed in books with high-quality scans.⁹

4.2 Synthetic Data

We create synthetic data by applying captured OCR noise on clean text. For English, French, and German, the clean text comes from Europarl v8 corpus (Koehn, 2005). For Ainu, there are 816 clean sentences from Rijhwani et al. (2020), from which

⁷Griko and Ainu are both under-resourced endangered languages.

⁸The quality of the OCR model on these high-resource languages are generally reliable.

⁹The English, French, and German data from ICDAR have lower-quality scans.

Language	Real CER	Syn. CER	Diff.
English	7.4	6.5	0.9
German	4.9	6.7	1.8
French	4.8	5.3	0.5
Griko	3.3	3.3	0
Ainu	1.4	1.0	0.4

Table 2: Our synthetically-noisy data have similar CER compared to the real OCR outputs, which implies that the real OCR noisy data can be mimicked by our noise simulation model.

we keep the first 300 lines as test set and use the rest to create synthetic data. Anastasopoulos et al. (2018) provide 10,009 clean sentences for Griko. Table 2 shows the CER comparison between our synthetic data and real OCR data.

4.3 Test Set and Gold Alignment

The test set and gold alignment for English-French come from Mihalcea and Pedersen (2003). For English-German, the test set and gold alignments come from Europarl v7 corpus (Koehn, 2005) and Vilar et al. (2006), respectively. To study the effect of OCR-like errors on alignment, we create synthetically-noised test sets for both languages pairs by applying noise on one side or both, which results in four copies of the same test set: clean-clean, clean-noisy, noisy-clean, and noisy-noisy.

For low-resource language pairs, Rijhwani et al. (2020) provide about 800 parallel sentence pairs for each. We use the first 300 sentence pairs as our test sets. For the purpose of fair evaluation in our method, we annotate a total of 4,101 *gold* word-level alignment pairs for Griko-Italian test set. On the other hand, we obtain *silver* alignments from awesome-align for Ainu-Japanese as there is no existing gold alignment data available.¹⁰

5 Experiments

In this section, we present multiple experiments and demonstrate that our method results in significant AER reductions.

5.1 Experimental Setup

Models We study the following models:

- IBM model 1&2 (Brown et al., 1993): the classic statistical word alignment models. They underpinned many other statistical machine translation and word alignment models.

¹⁰While not ideal, we can still measure how different results are when comparing alignments on clean versus noisy data.

	Model	Clean	OCRed	Diff.
	IBM 1	43.7	49.2	5.5
	IBM 2	37.3	43.4	6.1
	Giza++	14.5	20.8	6.3
	fast-align	19.8	25.7	5.9
	awesome-align	45.1	48.8	3.7

Table 3: AER comparison for Griko-Italian. Giza++ performs best on both settings, but it exhibits the largest drop in performance.

- Giza++ (Och, 2003): a popular statistical alignment model that is based on a pipeline of IBM and Hidden Markov models (Vogel et al., 1996).
- fast-align (Dyer et al., 2013): a simple but effective statistical word alignment model that is based on IBM Model 2, with an additional bias towards monotone alignment.
- awesome-align (Dou and Neubig, 2021): a neural word alignment model based on mBERT. It fine-tunes a pre-trained multilingual language model with parallel text and extracts the alignments from the resulting representations.

5.2 The Effect of OCR-like Noise

We use Griko-Italian as our main evaluation pair due to the presence of its gold alignments, which can most accurately reflect the model’s performance under a low-resource scenario.

We first benchmark model performance on clean and OCRed parallel text to quantify OCR-error effects on alignment (Table 3). We compute AER for the clean and OCRed versions of Griko-Italian by comparing their alignment against our manually created gold alignment. We benchmark five different models that lead to several observations. First, note that clean text always results in a better alignment for all models. Overall, Giza++ performs best among the models, but note that it also suffers the largest drop in performance when faced with noisy text. On the other hand, a vanilla awesome-align, which is otherwise a state-of-the-art model for languages that were included in the pre-training of its underlying model, performs the worst, not being better than a simple IBM 1.

We can thus conclude that OCR error does impact alignment quality for both statistical and neural based alignment models.

It is of note that for Griko-Italian every statistical model outperforms awesome-align in almost all cases. We hypothesize that this is due to the lack

	Griko-Italian		Ainu-Japanese	
	Clean	OCRed	Clean	OCRed
BASE	45.1	48.8	28.2	29.2
UNSUP-FT (A)	23.2±1.6	28±1.1	21.1 ±1	22.2±1.2
SUP-FT (B)	22.3±2	26.6±1.1	30.9±2.1	31.5±1.2
+ structural bias				
UNSUP-FT (A)	18.7±1	24.2±0.6	15.3±3.9	13.8±4.2
SUP-FT (B)	18.2±2.6	22.9±2.4	26.3 ±2.1	27.4±1.8
AER reduction	59.6%	53.1%	45.7%	52.7%

Table 4: For both endangered languages, our approach greatly reduces AER for both clean and OCRed data.

of structural knowledge; we deal with this in Section 5.3.1. awesome-align’s low performance can also be explained by the fact that Griko is not well supported by its underlying representation model: Griko was not part of the pre-training language mix, and it does not use the same script as its closest language that was included in pre-training (Greek),¹¹ an important factor according to Muller et al. (2021). Compared to statistical models, we also observe considerably fewer alignment pairs are produced by awesome-align (Appendix 8), which might also be a contributing factor.

5.3 Making awesome-align Robust

The performance of awesome-align raises an intriguing question - Is the state-of-the-art neural based model capable to align noisy text, especially from low-resource languages. Given its general higher performance on many popular languages (Dou and Neubig, 2021) and the stability between clean and noisy text,¹² we make awesome-align as our main experiment target.

5.3.1 Low-Resource Setting

We introduce structural bias and propose two models: model (A) and model (B) finetuned in unsupervised and supervised settings respectively.

Structural Bias Structural alignment biases are widely used in statistical alignment models such as Brown et al. (1993); Vogel et al. (1996); Och (2003); Dyer et al. (2013). However, it is a missing component in awesome-align. Following by Dyer et al. (2013), we introduce diagonal bias and apply it on the top of awesome-align’s attention layer. We create (i) a bias matrix M_b based on

¹¹Modern Greek uses the Greek alphabet, while Griko uses the Latin alphabet.

¹²Lowest AER difference between clean and noisy text amount to all models.

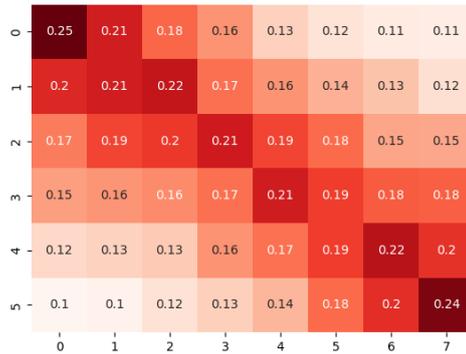

Figure 2: A sample 6×8 diagonal bias matrix. Darker color means stronger bias emphasis. We follow the same steps from Dyer et al. (2013) to calculate each position based on given rows and columns.

the position of the alignment, where the positions near the diagonal of the alignment matrix have the higher weights (See Figure 2); (ii) a tune-able hyper-parameter λ represents the weight of the bias. We set $\lambda=1$ for all low-resource language experiments; (iii) an average matrix M_{avg} that is the average of the original attention score, which is used for smoothing λ to make it where 1 represents maximum bias and 0 means no bias at all. We update the original awesome-align attention score A_{sc} :

$$A_{sc} = \lambda * A_{sc} + (1 - \lambda) * A_{sc} * M_b * M_{avg}$$

Our proposed models For our unsupervised-finetuned model (A), we create the synthetically-noised data by introducing OCR-like noise on clean parallel data, and then simply finetune the baseline model with all available data from both clean and synthetic text.

For the supervised-finetuned model (B), we first finetune an out-of-the-box awesome-align with the clean data from Anastasopoulos et al. (2018) and Rijhwani et al. (2020) for Griko-Italian and

Test Set	English-French				English-German		
	Baseline	Unsup-FT	Sup-FT	Reduction	Baseline	Unsup-FT	Reduction
CLEAN-CLEAN	5.6	4.6	15.9	17.0%	17.9	15.2	15.1%
CLEAN-SYNTH	40.5	36.3	29.4	27.4%	43.8	39.4	10.0%
NOISY-CLEAN	39.2	34.2	28.6	27.0%	52.8	50	5.3%
NOISY-NOISY	53.6	46.1	37.3	30.4%	66.6	63.5	4.7%

Table 5: Result of awesome-align on English to French and German alignment. Both unsupervised and supervised finetuning with noise-induced data leads to big AER reduction when aligning noisy data. Reductions in German are less pronounced. Unsupervised finetuning with noisy data also improves clean-data alignment.

	IBM 1		IBM 2		Giza++		fast-align	
	Clean	OCRed	Clean	OCRed	Clean	OCRed	Clean	OCRed
Baseline	43.7	49.2	37.3	43.4	14.5	20.8	19.8	25.7
Train w. clean	40.2	45.7	32.7	38.1	13.1	19.0	17.9	24.2
Train w. noise	84.2	84.6	80.0	80.8	19.7	25.8	22.8	27.9

Table 6: Experiment on Griko-Italian, every statistical model benefits from training with additional clean data but suffers significant performance drops with synthetic noisy data, suggesting that traditional statistical models rely on clean text.

Aiun-Japanese respectively, which produces silver alignment. Next, we use the silver alignment as supervision to finetune awesome-align with synthetic noisy data.

We report the average plus-minus standard deviation of three runs for each model. Table 4 summarizes the results for our proposed models. We end up with around **50%** AER reduction for both endangered language pairs.

5.3.2 High-Resource Setting

We evaluate our data augmentation method on high-resource language pairs. Up to 400K synthetically noised English-French data was used for unsupervised finetuning. We also offer an additional reference data point, using 100K synthetic noised English-German data for unsupervised fine-tuning.

For supervised finetuning, we use up to 1M synthetic data. As before, we use silver alignments from clean data as supervision to finetune its synthetic noisy version, which does not require any additional human annotation effort.
